Springer Handbook of Nanotechnology

Springer Handbook provides a concise compilation of approved key information on methods of research, general principles, and functional relationships in physics and engineering. The world's leading experts in the fields of physics and engineering will be assigned by one or several renowned editors to write the chapters comprising each volume. The content is selected by these experts from Springer sources (books, journals, online content) and other systematic and approved recent publications of physical and technical information.

The volumes will be designed to be useful as readable desk reference book to give a fast and comprehensive overview and easy retrieval of essential reliable key information, including tables, graphs, and bibliographies. References to extensive sources are provided.

Foreword by Neal Lane

In a January 2000 speech at the California Institute of Technology, former President W. J. Clinton talked about the exciting promise of "nanotechnology" and the importance of expanding research in nanoscale science and engineering and in the physical sciences, more broadly. Later that month, he announced in his State of the Union Address an ambitious $497 million federal, multi-agency national nanotechnology initiative (NNI) in the fiscal year 2001 budget; and he made the NNI a top science and technology priority within a budget that emphasized increased investment in U.S. scientific research. With strong bipartisan support in Congress, most of this request was appropriated, and the NNI was born.

Nanotechnology is the ability to manipulate individual atoms and molecules to produce nanostructured materials and sub-micron objects that have applications in the real world. Nanotechnology involves the production and application of physical, chemical and biological systems at scales ranging from individual atoms or molecules to about 100 nanometers, as well as the integration of the resulting nanostructures into larger systems. Nanotechnology is likely to have a profound impact on our economy and society in the early 21st century, perhaps comparable to that of information technology or advances in cellular and molecular biology. Science and engineering research in nanotechnology promises breakthroughs in areas such as materials and manufacturing, electronics, medicine and healthcare, energy and the environment, biotechnology, information technology and national security. It is widely felt that nanotechnology will lead to the next industrial revolution.

Nanometer-scale features are built up from their elemental constituents. Micro- and nanosystems components are fabricated using batch-processing techniques that are compatible with integrated circuits and range in size from micro- to nanometers. Micro- and nanosystems include Micro/NanoElectroMechanical Systems (MEMS/NEMS), micromechatronics, optoelectronics, microfluidics and systems integration. These systems can sense, control, and activate on the micro/nanoscale and can function individually or in arrays to generate effects on the macroscale. Due to the enabling nature of these systems and the significant impact they can have on both the commercial and defense applications, industry as well as the federal government have taken special interest in seeing growth nurtured in this field. Micro- and nanosystems are the next logical step in the "silicon revolution".

The discovery of novel materials, processes, and phenomena at the nanoscale and the development of new experimental and theoretical techniques for research provide fresh opportunities for the development of innovative nanosystems and nanostructured materials. There is an increasing need for a multidisciplinary, systems-oriented approach to manufacturing micro/nanodevices which function reliably. This can only be achieved through the cross-fertilization of ideas from different disciplines and the systematic flow of information and people among research groups.

Prof. Neal Lane

University Professor
Department of Physics and Astronomy and James A. Baker III Institute for Public Policy Rice University Houston, Texas USA

Served in the Clinton Administration as Assistant to the President for Science and Technology and Director of the White House Office of Science and Technology Policy (1998–2001) and, prior to that, as Director of the National Science Foundation (1993–1998). While at the White House, he was instrumental in creating NNI.

Nanotechnology is a broad, highly interdisciplinary, and still evolving field. Covering even the most important aspects of nanotechnology in a single book that reaches readers ranging from students to active researchers in academia and industry is an enormous challenge. To prepare such a wide-ranging book on nanotechnology, Professor Bhushan has harnessed his own knowledge and experience, gained in several industries and universities, and has assembled about 90 internationally recognized authors from three continents to write 38 chapters. The authors come from both academia and industry.

Professor Bharat Bhushan's comprehensive book is intended to serve both as a textbook for university courses as well as a reference for researchers. It is a timely addition to the literature on nanotechnology, which I anticipate will stimulate further interest in this important new field and serve as an invaluable resource to members of the international scientific and industrial community.

The Editor-in-Chief and his team are to be warmly congratulated for bringing together this exclusive, timely, and useful Nanotechnology Handbook.

Foreword by James R. Heath

Nanotechnology has become an increasingly popular buzzword over the past five years or so, a trend that has been fueled by a global set of publicly funded nanotechnology initiatives. Even as researchers have been struggling to demonstrate some of the most fundamental and simple aspects of this field, the term nanotechnology has entered into the public consciousness through articles in the popular press and popular fiction. As a consequence, the expectations of the public are high for nanotechnology, even while the actual public definition of nanotechnology remains a bit fuzzy.

Why shouldn't those expectations be high? The late 1990's witnessed a major information technology (IT) revolution and a minor biotechnology revolution. The IT revolution impacted virtually every aspect of life in the western world. I am sitting on an airplane at 30,000 feet at the moment, working on my laptop, as are about half of the other passengers on this plane. The plane itself is riddled with computational and communications equipment. As soon as we land, many of us will pull out cell phones, others will check email via wireless modem, some will do both. This picture would be the same if I was landing in Los Angeles, Beijing, or Capetown. I will probably never actually print this text, but will instead submit it electronically. All of this was unthinkable a dozen years ago. It is therefore no wonder that the public expects marvelous things to happen quickly. However, the science that laid the groundwork for the IT revolution dates back 60 years or more, with its origins in the fundamental solid state physics.

By contrast, the biotech revolution was relatively minor and, at least to date, not particularly effective. The major diseases that plagued mankind a quarter century ago are still here. In some third world countries, the average lifespan of individuals has actually decreased from where it was a full century ago. While the costs of electronics technologies have plummeted, health care costs have continued to rise. The biotech revolution may have a profound impact, but the task at hand is substantially more difficult to what was required for the IT revolution. In effect, the IT revolution was based on the advanced engineering of two-dimensional digital circuits constructed from relatively simple components – extended solids. The biotech revolution is really dependent upon the ability to reverse engineer three-dimensional analog systems constructed from quite complex components – proteins. Given that the basic science behind biotech is substantially younger than the science that has supported IT, it is perhaps not surprising that the biotech revolution has not really been a proper revolution yet, and it likely needs at least another decade or so to come to fruition.

Where does nanotechnology fit into this picture? In many ways, nanotechnology depends upon the ability to engineer two- and three-dimensional systems constructed from complex components such as macromolecules, biomolecules, nanostructured solids, etc. Furthermore, in terms of patents, publications, and other metrics that can be used to gauge the birth and evolution of a field, nanotech lags some 15–20 years behind biotech. Thus, now is the time that the fundamental science behind nanotechnology is being explored and developed. Nevertheless, progress with that science is moving forward at a dramatic pace. If the scientific community can keep up this pace and if the public sector will continue to support this science, then it is possible, and perhaps even likely, that in 20 years from now we may be speaking of the nanotech revolution.

The Nanotechnology Handbook is timely in assembling chapters in the broad field of nanotechnology with an emphasis on reliability. The handbook should be a valuable reference for experienced researchers as well as for a novice in the field.

Prof. James R. Heath

Department of Chemistry
Mail Code: 127-72
California Institute of Technology
Pasadena, CA 91125, USA

Worked in the group of Nobel Laureate Richard E. Smalley at Rice University (1984–88) and co-invented Fullerene molecules which led to a revolution in Chemistry including the realization of nanotubes. The work on Fullerene molecules was cited for the 1996 Nobel Prize in Chemistry. Later he joined the University of California at Los Angeles (1994–2002), and co-founded and served as a Scientific Director of The California Nanosystems Institute.

Preface

On December 29, 1959 at the California Institute of Technology, Nobel Laureate Richard P. Feynman gave a talk at the Annual meeting of the American Physical Society that has become one classic science lecture of the 20th century, titled "There's Plenty of Room at the Bottom." He presented a technological vision of extreme miniaturization in 1959, several years before the word "chip" became part of the lexicon. He talked about the problem of manipulating and controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature, building nanoobjects atom by atom or molecule by molecule. Since the 1980s, many inventions and discoveries in fabrication of nanoobjects have been a testament to his vision. In recognition of this reality, in a January 2000 speech at the same institute, former President W. J. Clinton talked about the exciting promise of "nanotechnology" and the importance of expanding research in nanoscale science and engineering. Later that month, he announced in his State of the Union Address an ambitious $ 497 million federal, multi-agency national nanotechnology initiative (NNI) in the fiscal year 2001 budget, and made the NNI a top science and technology priority. Nanotechnology literally means any technology done on a nanoscale that has applications in the real world. Nanotechnology encompasses production and application of physical, chemical and biological systems at size scales, ranging from individual atoms or molecules to submicron dimensions as well as the integration of the resulting nanostructures into larger systems. Nanofabrication methods include the manipulation or self-assembly of individual atoms, molecules, or molecular structures to produce nanostructured materials and sub-micron devices. Micro- and nanosystems components are fabricated using top-down lithographic and nonlithographic fabrication techniques. Nanotechnology will have a profound impact on our economy and society in the early 21st century, comparable to that of semiconductor technology, information technology, or advances in cellular and molecular biology. The research and development in nanotechnology will lead to potential breakthroughs in areas such as materials and manufacturing, nanoelectronics, medicine and healthcare, energy, biotechnology, information technology and national security. It is widely felt that nanotechnology will lead to the next industrial revolution.

Reliability is a critical technology for many micro- and nanosystems and nanostructured materials. No book exists on this emerging field. A broad based handbook is needed. The purpose of this handbook is to present an overview of nanomaterial synthesis, micro/nanofabrication, micro- and nanocomponents and systems, reliability issues (including nanotribology and nanomechanics) for nanotechnology, and industrial applications. The chapters have been written by internationally recognized experts in the field, from academia, national research labs and industry from all over the world.

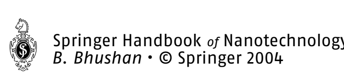
The handbook integrates knowledge from the fabrication, mechanics, materials science and reliability points of view. This book is intended for three types of readers: graduate students of nanotechnology, researchers in academia and industry who are active or intend to become active in this field, and practicing engineers and scientists who have encountered a problem and hope to solve it as expeditiously as possible. The handbook should serve as an excellent text for one or two semester graduate courses in nanotechnology in mechanical engineering, materials science, applied physics, or applied chemistry.

We embarked on this project in February 2002, and we worked very hard to get all the chapters to the publisher in a record time of about 1 year. I wish to sincerely thank the authors for offering to write comprehensive chapters on a tight schedule. This is generally an added responsibility in the hectic work schedules of researchers today. I depended on a large number of reviewers who provided critical reviews. I would like to thank Dr. Phillip J. Bond, Chief of Staff and Under Secretary for Technology, US Department of Commerce, Washington, D.C. for suggestions for chapters as well as authors in the handbook. I would also like to thank my colleague, Dr. Huiwen Liu, whose efforts during the preparation of this handbook were very useful.

I hope that this handbook will stimulate further interest in this important new field, and the readers of this handbook will find it useful.

September 2003

Bharat Bhushan
Editor



Editors Vita

Dr. Bharat Bhushan received an M.S. in mechanical engineering from the Massachusetts Institute of Technology in 1971, an M.S. in mechanics and a Ph.D. in mechanical engineering from the University of Colorado at Boulder in 1973 and 1976, respectively, an MBA from Rensselaer Polytechnic Institute at Troy, NY in 1980, Doctor Technicae from the University of Trondheim at Trondheim, Norway in 1990, a Doctor of Technical Sciences from the Warsaw University of Technology at Warsaw, Poland in 1996, and Doctor Honouris Causa from the Metal-Polymer Research Institute of National Academy of Sciences at Gomel, Belarus in 2000. He is a registered professional engineer (mechanical). He is presently an Ohio Eminent Scholar and The Howard D. Winbigler Professor in the Department of Mechanical Engineering, Graduate Research Faculty Advisor in the Department of Materials Science and Engineering, and the Director of the Nanotribology Laboratory for Information Storage & MEMS/NEMS (NLIM) at the Ohio State University, Columbus, Ohio. He is an internationally recognized expert of tribology on the macro- to nanoscales, and is one of the most prolific authors in the field. He is considered by some a pioneer of the tribology and mechanics of magnetic storage devices and a leading researcher in the fields of nanotribology and nanomechanics using scanning probe microscopy and applications to micro/nanotechnology. He has authored 5 technical books, 45 handbook chapters, more than 450 technical papers in referred journals, and more than 60 technical reports, edited more than 25 books, and holds 14 U.S. patents. He is founding editor-in-chief of World Scientific Advances in Information Storage Systems Series, CRC Press Mechanics and Materials Science Series, and Microsystem Technologies – Micro- & Nanosystems and Information Storage & Processing Systems (formerly called Journal of Information Storage and Processing Systems). He has given more than 250 invited presentations on five continents and more than 60 keynote/plenary addresses at major international conferences.

Dr. Bhushan is an accomplished organizer. He organized the first symposium on Tribology and Mechanics of Magnetic Storage Systems in 1984 and the first international symposium on Advances in Information Storage Systems in 1990, both of which are now held annually. He is the founder of an ASME Information Storage and Processing Systems Division founded in 1993 and served as the founding chair during 1993–1998. His biography has been listed in over two dozen Who's Who books including Who's Who in the World and has received more than a dozen awards for his contributions to science and technology from professional societies, industry, and U.S. government agencies. He is also the recipient of various international fellowships including the Alexander von Humboldt Research Prize for Senior Scientists, Max Planck Foundation Research Award for Outstanding Foreign Scientists, and the Fulbright Senior Scholar Award. He is a foreign member of the International Academy of Engineering (Russia), Belorussian Academy of Engineering and Technology and the Academy of Triboengineering of Ukraine, an honorary member of the Society of Tribologists of Belarus, a fellow of ASME, IEEE, and the New York Academy of Sciences, and a member of STLE, ASEE, Sigma Xi and Tau Beta Pi.

Dr. Bhushan has previously worked for the R & D Division of Mechanical Technology Inc., Latham, NY; the Technology Services Division of SKF Industries Inc., King of Prussia, PA; the General Products Division Laboratory of IBM Corporation, Tucson, AZ; and the Almaden Research Center of IBM Corporation, San Jose, CA.

List of Tables XXIX
List of Abbreviations XXXIII

1 **Introduction to Nanotechnology** 1
1.1 Background and Definition of Nanotechnology 1
1.2 Why Nano? 2
1.3 Lessons from Nature 2
1.4 Applications in Different Fields 3
1.5 Reliability Issues of MEMS/NEMS 4
1.6 Organization of the Handbook 5
References 5

Part A Nanostructures, Micro/Nanofabrication, and Micro/Nanodevices

2 **Nanomaterials Synthesis and Applications: Molecule-Based Devices** 9
2.1 Chemical Approaches to Nanostructured Materials 10
2.2 Molecular Switches and Logic Gates 14
2.3 Solid State Devices 22
2.4 Conclusions and Outlook 35
References 36

3 **Introduction to Carbon Nanotubes** 39
3.1 Structure of Carbon Nanotubes 40
3.2 Synthesis of Carbon Nanotubes 45
3.3 Growth Mechanisms of Carbon Nanotubes 59
3.4 Properties of Carbon Nanotubes 63
3.5 Carbon Nanotube-Based Nano-Objects 68
3.6 Applications of Carbon Nanotubes 73
References 86

4 **Nanowires** 99
4.1 Synthesis 100
4.2 Characterization and Physical Properties of Nanowires 110
4.3 Applications 131
4.4 Concluding Remarks 138
References 138

5 **Introduction to Micro/Nanofabrication** 147
5.1 Basic Microfabrication Techniques 148
5.2 MEMS Fabrication Techniques 159

5.3 Nanofabrication Techniques ... 170
References ... 180

6 **Stamping Techniques for Micro and Nanofabrication: Methods and Applications** ... 185
6.1 High Resolution Stamps ... 186
6.2 Microcontact Printing ... 187
6.3 Nanotransfer Printing ... 190
6.4 Applications ... 193
6.5 Conclusions ... 200
References ... 200

7 **Materials Aspects of Micro- and Nanoelectromechanical Systems** ... 203
7.1 Silicon ... 203
7.2 Germanium-Based Materials ... 210
7.3 Metals ... 211
7.4 Harsh Environment Semiconductors ... 212
7.5 GaAs, InP, and Related III-V Materials ... 217
7.6 Ferroelectric Materials ... 218
7.7 Polymer Materials ... 219
7.8 Future Trends ... 220
References ... 221

8 **MEMS/NEMS Devices and Applications** ... 225
8.1 MEMS Devices and Applications ... 227
8.2 NEMS Devices and Applications ... 246
8.3 Current Challenges and Future Trends ... 249
References ... 250

9 **Microfluidics and Their Applications to Lab-on-a-Chip** ... 253
9.1 Materials for Microfluidic Devices and Micro/Nano Fabrication Techniques ... 254
9.2 Active Microfluidic Devices ... 257
9.3 Smart Passive Microfluidic Devices ... 262
9.4 Lab-on-a-Chip for Biochemical Analysis ... 270
References ... 276

10 **Therapeutic Nanodevices** ... 279
10.1 Definitions and Scope of Discussion ... 280
10.2 Synthetic Approaches: "top-down" versus "bottom-up" Approaches for Nanotherapeutic Device Components ... 285
10.3 Technological and Biological Opportunities ... 288
10.4 Applications for Nanotherapeutic Devices ... 307
10.5 Concluding Remarks: Barriers to Practice and Prospects ... 315
References ... 317

Part B Scanning Probe Microscopy

11 **Scanning Probe Microscopy – Principle of Operation, Instrumentation, and Probes** 325
11.1 Scanning Tunneling Microscope 327
11.2 Atomic Force Microscope 331
11.3 AFM Instrumentation and Analyses 347
References 364

12 **Probes in Scanning Microscopies** 371
12.1 Atomic Force Microscopy 372
12.2 Scanning Tunneling Microscopy 382
References 383

13 **Noncontact Atomic Force Microscopy and Its Related Topics** 385
13.1 Principles of Noncontact Atomic Force Microscope (NC-AFM) 386
13.2 Applications to Semiconductors 391
13.3 Applications to Insulators 397
13.4 Applications to Molecules 404
References 407

14 **Low Temperature Scanning Probe Microscopy** 413
14.1 Microscope Operation at Low Temperatures 414
14.2 Instrumentation 415
14.3 Scanning Tunneling Microscopy and Spectroscopy 419
14.4 Scanning Force Microscopy and Spectroscopy 433
References 442

15 **Dynamic Force Microscopy** 449
15.1 Motivation: Measurement of a Single Atomic Bond 450
15.2 Harmonic Oscillator: A Model System for Dynamic AFM 454
15.3 Dynamic AFM Operational Modes 455
15.4 Q-Control 464
15.5 Dissipation Processes Measured with Dynamic AFM 468
15.6 Conclusion 471
References 471

16 **Molecular Recognition Force Microscopy** 475
16.1 Ligand Tip Chemistry 476
16.2 Fixation of Receptors to Probe Surfaces 478
16.3 Single-Molecule Recognition Force Detection 479
16.4 Principles of Molecular Recognition Force Spectroscopy 482
16.5 Recognition Force Spectroscopy: From Isolated Molecules to Biological Membranes 484
16.6 Recognition Imaging 489
16.7 Concluding Remarks 491
References 492

Part C Nanotribology and Nanomechanics

17 **Micro/Nanotribology and Materials Characterization Studies Using Scanning Probe Microscopy** ... 497
17.1 Description of AFM/FFM and Various Measurement Techniques ... 499
17.2 Friction and Adhesion ... 507
17.3 Scratching, Wear, Local Deformation, and Fabrication/Machining ... 518
17.4 Indentation ... 526
17.5 Boundary Lubrication ... 530
17.6 Closure ... 538
References ... 539

18 **Surface Forces and Nanorheology of Molecularly Thin Films** ... 543
18.1 Introduction: Types of Surface Forces ... 544
18.2 Methods Used to Study Surface Forces ... 546
18.3 Normal Forces Between Dry (Unlubricated) Surfaces ... 550
18.4 Normal Forces Between Surfaces in Liquids ... 554
18.5 Adhesion and Capillary Forces ... 564
18.6 Introduction: Different Modes of Friction and the Limits of Continuum Models ... 569
18.7 Relationship Between Adhesion and Friction Between Dry (Unlubricated and Solid Boundary Lubricated) Surfaces ... 571
18.8 Liquid Lubricated Surfaces ... 580
18.9 Role of Molecular Shape and Surface Structure in Friction ... 591
References ... 594

19 **Scanning Probe Studies of Nanoscale Adhesion Between Solids in the Presence of Liquids and Monolayer Films** ... 605
19.1 The Importance of Adhesion at the Nanoscale ... 605
19.2 Techniques for Measuring Adhesion ... 606
19.3 Calibration of Forces, Displacements, and Tips ... 610
19.4 The Effect of Liquid Capillaries on Adhesion ... 612
19.5 Self-Assembled Monolayers ... 618
19.6 Concluding Remarks ... 624
References ... 624

20 **Friction and Wear on the Atomic Scale** ... 631
20.1 Friction Force Microscopy in Ultra-High Vacuum ... 632
20.2 The Tomlinson Model ... 636
20.3 Friction Experiments on Atomic Scale ... 638
20.4 Thermal Effects on Atomic Friction ... 642
20.5 Geometry Effects in Nanocontacts ... 646
20.6 Wear on the Atomic Scale ... 649
20.7 Molecular Dynamics Simulations of Atomic Friction and Wear ... 651
20.8 Energy Dissipation in Noncontact Atomic Force Microscopy ... 654
20.9 Conclusion ... 656
References ... 657

21 **Nanoscale Mechanical Properties – Measuring Techniques and Applications** 661
21.1 Local Mechanical Spectroscopy by Contact AFM 662
21.2 Static Methods – Mesoscopic Samples 667
21.3 Scanning Nanoindentation: An Application to Bone Tissue 674
21.4 Conclusions and Perspectives 682
References 682

22 **Nanomechanical Properties of Solid Surfaces and Thin Films** 687
22.1 Instrumentation 688
22.2 Data Analysis 694
22.3 Modes of Deformation 702
22.4 Thin Films and Multilayers 707
22.5 Developing Areas 711
References 712

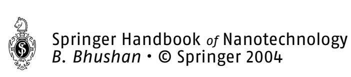
23 **Atomistic Computer Simulations of Nanotribology** 717
23.1 Molecular Dynamics 718
23.2 Friction Mechanisms at the Atomic Scale 723
23.3 Stick–Slip Dynamics 732
23.4 Conclusions 734
References 735

24 **Mechanics of Biological Nanotechnology** 739
24.1 Science at the Biology–Nanotechnology Interface 740
24.2 Scales at the Bio–Nano Interface 746
24.3 Modeling at the Nano–Bio Interface 752
24.4 Nature's Nanotechnology Revealed: Viruses as a Case Study 755
24.5 Concluding Remarks 760
References 761

25 **Mechanical Properties of Nanostructures** 763
25.1 Experimental Techniques for Measurement of Mechanical Properties of Nanostructures 765
25.2 Experimental Results and Discussion 770
25.3 Finite Element Analysis of Nanostructures with Roughness and Scratches 778
25.4 Closure 785
References 786

Part D Molecularly Thick Films for Lubrication

26 **Nanotribology of Ultrathin and Hard Amorphous Carbon Films** 791
26.1 Description of Commonly Used Deposition Techniques 795
26.2 Chemical Characterization and Effect of Deposition Conditions on Chemical Characteristics and Physical Properties 800



26.3 Micromechanical and Tribological Characterizations of Coatings Deposited by Various Techniques ... 805
References ... 827

27 **Self-Assembled Monolayers for Controlling Adhesion, Friction and Wear** ... 831
27.1 A Primer to Organic Chemistry ... 834
27.2 Self-Assembled Monolayers: Substrates, Head Groups, Spacer Chains, and End Groups ... 839
27.3 Tribological Properties of SAMs ... 841
27.4 Closure ... 856
References ... 857

28 **Nanoscale Boundary Lubrication Studies** ... 861
28.1 Lubricants Details ... 862
28.2 Nanodeformation, Molecular Conformation, and Lubricant Spreading ... 864
28.3 Boundary Lubrication Studies ... 866
28.4 Closure ... 880
References ... 881

29 **Kinetics and Energetics in Nanolubrication** ... 883
29.1 Background: From Bulk to Molecular Lubrication ... 885
29.2 Thermal Activation Model of Lubricated Friction ... 887
29.3 Functional Behavior of Lubricated Friction ... 888
29.4 Thermodynamical Models Based on Small and Nonconforming Contacts ... 890
29.5 Limitation of the Gaussian Statistics – The Fractal Space ... 891
29.6 Fractal Mobility in Reactive Lubrication ... 892
29.7 Metastable Lubricant Systems in Large Conforming Contacts ... 894
29.8 Conclusion ... 895
References ... 895

Part E Industrial Applications and Microdevice Reliability

30 **Nanotechnology for Data Storage Applications** ... 899
30.1 Current Status of Commercial Data Storage Devices ... 901
30.2 Opportunities Offered by Nanotechnology for Data Storage ... 907
30.3 Conclusion ... 918
References ... 919

31 **The "Millipede" – A Nanotechnology-Based AFM Data-Storage System** ... 921
31.1 The Millipede Concept ... 923
31.2 Thermomechanical AFM Data Storage ... 924
31.3 Array Design, Technology, and Fabrication ... 926

31.4 Array Characterization 927
31.5 *x*/*y*/*z* Medium Microscanner 929
31.6 First Write/Read Results with the 32×32 Array Chip 931
31.7 Polymer Medium 932
31.8 Read Channel Model 939
31.9 System Aspects 943
31.10 Conclusions 948
References 948

32 **Microactuators for Dual-Stage Servo Systems in Magnetic Disk Files** 951
32.1 Design of the Electrostatic Microactuator 952
32.2 Fabrication 962
32.3 Servo Control Design of MEMS Microactuator Dual-Stage Servo Systems 968
32.4 Conclusions and Outlook 978
References 979

33 **Micro/Nanotribology of MEMS/NEMS Materials and Devices** 983
33.1 Introduction to MEMS 985
33.2 Introduction to NEMS 988
33.3 Tribological Issues in MEMS/NEMS 989
33.4 Tribological Studies of Silicon and Related Materials 995
33.5 Lubrication Studies for MEMS/NEMS 1003
33.6 Component-Level Studies 1009
References 1017

34 **Mechanical Properties of Micromachined Structures** 1023
34.1 Measuring Mechanical Properties of Films on Substrates 1023
34.2 Micromachined Structures for Measuring Mechanical Properties 1024
34.3 Measurements of Mechanical Properties 1034
References 1037

35 **Thermo- and Electromechanics of Thin-Film Microstructures** 1039
35.1 Thermomechanics of Multilayer Thin-Film Microstructures 1041
35.2 Electromechanics of Thin-Film Microstructures 1061
35.3 Summary and Mention of Topics not Covered 1078
References 1078

36 **High Volume Manufacturing and Field Stability of MEMS Products** 1083
36.1 Manufacturing Strategy 1086
36.2 Robust Manufacturing 1087
36.3 Stable Field Performance 1102
References 1106

37 **MEMS Packaging and Thermal Issues in Reliability** 1111
37.1 MEMS Packaging 1111
37.2 Hermetic and Vacuum Packaging and Applications 1116
37.3 Thermal Issues and Packaging Reliability 1122
37.4 Future Trends and Summary 1128
References 1129

Part F Social and Ethical Implication

38 **Social and Ethical Implications of Nanotechnology** 1135
38.1 Applications and Societal Impacts 1136
38.2 Technological Convergence 1139
38.3 Major Socio-technical Trends 1141
38.4 Sources of Ethical Behavior 1143
38.5 Public Opinion 1145
38.6 A Research Agenda 1148
References 1149

List of Tables

Part A Nanostructures, Micro/Nanofabrication, and Micro/Nanodevices

3 **Introduction to Carbon Nanotubes**
Table 3.1 Different carbon morphologies ... 50
Table 3.2 Carbon nanofilament morphologies and some basic synthesis conditions ... 62
Table 3.3 Adsorption properties and sites of SWNTs and MWNTs ... 65
Table 3.4 Preparation and catalytic performances of some nanotube-supported catalysts ... 77
Table 3.5 Applications for nanotube-based multifunctional materials ... 84

4 **Nanowires**
Table 4.1 Selected syntheses of nanowires by material ... 101

5 **Introduction to Micro/Nanofabrication**
Table 5.1 Typical dry etch chemistries ... 157
Table 5.2 Surface micromachined sacrificial/structural combinations ... 165

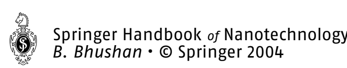
7 **Materials Aspects of Micro- and Nanoelectromechanical Systems**
Table 7.1 Selected materials for MEMS and NEMS ... 204

9 **Microfluidics and Their Applications to Lab-on-a-Chip**
Table 9.1 Overview of the different polymer micro/nano fabrication techniques ... 257

10 **Therapeutic Nanodevices**
Table 10.1 Ideal characteristics of nanodevices ... 282
Table 10.2 Orthogonal conjugation chemistries ... 295

Part B Scanning Probe Microscopy

11 **Scanning Probe Microscopy – Principle of Operation, Instrumentation, and Probes**
Table 11.1 Comparison of Various Conventional Microscopes with SPMs ... 326
Table 11.2 Relevant properties of materials used for cantilevers ... 339
Table 11.3 Measured vertical spring constants and natural frequencies of triangular (V-shaped) cantilevers made of PECVD Si_3N_4 ... 341
Table 11.4 Vertical and torsional spring constants of rectangular cantilevers made of Si and PECVD ... 341
Table 11.5 Noise in Interferometers ... 353



13 **Noncontact Atomic Force Microscopy and Its Related Topics**
Table 13.1 Comparison between the adatom heights observed in an AFM image and the variety of properties for inequivalent adatoms 393

Part C Nanotribology and Nanomechanics

17 **Micro/Nanotribology and Materials Characterization Studies Using Scanning Probe Microscopy**
Table 17.1 Comparison of typical operating parameters in SFA, STM, and AFM/FFM used for micro/nanotribological studies 498
Table 17.2 Surface roughness and coefficients of friction of various samples in air 518

18 **Surface Forces and Nanorheology of Molecularly Thin Films**
Table 18.1 Types of surface forces in vacuum vs. in liquid (colloidal forces) 545
Table 18.2 Van der Waals interaction energy and force between macroscopic bodies of different geometries 551
Table 18.3 Electrical "double-layer" interaction energy and force between macroscopic bodies 556
Table 18.4 The three main tribological regimes characterizing the changing properties of liquids 570
Table 18.5 Effect of molecular shape and short-range forces on tribological properties 592

19 **Scanning Probe Studies of Nanoscale Adhesion Between Solids in the Presence of Liquids and Monolayer Films**
Table 19.1 Interactions evaluated by atomic force microscopy adhesion measurements 620

21 **Nanoscale Mechanical Properties – Measuring Techniques and Applications**
Table 21.1 Summary of the mechanical properties of carbon nanotubes .. 672
Table 21.2 Absolute and relative changes of the indentation modulus with respect to the initial values under wet conditions 680

22 **Nanomechanical Properties of Solid Surfaces and Thin Films**
Table 22.1 Results for some experimental studies of multilayer hardness 710

24 **Mechanics of Biological Nanotechnology**
Table 24.1 Sizes of entities in comparison to the size of *E. coli* 748
Table 24.2 Time scales of various events in biological nanotechnology 750

25 **Mechanical Properties of Nanostructures**
Table 25.1 Hardness, elastic modulus, fracture toughness, and critical load results of the bulk single-crystal Si(100) and thin films of undoped polysilicon, SiO_2, SiC, Ni-P, and Au 770

Table 25.2 Summary of measured parameters from quasi-static bending tests ... 775
Table 25.3 Stresses and displacements for materials that are elastic, elastic-plastic, or elastic-perfectly plastic ... 784

Part D Molecularly Thick Films for Lubrication

26 **Nanotribology of Ultrathin and Hard Amorphous Carbon Films**
Table 26.1 Summary of the most commonly used deposition techniques . 796
Table 26.2 Experimental results from EELS and Raman spectroscopy ... 801
Table 26.3 Experimental results of FRS analysis ... 802
Table 26.4 Experimental results of physical properties ... 802
Table 26.5 Hardness, elastic modulus, fracture toughness, fatigue life, critical load during scratch, coefficient of friction of various DLC coatings ... 809

27 **Self-Assembled Monolayers for Controlling Adhesion, Friction and Wear**
Table 27.1 Relative electronegativity of selected elements ... 835
Table 27.2 Names and formulas of selected hydrocarbons ... 836
Table 27.3 Names and formulas of selected alcohols, ethers, phenols, and thiols ... 836
Table 27.4 Names and formulas of selected aldehydes and ketones ... 837
Table 27.5 Names and formulas of selected carboxylic acids and esters ... 838
Table 27.6 Names and formulas of selected organic nitrogen compounds 838
Table 27.7 Some examples of polar and nonpolar groups ... 839
Table 27.8 Organic groups listed in the increasing order of polarity ... 839
Table 27.9 Selected substrates and precursors used for formation of SAMs 840
Table 27.10 The roughness, thickness, tilt angles, and spacer chain lengths of SAMs ... 846
Table 27.11 Melting point of typical organic compounds similar to HDT and BPT SAMs ... 851
Table 27.12 Calculated and measured relative heights of HDT and MHA self-assembled monolayers ... 855
Table 27.13 Calculated and measured residual film thickness for SAMs under critical load ... 855
Table 27.14 Bond strengths of the chemical bonds in SAMs ... 856

28 **Nanoscale Boundary Lubrication Studies**
Table 28.1 Typical properties of Z-15 and Z-DOL ... 863

Part E Industrial Applications and Microdevice Reliability

30 **Nanotechnology for Data Storage Applications**
Table 30.1 A comparison of the parameters of HDD and ODD ... 903

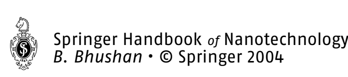


Table 30.2 Perceived technical limits for hard disk drive technology........ 904
Table 30.3 A table of probe storage operating parameters 909
Table 30.4 Probe storage projected performance 909

31 **The "Millipede" – A Nanotechnology-Based AFM Data-Storage System**
Table 31.1 Areal density and storage capacity 947

32 **Microactuators for Dual-Stage Servo Systems in Magnetic Disk Files**
Table 32.1 Parameters of the electrostatic microactuator 960

33 **Micro/Nanotribology of MEMS/NEMS Materials and Devices**
Table 33.1 Dimensions and masses in perspective 985
Table 33.2 Selected bulk properties of SiC and Si(100)............................. 996
Table 33.3 Surface roughness and micro- and macroscale coefficients of friction of selected samples.. 997

1. Introduction to Nanotechnology

by B. Bhushan

A biological system can be exceedingly small. Many of the cells are very tiny, but they are very active; they manufacture various substances; they walk around; they wiggle; and they do all kinds of marvelous things – all on a very small scale. Also, they store information. Consider the possibility that we too can make a thing very small which does what we want – that we can manufacture an object that maneuvers at that level.

(From the talk "There's Plenty of Room at the Bottom", delivered by Richard P. Feynman at the annual meeting of the American Physical Society at the California Institute of Technology, Pasadena, CA, on December 29, 1959.)

1.1 Background and Definition of Nanotechnology

On Dec. 29, 1959, at the California Institute of Technology, Nobel Laureate Richard P. Feynman gave a talk at the annual meeting of the American Physical Society that has become one of the twentieth century's classic science lectures, titled "There's Plenty of Room at the Bottom" [1.1]. He presented a technological vision of extreme miniaturization several years before the word "chip" became part of the lexicon. He talked about the problem of manipulating and controlling things on a small scale. Extrapolating from known physical laws, Feynman envisioned a technology using the ultimate toolbox of nature, building nanoobjects atom by atom or molecule by molecule. Since the 1980s, many inventions and discoveries in the fabrication of nanoobjects have become a testament to his vision. In recognition of this reality, the National Science and Technology Council (NSTC) of the White House created the Interagency Working Group on Nanoscience, Engineering and Technology (IWGN) in 1998. In a January 2000 speech at the same institute, former President William J. Clinton talked about the exciting promise of nanotechnology and, more generally, the importance of expanding research in nanoscale science and technology. Later that month, he announced in his State of the Union Address an ambitious $497 million federal, multi-agency National Nanotechnology Initiative (NNI) in the fiscal year 2001 budget, and made it a top science and technology priority [1.2, 3]. The objective of this initiative was to form a broad-based coalition in which academe, the private sector, and local, state, and federal governments would work together to push the envelope of nanoscience and nanoengineering to reap nanotechnology's potential social and economic benefits.

Nanotechnology literally means any technology performed on a nanoscale that has applications in the real world. Nanotechnology encompasses the production and application of physical, chemical, and biological systems at scales ranging from individual atoms or molecules to submicron dimensions, as well as the integration of the resulting nanostructures into larger systems. Nanotechnology is likely to have a profound impact on our economy and society in the early twenty-first century, comparable to that of semiconductor technology, information technology, or cellular and molecular biology. Science and technology research in nanotechnology promises breakthroughs in such areas as materials and manufacturing, nanoelectronics, medicine and healthcare, energy, biotechnology, information technology, and national security. It is widely felt that nanotechnology will be the next industrial revolution.

B. Bhushan • © Springer 2004

Nanometer-scale features are mainly built up from their elemental constituents. Chemical synthesis – the spontaneous self-assembly of molecular clusters (molecular self-assembly) from simple reagents in solution – or biological molecules (e.g., DNA) are used as building blocks for the production of three-dimensional nanostructures, including quantum dots (nanocrystals) of arbitrary diameter (about 10 to 10^5 atoms). A variety of vacuum deposition and nonequilibrium plasma chemistry techniques are used to produce layered nanocomposites and nanotubes. Atomically controlled structures are produced using molecular beam epitaxy and organo-metallic vapor phase epitaxy. Micro- and nanosystem components are fabricated using top-down lithographic and nonlithographic fabrication techniques and range in size from micro- to nanometers. Continued improvements in lithography for use in the production of nanocomponents have resulted in line widths as small as 10 nanometers in experimental prototypes. The nanotechnology field, in addition to the fabrication of nanosystems, provides the impetus to development of experimental and computational tools.

The micro- and nanosystems include micro/nanoelectromechanical systems (MEMS/NEMS) (e.g., sensors, actuators, and miniaturized systems comprising sensing, processing, and/or actuating functions), micromechatronics, optoelectronics, microfluidics, and systems integration. These systems can sense, control, and activate on the micro/nanoscale and function individually or in arrays to generate effects on the macroscale. The microsystems market in 2000 was about \$ 15 billion, and, with a projected 10–20 % annual growth rate, it is expected to increase to more than \$ 100 billion by the end of this decade. The nanosystems market in 2001 was about \$ 100 million and the integrated nanosystems market is expected to be more than \$ 25 billion by the end of this decade. Due to the enabling nature of these systems, and because of the significant impact they can have on the commercial and defense applications, venture capitalists, industry, as well as the federal government have taken a special interest in nurturing growth in this field. Micro- and nanosystems are likely to be the next logical step in the "silicon revolution."

1.2 Why Nano?

The discovery of novel materials, processes, and phenomena at the nanoscale, as well as the development of new experimental and theoretical techniques for research provide fresh opportunities for the development of innovative nanosystems and nanostructured materials. Nanosystems are expected to find various unique applications. Nanostructured materials can be made with unique nanostructures and properties. This field is expected to open new venues in science and technology.

1.3 Lessons from Nature

Nanotechnology is a new word, but it is not an entirely new field. Nature has many objects and processes that function on a micro- to nanoscale [1.2, 4]. The understanding of these functions can guide us in imitating and producing nanodevices and nanomaterials.

Billions of years ago, molecules began organizing themselves into the complex structures that could support life. Photosynthesis harnesses solar energy to support plant life. Molecular ensembles are present in plants, which include light harvesting molecules, such as chlorophyll, arranged within the cells on the nanometer to micrometer scales. These structures capture light energy, and convert it into the chemical energy that drives the biochemical machinery of plant cells. Live organs use chemical energy in the body. The flagella, a type of bacteria, rotates at over 10,000 RPM [1.5]. This is an example of a biological molecular machine. The flagella motor is driven by the proton flow caused by the electrochemical potential differences across the membrane. The diameter of the bearing is about 20–30 nm, with an estimated clearance of about 1 nm.

In the context of tribology, some biological systems have anti-adhesion surfaces. First, many plant leaves (such as lotus leaf) are covered by a hydrophobic cuticle, which is composed of a mixture of large hydrocarbon molecules that have a strong hydrophobia. Second, the surface is made of a unique roughness distribution [1.6, 7]. It has been reported that for some leaf surfaces, the roughness of the hydrophobic leaf surface decreases wetness, which is reflected in a greater contact angle of water droplets on such surfaces.

1.4 Applications in Different Fields

Science and technology continue to move forward in making the fabrication of micro/nanodevices and systems possible for a variety of industrial, consumer, and biomedical applications. A range of MEMS devices have been produced, some of which are commercially used [1.4, 8–12]. A variety of sensors are used in industrial, consumer, and biomedical applications. Various microstructures or microcomponents are used in micro-instruments and other industrial applications, such as micromirror arrays. Two of the largest "killer" industrial applications are accelerometers (about 85 million units in 2002) and digital micromirror devices (about $ 400 million in sales in 2001). Integrated capacitive-type, silicon accelerometers have been used in airbag deployment in automobiles since 1991 [1.13, 14]. Accelerometer technology was about a billion-dollar-a-year industry in 2001, dominated by Analog Devices followed by Motorola and Bosch. Commercial digital light processing (DLP) equipment using digital micromirror devices (DMD) were launched in 1996 by Texas Instruments for digital projection displays in portable and home theater projectors, as well as table-top and projection TVs [1.15, 16]. More than 1.5 million projectors were sold before 2002. Other major industrial applications include pressure sensors, inkjet printer heads, and optical switches. Silicon-based piezoresistive pressure sensors for manifold absolute pressure sensing for engines were launched in 1991 by NovaSensor, and their annual sales were about 25 million units in 2002. Annual sales of inkjet printer heads with microscale functional components were about 400 million units in 2002. Capacitive pressure sensors for tire pressure measurements were launched by Motorola. Other applications of MEMS devices include chemical sensors; gas sensors; infrared detectors and focal plane arrays for earth observations; space science and missile defense applications; pico-satellites for space applications; and many hydraulic, pneumatic, and other consumer products. MEMS devices are also being pursued in magnetic storage systems [1.17], where they are being developed for super-compact and ultrahigh recording-density magnetic disk drives. Several integrated head/suspension microdevices have been fabricated for contact recording applications [1.18, 19]. High-bandwidth, servo-controlled microactuators have been fabricated for ultrahigh track-density applications, which serve as the fine-position control element of a two-stage, coarse/fine servo system, coupled with a conventional actuator [1.20–23]. Millimeter-sized wobble motors and actuators for tip-based recording schemes have also been fabricated [1.24].

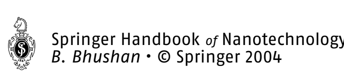
BIOMEMS are increasingly used in commercial and defense applications (e.g., [1.4, 25–28]). Applications of BIOMEMS include biofluidic chips (otherwise known as microfluidic chips, bioflips, or simply biochips) for chemical and biochemical analyses (biosensors) in medical diagnostics (e.g., DNA, RNA, proteins, cells, blood pressure and assays, and toxin identification) and implantable pharmaceutical drug delivery. The biosensors, also referred to as lab-on-a-chip, integrate sample handling, separation, detection, and data analysis onto one platform. Biosensors are designed to either detect a single or class of (bio)chemicals or system-level analytical capabilities for a broad range of (bio)chemical species known as micro total analysis systems (μTAS). The chips rely on microfluidics and involve the manipulation of tiny amounts of fluids in microchannels using microvalves for various analyses. The test fluid is pumped into the chip generally using an external pump for analyses. Some chips have been designed with an integrated electrostatically actuated diaphragm-type micropump. Silicon-based, disposable blood-pressure sensor chips were introduced in the early 1990s by NovaSensor for blood pressure monitoring (about 20 million units in 2002). A variety of biosensors are manufactured by various companies, including ACLARA, Agilent Technologies, Calipertech, and I-STAT.

After the tragedy of Sept. 11, 2001, concern over biological and chemical warfare has led to the development of handheld units with bio- and chemical sensors for the detection of biological germs, chemical or nerve agents, mustard agents, and chemical precursors to protect subways, airports, the water supply, and the population [1.29].

Other BIOMEMS applications include minimal invasive surgery, such as endoscopic surgery, laser angioplasty, and microscopic surgery. Implantable artificial organs can also be produced.

Micro-instruments and micro-manipulators are used to move, position, probe, pattern, and characterize nanoscale objects and nanoscale features. Miniaturized analytical equipment includes gas chromatography and mass spectrometry. Other instruments include micro-STM, where STM stands for scanning tunneling microscope.

Examples of NEMS include nanocomponents, nanodevices, nanosystems, and nanomaterials, such as



microcantilever with integrated sharp nanotips for STM and atomic force microscopy (AFM), AFM array (millipede) for data storage, AFM tips for nanolithography, dip-pen nanolithography for printing molecules, biological (DNA) motors, molecular gears, molecularly thick films (e.g., in giant magneto-resistive or GMR heads and magnetic media), nanoparticles, (e.g., nanomagnetic particles in magnetic media), nanowires, carbon nanotubes, quantum wires (QWRs), quantum boxes (QBs), and quantum transistors [1.30–34]. BIONEMS include nanobiosensors – a microarray of silicon nanowires, roughly a few nm in size, to selectively bind and detect even a single biological molecule, such as DNA or protein, by using nanoelectronics to detect the slight electrical charge caused by such binding, or a microarray of carbon nanotubes to electrically detect glucose, implantable drug-delivery devices – e.g., micro/nanoparticles with drug molecules encapsulated in functionized shells for a site-specific targeting application, and a silicon capsule with a nanoporous membrane filled with drugs for long term delivery, nanodevices for sequencing single molecules of DNA in the Human Genome Project, cellular growth using carbon nanotubes for spinal cord repair, nanotubes for nanostructured materials for various applications, such as spinal fusion devices, organ growth, and growth of artificial tissues using nanofibers.

Nanoelectronics can be used to build computer memory, using individual molecules or nanotubes to store bits of information, as well as molecular switches, molecular or nanotube transistors, nanotube flat-panel displays, nanotube integrated circuits, fast logic gates, switches, nanoscopic lasers, and nanotubes as electrodes in fuel cells.

1.5 Reliability Issues of MEMS/NEMS

There is an increasing need for a multidisciplinary, system-oriented approach to manufacturing micro/nanodevices that function reliably. This can only be achieved through the cross-fertilization of ideas from different disciplines and the systematic flow of information and people among research groups. Common potential failure mechanisms for MEMS/NEMS that need to be addressed in order to increase reliability are: adhesion, friction, wear, fracture, fatigue, and contamination. Surface micro/nanomachined structures often include smooth and chemically active surfaces. Due to the large surface area to volume ratio in MEMS/NEMS, they are particularly prone to stiction (high static friction) as part of normal operation. Fracture occurs when the load on a microdevice is greater than the strength of the material. Fracture is a serious reliability concern, particularly for the brittle materials used in the construction of these components, since it can immediately, or eventually, lead to catastrophic failures. Additionally, debris can be formed from the fracturing of microstructures, leading to other failure processes. For less brittle materials, repeated loading over a long period causes fatigue that would also lead to the breaking and fracturing of the device. In principle, this failure mode is relatively easy to observe and simple to predict. However, the materials properties of thin films are often not known, making fatigue predictions prone to error.

Many MEMS/NEMS devices operate near their thermal dissipation limit. They may encounter hot spots that can cause failures, particularly in weak structures such as diaphragms or cantilevers. Thermal stressing and relaxation caused by thermal variations can create material delamination and fatigue in cantilevers. In large temperature changes, as experienced in the space environment, bimetallic beams will also experience warping due to mismatched coefficients of thermal expansion. Packaging has been a big problem. The contamination, which probably happens in packaging and during storage, can also strongly influence the reliability of MEMS/NEMS. For example, a particulate dust landed on one of the electrodes of a comb drive can cause catastrophic failure. There are no MEMS/NEMS fabrication standards, which makes it difficult to transfer fabrication steps in MEMS/NEMS between foundaries.

Obviously, studies of determination and suppression of active failure mechanisms affecting this new and promising technology are critical to the high reliability of MEMS/NEMS and are determining factors in successful practical application.

Mechanical properties are known to exhibit a dependence on specimen size. Mechanical property evaluation of nanometer-scaled structures is carried out to help design reliable systems, since good mechanical properties are of critical importance in such applications. Some of the properties of interest are: Young's mod-

ulus of elasticity, hardness, bending strength, fracture toughness, and fatigue life. Finite element modeling is carried out to study the effects of surface roughness and scratches on stresses in nanostructures. When nanostructures are smaller than a fundamental physical length scale, conventional theory may no longer apply, and new phenomena may emerge. Molecular mechanics is used to simulate the behavior of a nano-object.

1.6 Organization of the Handbook

The handbook integrates knowledge from the fabrication, mechanics, materials science, and reliability points of view. Organization of the book is straightforward. The handbook is divided into six parts. This first part introduces the nanotechnology field, including an introduction to nanostructures, micro/nanofabrication and, micro/nanodevices. The second part introduces scanning probe microscopy. The third part provides an overview of nanotribology and nanomechanics, which will prepare the reader to understand the tribology and mechanics of industrial applications. The fourth part provides an overview of molecularly thick films for lubrication. The fifth part focuses on industrial applications and microdevice reliability. And the last part focuses on the social and ethical implications of nanotechnology.

2. Nanomaterials Synthesis and Applications: Molecule-Based Devices

The constituent components of conventional devices are carved out of larger materials relying on physical methods. This top-down approach to engineered building blocks becomes increasingly challenging as the dimensions of the target structures approach the nanoscale. Nature, on the other hand, relies on chemical strategies to assemble nanoscaled biomolecules. Small molecular building blocks are joined to produce nanostructures with defined geometries and specific functions. It is becoming apparent that nature's bottom-up approach to functional nanostructures can be mimicked to produce artificial molecules with nanoscaled dimensions and engineered properties. Indeed, examples of artificial nanohelices, nanotubes, and molecular motors are starting to be developed. Some of these fascinating chemical systems have intriguing electrochemical and photochemical properties that can be exploited to manipulate chemical, electrical, and optical signals at the molecular level. This tremendous opportunity has lead to the development of the molecular equivalent of conventional logic gates. Simple logic operations, for example, can be reproduced with collections of molecules operating in solution. Most of these chemical systems, however, rely on bulk addressing to execute combinational and sequential logic operations. It is essential to devise methods to reproduce these useful functions in solid-state configurations and, eventually, with single molecules. These challenging objectives are stimulating the design of clever devices that interface small assemblies of organic molecules with macroscaled and nanoscaled electrodes. These strategies have already produced rudimentary examples of diodes, switches, and transistors based on functional molecular components. The rapid and continuous progress of this exploratory research will, we hope, lead to an entire generation of molecule-based devices that might ultimately find useful applications in a variety of fields, ranging from biomedical research to information technology.

2.1 Chemical Approaches to Nanostructured Materials

The fabrication of conventional devices relies on the assembly of macroscopic building blocks with specific configurations. The shapes of these components are carved out of larger materials by exploiting physical methods. This top-down approach to engineered building blocks is extremely powerful and can deliver effectively and reproducibly microscaled objects. This strategy becomes increasingly challenging, however, as the dimensions of the target structures approach the nanoscale. Indeed, the physical fabrication of nanosized features with subnanometer precision is a formidable technological challenge.

2.1.1 From Molecular Building Blocks to Nanostructures

Nature efficiently builds nanostructures by relying on chemical approaches. Tiny molecular building blocks are assembled with a remarkable degree of structural control in a variety of nanoscaled materials with defined shapes, properties, and functions. In contrast to the top-down physical methods, small components are connected to produce larger objects in these bottom-up chemical strategies. It is becoming apparent that the limitations of the top-down approach to artificial nanostructures can be overcome by mimicking nature's bottom-up processes. Indeed, we are starting to see emerge beautiful and ingenious examples of molecule-based strategies to fabricate chemically nanoscaled building blocks for functional materials and innovative devices.

2.1.2 Nanoscaled Biomolecules: Nucleic Acids and Proteins

Nanoscaled macromolecules play a fundamental role in biological processes [2.1]. Nucleic acids, for example, ensure the transmission and expression of genetic information. These particular biomolecules are linear polymers incorporating nucleotide repeating units (Fig. 2.1a). Each nucleotide has a phosphate bridge and a sugar residue. Chemical bonds between the phosphate of one nucleotide and the sugar of the next ensures the propagation of a polynucleotide strand from the 5′ to the 3′ end. Along the sequence of alternating sugar and phosphate fragments, an extended chain of robust covalent bonds involving carbon, oxygen, and phosphorous atoms forms the main backbone of the polymeric strand.

Every single nucleotide of a polynucleotide strand carries one of the four heterocyclic bases shown in Fig. 2.1b. For a strand incorporating 100 nucleotide repeating units, a total of 4^{100} unique polynucleotide sequences are possible. It follows that nature can fabricate a huge number of closely related nanostructures relying only on four building blocks. The heterocyclic bases appended to the main backbone of alternating phosphate and sugar units can sustain hydrogen bonding and $[\pi \cdots \pi]$ stacking interactions. Hydrogen bonds, formed between [N−H] donors and either N or O acceptors, encourage the pairing of adenine (A) with thymine (T) and of guanine (G) with cytosine (C). The stacking interactions involve attractive contacts between the extended π-surfaces of heterocyclic bases.

In the *B* conformation of deoxyribonucleic acid (DNA), the synergism of hydrogen bonds and $[\pi \cdots \pi]$ stacking glues pairs of complementary polynucleotide strands in fascinating double helical supermolecules (Fig. 2.1c) with precise structural control at the subnanometer level. The two polynucleotide strands wrap around a common axis to form a right-handed double helix with a diameter of ca. 2 nm. The hydrogen bonded and $[\pi \cdots \pi]$ stacked base pairs lie at the core of the helix with their π-planes perpendicular to the main axis of the helix. The alternating phosphate and sugar units define the outer surface of the double helix. In *B*-DNA, approximately ten base pairs define each helical turn corresponding to a rise per turn or helical pitch of ca. 3 nm. Considering that these molecules can incorporate up to approximately 10^{11} base pairs, extended end-to-end lengths spanning from only few nanometers to hundreds of meters are possible.

Nature's operating principles to fabricate nanostructures are not limited to nucleic acids. Proteins are also built joining simple molecular building blocks, the amino acids, by strong covalent bonds [2.1]. More precisely, nature relies on 20 amino acids differing in their side chains to assemble linear polymers, called polypeptides, incorporating an extended backbone of robust [C−N] and [C−C] bonds (Fig. 2.2a). For a single polymer strand of 100 repeating amino acid units, a total of 20^{100} unique combinations of polypeptide sequences are possible. Considering that proteins can incorporate more than one polypetide chain with over 4,000 amino acid residues each, it is obvious that nature can assemble an enormous number of different biomolecules relying on the same fabrication strategy and a relatively small pool of building blocks.

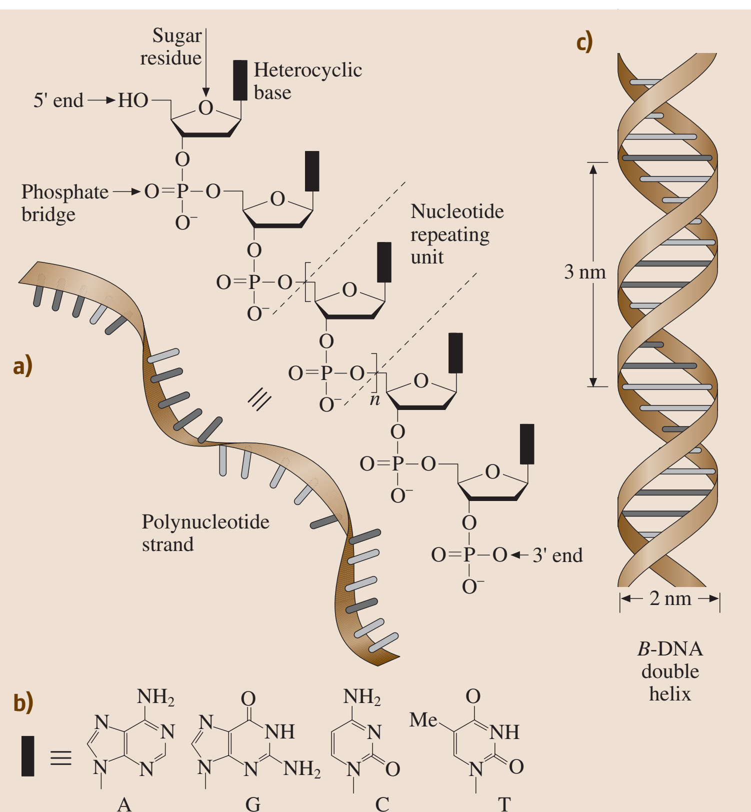

Fig. 2.1a–c A polynucleotide strand **(a)** incorporates alternating phosphate and sugar residues joined by covalent bonds. Each sugar carries one of four heterocyclic bases **(b)**. Noncovalent interactions between complementary bases in two independent polynucleotide strands encourage the formation of nanoscaled double helixes **(c)**

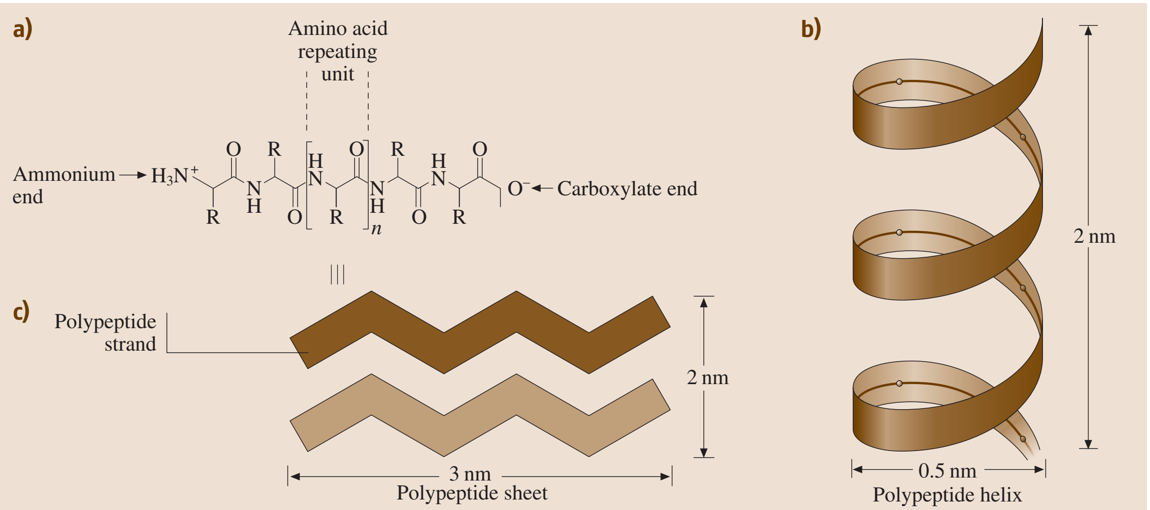

Fig. 2.2a–c A polypeptide strand **(a)** incorporates amino acid residues differing in their side chains and joined by covalent bonds. Hydrogen bonding interactions curl a single polypeptide strand into a helical arrangement **(b)** or lock pairs of strands into nanoscaled sheets **(c)**

The covalent backbones of the polypeptide strands form the main skeleton of a protein molecule. In addition, myriad secondary interactions, involving noncovalent contacts between portions of the amino acid residues, control the arrangement of the individual polypeptide chains. Intrastrand hydrogen bonds curl single polypeptide chains around a longitudinal axis in a helical fashion to form tubular nanostructures ca. 0.5 nm wide and ca. 2 nm long (Fig. 2.2b). Similarly, interstrand hydrogen bonds can align from 2 up to 15 parallel or antiparallel polypeptide chains to form nanoscaled sheets with average dimensions of 2×3 nm (Fig. 2.2c). Multiple nanohelices and/or nanosheets combine into a unique three-dimensional arrangement dictating the overall shape and dimensions of a protein.

2.1.3 Chemical Synthesis of Artificial Nanostructures

Nature fabricates complex nanostructures relying on simple criteria and a relatively small pool of molecular building blocks. Robust chemical bonds join the basic components into covalent scaffolds. Noncovalent interactions determine the three-dimensional arrangement and overall shape of the resulting assemblies. The multitude of unique combinations possible for long sequences of chemically connected building blocks provides access to huge libraries of nanoscaled biomolecules.

Modern chemical synthesis has evolved considerably over the past few decades [2.2]. Experimental procedures to join molecular components with structural control at the picometer level are available. A multitude of synthetic schemes to encourage the formation of chemical bonds between selected atoms in reacting molecules have been developed. Furthermore, the tremendous progress of crystallographic and spectroscopic techniques has provided efficient and reliable tools to probe directly the structural features of artificial inorganic and organic compounds. It follows that designed molecules with engineered shapes and dimensions can be now prepared in a laboratory relying on the many tricks of chemical synthesis and the power of crystallographic and spectroscopic analyses.

The high degree of sophistication reached in this research area translates into the possibility of mimicking the strategies successfully employed by nature to fabricate chemically nanostructures [2.3]. Small molecular building blocks can be synthesized and joined covalently following routine laboratory procedures. It is even possible to design the stereoelectronic properties of the assembling components in order to shape the geometry of the final product with the assistance of noncovalent interactions. For example, five bipyridine building blocks (Fig. 2.3) can be connected in five synthetic steps to produce an oligobipyridine strand [2.4]. The five repeating units are bridged by [C−O] bonds and can chelate metal cations in the bay regions defined by their two nitrogen atoms. The spontaneous assembly of two organic strands in a double helical arrangement occurs in the presence of inorganic cations. In the resulting helicate, the two oligobipyridine strands wrap around an axis defined by five Cu(I) centers. Each inorganic cation coordinates two bipyridine units with a tetrahedral geometry imposing a diameter of ca. 0.6 nm on the nanoscaled helicate [2.5]. The overall length from one end of the helicate to the other is ca. 3 nm [2.6]. The analogy between this artificial double helix and the *B*-DNA double helix shown in Fig. 2.1c is obvious. In both instances, a supramolecular glue combines two independent molecular strands into nanostructures with defined shapes and dimensions.

The chemical synthesis of nanostructures can borrow nature's design criteria as well as its molecular building blocks. Amino acids, the basic components of proteins, can be assembled into artificial macrocycles. In the example of Fig. 2.4, eight amino acid residues are joined through the formation of [C−N] bonds in multiple synthetic steps [2.7]. The resulting covalent backbone defines a circular cavity with a diameter of ca. 0.8 nm [2.8]. In analogy to the polypeptide chains of proteins, the amino acid residues of this artificial oligopeptide can sustain hydrogen bonding interactions. It follows that multiple macrocycles can pile on top of each other to form tubular nanostructures. The walls of the resulting nanotubes are maintained in position by the cooperative action of at least eight primary hydrogen bonding contacts per macrocycle. These noncovalent interactions maintain the mean planes of independent macrocycles in an approximately parallel arrangement with a plane-to-plane separation of ca. 0.5 nm.

2.1.4 From Structural Control to Designed Properties and Functions

The examples in Figs. 2.3 and 2.4 demonstrate that modular building blocks can be assembled into target compounds with precise structural control at the picometer level through programmed sequences of synthetic steps. Indeed, modern chemical synthesis offers access to complex molecules with nanoscaled dimensions and, thus, provides cost-effective strategies for the production

and characterization of billions of engineered nanostructures in parallel. Furthermore, the high degree of structural control is accompanied by the possibility of designing specific properties into the target nanostructures. Electroactive and photoactive components can be integrated chemically into functional molecular machines [2.9]. Extensive electrochemical investigations have demonstrated that inorganic and organic compounds can exchange electrons with macroscopic electrodes [2.10]. These studies have unraveled the processes responsible for the oxidation and reduction of numerous functional groups and indicated viable design criteria to adjust the ability of molecules to accept or donate electrons [2.11]. Similarly, detailed photochemical and photophysical investigations have elucidated the mechanisms responsible for the absorption and emission of photons at the molecular level [2.12]. The vast knowledge established on the interactions between light and molecules offers the opportunity to engineer chromophoric and fluorophoric functional groups with defined absorption and emission properties [2.11, 13].

The power of chemical synthesis to deliver functional molecules is, perhaps, better illustrated by the molecular motor shown in Fig. 2.5. The preparation of this [2]rotaxane requires 12 synthetic steps starting from known precursors [2.14]. This complex molecule incorporates a Ru(II)-trisbipyridine stopper bridged to a linear tetracationic fragment by a rigid triaryl spacer. The other end of the tetracationic portion is terminated by a bulky tetraarylmethane stopper. The bipyridinium unit of this dumbbell-shaped compound is encircled by a macrocyclic polyether. No covalent bonds join the macrocyclic and linear components.

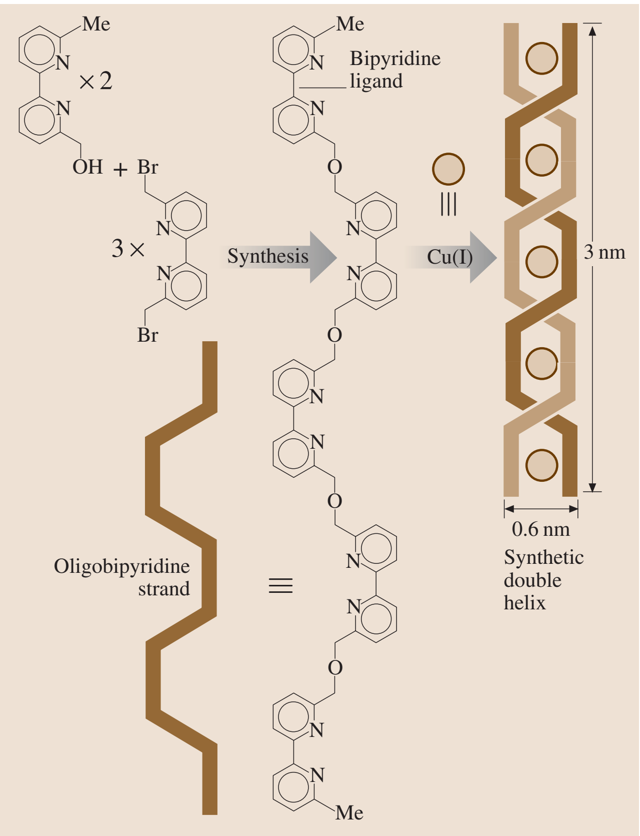

Fig. 2.3 An oligobipyridine strand can be synthesized joining five bipyridine subunits by covalent bonds. The tetrahedral coordination of pairs of bipyridine ligands by Cu(I) ions encourages the assembly two oligobipyridine strands into a double helical arrangement

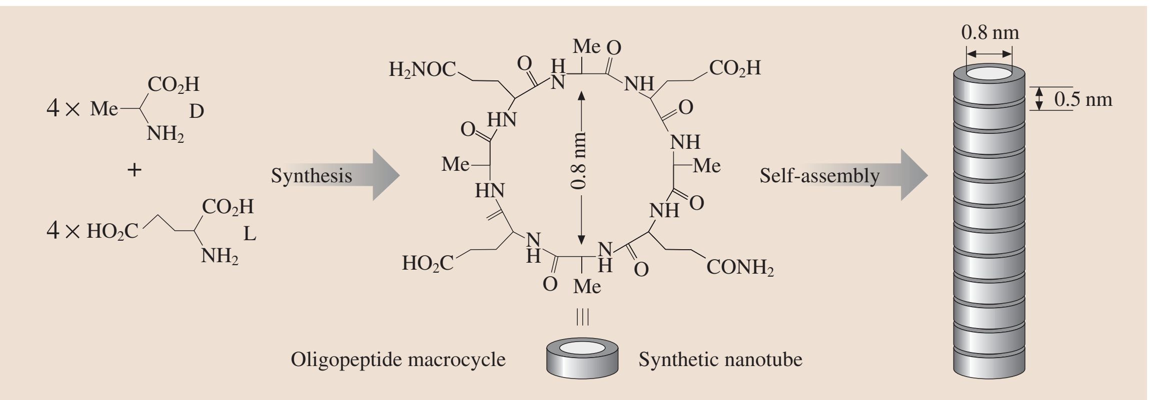

Fig. 2.4 Cyclic oligopeptides can be synthesized joining eight amino acid residues by covalent bonds. The resulting macrocycles self-assemble into nanoscaled tube-like arrays

Fig. 2.5 This nanoscaled [2]rotaxane incorporates a photoactive Ru(II)-trisbipyridine stopper and two electroactive bipyridinium units. Photoinduced electron transfer from the photoactive stopper to the encircled electroactive unit forces the macrocyclic polyether to shuttle to the adjacent bipyridinium dication

Rather, hydrogen bonding and $[\pi \cdots \pi]$ stacking interactions maintain the macrocyclic polyether around the bipyridinium unit. In addition, mechanical constrains associated with the bulk of the two terminal stoppers prevent the macrocycle to slip off the thread. The approximate end-to-end distance for this [2]rotaxane is ca. 5 nm.

The bipyridinium and the 3,3′-dimethyl bipyridinium units within the dumbbell-shaped component undergo two consecutive and reversible monoelectronic reductions [2.14]. The two methyl substituents on the 3,3′-dimethyl bipyridinium dication make this electroactive unit more difficult to reduce. In acetonitrile, its redox potential is ca. 0.29 V more negative than that of the unsubstituted bipyridinium dication. Under irradiation at 436 nm in degassed acetonitrile, the excitation of the Ru(II)-trisbipyridine stopper is followed by electron transfer to the unsubstituted bipyridinium unit. In the presence of a sacrificial electron donor (triethanolamine) in solution, the photogenerated hole in the photoactive stopper is filled, and undesired back electron transfer is suppressed. The permanent and light-induced reduction of the dicationic bipyridinium unit to a radical cation depresses significantly the magnitude of the noncovalent interactions holding the macrocyclic polyether in position. As a result, the macrocycle shuttles from the reduced unit to the adjacent dicationic 3,3′-dimethyl bipyridinum. After the diffusion of molecular oxygen into the acetonitrile solution, oxidation occurs restoring the dicationic form of the bipyridinium unit and its ability to sustain strong noncovalent bonds. As a result, the macrocyclic polyether shuttles back to its original position. This amazing example of a molecular shuttle reveals that dynamic processes can be controlled reversibly at the molecular level relying on the clever integration of electroactive and photoactive fragments into functional and nanoscaled molecules.

2.2 Molecular Switches and Logic Gates

Everyday, we routinely perform dozens of switching operations. We turn on and off our personal computers, cellular phones, CD players, radios, or simple light bulbs at a click of a button. Every single time, our finger exerts a mechanical stimulation on a control device, namely a switch. The external stimulus changes the physical state of the switch closing or opening an electric circuit and enabling or preventing the passage of electrons.

Overall, the switch transduces a mechanical input into an electrical output.

2.2.1 From Macroscopic to Molecular Switches

The use of switching devices is certainly not limited to electric circuits. For example, a switch at the junction of a railroad can divert trains from one track to another. Similarly, a faucet in a lavatory pipe can block or release the flow of water. Of course, the nature of the control stimulations and the character of the final outcome vary significantly from case to case, but the operating principle behind each switching device is the same. In all cases, input stimulations reach the switch changing its physical state and producing a specific output.

The development of nanoscaled counterparts to conventional switches is expected to have fundamental scientific and technological implications. For instance, one can envisage practical applications for ultraminiaturized switches in areas ranging from biomedical research to information technology. The major challenge in the quest for nanoswitches, however, is the identification of reliable design criteria and operating principles for these innovative and fascinating devices. Chemical approaches to implement molecule-sized switches appear to be extremely promising. The intrinsically small dimensions of organic molecules coupled with the power of chemical synthesis are the main driving forces behind these exploratory investigations.

Certain organic molecules adjust their structural and electronic properties when stimulated with chemical, electrical, or optical inputs. Generally, the change is accompanied by an electrochemical or spectroscopic response. Overall, these nanostructures transduce input stimulations into detectable outputs and, appropriately, are called molecular switches [2.15, 16]. The chemical transformations associated with these switching processes are often reversible. The chemical system returns to the original state when the input signal is turned off. The interconverting states of a molecular switch can be isomers, an acid and its conjugated base, the oxidized and reduced forms of a redox active molecule, or even the complexed and uncomplexed forms of a receptor [2.9, 15, 16]. The output of a molecular switch can be a chemical, electrical, and/or optical signal that varies in intensity with the interconversion process. For example, changes in absorbance, fluorescence, pH, or redox potential can accompany the reversible transformation of a molecular switch.

2.2.2 Digital Processing and Molecular Logic Gates

In present computer networks, data are elaborated electronically by microprocessor systems [2.17] and are exchanged optically between remote locations [2.18]. Data processing and communication require the encoding of information in electrical and optical signals in the form of binary digits. Using arbitrary assumptions, logic thresholds can be established for each signal and, then, 0 and 1 digits can be encoded following simple conventions. Sequences of electronic devices manipulate the encoded bits executing logic functions as a result of basic switching operations.

The three basic AND, NOT, and OR operators combine binary inputs into binary outputs following precise logic protocols [2.17]. The NOT operator converts an input signal into an output signal. When the input is 0, the output is 1. When the input is 1, the output is 0. Because of the inverse relationship between the input and output values, the NOT gate is often called "inverter" [2.19]. The OR operator combines two input signals into a single output signal. When one or both inputs are 1, the output is 1. When both inputs are 0, the output is 0. The AND gate also combines two input signals into one output signal. In this instance, however, the output is 1 only when both inputs are 1. When at least one input is 0, the output is 0.

The output of one gate can be connected to one of the inputs of another operator. A NAND gate, for example, is assembled connecting the output of an AND operator to the input of a NOT gate. Now the two input signals are converted into the final output after two consecutive logic operations. In a similar fashion, a NOR gate can be assembled connecting the output of an OR operator to the input of a NOT gate. Once again, two consecutive logic operations determine the relation between two input signals and a single output. The NAND and NOR operations are termed universal functions because any conceivable logic operation can be implemented relying only on one of these two gates [2.17]. In fact, digital circuits are fabricated routinely interconnecting exclusively NAND or exclusively NOR operators [2.19].

The logic gates of conventional microprocessors are assembled interconnecting transistors, and their input and output signals are electrical [2.19]. But the concepts of binary logic can be extended to chemical, mechanical, optical, pneumatic, or any other type of signal. First it is necessary to design devices that can respond to these stimulations in the same way transistors respond to electrical signals. Molecular switches respond

to a variety of input stimulations producing specific outputs and can, therefore, be exploited to implement logic functions [2.20, 21].

2.2.3 Molecular AND, NOT, and OR Gates

More than a decade ago, researchers proposed a potential strategy to execute logic operations at the molecular level [2.22]. Later, the analogy between molecular switches and logic gates was recognized in a seminal article [2.23], in which it was demonstrated that AND, NOT, and OR operations can be reproduced with fluorescent molecules. The pyrazole derivative **1** (Fig. 2.6) is a molecular NOT gate. It imposes an inverse relation between a chemical input (concentration of H^+) and an optical output (emission intensity). In a mixture of methanol and water, the fluorescence quantum yield of **1** is 0.13 in the presence of only 0.1 equivalents of H^+ [2.23]. The quantum yield drops to 0.003 when the equivalents of H^+ are 1,000. Photoinduced electron transfer from the central pyrazoline unit to the pendant benzoic acid quenches the fluorescence of the protonated form. Thus, a change in H^+ concentration (I) from a low to a high value switches the emission intensity (O) from a high to a low value. The inverse relationship between the chemical input I and the optical output O translates into the truth table of a NOT operation if a positive logic convention (low = 0, high = 1) is applied to both signals. The emission intensity is high (O = 1) when the concentration of H^+ is low (I = 0). The emission intensity is low (O = 0) when the concentration of H^+ is high (I = 1).

The anthracene derivative **2** (Fig. 2.6) is a molecular OR gate. It transduces two chemical inputs

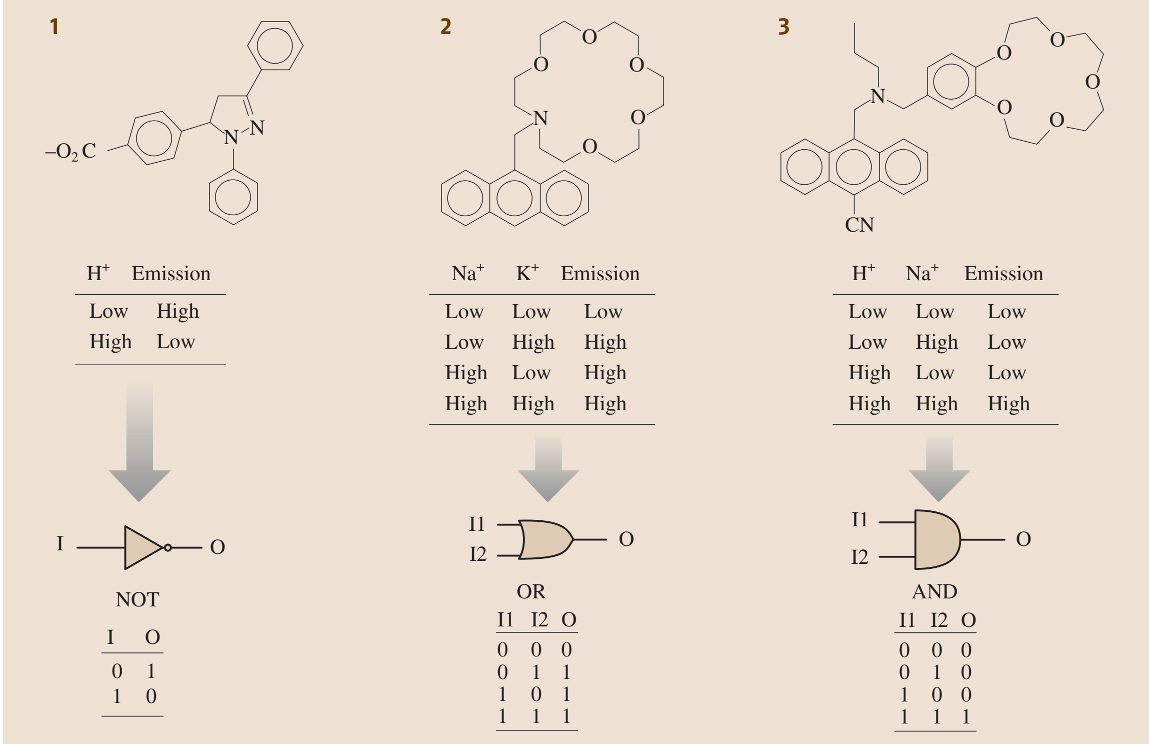

Fig. 2.6 The fluorescence intensity of the pyrazoline derivative **1** is high when the concentration of H^+ is low, and vice versa. The fluorescence intensity of the anthracene derivative **2** is high when the concentration of Na^+ and/or K^+ is high. The emission is low when both concentrations are low. The fluorescence intensity of the anthracene **3** is high only when the concentrations of H^+ and Na^+ are high. The emission is low in the other three cases. The signal transductions of the molecular switches **1**, **2**, and **3** translate into the truth tables of NOT, OR, and AND gates, respectively, if a positive logic convention is applied to all inputs and outputs (low = 0, high = 1)

(concentrations of Na^+ and K^+) into an optical output (emission intensity). In methanol, the fluorescence quantum yield is only 0.003 in the absence of metal cations [2.23]. Photoinduced electron transfer from the nitrogen atom of the azacrown fragment to the anthracene fluorophore quenches the emission. After the addition of 1,000 equivalents of either Na^+ or K^+, the quantum yield raises to 0.053 and 0.14, respectively. Similarly, the quantum yield is 0.14 when both metal cations are present in solution. The complexation of one of the two metal cations inside the azacrown receptor depresses the efficiency of the photoinduced electron transfer enhancing the fluorescence. Thus, changes in the concentrations of Na^+ (I1) and/or K^+ (I2) from low to high values switch the emission intensity (O) from a low to a high value. The relationship between the chemical inputs I1 and I2 and the optical output O translates into the truth table of an OR operation if a positive logic convention (low = 0, high = 1) is applied to all signals. The emission intensity is low (O = 0) only when the concentration of Na^+ and K^+ are low (I1 = 0, I2 = 0). The emission intensity is high (O = 1) for the other three input combinations.

The anthracene derivative **3** (Fig. 2.6) is a molecular AND gate. It transduces two chemical inputs (concentrations of H^+ and Na^+) into an optical output (emission intensity). In a mixture of methanol and *iso*-propanol, the fluorescence quantum yield is only 0.011 in the absence of H^+ or Na^+ [2.23]. Photoinduced electron transfer from either the tertiary amino group or the catechol fragment to the anthracene fluorophore quenches the emission. After the addition of either 100 equivalents of H^+ or 1,000 equivalents of Na^+, a modest change of the quantum yield to 0.020 and 0.011, respectively, is observed. Instead, the quantum yield increases to 0.068 when both species are present in solution. The protonation of the amino group and the insertion of the metal cation in the benzocrown ether receptor depress the efficiency of the photoinduced electron transfer processes enhancing the fluorescence. Thus, changes in the concentrations of H^+ (I1) and Na^+ (I2) from low to high values switch the emission intensity (O) from a low to a high value. The relationship between the chemical inputs I1 and I2 and the optical output O translates into the truth table of an AND operation if a positive logic convention (low = 0, high = 1) is applied to all signals. The emission intensity is high (O = 1) only when the concentration of H^+ and Na^+ are high (I1 = 1, I2 = 1). The emission intensity is low (O = 0) for the other three input combinations.

2.2.4 Combinational Logic at the Molecular Level

The fascinating molecular AND, NOT, and OR gates illustrated in Fig. 2.6 have stimulated the design of related chemical systems able to execute the three basic logic operations and simple combinations of them [2.20, 21]. Most of these molecular switches convert chemical inputs into optical outputs. But the implementation of logic operations at the molecular level is not limited to the use of chemical inputs. For example, electrical signals and reversible redox processes can be exploited to modulate the output of a molecular switch [2.24]. The supramolecular assembly **4** (Fig. 2.7) executes a XNOR function relying on these operating principles. The π-electron rich tetrathiafulvalene (TTF) guest threads the cavity of a π-electron deficient bipyridinium (BIPY) host. In acetonitrile, an absorption band associated with the charge-transfer interactions between the complementary π-surfaces is observed at 830 nm. Electrical stimulations alter the redox state of either the TTF or the BIPY units encouraging the separation of the two components of the complex and the disappearance of the charge-transfer band. Electrolysis at a potential of +0.5 V oxidizes the neutral TTF unit to a monocationic state. The now cationic guest is expelled from the cavity of the tetracationic host as a result of electrostatic repulsion. Consistently, the absorption band at 830 nm disappears. The charge-transfer band, however, is restored after the exhaustive back reduction of the TTF unit at a potential of 0 V. Similar changes in the absorption properties can be induced addressing the BIPY units. Electrolysis at −0.3 V reduces the dicationic BIPY units to their monocationic forms encouraging the separation of the two components of the complex and the disappearance of the absorption band. The original absorption spectrum is restored after the exhaustive back oxidation of the BIPY units at a potential of 0 V. Thus, this supramolecular system responds to electrical stimulations producing an optical output. One of the electrical inputs (I1) controls the redox state of the TTF unit switching between 0 and +0.5 V. The other (I2) determines the redox state of the bipyridinium units switching between −0.3 and 0 V. The optical output (O) is the absorbance of the charge-transfer band. A positive logic convention (low = 0, high = 1) can be applied to the input I1 and output O. A negative logic convention (low = 1, high = 0) can be applied to the input I2. The resulting truth table corresponds to that of a XNOR circuit (Fig. 2.7). The charge-transfer absorbance is high (O = 1) only when one voltage input is low and the other

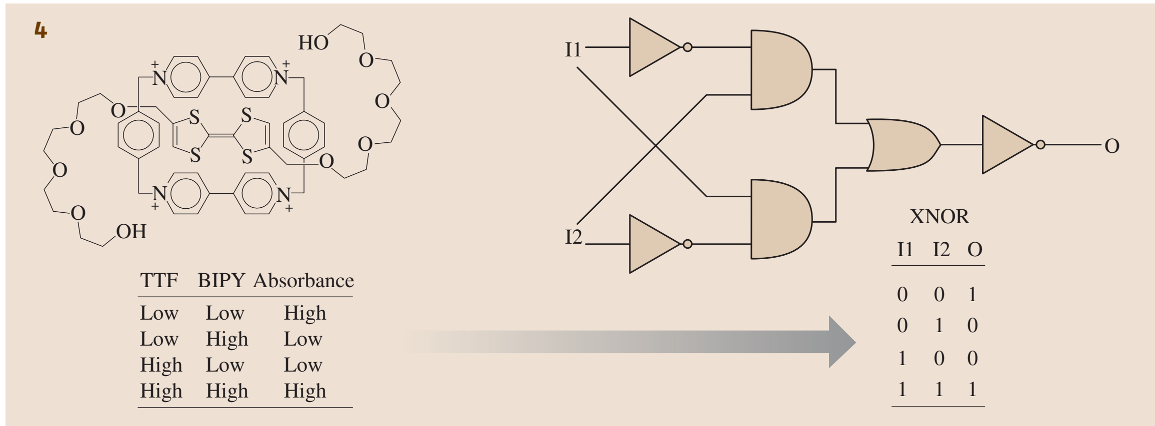

Fig. 2.7 The charge-transfer absorbance of the complex **4** is high when the voltage input addressing the tetrathiafulvalene (TTF) unit is low and that stimulating the bipyridinium (BIPY) units is high and vice versa. If a positive logic convention is applied to the TTF input and to the absorbance output (low = 0, high = 1) while a negative logic convention is applied to the BIPY input (low = 0, high = 1), the signal transduction of **4** translates into the truth table of a XNOR circuit

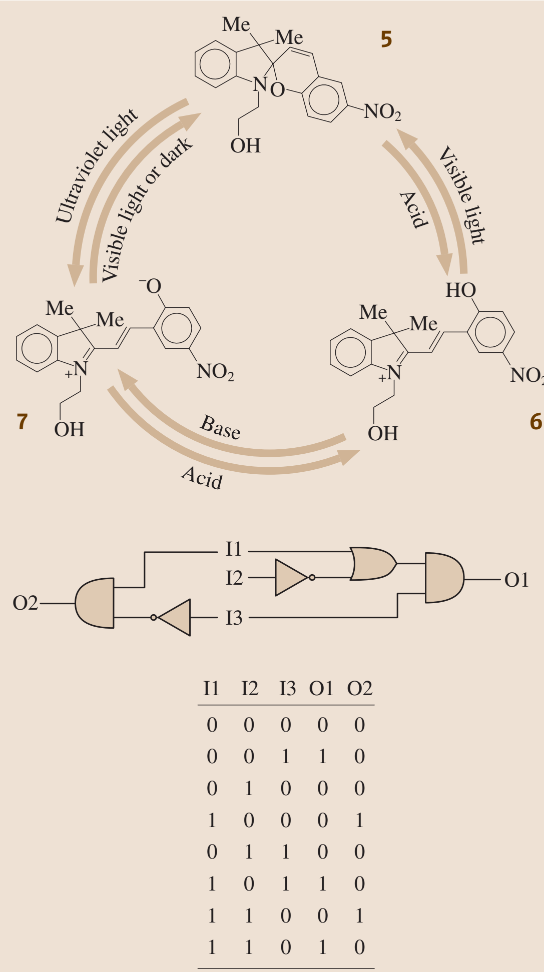
is high (I1 = 0, I2 = 0) or vice versa (I1 = 1, I2 = 1). It is important to note that the input string with both I1 and I2 equal to 1 implies that input potentials of +0.5 and −0.3 V are applied simultaneously to a solution containing the supramolecular assembly **4** and not to an individual complex. Of course, the concomitant oxidation of the TTF guest and reduction of the BIPY units in the very same complex would be unrealistic. In bulk solution, instead, some complexes are oxidized while others are reduced, leaving the average solution composition unaffected. Thus, the XNOR operation executed by this supramolecular system is a consequence of bulk properties and not a result of unimolecular signal transduction.

Optical inputs can be employed to operate the three-state molecular switch of Fig. 2.8 in acetonitrile solution [2.25]. This chemical system responds to three inputs producing two outputs. The three input stimulations are ultraviolet light (I1), visible light (I2), and the concentration of H^+ (I3). One of the two optical outputs is the absorbance at 401 nm (O1), which is high when the molecular switch is in the yellow-green state **6** and low in the other two cases. The other optical output is the absorbance at 563 nm (O2), which is high when the molecular switch is in the purple state **7** and low in the other two cases. The colorless spiropyran state **5** switches to the merocyanine form **7** upon irradiation with ultraviolet light. It switches to the protonated merocyanine from **6** when treated with H^+. The colored state **7** isomerizes back to **5** in the dark or upon irradiation with visible light. Alternatively, **7** switches to **6** when treated with H^+. The colored state **6** switches to **5**, when irradiated with visible light, and to **7**, after the removal of H^+. In summary, this three-state molecular switch responds to two optical inputs (I1 and I2) and one chemical input (I3) producing two optical outputs (O1 and O2). Binary digits can be encoded on each signal applying positive logic conventions (low = 0, high = 1). It follows that the three-state molecular switch converts input strings of three binary digits into output strings of two binary digits. The corresponding truth table (Fig. 2.8) reveals that the optical output O1 is high (O1 = 1) when only the input I3 is applied (I1 = 0, I2 = 0, I3 = 1), when only the input I2 is not applied (I1 = 1, I2 = 0, I3 = 0), or when all three inputs are applied (I1 = 1, I2 = 0, I3 = 0). The optical output O2 is high (O2 = 1) when only the input I1 is applied (I1 = 1, I2 = 0, I3 = 0) or when only the input I3 is not applied (I1 = 1, I2 = 0, I3 = 0). The combinational logic circuit (Fig. 2.8) equivalent to this truth table shows that all three inputs determine the output O1, while only I1 and I3 control the value of O2.

2.2.5 Intermolecular Communication

The combinational logic circuits in Figs. 2.7 and 2.8 are arrays of interconnected AND, NOT, and OR operators. The digital communication between these basic logic elements ensures the execution of a sequence of simple logic operations that results in the complex logic function processed by the entire circuit. It follows that



I1	I2	I3	O1	O2
0	0	0	0	0

1	1	0	1	0

Fig. 2.8 Ultraviolet light (I1), visible light (I2), and H^+ (I3) inputs induce the interconversion between the three states **5**, **6**, and **7**. The colorless state **5** does not absorb in the visible region. The yellow-green state **6** absorbs at 401 nm (O1). The purple state **7** absorbs at 563 nm (O2). The truth table illustrates the conversion of input strings of three binary digits (I1, I2, and I3) into output strings of two binary digits (O1 and O2) operated by this three-state molecular switch. A combinational logic circuit incorporating nine AND, NOT, and OR operators correspond to this particular truth table

the logic function of a given circuit can be adjusted altering the number and type of basic gates and their interconnection protocol [2.17]. This modular approach to combinational logic circuits is extremely powerful. Any logic function can be implemented connecting the appropriate combination of simple AND, NOT, and OR gates.

The strategies followed so far to implement complex logic functions with molecular switches are based on the careful design of the chemical system and on the judicious choice of the inputs and outputs [2.20, 21]. A specific sequence of AND, NOT, and OR operations is programmed in a single molecular switch. No digital communication between distinct gates is needed since they are built in the same molecular entity. Though extremely elegant, this strategy does not have the same versatility of a modular approach. A different molecule has to be designed, synthesized, and analyzed every single time a different logic function has to be realized. In addition, the degree of complexity that can be achieved with only one molecular switch is fairly limited. The connection of the input and output terminals of independent molecular AND, NOT, and OR operators, instead, would offer the possibility of assembling any combinational logic circuit from three basic building blocks.

In digital electronics, the communication between two logic gates can be realized connecting their terminals with a wire [2.19]. Methods to transmit binary data between distinct molecular switches are not so obvious and must be identified. Recently we developed two strategies to communicate signals between compatible molecular components. In one instance, a chemical signal is communicated between two distinct molecular switches [2.26]. They are the three-state switch illustrated in Fig. 2.8 and the two-state switch of Fig. 2.9. The merocyanine form **7** is a photogenerated base. Its *p*-nitrophenolate fragment, produced upon irradiation of the colorless state **5** with ultraviolet light, can abstract a proton from an acid present in the same solution. The resulting protonated form **6** is a photoacid. It releases a proton upon irradiation with visible light and can protonate a base co-dissolved in the same medium. The orange azopyridine **8** switches to the red-purple azopyridinium **9** upon protonation. This process is reversible, and the addition of a base restores the orange state **8**. It follows that photoinduced proton transfer can be exploited to communicate a chemical signal from **6** to **8** and from **9** to **7**. The two colored states **8** and **9** have different absorption properties in the visible region. In acetonitrile, the orange state **8** absorbs at 422 nm, and the red-purple state **9** absorbs at 556 nm. The changes in absorbance of these two bands can be exploited to monitor the photoinduced exchange of protons between the two communicating molecular switches.

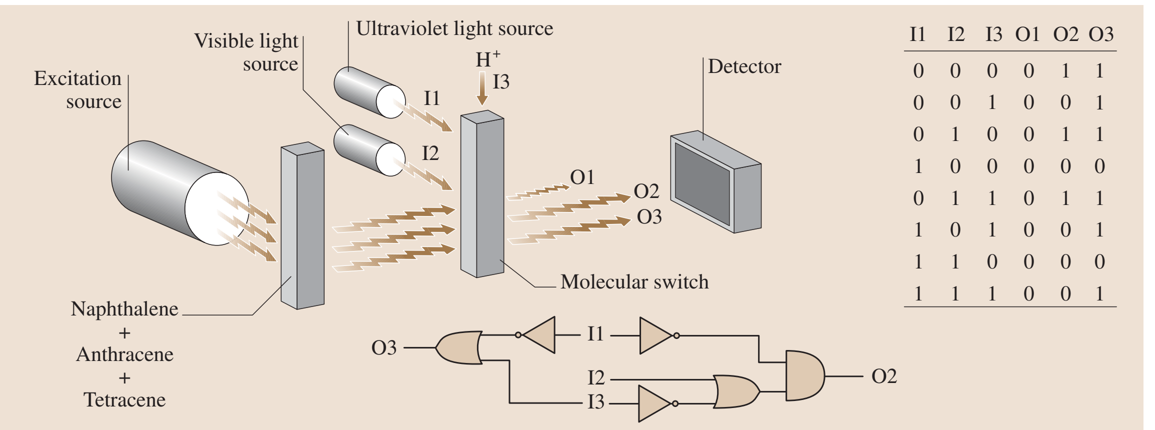
1	0	0
1	1	0

Fig. 2.9 The concentration of H^+ controls the reversible interconversion between the two states **8** and **9**. In response to ultraviolet (I1) and visible (I2) inputs, the three-state molecular switch in Fig. 2.7 modulates the ratio between these two forms and the absorbance (O) of **9** through photoinduced proton transfer. The truth table and sequential logic circuit illustrate the signal transduction behavior of the two communicating molecular switches. The interconversion between the five three-digit strings of input (I1 and I2) and output (O) data is achieved varying the input values in steps

The three-state molecular switch and the two-state molecular switch can be operated sequentially when dissolved in the same acetonitrile solution. In the presence of one equivalent of H^+, the two-state molecular switch is in state **9** and the absorbance at 556 nm is high (O = 1). Upon irradiation with ultraviolet light (I1 = 0), **5** switches to **7**. The photogenerated base deprotonates **9** producing **8** and **6**. As a result, the absorbance at 556 nm decreases (O = 0). Upon irradiation with visible light (I2 = 1), **6** switches to **5** releasing H^+. The result is the protonation of **8** to form **9** and restore the high absorbance at 556 nm (O = 1). In summary, the three-state molecular switch transduces two optical inputs (I1 = ultraviolet light, I2 = visible light) into a chemical signal (proton transfer) that is communicated to the two-state molecular switch and converted into a final optical output (O = absorbance at 556 nm).

The logic behavior of the two communicating molecular switches is significantly different from those of the chemical systems illustrated in Figs. 2.6, 2.7, and 2.8 [2.26]. The truth table in Fig. 2.9 lists the four possible combinations of two-digit input strings and the corresponding one-digit output. The output digit O for the input strings 01, 10, and 11 can take only one value. In fact, the input string 01 is transduced into a 1, and the input strings 10 and 11 are converted into 0. Instead, the output digit O for the input string 00 can be either 0 or 1. The sequence of events leading to the input string 00 determines the value of the output. The boxes ***a–e*** in Fig. 2.9 illustrates this effect. They correspond to the five three-digit input/output strings. The transformation of one box into any of the other four is achieved in one or two steps by changing the values of I1 and/or I2. In two instances (***a*** and ***b***), the two-state molecular switch is in state **9**, and the output signal is high (O = 1). In the other three cases (***c***, ***d***, and ***e***), the two-state molecular switch is in state **8**, and the output signal is low (O = 0). The strings 000 (***e***) and 001 (***a***) correspond to the first entry of the truth table. They share the same input digits but differ in the output value. The string 000 (***e***) can be obtained only from the string 100 (***c***) varying the value of I1. Similarly, the string 001 (***a***) can be accessed only from the string 011 (***b***) varying the value of I2. In both transformations, the output digit remains unchanged. Thus, the value of O1 in the parent string is memorized and maintained in the daughter string when both inputs become 0. This memory effect is the fundamental operating principle of sequential logic circuits [2.17], which are used extensively to assemble the memory elements of modern microprocessors. The sequential logic circuit equivalent to the truth table of the two communicating molecular switches is also shown in Fig. 2.9. In this circuit, the input data I1 and I2 are combined through NOT, OR, and AND operators. The output of the AND gate O is also an input of the OR gate and controls, together with I1 and I2, the signal transduction behavior.

The other strategy for digital transmission between molecules is based on the communication of optical signals between the three-state molecular switch (Fig. 2.8) and fluorescent compounds [2.27,28]. In the optical network of Fig. 2.10, three optical signals travel from an excitation source to a detector after passing through two quartz cells. The first cell contains an equimolar acetonitrile solution of naphthalene, anthracene, and tetracene. The second cell contains an acetonitrile solu-



I1	I2	I3	O1	O2	O3

1	1	0	0	0	0
1	1	1	0	0	1

Fig. 2.10 The excitation source sends three monochromatic light beams (275, 357, and 441 nm) to a quartz cell containing an equimolar acetonitrile solution of naphthalene, anthracene and tetracene. The three fluorophores absorb the exciting beams and reemit at 305, 401, and 544 nm, respectively. The light emitted in the direction perpendicular to the exciting beams passes through another quartz cell containing an acetonitrile solution of the three-state molecular switch shown in Fig. 2.7. Ultraviolet (I1), visible (I2), and H^+ (I3) inputs control the interconversion between the three states of the molecular switch. They determine the intensity of the optical outputs reaching the detector and correspond to the naphthalene (O1), anthracene (O2), and tetracene (O3) emissions. The truth table and equivalent combinational logic illustrate the relation between the three inputs and the three outputs. The output O1 is always 0, and it is not influenced by the three inputs. Only two inputs determine the value of O3, while all of them control the output O2

tion of the three-state molecular switch. The excitation source sends three consecutive monochromatic light beams to the first cell stimulating the emission of the three fluorophores. The light emitted in the direction perpendicular to the exciting beam reaches the second cell. When the molecular switch is in state **5**, the naphthalene emission at 335 nm is absorbed and a low intensity output (O1) reaches the detector. Instead, the anthracene and tetracene emissions at 401 and 544 nm, respectively, pass unaffected and high intensity outputs (O2 and O3) reach the detector. When the molecular switch is in state **6**, the naphthalene and anthracene emissions are absorbed and only the tetracene emission reaches the detector ($O1 = 0$, $O2 = 0$, $O3 = 1$). When the molecular switch is state **7**, the emission of all three fluorophores is absorbed ($O1 = 0$, $O2 = 0$, $O3 = 0$). The interconversion of the molecular switch between the three states is induced addressing the second cell with ultraviolet (I1), visible (I2) and H^+ (I3) inputs. Thus, three independent optical outputs (O1, O2 and O3) can be modulated stimulating the molecular switch with two optical and one chemical input. The truth table in Fig. 2.10 illustrates the relation between the three inputs (I1, I2 and I3) and the three outputs (O1, O2 and O3), when positive logic conventions are applied to all signals. The equivalent logic circuit shows that all three inputs control the anthracene channel O2, but only I1 and I3 influence the tetracene channel O3. Instead, the intensity of the naphthalene channel O1 is always low, and it is not affected by the three inputs.

The operating principles of the optical network in Fig. 2.10 can be simplified to implement all-optical logic gates. The chemical input inducing the formation of the protonated form **6** of the molecular switch can be eliminated. The interconversion between the remaining two states **5** and **7** can be controlled relying exclusively on ultraviolet inputs. Indeed, ultraviolet irradiation induces the isomerization of the colorless form **5** to the colored species **7**, which reisomerizes to the original state in the dark. Thus, a single ultraviolet source is sufficient to control the switching from **5** to **7** and vice versa. On the basis of these considerations, all-optical NAND, NOR, and NOT gates can be implemented operating sequentially or in parallel from one to three independent switching elements [2.28]. For example, the all-optical network illustrated in Fig. 2.11 is a three-input NOR gate. A monochromatic optical signal travels from a visible source to a detector. Three switching elements are aligned along the path of the traveling light. They are quartz cells containing an acetonitrile solution of the mo-

Fig. 2.11 The visible source sends a monochromatic beam (563 nm) to the detector. The traveling light is forced to pass through three quartz cells containing the molecular switch illustrated in Fig. 2.7. The three switching elements are operated by independent ultraviolet inputs. When at least one of them is on, the associated molecular switch is in the purple form **7**, which can absorb and block the traveling light. The truth table and equivalent logic circuit illustrate the relation between the three inputs I1, I2, and I3 and the optical output O

lecular switch shown in Fig. 2.8. The interconversion of the colorless form **5** into the purple isomer **7** is induced stimulating the cell with an ultraviolet input. The reisomerization from **7** to **5** occurs spontaneously, as the ultraviolet sources is turned off. Using three distinct ultraviolet sources, the three switching elements can be controlled independently.

The colorless form **5** does not absorb in the visible region, while the purple isomer **7** has a strong absorption band at 563 nm. Thus, a 563 nm optical signal leaving the visible source can reach the detector unaffected only if all three switching elements are in the nonabsorbing state **5**. If one of the three ultraviolet inputs I1, I2, or I3 is turned on, the intensity of the optical output O drops to 3–4% of its original value. If two or three ultraviolet inputs are turned on simultaneously, the optical output drops to 0%. Indeed, the photogenerated state **7** absorbs and blocks the traveling light. Applying positive logic conventions to all signals, binary digits can be encoded in the three optical inputs and in the optical output. The resulting truth table is illustrated in Fig. 2.11. The output O is 1 only if all three inputs I1, I2, or I3 are 0. The output O is 0 if at least one of the three inputs I1, I2, or I3 is 1. This signal transduction corresponds to that executed by a three-input NOR gate, which is a combination of one NOT and two OR operators.

2.3 Solid State Devices

The fascinating chemical systems illustrated in Figs. 2.6–2.11 demonstrate that logic functions can be implemented relying on the interplay between designed molecules and chemical, electrical and/or optical signals [2.20, 21].

2.3.1 From Functional Solutions to Electroactive and Photoactive Solids

These molecular switches, however, are operated exclusively in solution and remain far from potential applications in information technology at this stage. The integration of liquid components and volatile organic solvents in practical digital devices is hard to envisage. Furthermore, the logic operations executed by these chemical systems rely on bulk addressing. Although the individual molecular components have nanoscaled dimensions, macroscopic collections of them are employed for digital processing. In some instances, the operating principles cannot even be scaled down to the unimolecular level. Often bulk properties are responsible for signal transduction. For example, a single fluorescent compound **2** cannot execute an OR operation. Its azacrown appendage can accommodate only one metal cation. As a result, an individual molecu-

lar switch can respond to only one of the two chemical inputs. It is a collection of numerous molecular switches dissolved in an organic solvent that responds to both inputs enabling an OR operation.

The development of miniaturized molecule-based devices requires the identification of methods to transfer the switching mechanisms developed in solution to the solid state [2.29]. Borrowing designs and fabrication strategies from conventional electronics, researchers are starting to explore the integration of molecular components into functional circuits and devices [2.30–33]. Generally, these strategies combine lithography and surface chemistry to assemble nanometer-thick organic films on the surfaces of microscaled or nanoscaled electrodes. Two main approaches for the deposition of organized molecular arrays on inorganic supports have emerged so far. In one instance, amphiphilic molecular building blocks are compressed into organized monolayers at air/water interfaces. The resulting films can be transferred on supporting solids employing the Langmuir–Blodgett technique [2.34]. Alternatively, certain molecules can be designed to adsorb spontaneously on the surfaces of compatible solids from liquid or vapor phases. The result is the self-assembly of organic layers on inorganic supports [2.35].

2.3.2 Langmuir–Blodgett Films

Films of amphiphilic molecules can be deposited on a variety of solid supports employing the Langmuir–Blodgett technique [2.34]. This method can be extended to electroactive compounds incorporating hydrophilic and hydrophobic groups. For example, the amphiphile **10** (Fig. 2.12) has a hydrophobic hexadecyl tail attached to a hydrophilic bipyridinium dication [2.36, 37]. This compound dissolves in mixtures of chloroform and methanol, but it is not soluble in moderately concentrated aqueous solutions of sodium perchlorate.

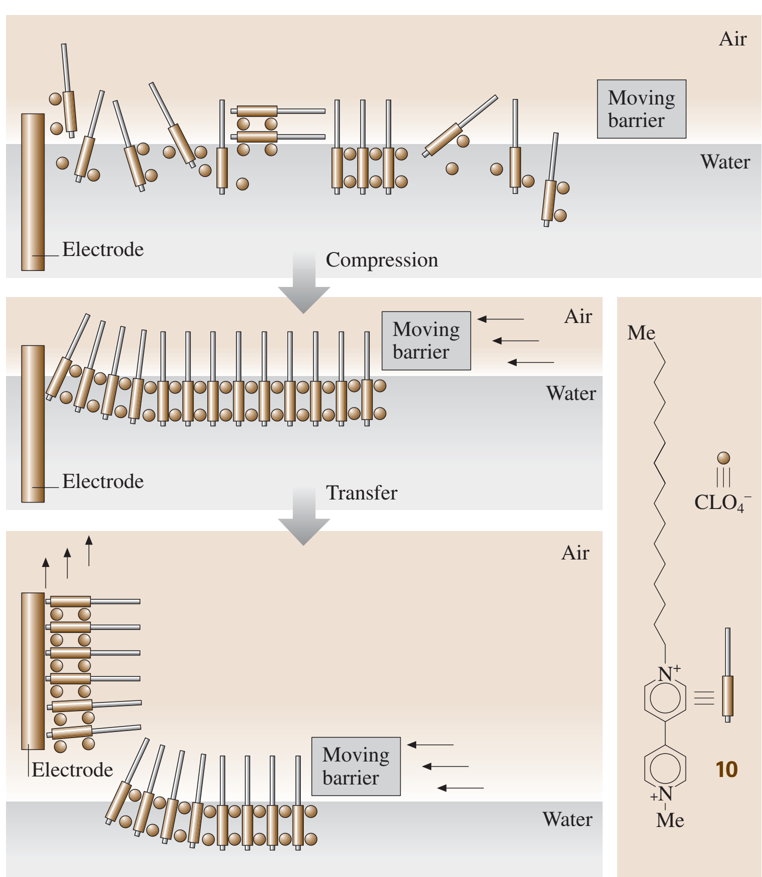

Fig. 2.12 The compression of the amphiphilic dication **10** with a moving barrier results in the formation of a packed monolayer at the air/water interface. The lifting of an electrode pre-immersed in the aqueous subphase encourages the transfer of part of the monolayer on the solid support

Thus the spreading of an organic solution of **10** on an aqueous sodium perchlorate subphase affords a collection of disorganized amphiphiles floating on the water surface (Fig. 2.12), after the organic solvent has evaporated. The molecular building blocks can be compressed into a monolayer with the aid of a moving barrier. The hydrophobic tails align away from the aqueous phase. The hydrophilic dicationic heads and the accompanying perchlorate counterions pack to form an organized monolayer at the air/water interface. The compression process can be monitored recording the surface pressure (π)-area per molecule (A) isotherm, which indicates a limiting molecular area of ca. 50 Å^2. This value is larger than the projected area of an oligomethylene chain. It correlates reasonably, however, with the overall area of a bipyridinium dication plus two perchlorate anions.

The monolayer prepared at the air/water interface (Fig. 2.12) can be transferred on the surface of a indium-tin oxide electrode pre-immersed in the aqueous phase. The slow lifting of the solid support drags the monolayer away from the aqueous subphase. The final result is the coating of the electrode with an organic film containing electroactive bipyridinium building blocks. The modified electrode can be integrated in a conventional electrochemical cell to probe the redox response of the electroactive layer. The resulting cyclic voltammograms reveal the characteristic waves for the first reduction process of the bipyridinium dications, confirming the successful transfer of the electroactive amphiphiles from the air/water interface to the electrode surface. The integration of the redox waves indicates a surface coverage of ca. 4×10^{10} mol cm^{-2}. This value corresponds to a molecular area of ca. 40 Å^2 and is in excellent agreement with the limiting molecular area of the π–A isotherm.

These seminal experiments demonstrate that electroactive amphiphiles can be organized into uniform monolayers at the air/water interface and then transferred efficiently on the surface of appropriate substrates to produce electrode/monolayer junctions. The resulting electroactive materials can become the functional components of molecule-based devices. For example, bipyridinium-based photodiodes can be fabricated following this approach [2.38, 39]. Their operating principles rely on photoinduced electron transfer from chromophoric units to bipyridinium acceptors. The electroactive and photoactive amphiphile **11** (Fig. 2.13) incorporates hydrophobic ferrocene and pyrene tails and a hydrophilic bipyridinium head. Chloroform solutions of **11** containing ten equivalents of arachidic acid can

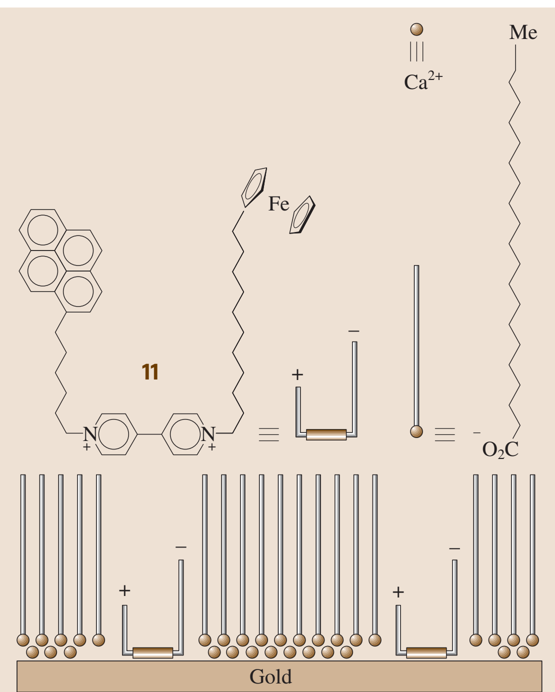

Fig. 2.13 Mixed monolayers of the amphiphile **11** and arachidic acid can be transferred from the air/water interface to the surface of an electrode to generate a molecule-based photodiode

be spread on an aqueous calcium chloride subphase in a Langmuir trough. The amphiphiles can be compressed into a mixed monolayer, after the evaporation of the organic solvent. Pronounced steps in the corresponding π–A isotherm suggest that the bulky ferrocene and pyrene groups are squeezed away from the water surface. In the final arrangement, both photoactive groups align above the hydrophobic dication.

A mixed monolayer of **11** and arachidic acid can be transferred from the air/water interface to the surface of a transparent gold electrode following the methodology illustrated for the system in Fig. 2.12. The coated electrode can be integrated in a conventional electrochemical cell. Upon irradiation at 330 nm under an inert atmosphere, an anodic photocurrent of ca. 2 nA develops at a potential of 0 V relative to a saturated calomel electrode. Indeed, the illumination of the electroactive monolayer induces the electron transfer from the pyrene appendage to the bipyridinium acceptor and then from the reduced acceptor to the electrode. A second intramolecular electron transfer from the ferrocene

donor to the oxidized pyrene fills its photogenerated hole. Overall, a unidirectional flow of electrons across the monolayer/electrode junction is established under the influence of light.

The ability to transfer electroactive monolayers from air/water interfaces to electrode surfaces can be exploited to fabricate molecule-based electronic devices. In particular, arrays of interconnected electrode/monolayer/electrode tunneling junctions can be assembled combining the Langmuir–Blodgett technique with electron beam evaporation [2.33]. Fig. 2.14 illustrates a schematic representation of the resulting devices. Initially, parallel fingers are patterned on a silicon wafer with a silicon dioxide overlayer by electron beam evaporation. The bottom electrodes deposited on the support can be either aluminum wires covered by an aluminum oxide or n-doped silicon lines with silicon dioxide overlayers. Their widths are ca. 6 or 7 μm, respectively. The patterned silicon chip is immersed in the aqueous subphase of a Langmuir trough prior to monolayer formation. After the compression of electroactive amphiphiles at the air/water interface, the substrate is pulled out of the aqueous phase to encourage the transfer of the molecular layer on the parallel bottom electrodes as well as on the gaps between them. Then, a second set of electrodes orthogonal to the first is deposited through a mask by electron beam evaporation. They consist of a titanium underlayer plus an aluminum overlayer. Their thicknesses are ca. 0.05 and 1 μm, respectively, and their width is ca. 10 μm. In the final assembly, portions of the molecular layer become sandwiched between the bottom and top electrodes. The active areas of these electrode/monolayer/electrode junctions are ca. 60–70 μm^2 and correspond to ca. 10^6 molecules.

The [2]rotaxane **12** (Fig. 2.14) incorporates a macrocyclic polyether threaded onto a bipyridinium-based backbone [2.40, 41]. The two bipyridinium dications are bridged by a m-phenylene spacer and terminated by tetraarylmethane appendages. These two bulky groups trap mechanically the macrocycle preventing its dis-

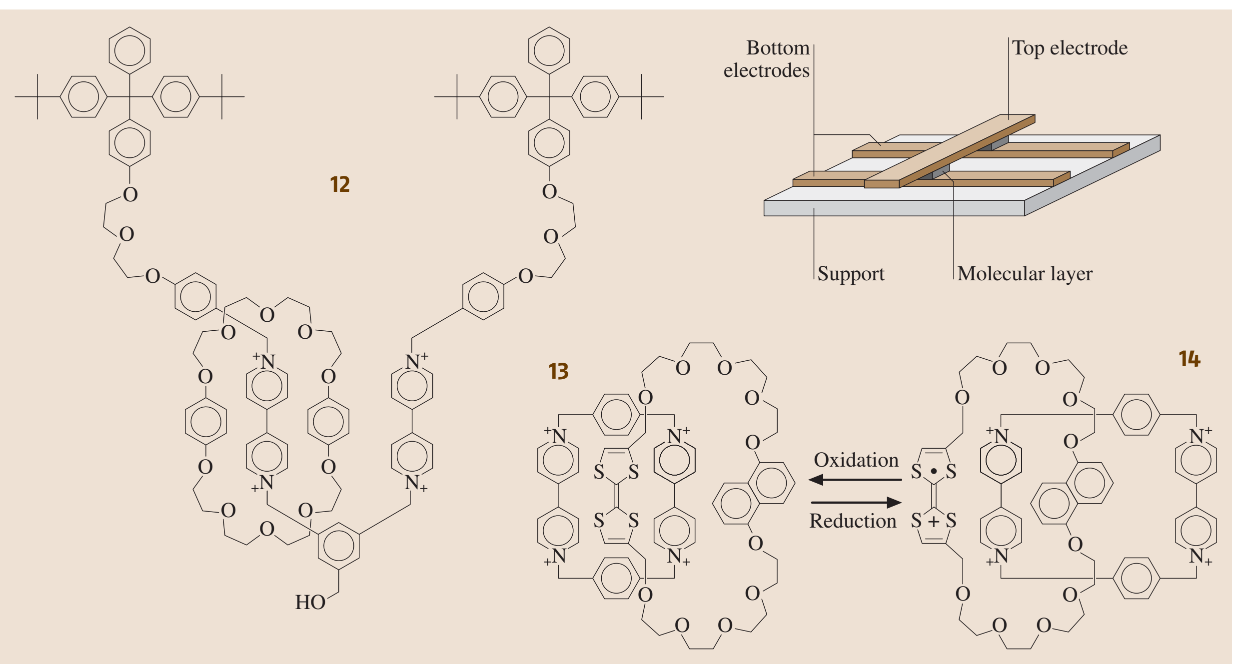

Fig. 2.14 The [2]rotaxane **12** and the [2]catenane **13** can be compressed into organized monolayers at air/water interfaces. The resulting monolayers can be transferred on the bottom electrodes of a patterned silicon support. After the deposition of a top electrode, electrode/monolayer/electrode junctions can be assembled. Note that only the portion of the monolayer sandwiched between the top and bottom electrodes is shown in the diagram. The oxidation of the tetrathiafulvalene unit of the [2]catenane **13** is followed by the circumrotation of the macrocyclic polyether to afford the [2]catenane **14**. The process is reversible, and the reduction of the cationic tetrathiafulvalene unit restores the original state

sociation from the tetracationic backbone. In addition, their hydrophobicity complements the hydrophilicity of the two bipyridinium dications imposing amphiphilic character on the overall molecular assembly. This compound does not dissolve in aqueous solutions and can be compressed into organized monolayers at air/water interfaces. The corresponding π–A isotherm reveals a limiting molecular area of ca. 130 Å^2. This large value is a consequence of the bulk associated with the hydrophobic tetraarylmethane tails and the macrocycle encircling the tetracationic backbone.

Monolayers of the [2]rotaxane **12** can be transferred from the air/water interface to the surfaces of the bottom aluminum/aluminum oxide electrodes of a patterned silicon chip with the hydrophobic tetraarylmethane groups pointing away from the supporting substrate. The subsequent assembly of a top titanium/aluminum electrode affords electrode/monolayer/electrode junctions. Their current/voltage signature can be recorded grounding the top electrode and scanning the potential of the bottom electrode. A pronounced increase in current is observed when the potential is lowered below −0.7 V. Under these conditions, the bipyridinium-centered LUMOs mediate the tunneling of electrons from the bottom to the top electrode leading to a current enhancement. A similar current profile is observed if the potential is returned to 0 and then back to −2 V. Instead, a modest increase in current in the opposite direction is observed when the potential is raised above +0.7 V. Presumably, this trend is a result of the participation of the phenoxy-centered HOMOs in the tunneling process. After a single positive voltage pulse, however, no current can be detected if the potential is returned to negative values. In summary, the positive potential scan suppresses irreversibly the conducting ability of the electrode/molecule/electrode junction. The behavior of this device correlates with the redox response of the [2]rotaxane **12** in solution. Cyclic voltammograms reveal reversible monoelectronic reductions of the bipyridinium dications. But they also show two irreversible oxidations associated, presumably, with the phenoxy rings of the macrocycle and tetraarylmethane groups. These observations suggest that a positive voltage pulse applied to the electrode/monolayer/electrode junction oxidizes irreversibly the sandwiched molecules suppressing their ability to mediate the transfer of electrons from the bottom to the top electrode under a negative bias.

The device incorporating the [2]rotaxane **13** can be exploited to implement simple logic operations [2.40]. The two bottom electrodes can be stimulated with voltage inputs (I1 and I2) while measuring a current output (O) at the common top electrode. When at least one of the two inputs is high (0 V), the output is low (< 0.7 nA). When both inputs are low (−2 V), the output is high (ca. 4 nA). If a negative logic convention is applied to the voltage inputs (low = 1, high = 0) and a positive logic convention is applied to the current output (low = 0, high = 1), the signal transduction behavior translates into the truth table of an AND gate. The output O is 1 only when both inputs are 1. Instead, an OR operation can be executed if the logarithm of the current is considered as the output. The logarithm of the current is −12 when both voltage inputs are 0 V. It raises to ca. −9 when one or both voltage inputs are lowered to −2 V. This signal transduction behavior translates into the truth table of an OR gate if a negative logic convention is applied to the voltage inputs (low = 1, high = 0) and a positive logic convention is applied to the current output (low = 0, high = 1). The output O is 1 when at least one of the two inputs is 1.

The [2]catenane **13** (Fig. 2.14) incorporates a macrocyclic polyether interlocked with a tetracationic cyclophane [2.42, 43]. Organic solutions of the hexafluorophosphate salt of this [2]catenane and six equivalents of the sodium salt of dimyristoylphosphatidic acid can be co-spread on the water surface of a Langmuir trough [2.44]. The sodium hexafluorophosphate formed dissolves in the supporting aqueous phase, while the hydrophilic bipyridinium cations and the amphiphilic anions remain at the interface. Upon compression, the anions align their hydrophobic tails away from the water surface forming a compact monolayer above the cationic bipyridinium derivatives. The corresponding π–A isotherm indicates limiting molecular areas of ca. 125 Å^2. This large value is a consequence of the bulk associated with the two interlocking macrocycles.

Monolayers of the [2]catenane **13** can be transferred from the air/water interface to the surfaces of the bottom n-doped silicon/silicon dioxide electrodes of a patterned silicon chip with the hydrophobic tails of the amphiphilic anions pointing away from the supporting substrate [2.45, 46]. The subsequent assembly of a top titanium/aluminum electrode affords electrode/monolayer/electrode arrays. Their junction resistance can be probed grounding the top electrode and maintaining the potential of the bottom electrode at +0.1 V. If a voltage pulse of +2 V is applied to the bottom electrode before the measurement, the junction resistance probed is ca. 0.7 GΩ. After a pulse of −2 V applied to the bottom electrode, the junction resistance probed at +0.1 V drops ca. 0.3 GΩ. Thus, alternat-

ing positive and negative voltage pulses can switch reversibly the junction resistance between high and low values. This intriguing behavior is a result of the redox and dynamic properties of the [2]catenane **13**.

Extensive spectroscopic and crystallographic studies [2.42, 43] demonstrated that the tetrathiafulvalene unit resides preferentially inside the cavity of the tetracationic cyclophane of the [2]catenane **13** (Fig. 2.14). Attractive $[\pi \cdots \pi]$ stacking interactions between the neutral tetrathiafulvalene and the bipyridinium dications are responsible for this co-conformation. Oxidation of the tetrathiafulvalene generates a cationic form that is expelled from the cavity of the tetracationic cyclophane. After the circumrotation of the macrocyclic polyether, the oxidized tetrathiafulvalene is exchanged with the neutral 1,5-dioxynaphthalene producing the [2]catenane **14** (Fig. 2.14). The reduction of the tetrathiafulvalene back to its neutral state is followed by the circumrotation of the macrocyclic polyether, which restores the original state **14**. The voltage pulses applied to the bottom electrode of the electrode/monolayer/junction oxidize and reduce the tetrathiafulvalene unit inducing the interconversion between the forms **13** and **14**. The difference in the stereoelectronic properties of these two states translates into distinct current/voltage signatures. Indeed, their ability to mediate the tunneling of electrons across the junction differs significantly. As a result, the junction resistance probed at a low voltage after an oxidizing pulse is significantly different from that determined under the same conditions after a reducing pulse.

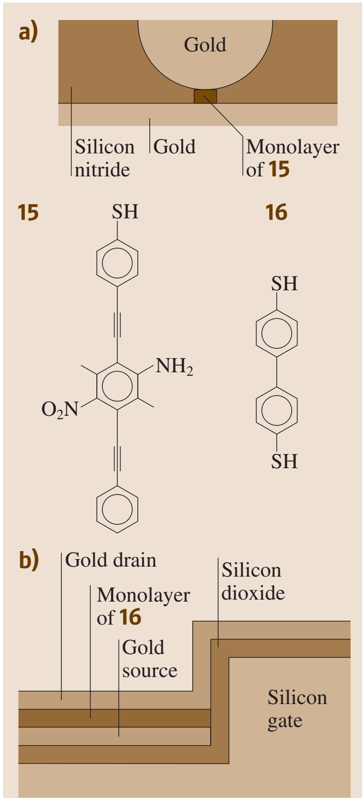

Fig. 2.15 **(a)** A monolayer of the thiol **15** is embedded between two gold electrodes maintained in position by a silicon nitride support. **(b)** A monolayer of the bisthiol **16** is located between two gold electrodes and stimulated by a silicon gate

2.3.3 Self-Assembled Monolayers

In the examples illustrated in Figs. 2.12–2.15, monolayers of amphiphilic and electroactive derivatives are assembled at air/water interfaces and then transferred on the surfaces of appropriate substrates. An alternative strategy to coat electrodes with molecular layers relies on the ability of certain compounds to adsorb spontaneously on solid supports from liquid or vapor phases [2.35]. In particular, the affinity of certain sulfurated functional groups for gold can be exploited to encourage the self-assembly of organic molecules on microscaled and nanoscaled electrodes.

The electrode/monolayer/electrode junction in Fig. 2.15a incorporates a molecular layer between two gold electrodes mounted on a silicon nitride support. This device can be fabricated combining chemical vapor deposition, lithography, anisotropic etching, and self-assembly [2.47]. Initially, a silicon wafer is coated with a 50 nm thick layer of silicon nitride by low pressure chemical vapor deposition. Then, a square of $400 \times 400\,\mu m$ is patterned on one side of the coated wafer by optical lithography and reactive ion etching. Anisotropic etching of the exposed silicon up to the other side of the wafer leaves a suspended silicon nitride membrane of $40 \times 40\,\mu m$. Electron beam lithography and reactive ion etching can be used to carve a bowl-shaped hole (diameter = 30–50 nm) in the membrane. Evaporation of gold on the membrane fills the pore producing a bowl-shaped electrode. Immersion of the substrate in a solution of the thiol **15** results in the self-assembly of a molecular layer on the narrow part of the bowl-shaped electrode. The subsequent evaporation of a gold film on the organic monolayer produces an electrode/monolayer/electrode junction (Fig. 2.15a) with a contact area of less than 2,000 nm^2 and approximately 1,000 molecules.

Under the influence of voltage pulses applied to one of the two gold electrodes in Fig. 2.15a, the conductivity of the sandwiched monolayer switches reversibly be-

tween low and high values [2.48]. In the initial state, the monolayer is in a low conducting mode. A current output of only 30 pA is detected, when a probing voltage of +0.25 V is applied to the bowl-shaped electrode. If the same electrode is stimulated with a short voltage pulse of +5 V, the monolayer switches to a high conducting mode. Now a current output of 150 pA is measured at the same probing voltage of +0.25 V. Repeated probing of the current output at various intervals of time indicates that the high conducting state is memorized by the molecule-based device, and it is retained for more than 15 min. The low conducting mode is restored after either a relatively long period of time or the stimulation of the bowl-shaped electrode with a reverse voltage pulse of −5 V. Thus the current output switches from a low to a high value, if a high voltage input is applied. It switches from a high to a low value, under the influence of a low voltage pulse. This behavior offers the opportunity to store and erase binary data in analogy to a conventional random access memory [2.17]. Binary digits can be encoded on the current output of the molecule-based device applying a positive logic convention (low = 0, high = 1). It follows that a binary 1 can be stored in the molecule-based device applying a high voltage input, and it can be erased applying a low voltage input [2.48].

The electrode/monolayer/electrode junctions in Fig. 2.14 and in Fig. 2.15a are two-terminal devices. A voltage input is applied to one terminal, and a current output is measured at the other. The implementation of molecule-based transistors, however, requires three terminals. A third electrode is needed to gate the current flowing between the source and drain terminals. These types of devices are much more versatile than their two-terminal counterparts for the implementation of logic functions. But the incorporation of molecular components in a three-terminal configuration is considerably more challenging. A remarkable example is the composite assembly in Fig. 2.15b [2.49]. This field-effect transistor integrates a monolayer of the bisthiol **16** and three electrodes. Conventional lithography and anisotropic etching are employed to define a vertical step in a doped silicon substrate. The resulting structure is covered with an insulating layer of silicon dioxide with a thickness of ca. 30 nm. Then gold is evaporated on the bottom part of the step to allow the self-assembly the bisthiol **16**. Under the influence of the gate voltage, the molecular components embedded in this device modulate the current flowing between the source and drain electrodes. The intensity of the drain current increases by five orders of magnitude if the gate voltage is lowered below −0.2 V. It is important to note, however, that only the molecules within 5 nm from the monolayer/insulator interface are responsible for conduction. Thus the current/voltage behavior of this three-terminal device is determined only by few thousand molecules.

Conventional transistors are the basic building blocks of digital circuits [2.19]. They are routinely interconnected with specific configurations to execute designed logic functions. The molecule-based transistor in Fig. 2.15b is no exception. It can be used to assemble real electronic circuits incorporating molecular components. The connection of the drain terminals of two molecule-based transistors affords an inverter [2.49]. In this basic circuit, an output voltage switches from a high (0 V) to a low value (−2 V) when an input voltage varies from a low (−2 V) to a high value (0 V) and vice versa. This signal transduction behavior translates into the truth table of a NOT gate, if a positive logic convention (low = 0, high = 1) is applied to the input and output voltages.

The ability of thiols to self-assemble on the surface of gold can be exploited to fabricate nanocomposite materials integrating organic and inorganic components. For example, the bisthiol **17** forms monolayers (Fig. 2.16a) on gold electrodes with surface coverages of ca. 4.1×10^{10} mol cm^{2} [2.50, 51]. The formation of a thiolate–gold bond at one of the two thiol ends of **17** is responsible for adsorption. The remaining thiol group points away from the supporting surface and can be exploited for further functionalization. Gold nanoparticles adsorb on the molecular layer (Fig. 2.16b), once again, as a result of thiolate–gold bond formation. The immersion of the resulting material in a methanol solution of **17** encourages the adsorption of an additional organic layer (Fig. 2.16c) on the composite material. Following these procedures, up to ten alternating organic and inorganic layers can be deposited on the electrode surface. The resulting assembly can mediate the unidirectional electron transfer from the supporting electrode to redox active species in solution. For example, the cyclic voltammogram of the $[Ru(NH_3)_6]^{3+/2+}$ couple recorded with a bare gold electrode reveals a reversible reduction process. In the presence of ten alternating molecular and nanoparticle layers on the electrode surface, the reduction potential shifts by ca. −0.2 V and the back oxidation wave disappears. The pronounced potential shift indicates that $[Ru(NH_3)_6]^{3+}$ accepts electrons only after the surface-confined bipyridinium dications have been reduced. The lack of reversibility indicates that the back oxidation to the bipyridinium dications inhibits the transfer of elec-

trons from the $[Ru(NH_3)_6]^{2+}$ to the electrode. Thus the electroactive multilayer allows the flow of electrons in one direction only in analogy to conventional diodes.

The current/voltage behavior of individual nanoparticles in Fig. 2.16b can be probed by scanning tunneling spectroscopy in an aqueous electrolyte under an inert atmosphere [2.52]. The platinum-iridium tip of a scanning tunneling microscope is positioned above one of the gold particles. The voltage of the gold substrate relative to the tip is maintained at -0.2 V while that relative to a reference electrode immersed in the same electrolyte is varied to control the redox state of the electroactive units. Indeed, the bipyridinium dications in the molecular layer can be reduced reversibly to a monocationic state. The resulting monocations can be reduced further and, once again, reversibly to a neutral form. Finally, the current flowing from the gold support to the tip of the scanning tunneling microscope is monitored as the tip–particle distance increases. From the distance dependence of the current, inverse length decays of ca. 16 and 7 nm^{-1} for the dicationic and monocationic states, respectively, of the molecular spacer can be determined. The dramatic decrease indicates that the reduction of the electroactive unit facilitates the tunneling of electrons through the gold/molecule/nanoparticle/tip junction. In summary, a change in the redox state of the bipyridinium components can be exploited to gate reversibly the current flowing through this nanoscaled device.

Similar nanostructured materials, combining molecular and nanoparticles layers, can be prepared on layers on indium-tin oxide electrodes following multistep procedures [2.53]. The hydroxylated surfaces of indium-tin oxide supports can be functionalized with 3-ammoniumpropylysilyl groups and then exposed to gold nanoparticles having a diameter of ca. 13 nm [2.54, 55]. Electrostatic interactions promote the adsorption of the nanoparticles on the organic layer (Fig. 2.17a). The treatment of the composite film with the bipyridinium cyclophane **18** produces an organic layer on the gold nanoparticles (Fig. 2.18b). Following this approach, alternating layers of inorganic nanoparticles and organic building blocks can be assembled on the indium-tin oxide support. Cyclic voltammograms of the resulting materials show the oxidation of the gold nanoparticles and the reduction of the bipyridinium units. The peak current for both processes increases with the number of alternating layers. Comparison of these values indicates that the ratio between the number of tetracationic cyclophanes and that of the nanoparticles is ca. 100 : 1.

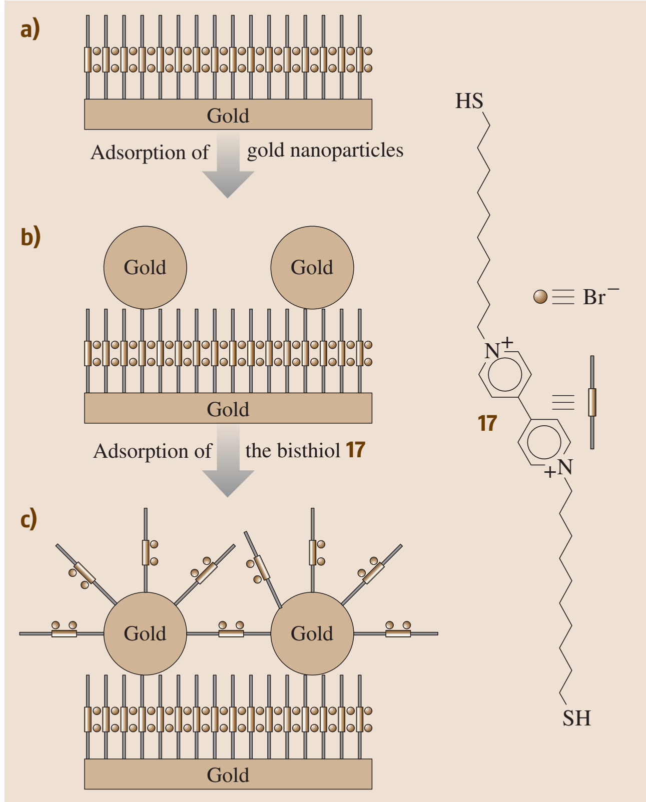

Fig. 2.16 (a) The bisthiol **18** self-assembles on gold electrodes as a result of thiolate–gold bond formation. **(b)** Gold nanoparticles adsorb spontaneously on the molecular layer. **(c)** Exposure of the composite assembly to a solution of **18** results in the formation of an additional molecular layer on the surface of the gold nanoparticles

The tetracationic cyclophane **18** binds dioxyarenes in solution [2.56, 57]. Attractive supramolecular forces between the electron deficient bipyridinium units and the electron rich guests are responsible for complexation. This recognition motif can be exploited to probe the ability of the composite films in Fig. 2.17b,c to sense electron rich analytes. In particular, hydroquinone is expected to enter the electron deficient cavities of the surface-confined cyclophanes. Cyclic voltammograms consistently reveal the redox waves associated with the reversible oxidation of hydroquinone even when very small amounts of the guest (ca. 1×10^5 M) are added to the electrolyte solution [2.54, 55]. No redox response can be detected with a bare indium–tin oxide electrode under otherwise identical conditions. The supramolecular association of the guest and the surface confined

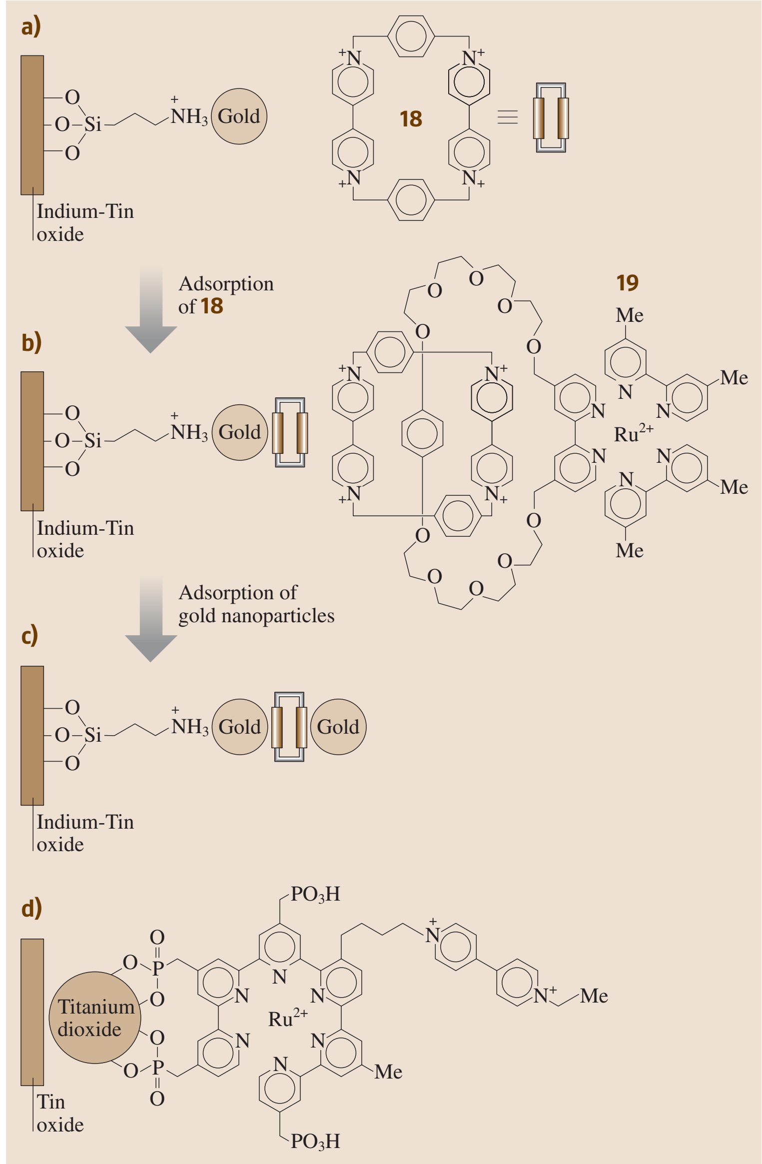

Fig. 2.17 **(a)** Gold nanoparticles assemble spontaneously on prefunctionalized indium-tin oxide electrodes. **(b)** Electrostatic interactions encourage the adsorption of the tetracationic cyclophane **18** on the surface-confined nanoparticles. **(c)** An additional layer of nanoparticles assembles on the cationic organic coating. Similar composite films can be prepared using the tetracationic [2]catenane **19** instead of the cyclophane **18**. **(d)** Phosphonate groups can be used to anchor molecular building blocks to titanium dioxide nanoparticles

cyclophanes increases the local concentration of hydroquinone at the electrode/solution interface enabling its electrochemical detection.

Following a related strategy, the [2]catenane **19** (Fig. 2.17) can be incorporated into similar composite arrays [2.58,59]. This interlocked molecule incorporates a Ru(II)/trisbipyridine sensitizer and two bipyridinium acceptors. Upon irradiation of the composite material at 440 nm, photoinduced electron transfer from the sensitizer to the appended acceptors occurs. The photogenerated hole in the sensitizer is filled after the transfer of an electron from a sacrificial electron donor present in the electrolyte solution. Under a positive voltage bias applied to the supporting electrode, an electron flow from the bipyridinium acceptors to the indium-tin oxide support is established. The resulting current switches between high and low values as the light source is turned on and off.

Another photoresponsive device, assembled combining inorganic nanoparticles with molecular building blocks, is illustrated in Fig. 2.17d. Phosphonate groups can be used to anchor a Ru(II)/trisbipyridine complex with an appended bipyridinium dication to titanium dioxide nanoparticles deposited on a doped tin oxide electrode [2.60, 61]. The resulting composite array can be integrated in a conventional electrochemical cell filled with an aqueous electrolyte containing triethanolamine. Under a bias voltage of -0.45 V and irradiation at 532 nm, 95% of the excited ruthenium centers transfer electrons to the titanium dioxide nanoparticles. The other 5% donate electrons to the bipyridinium dications. All the electrons transferred to the bipyridinium acceptors return to the ruthenium centers, while only 80% of those accepted by the nanoparticles return to the transition metal complexes. The remaining 15% reach the bipyridinium acceptors, while electron transfer from sacrificial triethanolamine donors fills the photogenerated holes left in the ruthenium sensitizers. The photoinduced reduction of the bipyridinium dication is accompanied by the appearance of the characteristic band of the radical cation in the absorption spectrum. This band persists for hours under open circuit conditions. But it fades in ca. 15 s under a voltage bias of $+1$ V, as the radical cation is oxidized back to the dicationic form. In summary, an optical stimulation accompanied by a negative voltage bias reduces the bipyridinium building block. The state of the photogenerated form can be read optically, recording the absorption spectrum in the visible region, and erased electrically, applying a positive voltage pulse.

2.3.4 Nanogaps and Nanowires

The operating principles of the electroactive and photoactive devices illustrated in Figs. 2.12–2.17 exploit the ability of small collections of molecular components to manipulate electrons and photons. Designed molecules are deposited on relatively large electrodes and can be addressed electrically and/or optically by controlling the voltage of the support and/or illuminating its surface. The transition from devices relying on collections of molecules to unimolecular devices requires the identification of practical methods to contact single molecules. This fascinating objective demands the rather challenging miniaturization of contacting electrodes to the nanoscale.

A promising approach to unimolecular devices relies on the fabrication of nanometer-sized gaps in metallic features followed by the insertion of individual molecules between the terminals of the gap. This strategy permits the assembly of nanoscaled three-terminal devices equivalent to conventional transistors [2.62–64]. A remarkable example is illustrated in Fig. 2.18a [2.62]. It incorporates a single molecule in the nanogap generated between two gold electrodes. Initially electron beam lithography is used to pattern a gold wire on a doped silicon wafer covered by an insulating silicon dioxide layer. Then the gold feature is broken by electromigration to generate the nanogap. The lateral size of the separated electrodes is ca. 100 nm and their thickness is ca. 15 nm. Scanning electron microcopy indicates that the facing surfaces of the separated electrodes are not uniform and that tiny gaps between their protrusions are formed. Current/voltage measurements suggest that the size of the smallest nanogap is ca. 1 nm. When the

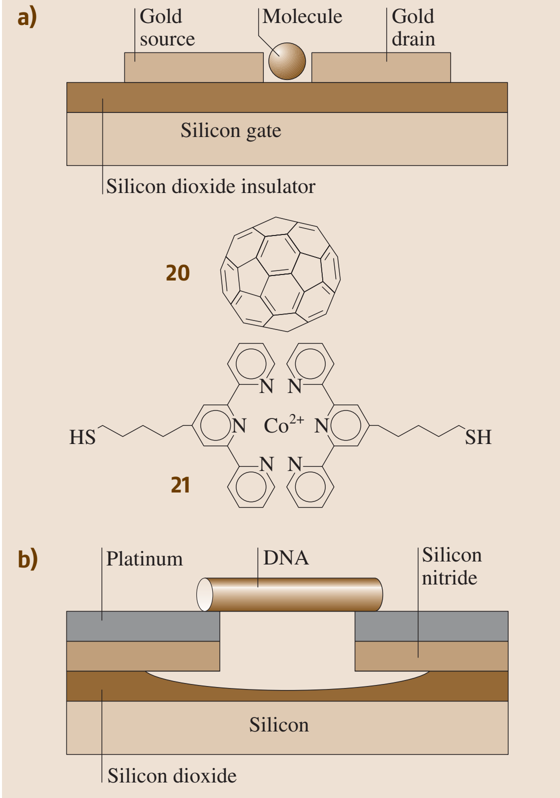

Fig. 2.18 (a) Nanoscaled transistors can be fabricated inserting a single molecule (**20** or **21**) between source and drain electrodes mounted on a silicon/silicon dioxide support. **(b)** A DNA nanowire can bridge nanoelectrodes suspended above a silicon dioxide support

breakage of the gold feature is preceded by the deposition of a dilute toluene solution of C_{60} (**20**), junctions with enhanced conduction are obtained. This particular molecule has a diameter of ca. 0.7 nm and can insert in the nanogap facilitating the flow of electrons across the junction.

The unique configuration of the molecule-based device in Fig. 2.18a can reproduce the functions of a conventional transistor [2.19] at the nanoscale. The two gold terminals of the junction are the drain and source of this nanotransistor, and the underlying silicon wafer is the gate. At a temperature of 1.5 K, the junction conductance is very small, when the gate bias is low, and increases in steps at higher voltages [2.62]. The conductance gap is a consequence of the finite energy required to oxidize/reduce the single C_{60} positioned in the junction. It is interesting that the zero-conductance window also changes with the gate voltage and can be opened and closed reversibly adjusting the gate bias.

A similar strategy can be employed to fabricate a nanoscaled transistor incorporating the Co(II) complex **21** shown in Fig. 2.18 [2.64]. In this instance, a silicon dioxide layer with a thickness of ca. 30 nm is grown thermally on a doped silicon substrate. Then a gold wire with a width of ca. 200 nm and a thicknesses of ca. 10–15 nm is patterned on the silicon dioxide overlayer by electron beam lithography. After extensive washing of the substrate with acetone and methylene chloride and cleaning with oxygen plasma, the gold wire is exposed to a solution of the bisthiol **21**. The formation of thiolate–gold bonds promotes the self-assembly of the molecular building block on the gold surface. At this point, electromigration-induced breakage produces a gap of 1–2 nm in the gold wire. The surface-confined bisthiol **21** is only 0.24 nm long and, therefore, it can insert in the nanogap producing an electrode/molecule/electrode junction.

The cobalt center in **21** can be oxidized/reduced reversibly between Co(II) and Co(III) [2.64]. When this electroactive molecule is inserted in a nanogap (Fig. 2.18a), its ability to accept and donate electrodes dictates the current/voltage profile of the resulting electrode/molecule/electrode junction. More precisely, no current flows across the junction below a certain voltage threshold. As the source voltage is raised above this particular value, the drain current increases in steps. The threshold associated with the source voltage varies in magnitude with the gate voltage. This intriguing behavior is a consequence of the finite energy necessary to oxidize/reduce the cobalt center and of a change in the relative stabilities of the oxidized and reduced forms Co(II) and Co(III) with the gate voltage. In summary, the conduction of the electrode/molecule/electrode junction can be tuned adjusting the voltage of the silicon support. The behavior of this molecule-based nanoelectronic device is equivalent to that of a conventional transistor [2.19]. In both instances, the gate voltage regulates the current flowing from the source to the drain.

The electromigration-induced breakage of preformed metallic features successfully produces nanogaps by moving apart two fragments of the same wire. Alternatively, nanogaps can be fabricated reducing the separation of the two terminals of much larger gaps. For example, gold electrodes separated by a distance of 20–80 nm can be patterned on a silicon/silicon dioxide substrate by electron beam lithography [2.65]. The relatively large gap between them can be reduced significantly by the electrochemical deposition of gold on the surfaces of both electrodes. The final result is the fabrication of two nanoelectrodes separated by ca. 1 nm and with a radius of curvature of 5–15 nm. The two terminals of this nanogap can be "contacted" by organic nanowires grown between them [2.66]. In particular, the electropolymerization of aniline produces polyaniline bridges between the gold nanoelectrodes. The conductance of the resulting junction can be probed immersing the overall assembly in an electrolyte solution. Employing a bipotentiostat, the bias voltage of the two terminals of the junction can be maintained at 20 mV, while their potentials are scanned relative to that of a silver/silver chloride reference electrode. Below ca. 0.15 V, the polymer wire is in an insulating state and the current flowing across the junction is less than 0.05 nA. At this voltage threshold, however, the current raises abruptly to ca. 30 nA. This value corresponds to a conductivity for the polymer nanojunction of 10–100 $S\,cm^{-1}$. When the potential is lowered again below the threshold, the current returns back to very low values. The abrupt decrease in current in the backward scan is observed at a potential that is slightly more negative than that causing the abrupt current increase in the forward scan. In summary, the conductance of this nanoscaled junction switches on and off as a potential input is switched above and below a voltage threshold.

It is interesting to note that the influence of organic bridges on the junction conductance can be exploited for chemical sensing. Nanogaps fabricated following a similar strategy but lacking the polyaniline bridge alter their conduction after exposure to dilute solutions of small organic molecules [2.67]. Indeed, the organic

analytes dock into the nanogaps producing a marked decrease in the junction conductance. The magnitude of the conductance drop happens to be proportional to the analyte–nanoelectrode binding strength. Thus the presence of the analyte in solution can be detected probing the current/voltage characteristics of the nanogaps.

Nanogaps between electrodes patterned on silicon/silicon dioxide supports can be bridged also by DNA double strands [2.68,69]. The device in Fig. 2.18b has a 10.4 nm long poly(G)–poly(C) DNA oligomer suspended between two nanoelectrodes. It can be fabricated patterning a 30 nm wide slit in a silicon nitride overlayer covering a silicon/silicon dioxide support by electron beam evaporation. Underetching the silicon dioxide layer leaves a silicon nitride finger, which can be sputtered with a platinum layer and chopped to leave a nanogap of 8 nm. At this point, a microdroplet of a dilute solution of DNA is deposited on the device and a bias of 5 V is applied between the two electrodes. Electrostatic forces encourage the deposition of a single DNA wire on top of the nanogap. As soon as the nanowire is in position, current starts to flow across the junction. The current/voltage signature of the electrode/DNA/electrode junction shows currents below 1 pA at low voltage biases. Under these conditions, the DNA nanowire is an insulator. Above a certain voltage threshold, however, the nanowire becomes conducting and currents up to 100 nA can flow across the junction through a single nanowire. Assuming that direct tunneling from electrode to electrode is extremely unlikely for a relatively large gap of 8 nm, the intriguing current/voltage behavior has to be a consequence of the participation of the molecular states in the electron transport process. Two possible mechanisms can be envisaged. Sequential hopping of the electrons between states localized in the DNA base pairs can allow the current flow above a certain voltage threshold. But this mechanism would presumably result in a Coulomb blockade voltage gap that is not observed experimentally. More likely, electronic states delocalized across the entire length of the DNA nanowire are producing a molecular conduction band. The off-set between the molecular conduction band and the Fermi levels of the electrodes is responsible for the insulating behavior at low biases. Above a certain voltage threshold, the molecular band and one of the Fermi levels align facilitating the passage of electrons across the junction.

Carbon nanotubes are extremely versatile building blocks for the assembly of nanoscaled electronic

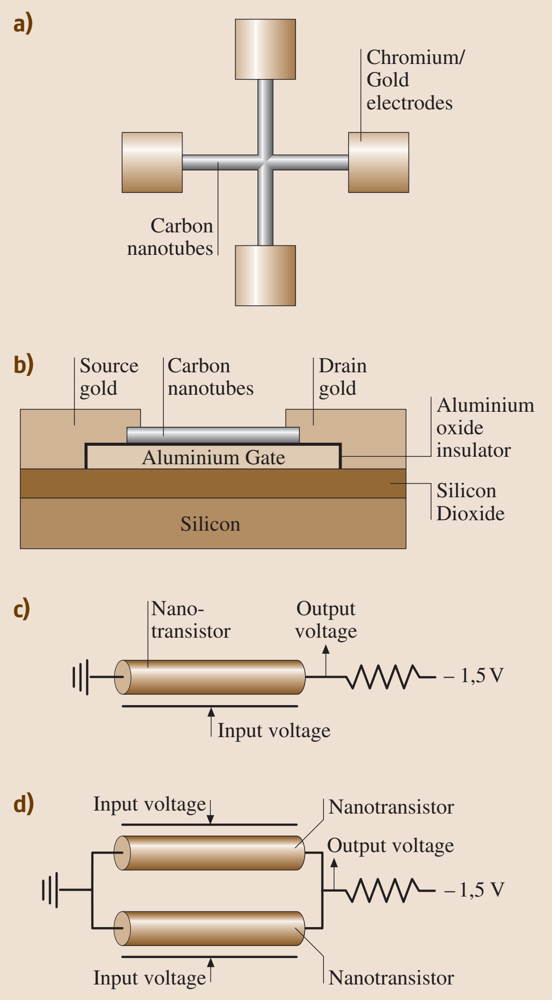

Fig. 2.19 **(a)** Nanoscaled junctions can be assembled on silicon/silicon dioxide supports crossing pairs of orthogonally arranged single-wall carbon nanotubes with chromium/gold electrical contacts at their ends. **(b)** Nanotransistors can be fabricated contacting the two ends of a single-wall carbon nanotube deposited on an aluminum/aluminum oxide gate with gold sources and drain. One or two nanotube transistors can be integrated into nanoscaled NOT **(c)** and NOR **(d)** logic gates

devices. They can be used to bridge nanogaps [2.70–73] and assemble nanoscaled cross junctions [2.74–76]. In Fig. 2.19a, a single-wall carbon nanotube crosses over another one in an orthogonal arrangement [2.74]. Both nanotubes have electrical contacts at their ends.

The fabrication of this device involves three main steps. First, alignment marks for the electrodes are patterned on a silicon/silicon dioxide support by electron beam lithography. Then the substrate is exposed to a dichloromethane suspension of single-wall SWNT carbon nanotubes. After washing with isopropanol, crosses of carbon nanotubes in an appropriate alignment relative to the electrode marks are identified by tapping mode atomic force microscopy. Finally chromium/gold electrodes are fabricated on top of the nanotube ends, again, by electron beam lithography. The conductance of individual nanotubes can be probed by exploiting the two electric contacts at their ends. These two-terminal measurements reveal that certain nanotubes have metallic behavior, while others are semiconducting. It follows that three distinct types of cross junctions differing in the nature of their constituent nanotubes can be identified on the silicon/silicon dioxide support. Four terminal current/voltage measurements indicate that junctions formed by two metallic nanotubes have high conductance and ohmic behavior. Similarly, high junction conductance and ohmic behavior is observed when two semiconducting nanotubes cross. The current/voltage signature of junctions formed when a metallic nanotube crosses a semiconducting one are, instead, completely different. The metallic nanotube depletes the semiconducting one at the junction region producing a nanoscaled Schottky barrier with a pronounced rectifying behavior.

Similar fabrication strategies can be exploited to assemble nanoscaled counterparts of conventional transistors. The device in Fig. 2.19b is assembled patterning an aluminum finger on a silicon/silicon dioxide substrate by electron beam lithography [2.76]. After exposure to air, an insulating aluminum oxide layer forms on the aluminum finger. Then a dichloromethane suspension of single-wall carbon nanotubes is deposited on the resulting substrate. Atomic force microscopy can be used to select carbon nanotubes with a diameter of ca. 1 nm positioned on the aluminum finger. After registering their coordinates relative to alignment markers, gold contacts can be evaporated on their ends by electron beam lithography. The final assembly is a nanoscaled three-terminal device equivalent to a conventional field effect transistor [2.19]. The two gold contacts are the source and drain terminals, while the underlying aluminum finger reproduces the function of the gate. At a source to drain bias of ca. -1.3 V, the drain current jumps from ca. 0 to ca. 50 nA when the gate voltage is lowered from -1.0 to -1.3 V. Thus moderate changes in the gate voltage vary significantly the current flowing through the nanotube-based device in analogy to a conventional enhancement mode *p*-type field effect transistor [2.19].

The nanoscaled transistor in Fig. 2.18a has a microscaled silicon gate that extends under the entire chip [2.62, 64]. The configuration in Fig. 2.19b, instead, has nanoscaled aluminum gates for every single carbon nanotube transistor fabricated on the same support [2.76]. It follows that multiple nanoscaled transistors can be fabricated on the same chip and operated independently following this strategy. This unique feature offers the possibility of fabricating nanoscaled digital circuits by interconnecting the terminals of independent nanotube transistors. The examples in Fig. 2.19c,d illustrate the configurations of nanoscaled NOT and NOR gates implemented using one or two nanotube transistors. In Fig. 2.19c, an off-chip bias resistor is connected to the drain terminal of a single transistor while the source is grounded. A voltage input applied to the gate modulates the nanotube conductance altering the voltage output probed at the drain terminal. In particular, a voltage input of -1.5 V lowers the nanotube resistance (26 MΩ) below that of the bias resistor (100 MΩ). As a result, the voltage output drops to 0 V. When the voltage input is raised to 0 V, the nanotube resistance increases above that of the bias resistor and the voltage output becomes -1.5 V. Thus the output of this nanoelectronic device switches from a high (0 V) and to a low (-1.5 V) level as the input shifts from a low (-1.5 V) to a high (0 V) value. The inverse relation between input and output translates into a NOT operation if a negative logic convention (low $=1$, high $=0$) is applied to both signals.

In Fig. 2.15d, the source terminals of two independent nanotube transistors fabricated on the same chip are connected by a gold wire and grounded [2.76]. Similarly, the two drain terminals are connected by another gold wire and contacted to an off-chip bias resistors. The gate of each nanotube can be stimulated with a voltage input and the voltage output of the device can be probed at their interconnected drain terminals. When the resistance of at least one of the two nanotubes is below that of the resistor, the output is 0 V. When both nanotubes are in a nonconducting mode, the output voltage is -1.5 V. Thus if a low voltage input -1.5 V is applied to one or both transistors, the output is high (0 V). When both voltage inputs are high (0 V), the output is low (-1.5 V). If a negative logic convention (low $=1$, high $=0$) is applied to all signals, the signal transduction behavior translates in to a NOR operation.

2.4 Conclusions and Outlook

Nature builds nanostructured biomolecules relying on a highly modular approach [2.1]. Small building blocks are connected by robust chemical bonds to generate long strands of repeating units. The synergism of a multitude of attractive supramolecular forces determines the three-dimensional arrangement of the resulting polymeric chains and controls the association of independent strands into single and well-defined entities. Nucleic acids and proteins are two representative classes of biomolecules assembled with subnanometer precision through the subtle interplay of covalent and noncovalent bonds starting from a relatively small pool of nucleotide and amino acid building blocks.

The power of chemical synthesis [2.2] offers the opportunity of mimicking nature's modular approach to nanostructured materials. Following established experimental protocols, small molecular building blocks can be joined together relying on the controlled formation of covalent bonds between designed functional groups. Thus artificial molecules with nanoscaled dimensions can be assembled piece by piece with high structural control. Indeed, helical, tubular, interlocked, and highly branched nanostructures have been all prepared already exploiting this general strategy and the synergism of covalent and noncovalent bonds [2.3].

The chemical construction of nanoscaled molecules from modular building blocks also offers the opportunity for engineering specific properties in the resulting assemblies. In particular, electroactive and photoactive fragments can be integrated into single molecules. The ability of these functional subunits to accept/donate electrons and photons can be exploited to design nanoscaled electronic and photonic devices. Indeed, molecules that respond to electrical and optical stimulations producing detectable outputs have been designed already [2.16]. These chemical systems can be employed to control the interplay of input and output signals at the molecular level. Their conceptual analogy with the signal transduction operated by conventional logic gates in digital circuits is evident. In fact, electroactive and photoactive molecules able to reproduce AND, NOT, and OR operations as well as simple combinational of these basic logic functions are already a reality [2.20, 21].

Most of the molecular switches for digital processing developed so far rely on bulk addressing. In general, relatively large collections of functional molecules are addressed simultaneously in solution. The realization of molecule-based devices with reduced dimensions as well as practical limitations associated with liquid phases in potential applications are encouraging a transition from the solution to the solid state. The general strategy followed so far relies on the deposition of functional molecules on the surfaces of appropriate electrodes following either the Langmuir–Blodgett methodology [2.34] or self-assembly processes [2.35]. The combination of these techniques with the nanofabrication of insulating, metallic, and semiconducting features on appropriate supports has already allowed the realization of fascinating molecule-based devices [2.30–33, 53]. The resulting assemblies integrate inorganic and organic components and, in some instances, even biomolecules to execute specific functions. They can convert optical stimulations into electrical signals. They can execute irreversible and reversible switching operations. They can sense qualitatively and quantitatively specific analytes. They can reproduce the functions of conventional rectifiers and transistors. They can be integrated within functioning nanoelectronic devices capable of simple logic operations.

The remarkable examples of molecule-based materials and devices now available demonstrate the great potential and promise for this research area. At this stage, the only limit left to the design of functional molecules is the imagination of the synthetic chemist. All sort of molecular building blocks with tailored dimensions, shapes, and properties are more or less accessible with the assistance of modern chemical synthesis. Now, the major challenges are (1) to master the operating principles of the molecule-based devices that have been and continue to be assembled and (2) to expand and improve the fabrication strategies available to incorporate molecules into reliable device architectures. As we continue to gather further insights in these directions, design criteria for a wide diversity of molecule-based devices will emerge. It is not unrealistic to foresee the evolution of an entire generation of nanoscaled devices, based on engineered molecular components, that will find applications in a variety of fields ranging from biomedical research to information technology. Perhaps nature can once again illuminate our path, teaching us not only how to synthesize nanostructured molecules but also how to use them. After all, nature is replete with examples of extremely sophisticated molecule-based devices. From tiny bacteria to higher animals, we are all a collection of molecule-based devices.

3. Introduction to Carbon Nanotubes

Introduction

Carbon nanotubes are among the amazing objects that science sometimes creates by accident, without meaning to, but that will likely revolutionize the technological landscape of the century ahead. Our society stands to be significantly influenced by carbon nanotubes, shaped by nanotube applications in every aspect, just as silicon-based technology still shapes society today. The world already dreams of space-elevators tethered by the strongest of cables, hydrogen-powered vehicles, artificial muscles, and so on – feasts that would be made possible by the emerging carbon nanotube science.

Of course, nothing is set in stone yet. We are still at the stage of possibilities and potential. The recent example of fullerenes – molecules closely related to nanotubes, whose importance was so anticipated that their discovery in 1985 brought a Nobel Prize to their finders in 1996 although few related applications have actually yet reached the market – teaches us to play the game of enthusiastic predictions with some caution. But in the case of carbon nanotubes, expectations are high. Taking again the example of electronics, the miniaturization of chips is about to reach its lowest limits. Are we going to accept that our video camera, computers, and cellular phones no longer decrease in size and increase in memory every six months? Surely not. Always going deeper, farther, smaller, higher is a characteristic unique to humankind, and which helps to explain its domination of the living world on earth. Carbon nanotubes can help us fulfill our expectation of constant technological progress as a source of better living.

In this chapter, after the structure, synthesis methods, growth mechanisms, and properties of carbon nanotubes will be described, an entire section will be devoted to nanotube-related nano-objects. Indeed, should pristine nanotubes reach any limitation in some area, their ready and close association to foreign atoms, molecules, and compounds offers the prospect of an even magnified set of properties. Finally, we will describe carbon nanotube applications supporting the idea that the future for the science and technology of carbon nanotubes looks very promising.

References 86

Carbon nanotubes have been synthesized for a long time as products from the action of a catalyst over the gaseous species originating from the thermal decomposition of hydrocarbons (see Sect. 3.2). Some of the first evidence that the nanofilaments thus produced were actually nanotubes – i. e., exhibiting an inner cavity – can be found in the transmission electron microscope micrographs published by *Hillert* et al. in 1958 [3.1]. This was of course related to and made possible by the progress in transmission electron microscopy. It is then likely that the carbon filaments prepared by *Hughes* and *Chambers* in 1889 [3.2], reported by *Maruyama* et al. [3.3] as probably the first patent ever deposited in the field, and whose preparation method was also based on the catalytically enhanced thermal cracking of hydrocarbons, were already carbon nanotube-related morphologies. The preparation of vapor-grown carbon fibers had actually been reported as early as more than one century ago [3.4, 5]. Since then, the interest in carbon nanofilaments/nanotubes has been recurrent, though within a scientific area almost limited to the carbon material scientist community. The reader is invited to consult the review published by *Baker* et al. [3.6] regarding the early works. The worldwide enthusiasm came unexpectedly in 1991, after the catalyst-free formation of nearly perfect concentric multiwall carbon nanotubes (c-MWNTs, see Sect. 3.1) was reported [3.7] as by-products of the formation of fullerenes by the electric-arc technique. But the real breakthrough occurred two years later, when attempts in situ to fill the nanotubes with various metals (see Sect. 3.5) led to the discovery – again unexpected – of single-wall carbon nanotubes (SWNTs) simultaneously by *Iijima* et al. [3.8] and *Bethune* et al. [3.9]. Single-wall carbon nanotubes were really new nano-objects many of whose properties and behaviors are quite specific (see Sect. 3.4). They are also beautiful objects for fundamental physics as well as unique molecules for experimental chemistry, still keeping some mystery since their formation mechanisms are a subject of controversy and are still debated (see Sect. 3.3). Potential applications seem countless, although few have reached a marketable status so far (see Sect. 3.6). Consequently, about five papers a day with carbon nanotubes as the main topic are currently published by research teams from around the world, an illustration of how extraordinarily active – and highly competitive – is this field of research. It is a quite unusual situation, similar to that of fullerenes, which, by the way, are again carbon nano-objects structurally closely related to nanotubes.

This is not, however, only about scientific exaltation. Economical aspects are leading the game to a greater and greater extent. According to experts, the world market is predicted to be more than 430 M \$ in 2004 and estimated to grow to several b \$ before 2009. That is serious business, and it will be closely related to how scientists and engineers will be able to deal with the many challenges found on the path from the beautiful, ideal molecule to the reliable – and it is hoped, cheap – manufactured product.

3.1 Structure of Carbon Nanotubes

It is simple to imagine a single-wall carbon nanotube (SWNT). Ideally, it is enough to consider a perfect graphene sheet (a graphene being the same polyaromatic mono-atomic layer made of an hexagonal display of sp^2 hybridized carbon atoms that genuine graphite is built up with), to roll it into a cylinder (Fig. 3.1) paying attention that the hexagonal rings put in contact join coherently, then to close the tips by two caps, each cap being a hemi-fullerene with the appropriate diameter (Fig. 3.2a–c).

3.1.1 Single-Wall Nanotubes

Geometrically, there is no restriction regarding the tube diameter. But calculations have shown that collapsing the single-wall tube into a flattened two-layer ribbon is energetically more favorable than maintaining the tubular morphology beyond a diameter value of ~ 2.5 nm [3.10]. On the other hand, it intuitively comes to mind that the shorter the radius of curvature, the higher the stress and the energetic cost, although SWNTs with diameters as low as 0.4 nm have been successfully synthesized [3.11]. A suitable energetic compromise is thus reached for ~ 1.4 nm, the most frequent diameter encountered regardless of the synthesis techniques (at least those based on solid carbon source) when conditions for high SWNT yields are used. There is no such restriction for nanotube length, which only depends on limitations brought by the preparation method and the specific conditions used for the synthesis (thermal gradients, res-

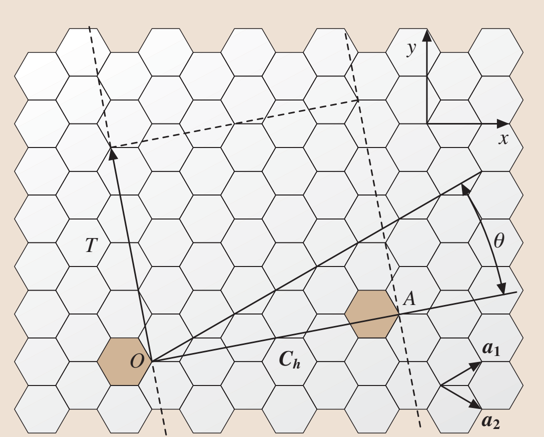

Fig. 3.1 Sketch of the way to make a single-wall carbon nanotube, starting from a graphene sheet (adapted from [3.12])

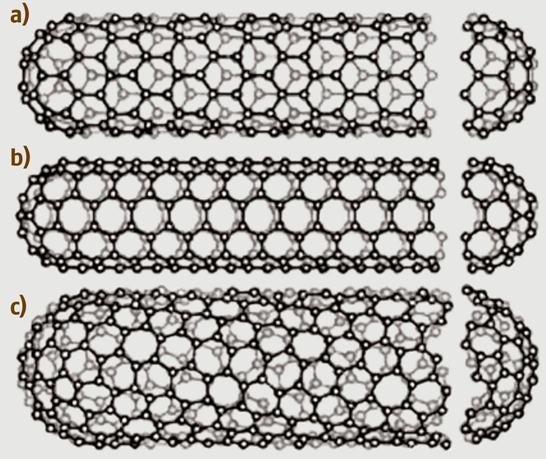

Fig. 3.2a–c Sketch of three different SWNT structures as examples for **(a)** a zig-zag-type nanotube, **(b)** an armchair-type nanotube, **(c)** a helical nanotube (adapted from [3.13])

idence time, etc.). Experimental data are consistent with these statements, since SWNTs wider than 2.5 nm are scarcely reported in literature, whatever the preparation method, while SWNT length can be in the micrometer or the millimeter range. These features make single-wall carbon nanotubes a unique example of single molecules with huge aspect ratios.

Two important consequences derive from the SWNT structure as described above:

1. All carbon atoms are involved in hexagonal aromatic rings only and are therefore in equivalent position, except at the nanotube tips where $6 \times 5 = 30$ atoms at each tip are involved in pentagonal rings (considering that adjacent pentagons are unlikely) – though not more, not less, as a consequence of the Euler's rule that also governs the fullerene structure. In case SWNTs are ideally perfect, their chemical reactivity will therefore be highly favored at the tube tips, at the very location of the pentagonal rings.
2. Though carbon atoms are involved in aromatic rings, the C=C bond angles are no longer planar as they should ideally be. This means that the hybridization of carbon atoms are no longer pure sp^2 but get some percentage of the sp^3 character, in a proportion that increases as the tube radius of curvature decreases. For example, the effect is the same as for the C_{60} fullerene molecules, whose radius of curvature is 0.35 nm, and the subsequent sp^3 character proportion about 30%. On the one hand, this is supposed to make the SWNT surface (though consisting of aromatic ring faces) a bit more reactive than regular, planar graphene, relatively speaking. On the other hand, this somehow induces a variable overlapping of the bands of density of states, thereby inducing a unique versatile electronic behavior (see Sect. 3.4).

As illustrated by Fig. 3.2, there are many ways to roll a graphene into a single-wall nanotube, some of the resulting nanotubes enabling symmetry mirrors both parallel and perpendicular to the nanotube axis (such as the SWNTs from Fig. 3.2a and 3.2b), some others not (such as the SWNT from Fig. 3.2c). By correspondence with the terms used for molecules, the latter are commonly called "chiral" nanotubes. "Helical" should be preferred, however, in order to respect the definition of chirality, which makes all chiral molecules unable to be superimposed on their own image in a mirror. The various ways to roll graphene into tubes are therefore mathematically defined by the vector of helicity $\boldsymbol{C}_\mathrm{h}$, and the angle of helicity θ, as follows (referring to Fig. 3.1):

$$\boldsymbol{OA} = \boldsymbol{C}_\mathrm{h} = n\boldsymbol{a}_1 + m\boldsymbol{a}_2$$

with

$$\boldsymbol{a}_1 = \frac{a\sqrt{3}}{2}\boldsymbol{x} + \frac{a}{2}\boldsymbol{y} \quad \text{and} \quad \boldsymbol{a}_2 = \frac{a\sqrt{3}}{2}\boldsymbol{x} - \frac{a}{2}\boldsymbol{y}$$
$$\text{where} \quad a = 2.46\,\text{Å}$$

and

$$\cos\theta = \frac{2n+m}{2\sqrt{n^2+m^2+nm}}$$

Part A | 3.1

where n and m are the integers of the vector $\boldsymbol{OA}$ considering the unit vectors $\boldsymbol{a}_1$ and $\boldsymbol{a}_2$.

The vector of helicity $\boldsymbol{C}_\mathrm{h}(=\boldsymbol{OA})$ is perpendicular to the tube axis, while the angle of helicity θ is taken with respect to the so-called zig-zag axis, i. e., the vector of helicity that makes nanotubes of the "zig-zag" type (see below). The diameter D of the corresponding nanotube is related to $\boldsymbol{C}_\mathrm{h}$ by the relation:

$$D = \frac{|\boldsymbol{C}_\mathrm{h}|}{\pi} = \frac{a_\mathrm{CC}\sqrt{3(n^2+m^2+nm)}}{\pi} ,$$

where

$$\underset{\text{(graphite)}}{1.41\,\text{Å}} \le a_{\mathrm{C=C}} \le \underset{(\mathrm{C}_{60})}{1.44\,\text{Å}} .$$

The C−C bond length is actually elongated by the curvature imposed, taking the average value for the C_{60} fullerene molecule as a reasonable upper limit, and the value for flat graphenes in genuine graphite as the lower limit (corresponding to an infinite radius of curvature). Since $\boldsymbol{C}_\mathrm{h}$, θ, and D are all expressed as a function of the integers n and m, they are sufficient to define any SWNT specifically, by noting them (n, m). Obtaining the values of n and m for a given SWNT is simple by counting the number of hexagons that separate the extremities of the $\boldsymbol{C}_\mathrm{h}$ vector following the unit vector $\boldsymbol{a}_1$ first, then $\boldsymbol{a}_2$ [3.12]. In the example of Fig. 3.1, the SWNT that will be obtained by rolling the graphene so that the two shaded aromatic cycles superimpose exactly is a (4,2) chiral nanotube. Similarly, SWNTs from Fig. 3.2a to 3.2c are (9,0), (5,5), and (10,5) nanotubes respectively, thereby providing examples of zig-zag–type SWNT (with an angle of helicity $= 0°$), armchair-type SWNT (with an angle of helicity of $30°$) and a chiral SWNT, respectively. This also illustrates why the term "chiral" is sometimes inappropriate and should preferably be replaced by "helical". Armchair (n, n) nanotubes, though definitely achiral from

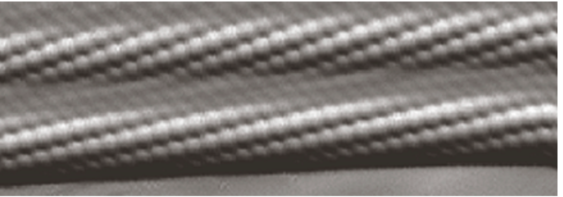

Fig. 3.3 Image of two neighboring chiral SWNTs within a SWNT bundle as seen by high resolution scanning tunneling microscopy (by courtesy of Prof. Yazdani, University of Illinois at Urbana, USA)

a standpoint of symmetry, exhibit a "chiral angle" different from 0. "Zig-zag" and "armchair" qualifications for achiral nanotubes refer to the way carbon atoms are displayed at the edge of the nanotube cross section (Fig. 3.2a and 3.2b). Generally speaking, it is clear from Figs. 3.1 and 3.2a that having the vector of helicity perpendicular to any of the three overall C=C bond directions will provide zig-zag–type SWNTs, noted $(n,0)$, while having the vector of helicity parallel to one of the three C=C bond directions will provide armchair-type SWNTs, noted (n, n). On the other hand, because of the sixfold symmetry of the graphene sheet, the angle of helicity θ for the chiral (n, m) nanotubes is such as $0 < \theta < 30°$. Figure 3.3 provides two examples of what chiral SWNTs look like, as seen by means of atomic force microscopy.

Planar graphenes in graphite have π electrons, which are satisfied by the stacking of graphenes that allows van der Waals forces to develop. Similar reasons make fullerenes gather and order into fullerite crystals and SWNTs into SWNT ropes (Fig. 3.4a). Spontaneously, SWNTs in ropes tend to arrange into an hexagonal array, which corresponds to the highest compactness achievable (Fig. 3.4b). This feature brings new periodicities

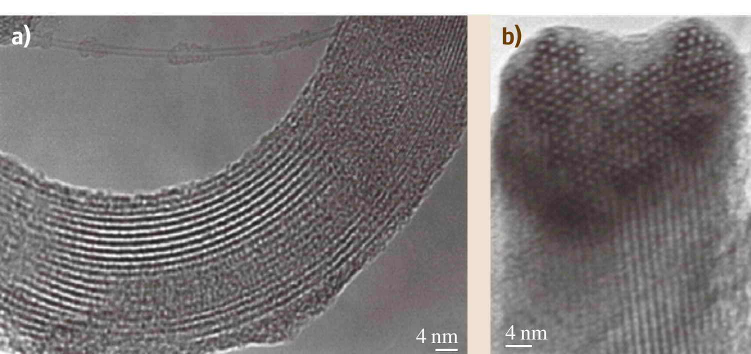

Fig. 3.4a,b High resolution transmission electron microscopy images of a SWNT rope **(a)** longitudinal view. At the top of the image an isolated single SWNT also appears. **(b)** cross section view (from [3.14])

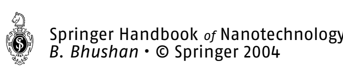
with respect to graphite or turbostratic polyaromatic carbon crystals. Turbostatic structure corresponds to graphenes which are stacked with random rotations or translations instead of being piled up following sequential ABAB positions, as in graphite structure. This implies that no lattice atom plane exists anymore other than the graphene planes themselves (corresponding to the (001) atom plane family). These new periodicities make diffraction patterns specific and quite different from that of other sp^2-carbon-based crystals, although *hk* reflections, which account for the hexagonal symmetry of graphene plane, are still present. On the other hand, 00*l* reflections, which account for the stacking sequence of graphenes in regular, "multilayered" polyaromatic crystals that does not exist in SWNT ropes, are absent. Such a hexagonal packing of SWNTs within the ropes requires that SWNTs exhibit similar diameters, which is the common case for SWNTs prepared by the electric arc or the laser vaporization processes. SWNTs prepared these ways are actually about 1.35 nm wide (diameter value for a (10,10) tube, among others), for reasons still unclear but related to the growth mechanisms specific to the conditions provided by these techniques (see Sect. 3.3).

3.1.2 Multiwall Nanotubes

Building multiwall carbon nanotubes is a little bit more complex, since it has to deal with the various ways graphenes can be displayed and mutually arranged within a filament morphology. Considering the usual textural versatility of polyaromatic solids, a similar versatility can be expected. Likewise, diffraction patterns no longer differentiate from that of anisotropic polyaromatic solids. The easiest MWNT to imagine is the concentric type (c-MWNT), in which SWNTs with regularly increasing diameters are coaxially displayed according to a Russian-doll model into a multiwall nanotube (Fig. 3.5). Such nanotubes are generally formed either by the electric-arc technique (without need of any catalyst) or by catalyst-enhanced thermal cracking of gaseous hydrocarbons or CO disproportionation (see Sect. 3.2). The number of walls (or number of coaxial tubes) can be anything, starting from two, with no upper limit. The intertube distance is approximately that of the intergraphene distance in turbostratic, polyaromatic solids, i. e. 0.34 nm (as opposed to 0.335 nm in genuine graphite), since the increasing radius of curvature imposed on the concentric graphenes prevents the carbon atoms from being displayed as in graphite, i. e., each of the carbon atoms from a graphene facing alternatively either a ring center or a carbon atom from the neighboring graphene. But two cases allow such a nanotube to reach – totally or partially – the 3-D crystal periodicity of graphite. One is to consider a high number of concentric graphenes, i. e. concentric graphenes with long radius of curvature. In that case, the shift of the relative positions of carbon atoms from superimposed graphenes is so small with respect to that in graphite that some commensurability is possible. It may result in MWNTs with the association of both structures, i. e. turbostratic in the core and graphitic in the outer part [3.15]. The other case occurs for c-MWNTs exhibiting faceted morphologies, originating either from the synthesis process or more likely from

Fig. 3.5 High resolution transmission electron microscopy image (longitudinal view) of a concentric multiwall carbon nanotube (c-MWNT) prepared by electric arc. In *insert*, sketch of the Russian-doll-like display of graphenes



subsequent heat-treatments at high temperatures (e.g., 2,500 °C) in inert atmospheres. Obviously, facets allow graphenes to get back a flat arrangement of atoms – except at the junction between neighboring facets – in which the specific stacking sequence of graphite can develop.

Another frequent inner texture for multiwall carbon nanotubes is the so-called herringbone texture (h-MWNTs), in which graphenes make an angle with respect to the nanotube axis (Fig. 3.6). The angle value varies upon the processing conditions (e.g., the catalyst morphology or the atmosphere composition), from 0 (in which case the texture turns into that of a c-MWNT) to 90° (in that case, the filament is no longer a tube, see below), and the inner diameter varies so that the tubular feature can be lost [3.19], justifying that the latter can be called nanofibers rather than nanotubes. h-MWNTs are exclusively obtained by processes involving catalysts, generally catalyst-enhanced thermal cracking of hydrocarbons or CO disproportionation.

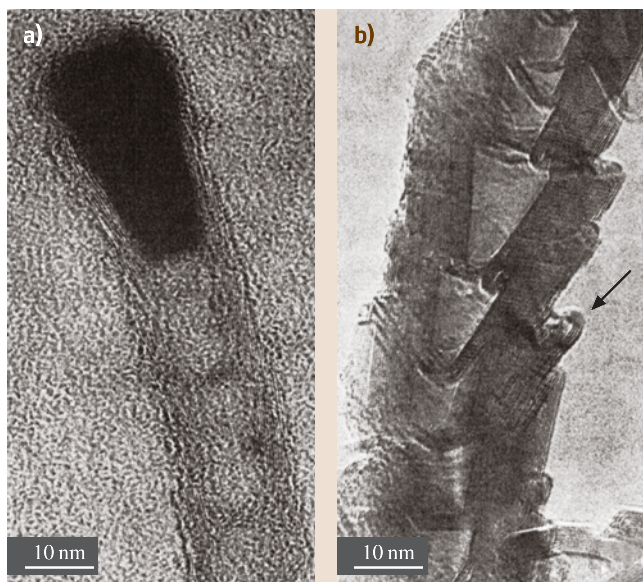


Fig. 3.6a,b One of the earliest high resolution transmission electron microscopy image of a herringbone (and bamboo) multi-wall nanotube (bh-MWNT, longitudinal view) prepared by CO disproportionation on Fe-Co catalyst. **(a)** as-grown. The nanotube surface is made of free graphene edges. **(b)** after 2,900 °C heat-treatment. Both the herringbone and the bamboo textures have become obvious. Graphene edges from the surface have buckled with neighbors (*arrow*), closing the access to the intergraphene spacing (adapted from [3.16])

One unresolved question is whether the herringbone texture, which actually describes the texture projection rather than the overall three-dimensional texture, originates from the scroll-like spiral arrangement of a single graphene ribbon or from the stacking of independent truncated-cone-like graphenes. Although the former is more likely for energetic reasons since providing a minimal and constant amount of transitorily unsatisfied bonds during the nanotube growth (similar to the well-known growth mechanism from a screw dislocation), the question is still debated.

Another common feature is the occurrence, at a variable frequency, of a limited amount of graphenes oriented perpendicular to the nanotube axis, thus forming the so-called "bamboo" texture. It cannot be a texture by its own but affects in a variable extent either c-MWNT (bc-MWNT) or h-MWNT (bh-MWNT) textures (Figs. 3.6 and 3.7). The question may be addressed whether such filaments, though hollowed, should still be called nanotubes, since the inner cavity is no longer opened all along the filament as it is for a genuine tube. They therefore are sometimes referred as "nanofibers" in literature.

Nanofilaments that definitely cannot be called nanotubes are those built from graphenes oriented perpendicular to the filament axis and stacked as piled-up plates. Although they actually correspond to h-MWNTs with the graphene/MWNT axis angle = 90°, the occurrence of inner cavity is no longer possible, and such filaments are therefore most often referred to as "platelet-nanofibers" in literature [3.19].

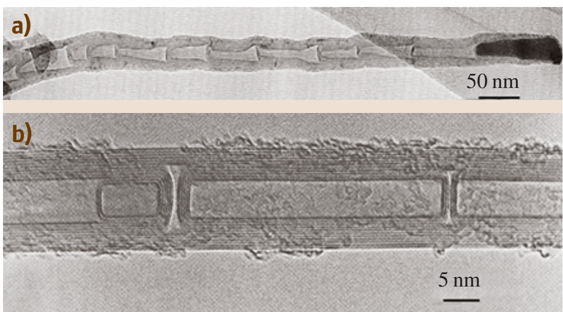

Fig. 3.7a,b Transmission electron microscopy images from bamboo-multi-wall nanotubes (longitudinal views). **(a)** low magnification of a bamboo-herringbone multi-wall nanotube (bh-MWNT) showing the nearly periodic feature of the texture, which is very frequent. (from [3.17]); **(b)** high resolution image of a bamboo-concentric multi-wall nanotube (bc-MWNT) (modified from [3.18])

Springer Handbook *of* Nanotechnology
B. Bhushan • © Springer 2004

As opposed to SWNTs, whose aspect ratio is so high that acceding the tube tips is almost impossible, aspect ratio for MWNTs (and carbon nanofibers) are generally lower and often allow one to image tube ends by transmission electron microscopy. Except for c-MWNTs from electric arc (see Fig. 3.5) that grow following a catalyst-free process, nanotube tips are frequently found associated with the catalyst crystal from which they have been formed.

MWNT properties (see Sect. 3.4) will obviously depend on the perfection and orientation of graphenes in the tube more than any other feature (e.g., the respective spiral angle of the constituting nanotubes for c-MWNTs has little importance). Graphene orientation is a matter of texture, as described above. Graphene perfection is a matter of nanotexture, which is commonly used to describe other polyaromatic carbon materials, and which is quantified by several parameters preferably obtained from high resolution transmission electron microscopy (Fig. 3.8). Both texture and nanotexture depend on the processing conditions. While the texture type is a permanent, intrinsic feature only able to go toward complete alteration upon severe degradation treatments (e.g., oxidation), however, nanotexture can be improved by subsequent thermal treatments at high temperatures (e.g., $> 2{,}000\,°C$) or, reversibly, possibly degraded by chemical treatments (e.g., slight oxidation conditions).

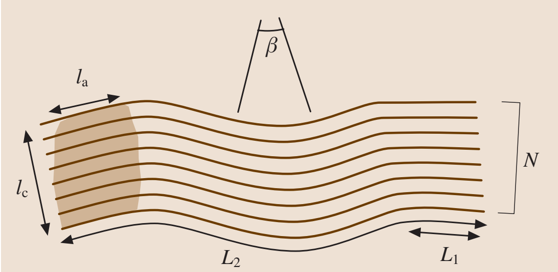

Fig. 3.8 Sketch explaining the various parameters obtained from high resolution (lattice fringe mode) transmission electron microscopy for quantifying nanotexture: L_1 is the average length of perfect (distortion-free) graphenes of coherent areas; N is the number of piled-up graphenes in the coherent (distortion-free) areas; L_2 is the average length of continuous though distorted graphenes within graphene stacks; β is the average distortion angle. L_1 and N are more or less related to L_a and L_c obtained from X-ray diffraction

3.2 Synthesis of Carbon Nanotubes

Producing carbon nanotubes so that the currently planned applications become marketable requires solving some problems that are more or less restrictive depending on the cases. One example is to specifically control the configuration (chirality), the purity, or the structural quality of SWNTs, with the production capacity adapted to the application. One condition would be to understand perfectly the mechanism of nanotube nucleation and growth, which remains the object of a lot of controversy in spite of an intense, worldwide experimental effort. This problem is partly explained by the lack of knowledge regarding several parameters controlling the synthesis conditions. For instance, neither the temperatures of nanotube condensation and formation nor the manner in which they are influenced by the synthesis parameters are known. Equally often unknown is the exact and accurate role of the catalysts in nanotube growth. Given the large number of experimental parameters and considering the large range of conditions that the several synthesis techniques correspond to, it is quite legitimate to think of more than one mechanism intervening in the nanotube formation.

3.2.1 Solid Carbon Source-Based Production Techniques for Carbon Nanotubes

Among the different SWNT production techniques, the three processes (laser ablation, solar energy, and electric arc) presented in this section have at least two common points: a high temperature ($1{,}000\,K < T < 6{,}000\,K$) medium and the fact that the carbon source originates from the erosion of solid graphite. In spite of these common points, both the morphologies of the carbon nanostructures and the SWNT yields can differ notably with respect to the experimental conditions.

Before being utilized for carbon nanotube synthesis, these techniques permitted the production of fullerenes. Laser vaporization of graphite was actually the very first method to demonstrate the existence of fullerenes, including the most popular one (because the most stable and therefore the most abundant), C_{60} [3.20]. On the other hand, the electric arc technique was (and still is) the first method to produce fullerenes in relatively large quantities [3.21]. As opposed to the fullerene formation, which requires the presence of carbon atoms

in high temperature media and the absence of oxygen, the utilization of these techniques for the synthesis of nanotubes requires an additional condition, i. e. the presence of catalysts in one of the electrode or the target.

In case of these synthesis techniques requiring relatively high temperatures to sublime graphite, the different mechanisms such as the carbon molecule dissociation and the atom recombination processes take place at different time scales, from nanosecond to microsecond and even millisecond. The formation of nanotubes and other graphene-based products appears afterward with a relatively long delay.

The methods of laser ablation, solar energy, and electric arc are based on an essential mechanism, i. e. the energy transfer resulting from the interaction between either the target material and an external radiation (laser beam or radiation emanating from solar energy) or the electrode and the plasma (in case of electric arc). This interaction is at the origin of the target or anode erosion leading to the formation of a plasma, i. e. an electrically neutral ionized gas, composed of neutral atoms, charged particles (molecules and ionized species), and electrons. The ionization degree of this plasma, defined by the ratio (n_e/n_e+n_o), where n_e and n_o are the density of electrons and that of neutral atoms respectively, highlights the importance of energy transfer between the plasma and the material. The characteristics of this plasma and notably the fields of temperature and of concentration of the various species present in the plasma thereby depend not only on the nature and composition of the target or that of the electrode but also on the energy transferred.

One of the advantages of these different synthesis techniques is the possibility of varying a large number of parameters, which allow the composition of the high temperature medium to be modified and, consequently, the most relevant parameters to be determined, in order to define the optimal conditions for the control of carbon nanotube formation. But a major drawback of these techniques – as for any other technique for the production of SWNTs – is that SWNTs never come pure, i. e. they are associated with other carbon phases and catalyst remnants. Although purification processes are proposed in literature and by some commercial companies to rid these undesirable phases, they are all based on oxidation (e.g. acidic) processes that are likely to affect deeply the SWNT structure [3.14]. Subsequent thermal treatments at $\sim 1{,}200\,°\mathrm{C}$ under inert atmosphere, however, succeed somewhat in recovering the former structure quality [3.24].

Laser Ablation

After the first laser was built in 1960, physicists immediately made use of it as a means of concentrating a large quantity of energy inside a very small volume within a relatively short time. The consequences of this energy input naturally depends on the characteristics of the device employed. During the interaction between the laser beam and the material, numerous phenomena superimpose and/or follow each other within the time range, each of these processes being sensitive to such different parameters as the laser beam characteristics, the incoming power density (also termed "fluence"), the nature of the target, and the environment surrounding it. For instance, the solid target can merely heat up, or melt, or vaporize depending on the power provided.

While this technique was used successfully to synthesize fullerene-related structures for the very first time [3.20], the synthesis of SWNTs by laser ablation came only ten years later [3.22].

Laser Ablation – Experimental Devices

Two types of laser devices are utilized nowadays for carbon nanotube production: lasers operating in pulsed mode on the one hand and lasers operating in continuous mode on the other hand, the latter generally providing a smaller influence.

An example of the layout indicating the principle of a laser ablation device is given in Fig. 3.9. A graphite pellet containing the catalyst is put in the middle of an inert gas-filled quartz tube placed in an oven maintained at a temperature of $1{,}200\,°\mathrm{C}$ [3.22, 23]. The energy of the laser beam focused on the pellet permits it to vaporize and sublime the graphite by uniformly bombarding its surface. The carbon species swept by a flow of neutral gas are thereafter deposited as soot in different regions: on the conical water-cooled copper collector, on the quartz tube walls, and on the backside of the pellet.

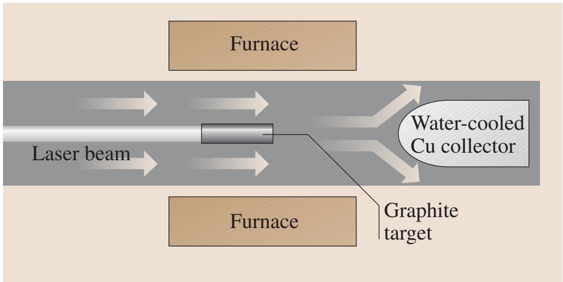

Fig. 3.9 Sketch of an early laser vaporization apparatus (adapted from [3.22, 23])

Various improvements have been made to this device in order to increase the production efficiency. For example, *Thess* et al. [3.25] employed a second pulsed laser that follows the initial impulsion but at a different frequency in order to ensure a more complete and efficient irradiation of the pellet. This second impulsion has the role of vaporizing the coarse aggregates issued from the first ablation and thereby making them participate in the active carbon feedstock involved in the nanotube growth. Other modifications were brought by *Rinzler* et al. [3.24], who inserted a second quartz tube of a smaller diameter coaxially disposed inside to the first one. This second tube has the role of reducing the vaporization zone and thereby permitting an increase in the quantity of sublimed carbon. They also arranged to place the graphite pellet on a revolving system so that the laser beam uniformly scans its whole surface.

Other groups have realized that, as far as the target contains both the catalyst and the graphite, the latter evaporates in priority and the pellet surface becomes more and more metal rich, resulting in a decrease of the efficiency in nanotube formation in the course of the process. To solve this problem, *Yudasaka* et al. [3.27] utilized two pellets facing each other, one entirely made from the graphite powder and the other from an alloy of transition metals (catalysts), and irradiated simultaneously.

A sketch of a synthesis reactor based on the vaporization of a target at a fixed temperature by a continuous CO_2 laser beam ($\lambda = 10.6\,\mu m$) is shown in Fig. 3.10 [3.26]. The power can be varied from 100 W to 1,600 W. The temperature of the target is measured with an optical pyrometer, and these measurements are used to regulate the laser power to maintain a constant vaporization temperature. The gas, heated by the contact with the target, acts as a local furnace and creates an extended hot zone, making an external furnace unnecessary. The gas is extracted through a silica pipe, and the solid products formed are carried away by the gas flow through the pipe and then collected on a filter. The synthesis yield is controlled by three parameters: the cooling rate of the medium where the active, secondary catalyst particles are formed, the residence time, and the temperature (in the 1,000–2,100 K range) at which SWNTs nucleate and grow [3.28].

But devices equipped with facilities to gather in situ data such as the target temperature are few and, generally speaking, among the numerous parameters of the laser ablation synthesis technique. The most studied are the nature of the target, the nature and concentration of the catalysts, the nature of the neutral gas flow, and the temperature of the outer oven (when any).

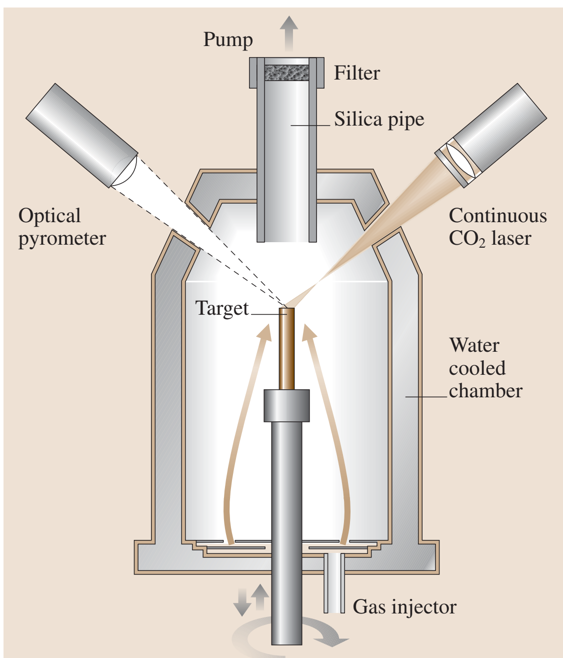

Fig. 3.10 Sketch of a synthesis reactor with a continuous CO_2 laser device (adapted from [3.26])

Laser Ablation – Results

In the absence of catalysts in the target, the soot collected mainly contains multiwall nanotubes (c-MWNTs). Their lengths can reach 300 nm. Their quantity and structure quality are dependent on the oven temperature. The best quality is obtained for an oven temperature set at 1,200 °C. At lower oven temperatures, the structure quality decreases, and the nanotubes start presenting many defects [3.23]. As soon as small quantities (few percents or less) of transition metals (Ni, Co) playing the role of catalysts are incorporated into the graphite pellet, products yielded undergo significant modifications, and SWNTs are formed instead of MWNTs. The yield of SWNTs strongly depends on the type of metal catalyst used and is seen to increase with furnace temperature, among other factors. The SWNTs have remarkably uniform diameter and they self-organize into rope-like crystallites 5–20 nm in diameter and tens to hundreds of micrometers in length (Fig. 3.11). The ends of all SWNTs appear to be perfectly closed with hemispherical end caps showing no evidence of any as-

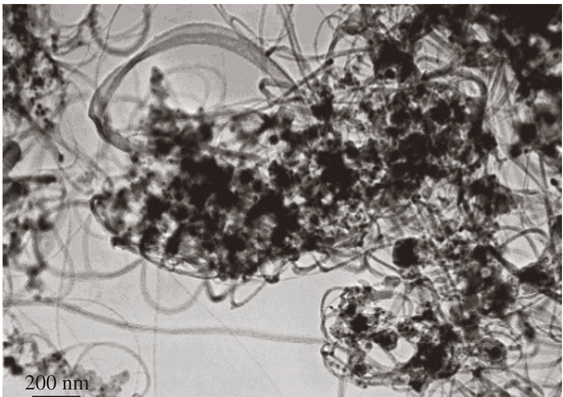

Fig. 3.11 Low magnification TEM images of a typical raw SWNT material obtained from the laser vaporization technique. Fibrous morphologies are SWNT bundles, and dark particles are catalyst remnants. Raw SWNT materials from electric arc exhibit a similar aspect (from [3.14])

sociated metal catalyst particle, although, as pointed out in Sect. 3.1, finding the two tips of a SWNT is rather challenging, considering the huge aspect ratio of the nanotube and their entanglement. Another feature of SWNTs produced with this technique is that they are supposedly "cleaner" than those produced employing other techniques, i. e., associated with a lower amount of an amorphous carbon phase, either coating the SWNTs or gathered into nano-particles. Such an advantage, however, stands only for synthesis conditions specifically set to ensure high quality SWNTs. It can no longer be true when conditions are such that high yields are preferred, and SWNTs from electric arc may appear cleaner than SWNTs from laser vaporization [3.14].

The laser vaporization technique is one of the three methods currently used to prepare SWNTs as commercial products. SWNTs prepared that way were first marketed by Carbon Nanotechnologies Inc. (Texas, USA), with prices as high as $ 1,000/g (raw materials) until December 2002. As a probable consequence of the impossibility to lower the amount of impurities in the raw materials, they have recently decided to focus on fabricating SWNTs by the HiPCo technique (see Sect. 3.2.2). Though laser-based method are generally considered not competitive in the long term for the low-cost production of SWNTs compared to CCVD-based methods (see Sect. 3.2.2), prediction of prices as low as $ 0.03 per gram of raw high concentration SWNT soot are expected in the near future (Acolt S.A., Switzerland).

Electric-Arc Method

Electric arcs between carbon electrodes have been studied as light sources and radiation standards for a very long time. Lately they have received renewed attention for their use in producing new fullerenes-related molecular carbon nanostructures such as genuine fullerenes or nanotubes. This technique was first brought to light by *Krätschmer* et al. [3.21] who utilized it to achieve the production of fullerenes in macroscopic quantities. In the course of investigating the other carbon nanostructures formed along with the fullerenes and more particularly the solid carbon deposit forming onto the cathode, Iijima [3.7] discovered the catalyst-free formation of perfect c-MWNT-type carbon nanotubes. Then, as mentioned in the introduction of this chapter, the catalyst-promoted formation of SWNTs was incidentally discovered after some amounts of transition metals were introduced into the anode in an attempt to fill the c-MWNTs with metals while they grow [3.8, 9]. Since then, a lot of work has been carried out by many groups using this technique to understand the mechanisms of nanotube growth as well as the role played by the catalysts (when any) for the synthesis of MWNTs and/or SWNTs [3.29–41].

Electric-Art Method – Experimental Devices

The principle of this technique is to vaporize carbon in the presence of catalysts (iron, nickel, cobalt, yttrium, boron, gadolinium, and so forth) under reduced atmosphere of inert gas (argon or helium). After the triggering of the arc between two electrodes, a plasma is formed consisting of the mixture of carbon vapor, the rare gas (helium or argon), and the vapors of catalysts. The vaporization is the consequence of the energy transfer from the arc to the anode made of graphite doped with catalysts. The anode erosion rate is more or less important depending on the power of the arc and also on the other experimental conditions. It is noteworthy that a high anode erosion does not necessarily lead to a high carbon nanotube production.

An example of a reactor layout is shown in Fig. 3.12. It consists of a cylinder of about 30 cm in diameter and about 1 m in height, equipped with diametrically opposed sapphire windows located so that they face the plasma zone in view of observing the arc. The reactor possesses two valves, one for carrying out the primary evacuation (0.1 Pa) of the chamber, the other permitting it to fill with a rare gas up to the desired working pressure.

Contrary to the solar energy technique, SWNTs are deposited (provided appropriate catalysts are used) in

Springer Handbook *of* Nanotechnology
B. Bhushan • © Springer 2004

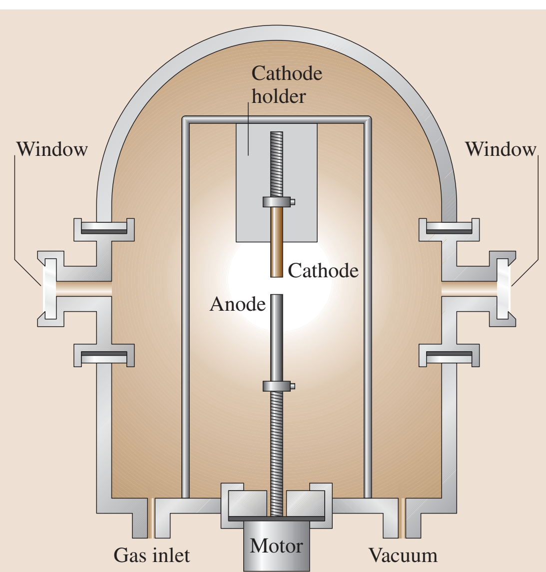

Fig. 3.12 Sketch of an electric arc reactor

different regions of the reactor: (1) the collaret, which forms around the cathode; (2) the web-like deposits found above the cathode; (3) the soot deposited all around the reactor walls and bottom. On the other hand, MWNTs are formed embedded in a hard deposit adherent to the cathode, whenever catalysts are used or not. The cathode deposits formed under the cathode. The formation of collaret and web is not systematic and depends on the experimental conditions as indicated in Table 3.1, as opposed to cathode deposit and soot that are systematically found.

Two graphite rods of few millimeters in diameter constitute the electrodes between which a potential difference is applied. The dimensions of these electrodes vary according to the authors. In certain cases, the cathode has a greater diameter than the anode in order to facilitate their alignment [3.32, 42]. Other authors utilize electrodes of the same diameter [3.41]. The whole device can be designed horizontally [3.33, 41] or vertically [3.34, 36–38]. The advantage of the latter is the symmetry brought by the verticality with respect to gravity, which facilitates computer modeling (regarding convection flows, for instance).

Two types of anodes can be utilized as soon as catalysts need to be introduced: (1) graphite anodes in which a coaxial hole is drilled several centimeters in length and in which catalyst and graphite powders are mixed; (2) graphite anodes in which the catalysts are homogeneously dispersed [3.43]. The former are by far the most popular, due to their ease of fabrication.

The optimization of the process regarding the nanotube yield and quality is attempted by studying the role of various parameters such as the type of doped anode (homogeneous or heterogeneous catalyst dispersion), the nature as well as the concentration of catalysts, the nature of the plasmagenic gas, the buffer gas pressure, the arc current intensity, and the distance between electrodes. Investigating the result of varying these parameters on the type and amount of carbon nanostructures formed is, of course, the preliminary work that has been done. Though electric arc reactors equipped with the related facilities are few (see Fig. 3.12), investigating the missing link, i. e. the effect of varying the parameters on the plasma characteristics (fields of concentration species and temperature), is likely to provide a more comprehensive understanding of the phenomena involved in nanotube formation. This has been recently developed by atomic and molecular optical emission spectroscopy [3.34, 36–39, 41].

Finally, mention has to be made of attempts to make the electric arc within liquid media such as liquid nitrogen [3.44] or water [3.45, 46], the goal being easier processing since they do not require pumping devices or a closed volume and therefore are likely to allow continuous synthesis. This adaptation has not, however, reached the state of mass production.

Electric-Arc Method – Results

In view of the numerous results obtained with this electric-arc technique, it appears clearly that both the nanotube morphology and the nanotube production efficiency strongly depend on the experimental conditions and, in particular, on the nature of the catalysts. It is worth noting that the products obtained do not consist solely in carbon nanotubes but also in nontubular forms of carbon such as nanoparticles, fullerene-like structures including C_{60}, poorly organized polyaromatic carbons, nearly amorphous nanofibers, multiwall shells, singlewall nanocapsules, and amorphous carbon as reported in Table 3.1 [3.35, 37, 38]. In addition, catalyst remnants are found all over the place, i. e. in the soot, collaret, web, and cathode deposit in various concentration. Generally, at pressure value of about 600 mbar of helium, for 80 A arc current and 1 mm electrode gap, the use of Ni/Y as coupled catalysts favors more particularly the synthesis of SWNTs [3.8, 33, 47]. For such conditions providing high SWNT yields, SWNT concentrations are higher in the collaret (in the range of 50–70 %), then in the web ($\sim$ 50% or less), then in the soot. On the

Abundant – Present – [*Rare*]
Glossary: AC: amorphous carbon; POPAC: poorly organised polyaromatic carbon; Cn: fullerene-like structure, including C_{60}; NANF: nearly amorphous nanofiber; MWS: multiwall shell; SWNT: single-wall nanotube; DWNT: double-wall nanotube, MWNT: multiwall nanotube; SWNC: single-wall nanocapsule.

other hand, c-MWNTs are found in the cathode deposit. SWNT lengths are micrometric and, typically, outer diameters range around 1.4 nm. Taking the latter conditions as a reference experiment (Table 3.1, column 4), Table 3.1 illustrates the consequence of changing the parameters. For instance (Table 3.1, column 3), using Ni/Co instead of Ni/Y as catalysts prevents the formation of SWNTs. But when the Ni/Co catalysts are homogeneously dispersed in the anode (Table 3.1, column 1), the formation of nanotubes is promoted again, but MWNTs with two or three walls prevail over SWNTs, among which DWNTs (double-wall nanotubes) make a majority. But it is enough to decrease the ambient pressure from 60 to 40 kPa (Table 3.1, column 2) for getting back to conditions where the nanotube formation is impeached.

Recent works have attempted to replace graphite powder (sp^2 hybridized carbon) by diamond powder (sp^3 hybridized carbon) to mix with the catalyst powder and fill hollowed-type graphite anodes. The result was an unexpected but quite significant increase (up to +230%) in the SWNT yield [3.39,40]. Such experiments reveal, as for the comparison between the results from using homogeneous instead of heterogeneous anodes that the physical phenomena (charge and heat transfers) that occurred in the anode during the arc are of utmost importance, which was neglected until now.

It is clear that while the use of rare earth element (such as Y) as a single catalyst does not provide the conditions to grow SWNTs, associating it with a transition metal (such as Ni/Y) seems to correspond to the most appropriate combinations, leading to the highest SWNT yields [3.42]. On the other hand, using a single rare earth element may lead to unexpected results, such as the anticipated closure of graphene edges from a c-MWNT wall with the neighboring graphene edges from the same wall side, leading to the preferred formation of telescope-like and open c-MWNTs able to contain nested Gd crystals [3.36,38]. Such a need for bimetallic catalysts has just begun to be understood as a possible requirement to promote the transitory formation of nickel particles coated with yttrium carbide, whose lattice constants are somewhat commensurable with that of graphenes [3.48].

Figure 3.13 illustrates the kind of information provided by the analysis of the plasma by means of emission spectroscopy, i.e. radial temperature (Fig. 3.13a) or C_2 species concentration (Fig. 3.13b) profiles in the plasma. A common feature is that a huge vertical gradient (~ 500 K/mm) rapidly establishes (at ~ 0.5 mm from the center in the radial direction) from the bottom to the top of the plasma, as a probable consequence of convection phenomena (Fig. 3.13a). The zone of actual SWNT formation is beyond the limit of the volume analyzable in the radial direction, corresponding to colder areas. The C_2 concentration increases dramatically from the anode to the cathode and decreases dramatically in the radial direction (Fig. 3.13b). This demonstrates that C_2 moieties are secondary products resulting from the recombination of primary species formed from the anode. It also suggests that C_2 moieties may be the building blocks for MWNTs (formed at the cathode) but not for SWNTs [3.38, 40].

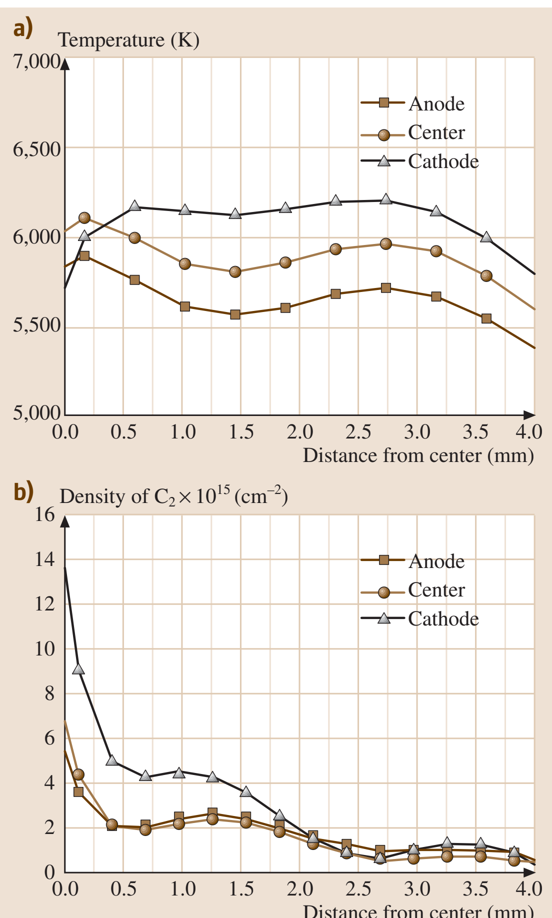

Fig. 3.13a,b Typical temperature **(a)** and C_2 concentration **(b)** profiles in the plasma at the anode surface (*square*), at the plasma center (*dot*), and at the cathode surface (*triangle*) for "standard" conditions (see text). Gradients are similar whatever the catalyst, although absolute value may vary

Although many aspects of it still need to be understood, the electric-arc method is one of the three methods currently used to produce SWNTs as commercial products. At the French company Nanoledge S.A. (Montpellier, France), for instance, current production (for 2003) reaches ∼ 20 kg/year (raw SWNTs, i. e. not purified), with a marketed price of ∼ 90 Euros/g, which is much cheaper than any other production method so far. A decrease to 2–5 Euros/g is expected for sometime before 2007, with a SWNT production capacity of 4–5 tons/year. Amazingly, raw SWNTs from electric arc proposed by Bucky USA (Texas, USA) are still proposed at a marketed price of $ 1,000/g.

Solar Furnace

Solar furnace devices were originally utilized by several groups to produce fullerenes [3.49–51]. *Heben* et al. [3.52] and *Laplaze* et al. [3.53] later modified their former devices in order to use them for carbon nanotube production. This modification consisted mainly in using more powerful ovens [3.54, 55].

Solar Furnace – Experimental Devices

The principle of this technique is again based on the sublimation in an inert gas of a mixture of graphite powder and catalysts formerly placed in a crucible. An example of such a device is shown in Fig. 3.14. The solar rays are collected by a plain mirror and reflected toward a parabolic mirror that focuses them directly onto a graphite pellet under controlled atmosphere. The high temperature of about 4,000 K permits both the carbon and the catalysts to vaporize. The vapors are then dragged by the neutral gas and condense onto the cold walls of the thermal screen. The reactor consists of a brass support cooled by water circulation, on which Pyrex® chambers with various shapes can be fixed (Fig. 3.14b). This support contains a watertight passage permitting the introduction of the neutral gas and a copper rod on which the target is mounted. The target is surrounded by a graphite tube that plays both the role of a thermal screen to reduce radiation losses (very important in the case of graphite) and the role of a duct to lead carbon vapors to a filter in order to avoid soot deposits on the Pyrex® chamber wall. A graphite crucible filled with powdered graphite (for fullerene synthesis) or a mixture of graphite and catalysts (for nanotube synthesis) is utilized in order to reduce the conduction losses.

These studies primarily investigated the target composition, the type and concentration of catalysts, the flow-rate, the composition and pressure of the plasmagenic gas inside the chamber, and the oven power. The objectives are similar to that of works carried out with the other solid-carbon-source-based processes. When possible, specific in situ diagnostics (pyrometry, optical emission spectroscopy, etc.) are also performed in order to understand better the role of the various parameters (temperature measurements at the crucible surface, along the graphite tube acting as thermal screen, C_2 radical concentration in the immediate vicinity of the crucible).

Solar Furnace – Results

Some results obtained by different groups concerning the influence of the catalysts can be summarized as follows. With Ni/Co and at low pressure, the sample collected contains mainly MWNTs with bamboo texture, carbon shells, and some bundles of SWNTs [3.54]. At higher pressures, only bundles of SWNTs are obtained with fewer carbon shells. With Ni/Y and at a high pressure, relatively long bundles of SWNTs are observed. With Co, SWNT bundles are obtained in the soot with SWNT diameters ranging from 1 to 2 nm. Laplaze et al. [3.54] observed very few nanotubes but a large quantity of carbon shells.

In order to proceed to a large-scale synthesis of single-wall carbon nanotubes, which is still a challenge for chemical engineers, *Flamant* et al. [3.56] recently demonstrated that solar energy–based synthesis is a versatile method to obtain SWNTs and can be scaled from 0.1–0.5 g/h to 10 g/h and then to 100 g/h productivity using existing solar furnaces. Experiments at medium scale (10-g/h, 50 kW solar power) have proven the feasibility of designing and building such a reactor and of the scaling-up method. Numerical simulation was meanwhile performed in order to improve the selectivity of the synthesis, in particular by controlling the carbon vapor cooling rate.

3.2.2 Gaseous Carbon Source–Based Production Techniques for Carbon Nanotubes

As mentioned in the introduction of this chapter, the catalysis-enhanced thermal cracking of gaseous carbon source (hydrocarbons, CO) – commonly referred to as catalytic chemical vapor deposition (CCVD) – has been known to produce carbon nanofilaments for a long time [3.4], so that reporting all the works published in the field since the beginning of the century is almost impossible. Until the 90s, however, carbon nanofilaments were mainly produced to act as a core substrate for the subsequent growth of larger (micro-

metric) carbon fibers – so-called vapor-grown carbon fibers – by means of thickening through mere catalyst-free CVD processes [3.57, 58]. We therefore are going to focus instead on the more recent attempts made to prepare genuine carbon nanotubes.

The synthesis of carbon nanotubes (either single- or multiwalled) by CCVD methods involves the catalytic decomposition of a carbon containing source on small metallic particles or clusters. This technique involves either an heterogeneous process if a solid substrate has a role or an homogeneous process if everything takes place in the gas phase. The metals generally used for these reactions are transition metals, such as Fe, Co, and Ni. It is a rather "low temperature" process compared to arc-discharge and laser-ablation methods, with the formation of carbon nanotubes typically occurring between 600 °C and 1,000 °C. Because of the low temperature, the selectivity of the CCVD method is generally better for the production of MWNTs with respect to graphitic particles and amorphous-like carbon, which remain an important part of the raw arc-discharge SWNT samples, for example. Both homogeneous and heterogeneous processes appear very sensitive to the nature and the structure of the catalyst used, as well as to the operating conditions. Carbon nanotubes prepared by CCVD methods are generally much longer (few tens to hundreds of micrometers) than those obtained by arc discharge (few micrometers). Depending on the experimental conditions, it is possible to grow dense arrays of nanotubes. It is a general statement that MWNTs from CCVD contain more structural defects (i. e., exhibit a lower nanotexture) than MWNTs from arc, due to the lower temperature reaction, which does not allow any structural rearrangements. These defects can be removed by subsequently applying heat treatments in vacuum or inert atmosphere to the products. Whether such a discrepancy is also true for SWNTs remains questionable. CCVD SWNTs are generally gathered into bundles that are generally of smaller diameter (few tens of nm) than their arc-discharge and laser-ablation counterparts (around 100 nm in diameter). CCVD provides reasonably good perspectives of large-scale and low-cost processes for the mass production of carbon nanotubes, a key point for their applications at the industrial scale.

A last word concerns the nomenclature. Because work in the field started more than one century ago, denomination of the carbon objects prepared by this method has changed with time with regard to the authors, research areas, and fashions. The same objects are found to be called vapor grown carbon fibers, nanofilaments, nanofibers, and from now on, nanotubes. Specifically regarding multilayered fibrous morphologies (since single-layered fibrous morphologies cannot be otherwise than SWNT anyway), the exact name should be vapor-grown carbon nanofilaments (VGCNF). Whether or not the filaments are then tubular is a matter of textural description, which should go with other textural features such as bamboo, herringbone, concentric, etc. (see Sect. 3.1.2). But the usage has decided otherwise. In the following, we will therefore use MWNTs for any hollowed nanofilament, whether they contain transversally oriented graphene walls or not. Any other nanofilament will be named "nanofiber."

Heterogeneous Processes

Heterogeneous CCVD processes are basically simple and consist, within a furnace heated to the desired temperature, in passing a gaseous flow containing a given proportion of a hydrocarbon (mainly CH_4, C_2H_2, C_2H_4, or C_6H_6, usually as a mixture with either H_2 or an inert gas such as Ar) over small transition metal particles (Fe, Co, Ni). The latter are previously deposited onto an inert substrate, for instance, by spraying a suspension of the metal particles on it, or any other method. The reac-

tion is chemically defined as catalysis-enhanced thermal cracking

$$C_xH_y \rightarrow x\,C + y/2\,H_2 \,.$$

Catalysis-enhanced thermal cracking was used as early as the late 19th century (see beginning of chapter). Further extensive works before the 90s include those by Baker et al. [3.6, 59], or *Endo* et al. [3.60, 61]. Several review papers have been published since then, such as [3.62], in addition to many regular papers.

CO can be used instead of hydrocarbons, the reaction is then chemically defined as catalysis-enhanced disproportionation

$$2\,CO \rightarrow C + CO_2 \,.$$

Heterogeneous Processes – Experimental Devices

The ability of catalysis-enhanced CO disproportionation in making carbon nanofilaments was reported by *Davis* et al. [3.63] as early as 1953, probably for the first time. Extensive following works were performed by *Boehm* [3.64], *Audier* et al. [3.16, 65–67], and *Gadelle* et al. [3.68–71].

Although formation mechanisms for SWNTs and MWNTs can be quite different (see Sect. 3.3, or refer to a review article such as [3.72]), many of the parameters of the catalytic processes have a similar and important role on the type of nanotubes formed: the temperature, the duration of the treatment, the gas composition and flow rate, and of course the catalyst nature and size. At a given temperature, depending mainly on the nature of both the catalyst and the carbon-containing gas, the catalytic decomposition will take place at the surface of the metal particles, followed by a mass-transport of the freshly produced carbon either by surface or volume diffusion until the carbon concentration reaches the solubility limit, and the precipitation starts.

It is now agreed that the formation of CCVD carbon nanotubes occurs on metal particles of a very small size, typically in the nanometer-size range [3.72]. These catalytic metal particles are prepared mainly by reduction of transition metals compounds (salts, oxides) by H_2, prior to the nanotube formation step (where the carbon containing gas is required). It is possible, however, to produce these catalytic metal particles in situ in presence of the carbon source, allowing for a one-step process [3.73]. Because the control of the metal particle size is the key point (they have to be kept at a nanometric size), their coalescence is generally avoided by supporting them on an inert support such as an oxide (Al_2O_3, SiO_2, zeolites, $MgAl_2O_4$, MgO, etc.), or more rarely on graphite. A low concentration of the catalytic metal precursor is required to limit the coalescence of the metal particles that may happen during the reduction step.

There are two main ways for the preparation of the catalyst: (a) the impregnation of a substrate with a solution of a salt of the desired transition metal catalyst, and (b) the preparation of a solid solution of an oxide of the chosen catalytic metal in a chemically inert and thermally stable host oxide. The catalyst is then reduced to form the metal particles on which the catalytic decomposition of the carbon source will lead to carbon nanotube growth. In most cases, the nanotubes can then be separated from the catalyst (Fig. 3.15).

Heterogeneous Processes – Results with CCVD Involving Impregnated Catalysts

A lot of work was already done in this area even before the discovery of fullerenes and carbon nanotubes, but although the formation of tubular carbon structures by catalytic processes involving small metal particles was clearly identified, the authors did not focus on the preparation of SWNTs or MWNTs with respect to the other carbon species. Some examples will be given here to illustrate the most striking improvements obtained.

With the impregnation method, the process generally involves four different and successive steps: (1) the impregnation of the support by a solution of a salt (nitrate, chloride) of the chosen metal catalyst; (2) the drying and calcination of the supported catalyst to get the oxide of the catalytic metal; (3) the reduction in a H_2-containing atmosphere to make the catalytic metal particles and at last (4) the decomposition of a carbon-containing gas over the freshly prepared metal particles that will lead to the nanotube growth. For example, *Ivanov* et al. [3.74] have prepared nanotubes by the decomposition of C_2H_2 (pure or in mixture with H_2) on well-dispersed transition metal particles (Fe, Co, Ni, Cu) supported on graphite or SiO_2. Co-SiO_2 was found to be the best catalyst/support combination for the preparation of MWNTs, but most of the other combinations led to carbon filaments, sometimes covered with amorphous-like carbon. The same authors have developed a precipitation-ion-exchange method that provides a better dispersion of metals on silica compared to the classical impregnation technique. The same group has then proposed the use of a zeolite-supported Co catalyst [3.75, 76], resulting in very finely dispersed metal particles (from 1 to 50 nm in diameter). Only on this catalyst could they observe MWNTs with a diameter around 4 nm and only two or three walls. *Dai* et al. [3.77] have prepared SWNTs by CO dispro-

portionation on nano-sized Mo particles. The diameters of the nanotubes obtained are closely related to that of the original particles and range from 1 to 5 nm. The nanotubes obtained by this method are free of amorphous carbon coating. It is also found that a synergetic effect occurs in the case of an alloy instead of the components alone, and one of the most striking examples is the addition of Mo to Fe [3.78] or Co [3.79].

Heterogeneous Processes – Results with CCVD Involving Solid-Solutions-Based Catalysts

A solid solution of two metal oxides is formed when some ions of one of the metals are found in substitution of the other metal ions. For example, Fe_2O_3 can be prepared in solid solution into Al_2O_3 to give a $Al_{2-2x}Fe_{2x}O_3$ solid solution. The use of a solid solution allows a perfect homogeneity of the dispersion of each oxide one in the other. These solid solutions can be prepared by different ways but the co-precipitation of mixed-oxalates and the combustion synthesis have been used mainly for the preparation of nanotubes. The synthesis of nanotubes by catalytic decomposition of CH_4 over $Al_{2-2x}Fe_{2x}O_3$ solid solutions was originated by *Peigney* et al. [3.73] and then studied extensively by the same group using different oxides such as spinel-based solid solutions ($Mg_{1-x}M_xAl_2O_4$ with M = Fe, Co, Ni, or a binary alloy [3.80, 81] or magnesia-based solid solutions [3.80, 82] ($Mg_{1-x}M_xO$, with M = Fe, Co or Ni)). Because of the very homogeneous dispersion of the catalytic oxide, it is possible to produce very small catalytic metal particles, at the high temperature required for the decomposition of CH_4 (which was chosen for its greater thermal stability compared to other hydrocarbons). The method proposed by these authors involves the heating of the solid solution from room temperature to a temperature between 850 °C and 1,050 °C in a mixture of H_2 and CH_4, typically containing 18 mol.% of CH_4. The nanotubes obtained depend clearly on the nature of both the transition metal (or alloy) used and the inert oxide (matrix), the latter because the Lewis acidity seems to play an important role [3.83]. For example, in the case of solid solutions containing around 10 wt% of Fe, the amount of carbon nanotubes obtained is decreasing in the following order depending of the matrixoxide: $MgO > Al_2O_3 > MgAl_2O_4$ [3.80]. In the case of MgO-based solid solutions the nanotubes can be very easily separated from the catalyst by dissolving it, in diluted HCl, for example [3.82]. The nanotubes obtained are typically gathered into small diameter bundles (less than 15 nm) with lengths up to 100 µm. The nanotubes are mainly SWNTs and DWNTs, with diameters ranging between 1 and 3 nm.

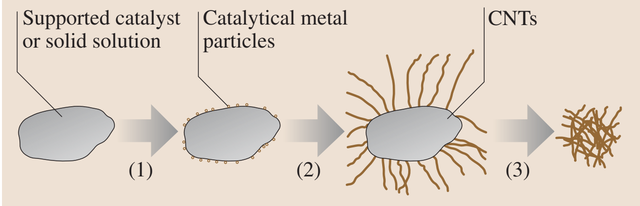

Fig. 3.15 Formation of nanotubes by the CCVD-based impregnation technique. (1) Formation of the catalytic metal particles by reduction of a precursor; (2) Catalytic decomposition of a carbon-containing gas, leading to the growth of carbon nanotubes (CNTs); (3) Removal of the catalyst to recover the CNTs (from [3.80])

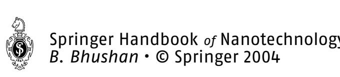
Obtaining pure nanotubes by the CCVD method requires, as for all the other techniques, the removal of the catalyst. When a catalyst supported (impregnation) in a solid solution is used, the supporting – and catalytically inactive – oxide is the main impurity, both in weight and volume. When oxides such as Al_2O_3 or SiO_2 (or even combinations) are used, aggressive treatments involving hot caustic solutions (KOH, NaOH) for Al_2O_3 or the use of HF for SiO_2 are required. These treatments have no effect, however, on the other impurities such as other forms of carbon (amorphous-like carbon, graphitized carbon particles and shells, and so on). Oxidizing treatments (air oxidation, use of strong oxidants such as HNO_3, $KMnO_4$, H_2O_2) are thus required and allow for the removal of most of the unwanted forms of carbon but are resulting in a low yield of remaining carbon nanotubes, which are often quite damaged. *Flahaut* et al. [3.82] were the first to use a MgCoO solid solution to prepare SWNTs and DWNTs that could be easily separated without any damage by a fast and safe washing with an aqueous HCl solution.

In most cases, only very small quantities of catalyst (typically less than 500 mg) have been used, and most claims for "high yield" productions of nanotubes are based on laboratory experimental data, without taking into account all the technical problems related to the scaling up of a laboratory-scale CCVD reactor. At the present time, although the production of MWNTs is possible at an industrial scale, the production of SWNTs at an affordable cost is still a challenge.

Homogeneous Processes

The homogenous route, also called "floating catalyst method," differs from the other CCVD-based meth-



ods because it uses only gaseous species and does not require the presence of any solid phase in the reactor. The basic principle of this technique, similar to the other CCVD processes, is to decompose a carbon source (ethylene, xylene, benzene, carbon monoxide, etc.) on nanometric transition metallic (generally Fe, Co, or Ni) particles in order to obtain carbon nanotubes. The catalytic particles are formed directly in the reactor, however, and are not introduced before the reaction, as it happens in the supported CCVD, for instance.

Homogeneous Processes – Experimental Devices

The typical reactor used in this technique is a quartz tube placed in an oven to which the gaseous feedstock, containing the metal precursor, the carbon source, some hydrogen, and a vector gas (N_2, Ar, or He), is sent. The first zone of the reactor is kept at a lower temperature, and the second zone, where the formation of tubes occurs, is heated to 700–1,200 °C. The metal precursor is generally a metal-organic compound, such as a zero-valent carbonyl compound like $Fe(CO)_5$ [3.84], or a metallocene [3.85–87], for instance ferrocene, nickelocene or cobaltocene. It may be advantageous to make the reactor vertical, in order for the effect of gravity to be symmetrically dispatched on the gaseous volume inside the furnace and to help in maintaining for a while the solid products in fluidized bed.

Homogeneous Processes – Results

The metal-organic compound decomposes in the first zone of the reactor to generate the nanometric metallic particles that can catalyze the nanotubes formation. In the second part of the reactor, the carbon source is decomposed to atomic carbon which then is responsible for the formation of nanotubes.

This technique is quite flexible and both single-walled nanotubes [3.88] and multiwalled nanotubes [3.89] have been obtained depending on the carbon feedstock gas; it has also been exploited for some years in the production of vapor grown carbon nanofibers [3.90].

The main drawback of this type of process is again, as for heterogeneous processes, the difficulty to control the size of the metal nanoparticles, and thus the nanotube formation is often accompanied by the production of undesired carbon forms (amorphous carbon or polyaromatic carbon phases found as various phases or as coatings). In particular, encapsulated forms have been often found, as the result of the creation of metallic particles that are too big to be active for growing nanotubes (but are still effective for catalytically decomposing the carbon source) and be totally recovered by graphene layers.

The same kind of parameters as for heterogeneous processes have to be controlled in order to finely tune this process and obtain selectively the desired morphology and structure of the nanotubes formed, such as: the choice of the carbon source; the reaction temperature; the residence time; the composition of the incoming gaseous feedstock with a particular attention paid to the role played by hydrogen proportion, which can control the orientation of graphenes with respect to the nanotube axis thus switching from c-MWNT to h-MWNT [3.69]; and the ratio of the metallorganic precursor to the carbon source (for lower values, SWNTs are obtained [3.85]). As recently demonstrated, the overall process can be improved by adding other compounds such as ammonia or sulfur-containing species to the reactive gas phase. The former allows aligned nanotubes and mixed C-N nanotubes [3.91] to be obtained, the latter results in a significant increase in productivity [3.90].

It should be emphasized that only small productions have been achieved so far, and the scale up toward industrial exploitation seems quite difficult because of the large number of parameters that have to be considered. A critical one is to be able to increase the quantity of metallorganic compound that has to be sent in the reactor, as a requirement to increase the production, without obtaining too big particles. This problem has not yet been solved. An additional problem inherent in the process is the possibility of clogging the reactor due to the deposition of metallic nanoparticles on the reactor walls followed by carbon deposition.

A significant breakthrough concerning this technique could be the process developed at Rice University, the so-called HiPCo^{TM} process to produce SWNTs of very high purity [3.92]. This gas phase catalytic reaction uses carbon monoxide to produce, from $[Fe(CO)_5]$, a SWNT material claimed to be relatively free of by-products. The temperature and pressure conditions required are applicable to industrial plants. The company Carbon Nanotechnologies Inc. (Houston, TX, USA) actually sells raw SWNT materials prepared that way, at a marketed price of \$ 375/g, doubled if purified (2003 data). Other companies are more specialized in MWNTs such as Applied Sciences Inc. (Cedarville, Ohio, USA), which currently has a production facility of ∼ 40 tons/year of ∼ 100 nm large MWNTs (Pyrograf-III), or Hyperion Catalysis (Cambridge, MA, USA), which makes MWNT-based materials.

Templating

Another technique interesting to describe briefly, though definitely not suitable for mass production, is the templating technique. It is the second method only (the first being the electric-arc technique, when considering the formation of MWNTs on the cathode) able to synthesize carbon nanotubes without any catalyst. Any other work reporting the catalyst-free formation of nanotubes is likely to have been fooled by metallic impurities present in the reactor or by some other factors having brought a chemical gradient to the system. Another original aspect is that it allows aligned nanotubes to be obtained naturally, without the help of any subsequent alignment procedure. But recovering the nanotubes only requires the template to be removed (dissolved), which means the former alignment of the nanotubes is lost.

Templating – Experimental Devices

The principle of the technique is to deposit a solid carbon coating obtained from CVD method onto the walls of an appropriate porous substrate whose pores are displayed as parallel channels. The feedstock is again a hydrocarbon, as a common carbon source. The substrate can be alumina or zeolite for instance, however, which present natural channel pores, while the whole is heated to a temperature able to crack the hydrocarbon selected as carbon source (Fig. 3.16).

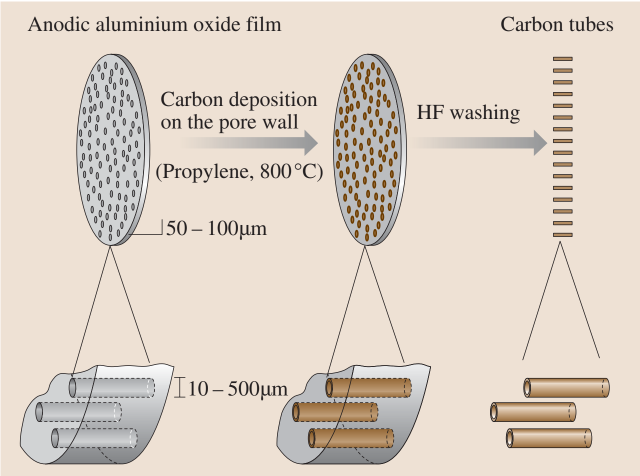


Fig. 3.16 Principle of the templating technique for the catalyst-free formation of single-walled or concentric-type multi-walled carbon nanotubes (from [3.93])

Templating – Results

Provided the chemical vapor deposition mechanism (which is actually better described as a chemical vapor infiltration mechanism) is well controlled, the synthesis results in the coating of the channel pore walls by a variable number of graphenes. Both MWNTs (exclusively concentric type) or SWNTs can be obtained. The smallest SWNTs (diameters ∼ 0.4 nm) ever obtained mentioned in Sect. 3.1 have actually been synthesized by this technique [3.11]. Lengths are directly determined by channel lengths, i. e. by the thickness of the substrate plate. A main advantage is the purity of the tubes (no catalyst remnants, and little other carbon phases). On the other hand, the nanotube structure is not closed at both ends, which can be an advantage or a drawback, depending on the application. For instance, recovering the tubes requires the porous matrix to dissolve using one of the chemical treatment previously cited. The fact that tubes are open makes them even more sensitive to the acid attack.

3.2.3 Miscellaneous Techniques

In addition to the major techniques described in Sects. 3.2.1 and 3.2.2, many attempts can be found in literature to produce nanotubes by various ways, with a generally specific goal, such as looking for a low-cost or a catalyst-free production process. None has been sufficiently convincing so far to be presented as a serious alternative to the major processes described previously. Some examples are provided in the following.

Hsu et al. [3.94] have succeeded in preparing MWNTs (including coiled MWNTs, a peculiar morphology resembling a spring) by a catalyst-free (although Li was present) electrolytic method, by running a 3–5 A current between two graphite electrodes (a graphite crucible as the anode and a graphite rod as the cathode). The graphite crucible was filled with lithium chloride, while the whole was heated in air or argon at ∼ 600 °C. As with many other techniques, by-products such as encapsulated metal particles, carbon shells, amorphous carbon, and so on, are formed.

Cho et al. [3.95] have proposed a pure chemistry route, by the polyesterification of citric acid onto ethylen glycol at 50 °C, followed by a polymerization at 135 °C, then carbonized at 300 °C under argon, then oxidized at 400 °C in air. Despite the latter oxidation step, the solid product surprisingly contains short MWNTs, although obviously with a poor nanotexture. By-products such as carbon shells and amorphous carbon are also formed.

Part A | 3.2

Li et al. [3.96] have also obtained short MWNTs by a catalyst-free (although Si is present) pyrolytic method which involves heating silicon carbonitride nanograins in a BN crucible to 1,200–1,900 °C in nitrogen within a graphite furnace. No details are given about the possible occurrence of by-products, but they are likely considering the complexity of the chemical system (Si-C-B-N) and the high temperatures involved.

Terranova et al. [3.98] have investigated the catalyzed reaction between a solid carbon source and atomic hydrogen. Graphite nanoparticles ($\sim$ 20 nm) are sent with a stream of H_2 onto a Ta filament heated at 2,200 °C. The species produced, whatever they are, then hit a Si polished plate warmed to 900 °C and supporting transition metal particles. The whole chamber is under a dynamic vacuum of 40 torr. SWNTs are supposed to form according to the authors, although images are poorly convincing. One major drawback of the method, besides its complexity compared to others, is the difficulty of recovering the "nanotubes" from the Si substrates onto which they seem to be firmly bonded.

A last example is an attempt to prepare nanotubes by diffusion flame synthesis [3.99]. A regular gaseous hydrocarbon source (ethylene, ...) added with ferrocene vapor is sent within a laminar diffusion flame made from air and CH_4 whose temperature range is 500–1,200 °C. SWNTs are actually formed, together with encapsulated metal particles, soot, and so on. In addition to a low yield, the SWNT structure is quite poor.

3.2.4 Synthesis of Aligned Carbon Nanotubes

Several applications (such as field-emission-based display, see Sect. 3.6) require that carbon nanotubes grow as highly aligned bunches, in highly ordered arrays, or located at specific positions. In that case, the purpose of the process is not mass production but controlled growth and purity, with subsequent control of nanotube morphology, texture, and structure. Generally speaking, the more promising methods for the synthesis of aligned nanotubes are based on CCVD processes, which involve molecular precursors as carbon source, and method of thermal cracking assisted by the catalytic activity of transition metal (Co, Ni, Fe) nanoparticles deposited onto solid supports. Few attempts have been made so far to obtain such materials with SWNTs. But the catalyst-free templating methods related to that described in Sect. 3.2.2 are not considered here, due to the lack of support after the template removal, which does not allow the former alignment to be maintained.

During the CCVD-growth, nanotubes can self-assemble into nanotube bunches aligned perpendicular to the substrate if the catalyst film on the substrate has a critical thickness [3.100], the driving forces for this alignment are the van der Waals interactions between the nanotubes, which allow them to grow perpendicularly to the substrates. If the catalyst nanoparticles are deposited onto a mesoporous substrate, the mesoscopic pores may also cause a certain effect on the alignment when the growth starts, thus controlling the growth direction of the nanotubes. Two kinds of substrates have been used so far in this purpose: mesoporous silica [3.101, 102] and anodic alumina [3.103].

Different methods have been reported in the literature for metal particles deposition onto substrates: (i) deposition of a thin film on alumina substrates from metallic-salt precursor impregnation followed by oxidation/reduction steps [3.104], (ii) embedding catalyst particles in mesoporous silica by sol-gel processes [3.101], (iii) thermal evaporation of Fe, Co, Ni, or Co-Ni metal alloys on SiO_2 or quartz substrates under high vacuum [3.105, 106], (iv) photolithographic patterning of metal-containing photoresist polymer with the aid of conventional black and white films as a mask [3.107] and, electrochemical deposition at the bottom of the pores in anodic aluminum oxide templates [3.103].

Depositing the catalyst nanoparticles onto a previously patterned substrate allows one to control the frequency of local occurrence and the display of the MWNT bunches formed. The as-produced materials mainly consist in arrayed, densely packed, freestanding, aligned MWNTs (Fig. 3.17), which is quite

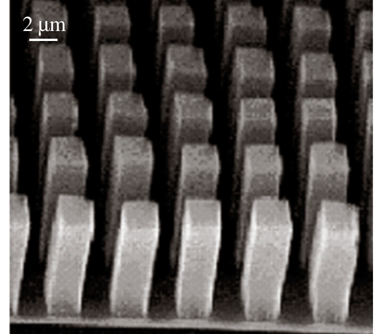

Fig. 3.17 Example of a free-standing MWNT array obtained from the pyrolysis of a gaseous carbon source over catalyst nanoparticles previously deposited onto a patterned substrate. Each square-base rod is a bunch of MWNTs aligned perpendicular to the surface (from [3.97])

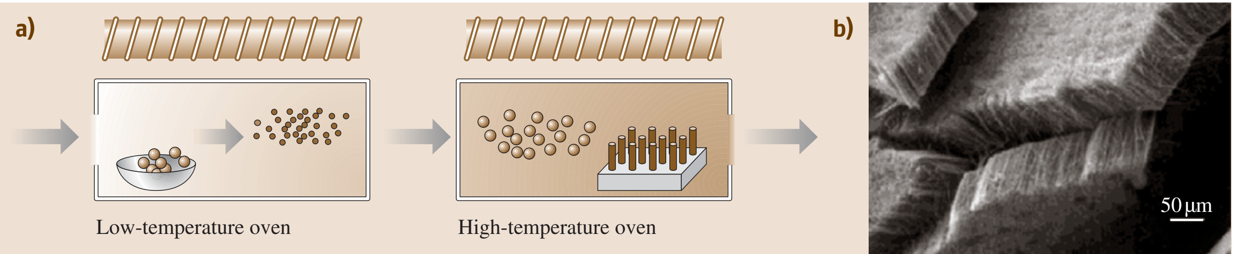

Fig. 3.18a–c Sketch of a double-furnace CCVD device for the organo-metallic/hydrocarbon co-pyrolysis process. suitable for field emission-based applications for instance [3.97].

When a densely packed coating of vertically aligned MWNTs is desired (Fig. 3.18b), another route is the pyrolysis of hydrocarbons in the presence of organometallic precursor molecules like ferrocene or iron pentacarbonyl, operating in a dual furnace system (Fig. 3.18a). The organo-metallic precursor (e.g., ferrocene) is first sublimed at low temperature in the first furnace or is injected as a solution along with the hydrocarbon feedstock, then the whole components are pyrolyzed at higher temperature in the second furnace [3.88, 108–111]. The parameters that must be taken into account are the heating or feeding rate of ferrocene, the flow rate of the vector gas (Ar or N_2) and of the gaseous hydrocarbon, and the temperature of pyrolysis (650–1,050 °C). Generally speaking, the co-deposition process using $[Fe(CO)_5]$ as catalyst source implies its thermal decomposition at elevated temperatures to produce atomic iron that deposits on the substrates in the hot zone of the reactor. As the nanotube growth occurs simultaneously with the introduction of $[Fe(CO)_5]$, the temperatures chosen for the growth depend on the carbon feedstock utilized, e.g., they can vary from 750 °C for acetylene to 1,100 °C for methane. Mixtures of $[FeCp_2]$ and xylene or $[FeCp_2]$ and acetylene have also been used successfully for the production of freestanding MWNTs.

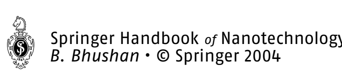
The nanotube yield and quality are directly linked with the amount and size of the catalyst particles, and since the planar substrates used do not exhibit high surface area, the dispersion of the metal can be a key step in the process. It has been observed that an etching pretreatment of the surface of the deposited catalyst thin film with NH_3 may be critical for an efficient growth of nanotubes by bringing the appropriate metal particle size distribution. It may also favor the alignment of MWNTs and prevent the formation of amorphous carbon from thermal cracking of acetylene [3.112].

3.3 Growth Mechanisms of Carbon Nanotubes

Growth mechanisms of carbon nanotubes are still debated. But researchers have been impressively imaginative and have made a number of hypotheses. One reason is that conditions allowing carbon nanofilaments to grow are very diverse, which means that related growing mechanisms are many. For given conditions, the truth is even probably a combination or a compromise between some of the proposals. Another reason is that phenomena are quite fast and difficult to observe in situ. It is generally agreed, however, that growth should occur so that the number of dangling bonds is limited, for energetic reasons.

3.3.1 Catalyst-Free Growth

As already mentioned, in addition to the templating technique which merely relates to chemical vapor infiltration mechanism for pyrolytic carbon, the growth of c-MWNT as a deposit onto the cathode in the electric-arc method is a rare example of catalyst-free carbon nanofilament growth. The driving forces are obviously related to the electric field, i. e. related to charge transfers from an electrode to the other via the particles contained in the plasma. How the MWNT nucleus forms is not clear, but once it has started, it may include the direct incorpora-



tion of C_2 species to the primary graphene structure as it was formerly proposed for fullerenes [3.113]. This is supported by recent C_2 radical concentration measurements that revealed an increasing concentration of C_2 from the anode being consumed to the growing cathode (Fig. 3.13), indicating, first, that C_2 are secondary species only, and second, that C_2 species could actually participate actively in the growth mechanism of c-MWNTs in the arc method.

3.3.2 Catalytically Activated Growth

Growth mechanisms involving catalysts are more difficult to ascertain, since they are more diverse. Although a more or less extensive contribution of a VLS (Vapor-Liquid-Solid [3.114]) mechanism is rather well admitted, it is quite difficult to find comprehensive and plausible explanations able to account for both the various conditions used and the various morphologies observed. What follows is an attempt to provide overall explanations of most of the phenomena, while remaining consistent with the experimental data. We did not consider hypotheses for which there are a lack of experimental evidence, such as the moving nano-catalyst mechanism, which proposed that dangling bonds from a growing SWNT may be temporarily stabilized by a nano-sized catalyst located at the SWNT tip [3.23], or the scooter mechanism, which proposed that C dangling bonds are temporarily stabilized by a single catalyst atom, moving all around the SWNT cross section edge, allowing subsequent C atom addition [3.115].

From the various results, it appears that the most important parameters are probably the thermodynamic conditions (only temperature will be considered here), the catalyst particle size, and the presence of a substrate. Temperature is critical and basically corresponds to the discrepancy between CCVD methods and solid-carbon-source based method.

Low Temperature Conditions

Low temperature conditions are typical from CCVD conditions, since nanotubes are frequently found to grow far below 1,000 °C. If conditions are such that the catalyst is a crystallized solid, the nanofilament is probably formed according to a mechanism close to a VLS mechanism, in which three steps are defined: (i) adsorption then decomposition of C-containing gaseous moieties at the catalyst surface; (ii) dissolution then diffusion of the C-species through the catalyst, thus forming a solid solution; (iii) back precipitation of solid carbon as nanotube walls. The texture is then determined by the orientation of the crystal faces relative to the filament axis (Fig. 3.19), as demonstrated beyond doubt by transmission electron microscopy images such as that in *Rodriguez* et al. [3.19]. This mechanism can therefore provide either c-MWNT, or h-MWNT, or platelet nanofiber.

If conditions are such that the catalyst is a liquid droplet, either because of higher temperature conditions or because of lower temperature melting catalyst, a mechanism similar to that above can still occur, really VLS (vapor = gaseous C species, liquid = molten catalyst, S = graphenes), but there are obviously no more crystal faces to orientate preferentially the rejected graphenes. Energy minimization requirements will therefore tend to make them concentric and parallel to the filament axis.

With large catalyst particles (or in the absence of any substrate), the mechanisms above will generally follow a "tip growth" scheme, i. e., the catalyst will move forward while the rejected carbon form the nanotube behind, whether there is a substrate or not. In that case,

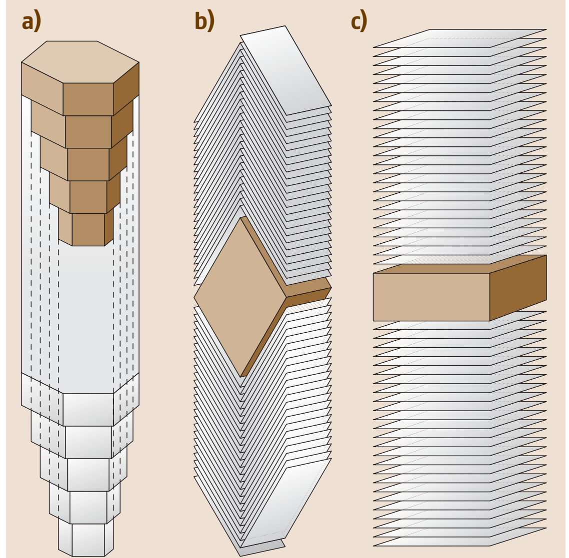


Fig. 3.19 Illustration of the relationships between the catalyst crystal outer morphology and the subsequent carbon nanofilament inner texture. Crystal are drawn from their images in the projected plane perpendicular to the electron beam in a transmission electron microscope, i. e. crystal morphology in the out-of-plane dimension is not ascertained (adapted from [3.19])

chances are high that one end is open. On the contrary, when catalyst particles deposited onto a substrate are small enough (nanoparticles) to be refrained to move by the interaction forces with the substrate, the growth mechanism will follow a "base growth" scheme, i. e. the carbon nanofilament grows away from the substrate leaving the catalyst nanoparticle attached to the substrate (Fig. 3.20).

The bamboo texture that affects both the herringbone and the concentric texture may reveal a specificity of the dissolution-rejection mechanism, i. e. a periodic, discontinuous dynamics of the phenomenon. Once the catalyst has reached the saturation threshold regarding its content in carbon, it expulses it quite suddenly. Then it becomes again able to incorporate a given amount of carbon without having any catalytic activity for a little while, then over-saturation is reached again, etc. Factors controlling such a behavior, however, are not determined.

It is then clear that, in any of the mechanisms above, 1 catalyst particle = 1 nanofilament. This explains why, although making SWNT by CCVD methods is possible, controlling the catalyst particle size is critical, since it thereby controls the subsequent nanofilament to be grown from it. Reaching a really narrow size distribution in CCVD is quite challenging, specifically as far as nanosizes are concerned when growing SWNTs is the goal. Only particles < 2 nm will be able to make it (Fig. 3.20), since larger SWNTs would energetically not be favored [3.10]. Another specificity of the CCVD method and from the related growth mechanisms is that the process can be effective all along the isothermal zone of the reactor furnace since continuously fed with a carbon-rich feedstock, which is generally in excess, with a constant composition at a given time of flight of the species. Coarsely, the longer the isothermal zone in gaseous carbon excess conditions, the longer the nanotubes. This is why the nanotube lengths can be much longer than that obtained by solid-carbon-source-based methods.

Table 3.2 provides guidelines for the relationships between the synthesis conditions and the type of nanotube formed.

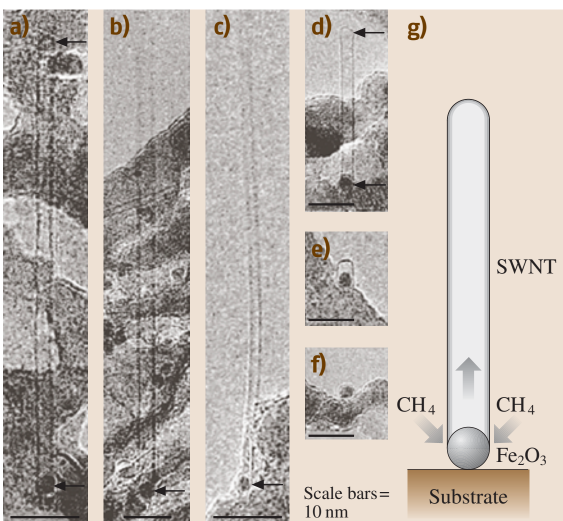

Fig. 3.20 High resolution transmission electron microscopy images of several SWNTs grown from iron-based nanoparticles by CCVD method, showing that particle sizes determine SWNT diameters in that case (adapted from [3.116])

High Temperature Conditions

High temperature conditions are typical from solid-carbon-source based methods such as electric arc, laser vaporization, or solar furnace (see Sect. 3.2). The huge temperatures involved (several thousands °C) atomize both the carbon source and the catalyst. Of course, catalyst-based SWNTs do not form in the area of highest temperatures (contrary to c-MWNT in the electric arc method), but the medium is made of atoms and radicals all mixed, some of which are likely to condense into the same droplet (since it will be liquid at the beginning). At some distance from the atomization zone, the medium is therefore made of carbon metal alloy droplets and of secondary carbon species that range from C_2 to higher order molecules such as corannulene which is made of a central pentagon surrounded by 5 hexagons. (The preferred formation of such a molecule can be explained by the former association of carbon atoms into a pentagon, because it is the fastest way to limit dangling bonds at low energetic cost, thereby providing a fixation site for other carbon atoms (or C_2) which also will tend to close into a ring, again to limit dangling bonds. Since adjacent pentagons are not energetically favoured, these cycles will be hexagons. Such a molecule is thought to be a probable precursor for fullerenes. Fullerenes are actually always produced, even in conditions which produce SWNTs.) The same event of saturation in C of the carbon-metal alloy droplet occurs as described in Sect. 3.3.2, resulting in the precipitation of excess C outside the particle upon the effect of the decreasing thermal gradient in the reactor, which decreases the solubility threshold of C in the metal [3.117]. Once the "inner" carbon atoms reach the catalyst particle surface, they meet the "outer" carbon species, including corannulene, that will con-

Table 3.2 Guidelines indicating the relationships between possible carbon nanofilament morphologies and some basic synthesis conditions

tribute to cap the merging nanotubes. Once formed and capped, nanotubes can grow both from the inner carbon atoms (Fig. 3.21a), according to the VLS mechanism proposed by *Saito* et al. [3.117], and from the outer carbon atoms, according the adatom mechanism proposed by *Bernholc* et al. [3.118]. In the latter, carbon atoms from the surrounding medium in the reactor are attracted then stabilized by the carbon/catalyst interface at the nanotube/catalyst surface contact, promoting their subsequent incorporation at the tube base. The growth mechanism therefore mainly follows the base growth scheme. But once the nanotubes are capped, C_2 species still remaining in the medium and which meet the growing nanotubes far from the nanotube/catalyst interface, may still incorporate the nanotubes from both the side wall or the tip, thereby giving rise to some proportion of Stone–Wales defects [3.40]. The occurrence of a nanometer-thick surface layer of yttrium carbide (onto the main Ni-containing catalyst core), whose some lattice distances are commensurable with that of the C−C distance in graphene, as recently revealed by *Gavillet* et al. [3.48], could possibly play a beneficial role in the stabilization effect at the nanotube/catalyst interface and explain why SWNT yield is enhanced by such bimetallic alloys (as opposed to single metal catalysts).

A major difference with the low temperature mechanisms described for CCVD methods is that many nanotubes are formed from a single, relatively large (∼ 10–50 nm) catalyst particle (Fig. 3.21b), whose size distribution is therefore not as critical as for the low

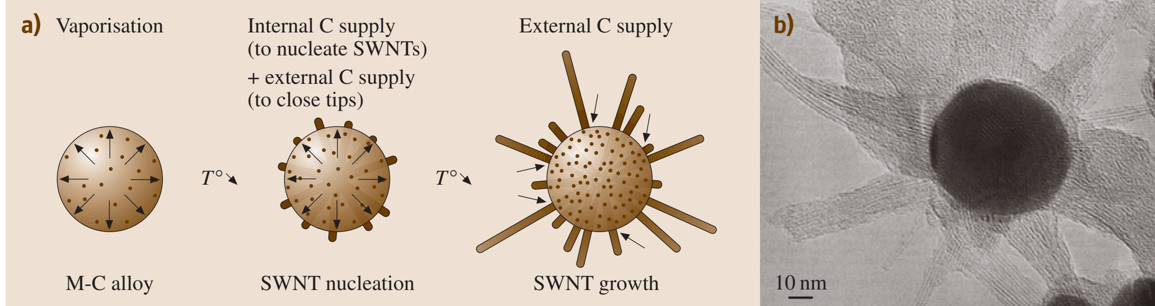

Fig. 3.21 **(a)** Mechanism proposed for SWNT growth (see text). **(b)** Transmission electron microscopy image of SWNT growing radial to a large Ni catalyst particle surface in the electric arc experiment. (modified from [3.17])

temperature mechanisms (particles that are too large, however, would induce polyaromatic shells instead of nanotubes). That is why SWNT diameters are much more homogeneous than for CCVD methods. Why the most frequent diameter is ∼ 1.4 nm is again a matter of energy balance. Single-wall nanotubes larger than ∼ 2.5 nm are not stable [3.10]. On the other hand, strain to the C−C angles increases as the radius of curvature decreases. Such diameter (1.4 nm) should therefore correspond to the best energetic compromise. Another difference with the low temperature mechanisms for CCVD is that temperature gradients are huge, and the gas phase composition surrounding the catalysts droplets is also subjected to rapid changes (as opposed to what could happen in a laminar flow of a gaseous feedstock whose carbon source is in excess). This explains why nanotubes from arc are generally shorter than nanotubes from CCVD, and why mass production by CCVD should be favored. In the latter, the catalytic role of the metallic particle can be recurrent as long as the conditions are maintained. In the former, surrounding conditions change continuously, and the window for efficient catalysis effect can be very narrow. Lowering temperature gradients in solid carbon source-based SWNT producing methods such as the electric-arc reactor should therefore be a way to increase the SWNT yield and length [3.119]. Amazingly, this is in opposition to fullerene production from arc.

3.4 Properties of Carbon Nanotubes

Carbon is a unique light atom that can form one-, two-, or threefold strong chemical bonds. The planar threefold configuration forms graphene planes that can, under certain growth conditions (see Sect. 3.3), adopt a tubular geometry. Properties of the so-called carbon nanotubes may change drastically depending on whether SWNTs or MWNTs are considered (see Sect. 3.1).

3.4.1 Variability of Carbon Nanotube Properties

Properties of MWNTs are generally not much different from that of regular polyaromatic solids (which may exhibit graphitic, or turbostratic, or intermediate crystallographic structure), and variations are then mainly driven by the textural type of the MWNTs considered (concentric, herringbone, bamboo) and the quality of the nanotexture (see Sect. 3.1), both of which control the extent of anisotropy. Actually, for polyaromatic solids, whose structural entities are built with stacked graphenes, bond strength is quite different depending on whether the in-plane direction is considered (which includes only very strong – covalent – and therefore very short – 0.142 nm bonds) or the direction perpendicular to it (which includes only very weak – van der Waals – and therefore very loose – ∼ 0.34 nm bonds). Such heterogeneity is not found in single (isolated) SWNTs. But the heterogeneity is back along with the related consequences when SWNTs associate into bundles. Therefore, properties – and applicability – for SWNTs may also change dramatically depending on whether single SWNT or SWNT ropes are involved.

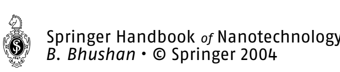
In the following, we will emphasize SWNT properties, as far as their original structure often leads to original properties with respect to that of regular polyaromatic solids. But we will also sometimes cite properties of MWNTs for comparison.

3.4.2 General Properties

SWNT-type carbon nanotube diameters fall in the nanometer range and can be hundreds of micrometers long. SWNTs are narrower in diameter than the thinnest line able to be obtained by electron beam lithography. SWNTs are stable up to 750 °C in air (but start being damaged earlier through oxidation mechanisms, as demonstrated by their subsequent ability to be filled with molecules, see Sect. 3.5) and up to ∼ 1,500–1,800 °C in inert atmosphere beyond which they transform into regular, polyaromatic solids (i. e., phases built with stacked graphenes instead of single graphenes) [3.120]. They have half the mass density of aluminum. While the length of SWNTs can be macroscopic, the diameter has a molecular dimension. As a molecule, properties are closely influenced by the way atoms are displayed along the molecule direction. The physical and chemical behavior of SWNTs are therefore related to their unique structural features [3.121].

3.4.3 SWNT Adsorption Properties

An interesting feature of SWNTs is their very high surface area, the highest ever due to the fact that a single graphene sheet is probably the unique example of a ma-



terial energetically stable in normal conditions while consisting of a single layer of atoms. Ideally, i. e. not considering SWNTs in bundles but isolated SWNTs, and provided the SWNTs have one end opened (by oxidation treatment for instance), the real surface area can be equal to that of a single, flat graphene, i. e. $\sim 2{,}700\,\mathrm{m}^2/\mathrm{g}$ (accounting for both sides).

But practically, nanotubes – specifically SWNTs – are more often associated with many other nanotubes to form bundles, then fibers, films, papers, etc. than as a single entity. Such architectures develop various porosity ranges important for determining adsorption properties (the latter aspects are also developed in Sect. 3.6.2, focused on applications). It is thus most appropriate to discuss adsorption on SWNT-based materials in term of adsorption on the outer or inner surfaces of such bundles. Furthermore, theoretical calculations have predicted that the molecule adsorption on the surface or inside of the nanotube bundle is stronger than that on an individual tube. A similar situation exists for MWNTs where adsorption could occur either on or inside the tubes or between aggregated MWNTs. Additionally, it has been shown that the curvature of the graphene sheets constituting the nanotube walls can result in a lower heat for adsorption with respect to that of a planar graphene (see Sect. 3.1.1).

Accessible SWNT Surface Area

Various studies dealing with the adsorption of nitrogen on MWNTs [3.122, 123] and SWNTs [3.124] have highlighted the porous nature of these two materials. Pores in MWNTs can be divided mainly into inner hollow cavities of small diameter (narrowly distributed, mainly 3–10 nm) and aggregated pores (widely distributed, 20–40 nm), formed by interaction of isolated MWNTs. It is also worth noting that the ultra-strong nitrogen capillarity in the aggregated pores contributes to the major part of the total adsorption, showing that the aggregated pores are much more important than the inner cavities of the MWNTs for adsorption. Adsorption of N_2 has been studied on as-prepared and acid-treated SWNTs, and the results obtained point out the microporous nature of SWNT materials, as opposed to the mesoporous MWNT materials. Also, as opposed to isolated SWNTs (see above), surface areas well above $400\,\mathrm{m}^2\mathrm{g}^{-1}$ have been measured for SWNT-bundle-containing materials, with internal surface areas of $300\,\mathrm{m}^2\mathrm{g}^{-1}$ or higher.

The theoretical specific surface area of carbon nanotubes ranges over a broad scale, from 50 to $1{,}315\,\mathrm{m}^2\mathrm{g}^{-1}$ depending on the number of walls, the diameter, or the number of nanotubes in a bundle of SWNTs [3.125]. Experimentally, the specific surface area of SWNTs is often larger than that of MWNTs. Typically, the total surface area of as-grown SWNTs ranges between 400 and $900\,\mathrm{m}^2\mathrm{g}^{-1}$ (micropore volume, $0.15–0.3\,\mathrm{cm}^3\mathrm{g}^{-1}$), whereas values ranging between 200 and $400\,\mathrm{m}^2\mathrm{g}^{-1}$ for as-produced MWNTs are often reported. In the case of SWNTs, the diameter of the tubes and the number of tubes in the bundle will affect mainly the BET value. It is worth noting that opening/closing of the central canal noticeably contributes to the adsorption properties of nanotubes. In the case of MWNTs, chemical treatments such as KOH activation are efficient to develop a microporosity, and surface areas as high as $1{,}050\,\mathrm{m}^2\mathrm{g}^{-1}$ have been reported [3.126]. Thus it appears that opening or cutting as well as chemical treatments (purification step for example) of carbon nanotubes can considerably affect their surface area and pore structure.

Adsorption Sites and Binding Energy of the Adsorbates

An important problem to solve when considering adsorption on nanotubes is the identification of the adsorption sites. Adsorption of gases in a SWNT bundle can occur inside the tubes (pore), in the interstitial triangular channels between the tubes, on the outer surface of the bundle, or in a groove formed at the contact between adjacent tubes on the outside of the bundle (Fig. 3.22). Starting from closed-end SWNTs, simple molecules can adsorb on the walls of the outer nanotubes of the bundle and preferably on the external grooves. For the more attractive sites, corresponding to the first adsorption stages, it seems that adsorption or condensation in the interstitial channel of SWNT bundles depends on the size of the molecule (or on the SWNT diameters) and on their interaction energies [3.127]. Then, adapted treatments to open the tubes will favour the gas adsorption (e.g., O_2, N_2 in the inner walls [3.128, 129]). For hydro-

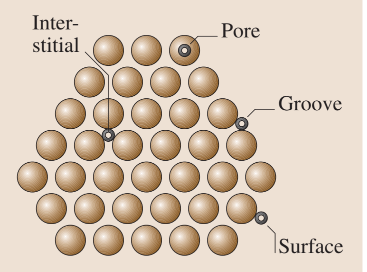


Fig. 3.22 Sketch of a SWNT bundle illustrating the four different adsorption sites

gen and other small molecules, computational methods have shown that, for open SWNTs, the pore, interstitial, and groove sites are energetically more favourable than the surface site, with respect to the increasing number of carbon nanotubes interacting with the adsorbed molecules [3.130].

For MWNTs, adsorption can occur in the aggregated pores, inside the tube or on the external walls. In the latter case, the presence of defects, as incomplete graphene layers, has to be taken into consideration. Although adsorption between the graphenes (intercalation) has been proposed in the case of hydrogen adsorption in h-MWNTs or platelet nanofibers [3.132], it is unlikely for many molecules due to steric effect and should not prevail for small molecules due to long diffusion path.

Few studies deal with adsorption sites in MWNTs, however it has been shown that butane adsorbs more in the case of MWNTs with smaller outside diameters, which is consistent with another statement that the strain brought to curved graphene surfaces affects sorption. Most of the butane adsorbs to the external surface of the MWNTs while only a small fraction of the gas condensed in the pores [3.133]. Comparative adsorption of krypton or of ethylene on MWNTs or on graphite has allowed scientists to determine the dependence of the adsorption and wetting properties on the specific morphology of the nanotubes. Higher condensation pressure and lower heat of adsorption were found on nanotubes with respect to graphite [3.134]. These differences result mainly from a decrease in the lateral interactions between the adsorbed molecules, related to the curvature of the graphene sheets.

A limited number of theoretical as well as experimental works exist on the values of the binding energies for gases on carbon nanotubes. If most of these studies report low binding energies on SWNTs, consistent with a physisorption, some experimental results, in particular in the case of hydrogen, are still controversial (see Sect. 3.6.2). In the case of platelet nanofibers, the initial dissociation of hydrogen on graphite edge sites, which constitute the majority of the nanofiber surface has been proposed [3.135]. For carbon nanotubes, a mechanism that involves H_2 dissociation on residual metal catalyst followed by H spillover and adsorption on the most reactive nanotube sites could be envisaged [3.136]. Doping nanotubes with alkali may enhance hydrogen adsorption, due to the charge transfer from the alkali metal to the nanotube, which polarizes the H_2 molecule and induces dipole interaction [3.137].

Generally speaking, the adsorbates can be either charge donors or acceptors to the nanotubes. The observed trends in the binding energies of gases with different van der Waals radii suggest that the groove sites of SWNTs are the preferred low coverage adsorption sites due to their higher binding energies. Finally, several studies have shown that, at low coverage, the binding energy of the adsorbate on SWNT is between 25% and 75% higher than the binding energy on a single graphene. This discrepancy can be attributed to an increase of the effective coordination in the binding sites, such as the groove sites, in SWNTs bundles [3.138, 139]. Representative results concerning the adsorption properties of SWNTs and MWNTs are summarized on Table 3.3.

Table 3.3 Adsorption properties and sites of SWNTs and MWNTs. Letters in column 5 refer to Fig. 3.22. Data of two last columns are from [3.131]

Type of nanotube	Porosity (cm^3g^{-1})	Surface area (m^2/g)	Binding energy of the adsorbate	Adsorption sites	Attractive potential per site (eV)	Surface area per site (m^2/g)

3.4.4 Transport Properties

The narrow diameter of SWNTs has a strong influence on its electronic excitations due to its small size compared to the characteristic length scale of low energy electronic excitations. Combined with the particular shape of the electronic band structure of graphene, carbon nanotubes are ideal quantum wires. The conduction and the valence band of the graphene touch on the 6 corners (K points) of the Brillouin zone [3.140]. By rolling the graphene to form a tube, new periodic boundary conditions for the electronic wave functions superimpose, which give rise to one-dimensional sub-bands: $C_n K = 2q$ where q is an integer and C_n the vector $na_1 + ma_2$ characteristic of the diameter and the helicity of the tube (see Sect. 3.1). If one of these sub-bands passes through one of the K points, the nanotube will be metallic, otherwise it will be semiconductor with a gap inversely proportional with the diameter. For a tube with a diameter of 3 nm, the gap falls in the range of the thermal energy at room temperature. As pointed out in Sect. 3.1 already, knowing (n, m) then allows one to predict whether or not the tube exhibits a metallic behavior. To summarize, we can say that the electronic structure of SWNTs depends both on the orientation of the honeycomb lattice with respect to the tube axis and the radius of curvature imposed to the bent graphene sheet. This explains why properties of MWNTs quickly become no different from regular, polyaromatic solids as the number of walls (graphenes) increases, since the radius of curvature increases meanwhile. In addition, the conduction occurs essentially through the external tube (for c-MWNTs), but the interactions with the internal coaxial tubes may make the electronic properties vary. For small diameter MWNTs exhibiting a low number of walls, typically two (DWNTs), the relative lattice orientation of the two superimposed graphenes remains determinant, and the resulting overall electronic behavior can either be metallic or semiconductor upon structural considerations [3.141]. Another consequence, valid for any nano-sized carbon nanotube whatever the number of walls, is that applying stresses to the tube is also likely to change its electronic behavior, as a consequence of the variation brought to the position of the sub-bands with respect to the K points of the Brillouin zone [3.142].

The details of electronic properties of SWNTs are not well understood yet, and numerous theoretical and experimental works have revealed fascinating effects [3.143]. An assembly of agglomerated tubes (ropes) increases the complexity. Moreover, investigating the electron properties of a single SWNT requires one to characterize and control the properties of the electrical contacts. Likewise, the interaction with the substrate influence the bulk transport properties a lot when SWNTs embedded in a medium (e.g., a composite) are considered. The conduction of charge carriers in metallic SWNTs is thought to be ballistic (i. e., independent from length) due to the expected small number of defects [3.144–146] with a predicted electric conductance twice the fundamental conductance unit $G_0 = 4e/h$ because of the existence of two propagating modes. Because of the reduced scattering, metallic SWNTs can transport huge current densities (max $10^9\ \mathrm{A/cm^2}$) without being damaged, i. e. about three orders of magnitude higher than in Cu. On the other hand, in a one-dimensional system, electrons often localize due to structural defects or disorder. In case the contact resistance is too high, a tunnel barrier is formed, and the charge transport is dominated by tunneling effects. Several transport phenomena were reported in the literature of this regime: weak localization due to quantum interferences of the electronic wave functions that leads to an increase of the resistivity [3.147–149], Coulomb blockade at low temperature that characterizes by conductance oscillations as the gate voltage increases [3.148], superconductivity induced by superconductor contacts [3.150], or spin polarization effects induced by ferromagnetic contacts [3.151]. Furthermore, due to enhanced Coulomb interactions, one-dimensional metals are expected to show drastic changes in the density of states at the Fermi level and are described by a Luttinger liquid [3.148]. This behavior is expected to result in the variation of conductance vs. temperature that follows a power law, with a zero conductance at low temperature.

As mentioned previously, SWNTs are model systems to study one-dimensional charge transport phenomena. Due to the of mesoscopic dimension of the morphology, the one-dimensional structure of the nanotube has strong singularities in the electronic density of states (DOS) that fall in the energy range of visible light. As a consequence, visible light is strongly absorbed. It has been observed that flash illumination with a broadband light can lead to spontaneous burning of a macroscopic sample of agglomerated (i. e., ropes) carbon nanotubes in air and room temperature [3.152].

As a probable consequence of both the small number of defects (at least the kind of defects that oppose phonon transport) and the cylindrical topography, SWNTs exhibit a large phonon mean free path, which results in a high thermal conductivity. The thermal conductivity of SWNTs is comparable to that of a single, isolated

graphene layer or high purity diamond [3.153] or possibly higher (∼ 6,000 W/mK).

Finally, carbon nanotubes may also exhibit a positive or negative magneto-resistance depending on the current, the temperature, and the field, whether they are MWNTs [3.154] or SWNTs [3.149].

3.4.5 Mechanical Properties

While tubular nano-morphology is also observed for many two-dimensional solids, carbon nanotubes are unique through the particularly strong threefolded bonding (sp^2 hybridization of the atomic orbitals) of the curved graphene sheet, which is stronger than in diamond (sp^3 hybridization) as revealed by their difference in C−C bond length (0.142 vs. 0.154 nm for graphene and diamond respectively). This makes carbon nanotubes – SWNTs or c-MWNTs – particularly stable against deformations. The tensile strength of SWNTs can be 20 times that of steel [3.155] and has actually been measured equal to ∼ 45 GPa [3.156]. Very high tensile strength values are also expected for ideal (defect-free) c-MWNTs, since combining perfect tubes concentrically is not supposed to be detrimental to the overall tube strength, provided the tube ends are well capped (otherwise, concentric tubes could glide relative to each other, inducing high strain). Tensile strength values as high as ∼ 150 GPa have actually been measured for perfect MWNTs from electric arc [3.157], although the reason for such a high value compared to that measured for SWNTs is not clear. It probably reveals the difficulty in carrying out such measurements in a reliable manner. At least, flexural modulus, for perfect MWNTs should logically exhibit higher values than SWNTs [3.155], with a flexibility that decreases as the number of walls increases. On the other hand, measurements performed on defective MWNTs obtained from CCVD gave a range of 3–30 GPa [3.158]. Tensile modulus, also, reaches the highest values ever, 1 TPa for MWNTs [3.159], and possibly even higher for SWNTs, up to 1.3 TPa [3.160, 161]. Figure 3.23 illustrates how spectacularly defect-free carbon nanotubes could revolutionize the current panel of high performance fibrous materials.

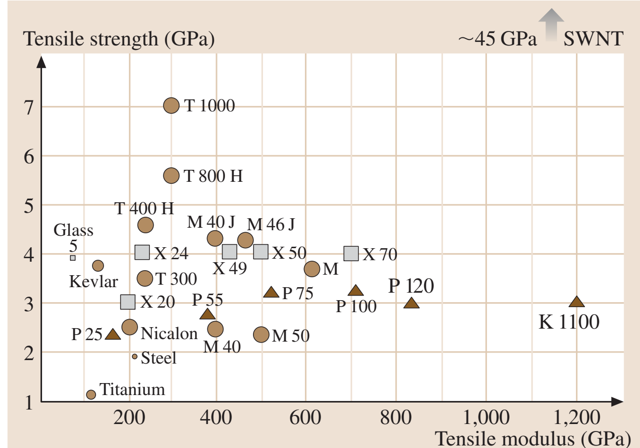

Fig. 3.23 Plot of the tensile strength versus tensile modulus for current fibrous materials, as compared to SWNTs. *Large circles* are PAN-based carbon fibers, which include the highest tensile strength fiber available on the market (T1000 from Torayca); *Triangles* are pitch-based carbon fibers, which include the highest tensile modulus fiber on the market (K1100 from Amoco)

3.4.6 Reactivity

The chemical reactivity of graphite, fullerenes, and carbon nanotubes exhibits some common features. Like any small object, carbon nanotubes have a large surface with which they can interact with their environment (see Sect. 3.4.1). It is worth noting, however, that the chemistry of nanotubes chemistry differs from that of regular polyaromatic carbon materials because of their unique shape, small diameter, and structural properties. Compared to graphite, perfect SWNTs have no chemically active dangling bonds (the reactivity of polyaromatic solids is known to occur mainly through graphene edges). Compared to fullerenes, the ratio of "weak" sites (C−C bonds involved in heterocycles) over strong sites (C−C bonds between regular hexagons) is only slightly different from 0 for ideally perfect tubes (as opposed to 1 in C_{60} fullerenes – C_{60} molecules have 12 pentagons (therefore accounting for $5 \times 12 = 30$ C−C bonds) and 20 hexagons, each of them having three C−C bonds not involved in an adjacent pentagon but shared with a neighboring hexagon (therefore accounting for $20 \times 3 \times 1/2 = 30$ C−C bonds involved in hexagons only). Although graphene faces are chemically relatively inert, the radius of curvature imposed on the graphene in nanotubes enforces the three formerly planar C−C bonds characteristic of the genuine sp^2 hybridization to accept distortions in bond angles that make them closer and closer to the situation of three of the four C−C bonds in diamond (characteristic of the genuine sp^3 hybridization) as the radius of curvature decreases. Even though it is not enough to bring a genuine chemical reactivity to the carbon atoms, a consequence is to consider that either nesting sites are created at the concave sur-

face, or strong physisorption sites are created above each carbon atom of the convex surface, both with a bonding efficiency that increases as the nanotube diameter decreases.

As already pointed out in Sect. 3.1, the chemical reactivity of SWNTs (and c-MNWTs) is supposed to come mainly from the caps, since they contain six pentagons each, as opposed to the tube body, which supposedly contains hexagons only. Indeed, oxidizing treatments applied to carbon nanotubes (air oxidation, wet-chemistry oxidation) are known to open the nanotube tips rather selectively [3.162]. But the ability of SWNTs to be opened by oxidation methods then filled with foreign molecules such as fullerenes (see Sect. 3.5) reveals the occurrence of side defects [3.14], whose identification and occurrence were discussed then proposed to be an average of one Stone–Wales defect every 5 nm along the tube length, involving an amount of about 2% of the carbon atoms for the example of a regular (10,10) SWNT [3.163] – a Stone–Wales defect is made of four adjacent heterocycles, two pentagons and two heptagons, displayed by pairs in opposition. Such a defect actually allows localized double bonds to be formed between the carbon atoms involved in the defect (instead of the electrons participating to the delocalized electron cloud above the graphene as usual, enhancing the chemical reactivity, e.g. toward chlorocarbenes [3.163]). This means that the overall chemical reactivity of carbon nanotubesshould strongly depend on the way they are synthesized. For example, SWNTs prepared by the arc-discharge method are supposed to contain fewer structural defects compared to CCVD-synthesized SWNTs, which have a higher chemical reactivity. Of course, the reactivity of h-MWNT-type nanotubes is intrinsically higher, due to the occurrence of accessible graphene edges at the nanotube surface.

3.5 Carbon Nanotube-Based Nano-Objects

3.5.1 Hetero-Nanotubes

Hetero-nanotubes are defined here as carbon nanotubes whose carbon atoms, part or all of them, are substituted with another element while the overall honeycomb lattice-based graphene structure is maintained. Elements involved are, therefore, boron and/or nitrogen. Benefits can be new behaviors (e.g., BN nanotubes are electrical insulators), improved properties (e.g., regarding the resistance to oxidation), or better control of the properties. One current challenge is actually to control the processing so that the desired SWNT structure is selectively synthesized (metallic or semiconductor). In this regard, it was demonstrated that substituting some C atoms by N or B atoms lead to SWNTs whose electrical behavior is systematically metallic [3.164, 165].

Some examples of hetero-nanotubes, though mainly MWNTs, are found in literature, whose hetero-atom involved is generally nitrogen due to the ease of introducing some gaseous or solid nitrogen and/or boron containing species (e.g., N_2, NH_3, BN, HfB_2) in existing MWNT synthesis devices [3.164, 166] until complete substitution of carbon [3.167, 168]. An amazing result of such attempts to synthesize hetero-MWNTs was the subsequent formation of "multilayered" c-MWNTs, i. e. MWNTs whose constituting coaxial tubes were alternatively made of carbon graphenes and boron nitride graphenes [3.169]. On the other hand, examples of hetero-SWNTs are few. But the synthesis of B- or N-containing SWNTs has been recently reported [3.165, 170].

3.5.2 Hybrid Carbon Nanotubes

Hybrid carbon nanotubes are here defined as carbon nanotubes, SWNTs or MWNTs, whose inner cavity has been filled, partially or entirely, by foreign atoms, molecules, compounds, or crystals. Such hybrids are thereby noted as X@SWNT (or X@MWNT, if appropriate, where X is the atom, molecule, etc. involved) [3.171].

Motivation

Why filling carbon nanotubes? The very small inner cavity of nanotubes is an amazing tool to prepare and study the properties of confined nanostructures of any nature, such as salts, metals, oxides, gases, or even discrete molecules like C_{60}, for example. Because of the almost one-dimensional structure of carbon nanotubes (specifically considering SWNTs), different physical and/or chemical properties can be expected for the encapsulated foreign materials or possibly for the overall hybrid materials. Indeed, when the volume available inside a carbon nanotube is small enough, the foreign material can be made mainly of "surface atoms" of reduced coordinence. The overall former motivation was then to tenta-

tively form metal nanowires likely to be interesting for electronic applications (quantum wires). Metals were the preferred fillers, and nanotubes were mostly considered merely as nano-molds, likely to be removed afterward. But it is likely that the removal of the SWNT "container" to liberate the confined one-dimensional structure may destroy or at least transform it because of the stabilizing effect brought by the interactions with the nanotube wall.

Filling nanotubes while they grow (in situ filling) was one of the pioneering methods. In most cases, however, the filling step is separated from the step of synthesis of the nanotubes. Three methods can then be distinguished: (a) wet chemistry procedures, and physical procedures, involving (b) capillarity filling by a molten material or (c) filling by a sublimated material.

Generally speaking, the estimation of the filling rate is problematic and most of the time is taken merely from the TEM observation, without any statistics on the number of tubes observed. Moreover, as far as SWNTs are concerned, the fact that the nanotubes are gathered into bundles makes difficult the observation of the exact number of filled tubes, as well as the estimation of the filled length for each tube.

Filling carbon nanotubes with materials that could not have been introduced directly is also possible. This can be accomplished by first filling the nanotubes with an appropriate precursor (i. e., able to sublime, or melt, or solubilize) that will later be transformed by chemical reaction or by a physical interaction such as electron beam irradiation, for example [3.172]. In the case of secondary chemical transformation, the reduction by H_2 is the most frequently used to obtain nanotubes filled with metals [3.173]. Sulfides can be obtained as well by using H_2S as reducing agent [3.173].

Because the inner diameter of SWNTs is generally smaller than that of MWNTs, it is more difficult to fill them, and the driving forces involved in the phenomena are not yet totally understood (see the review paper by [3.163]). Consequently, more than one hundred articles dealing with filled MWNTs were already published by the time this chapter was written. We, therefore, did not attempt to review all the works. We chose to cite the pioneering works, then to focus on the more recent works dealing with the more challenging topic of filling SWNTs.

In Situ Filling Method

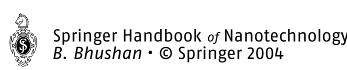
Most of the first hybrid carbon nanotubes ever synthesized were directly obtained in the course of their processing. This concerns only MWNTs, prepared by the arc-discharge method in its early hours, for which the filling materials were easily introduced in the system by drilling a central hole in the anode and filling it with the heteroelements. First attempts were all reported the same year [3.174–178], with elements such as Pb, Bi, YC_2, TiC, etc. Later on, *Loiseau* et al. [3.179] showed that MWNTs could also be filled to several μm in length by elements such as Se, Sb, S, and Ge, but only as nanoparticles with elements such as Bi, B, Al and Te. Sulfur was suggested to play an important role during the in situ formation of filled MWNTs by arc-discharge [3.180]. This technique is no longer the preferred one because of the difficulty in controling the filling ratio and yield and in achieving mass production.

Wet Chemistry Filling Method

The wet chemistry method requires the opening of the nanotubes tips by chemical oxidation prior to the filling step. This is generally obtained by refluxing the nanotubes in diluted nitric acid [3.181–183], although other oxidizing liquid media may work as well, e.g. $[HCl + CrO_3]$ [3.184] or chlorocarbenes formed from the photolytic dissociation of $CHCl_3$ [3.163] as a rare example of a nonacidic liquid route for opening SWNTs. If a dissolved form (salt, oxide, etc.) of the desired metal is meanwhile introduced during the opening step, some of it will get inside the nanotubes. An annealing treatment (after washing and drying of the treated nanotubes) may then lead to the oxide or to the metal, depending on the annealing atmosphere [3.162]. Although the wet chemistry method looked promising because a wide variety of materials can be introduced within nanotubes this way, and because it operates at temperature not much different from room temperature, attention has to be paid to the oxidation method that has to be carried out as the first steps. The damages brought to the nanotubes by severe treatments (e.g., nitric acid) make them improper for use with SWNTs. Moreover, the filling yield is not very important, as a probable consequence of the presence of the solvent molecules that also enter the tube cavity, and the subsequent filled lengths rarely exceed 100 nm. Recent results have been obtained, however, using wet chemistry filling by *Mittal* et al. [3.184] who have filled SWNTs ropes by CrO_3 with an average yield of $\sim 20\%$.

Molten State Filling Method

The physical method involving a liquid (molten) phase is more restrictive, first, because some materials may start decomposing when they melt, and second because the melting point has to be compatible with the nanotubes, i. e. thermal treatment temperature should remain below the temperature of transformation or damaging



of the nanotubes. Because the filling is occurring by capillarity, the surface tension threshold of the molten material was found to be 100–200 N/cm^2 [3.185]. But this threshold was proposed for MWNTs, whose inner diameters (5–10 nm) are generally larger than those of SWNTs (1–2 nm). In a typical filling experiment, the MWNTs are closely mixed with the desired amount of filler by gentle grinding, and the mixture is then vacuum-sealed in a silica ampoule. The ampoule is then slowly heated to a temperature above the melting point of the filler, then is slowly cooled. The use of this method does not require any opening of the nanotubes prior to the heat treatment. The mechanism of nanotube opening is not yet established clearly, but it is certainly related to the chemical aggressivity of the molten materials toward carbon and more precisely toward graphene defects in the tube structure (see Sect. 3.4.4).

Most of the works on SWNTs involving this method were performed by Sloan and coworkers at Oxford University [3.187], although other groups followed the same procedure [3.86, 181, 183]. Precursors to fill the nanotubes were mainly metals halides. Although little is known yet about the physical properties of halides crystallized within carbon nanotubes, the crystallization itself of molten salts within small diameter SWNTs has been studied in detail, revealing a strong interaction between the one-dimensional crystals and the surrounding graphene wall. For example, *Sloan* et al. [3.188] have described two-layer 4 : 4 coordinated KI crystals formed within SWNTs of around 1.4 nm diameter. These two-layer crystals are "all surface" and have no "internal" atoms. Significant lattice distortions occur compared to the bulk structure of KI, where the normal coordinence is 6 : 6 (meaning that each ion is surrounded by six identical closer neighbors). Indeed, the distance between two ions across the SWNT capillary is 1.4 times the same distance along the tube axis. This denotes an accommodation of the KI crystal to the confined space provided by the inner nanotube cavity in the constrained crystal direction (across the tube axis). This implies that the interactions between the ions and the surrounding carbon atoms are strong. The volume dimension available within the nanotubes thus somehow controls the crystal structure of inserted materials. For instance, the structure and orientation of encapsulated PbI_2 crystals inside their capillaries were found to arrange in different ways inside SWNTs and DWNTs, with respect to the diameter of the confining nanotubes [3.186]. In the case of SWNTs, most of the obtained encapsulated one-dimensional PbI_2 crystals exhibit a strong preferred orientation with their (110) planes aligning at an angle of ca. 60° to the SWNT axes as shown in Fig. 3.24a and 3.24b. Due to the extremely small diameter of the nanotube capillaries, individual crystallites are often only a few polyhedral layers thick, as outlined in Fig. 3.24d to 3.24h. As a result of lattice terminations enforced by capillary confinement, the edging polyhedra must be of reduced coordination, as indicated in Fig. 3.24g and 3.24h. In the case of PbI_2 formed inside DWNTs, similar crystal growth behavior was generally observed to occur in narrow nanotubes with diameters comparable to that of SWNTs. As the diameter of the encapsulating capillaries increases, however, different preferred orientations are frequently observed (Fig. 3.25). In this example, the PbI_2 crystal is oriented with the [121] direction parallel to the direction of the electron beam (Fig. 3.25a to 3.25d). If the PbI_2@DWNT hybrid is viewed "side-on" (as indicated by the arrow in Fig. 3.25e) polyhedral slabs are seen to arrange along the capillary, oriented at an angle of ca. 45° with respect to the tubule axis.

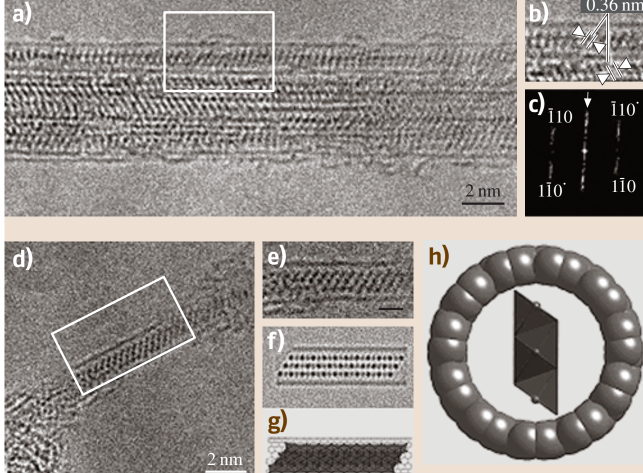


Fig. 3.24 HRTEM images and corresponding structural model for PbI_2 filled SWNTs (from [3.186])

Sublimation Filling Method

This method is even more restrictive than the previous one, since it is applicable only to a very limited number of compounds due to the requirement for the filling materials to sublimate within the temperature range of thermal stability of the nanotubes. Examples are therefore few. Actually, except for an attempt to fill SWNTs with $ZrCl_4$ [3.189], the only example published so far is the formation of C_{60}@SWNT (whose popular nickname

is "peapods"), reported for the first time in 1998 [3.190], where regular ~ 1.4 nm large SWNTs are filled with C_{60} fullerene molecule chains (Fig. 3.26a). Of course, the process requires a pre-opening of the SWNTs by some method, as discussed previously, typically either acid attack [3.191] or heat-treatment in air [3.192]. Then the opened SWNTs are put into a sealed glass tube together with fullerene powder and placed into a furnace heated above the sublimation temperature for fullerite (>~ 350 °C). Since there is no limitation related to Laplace's law or the presence of solvent since only gaseous molecules are involved, filling efficiency may actually reach ~ 100% [3.192].

Remarkable behaviors have been revealed since then, such as the ability of the C_{60} molecules to move freely within the SWNT cavity (Fig. 3.26b and 3.26c) upon random ionization effects from electron irradiation [3.193], or to coalesce into 0.7 nm large inner elongated capsules upon electron irradiation [3.194], or into a 0.7 nm large nanotube upon subsequent thermal treatment above 1,200 °C [3.193, 195]. Annealing of C_{60}@SWNT materials may thus appear as an efficient way to produce DWNTs with nearly constant inner (~ 0.7 nm) and outer (~ 1.4 nm) diameters. DWNTs produced this way are actually the smallest MWNTs synthesized so far.

Based on the successful synthesis of so-called endofullerenes previously achieved [3.13], further development of the process has recently led to the synthesis of more complex nanotube-based hybrid materials such as La_2@C_{80}@SWNTs [3.196], Gd@C_{82}@SWNTs [3.197], or $Er_xSc_{3-x}N$@C_{80}@SWNT [3.198] among other examples. These provide even more extended perspective regarding the potential applications of peapods, which are still being investigated.

Finally the last example to cite is the successful attempt to produce peapods by a related method, by using accelerated fullerene ions (instead of neutral gaseous molecules) to enforce the fullerenes to enter the SWNT structure [3.199].

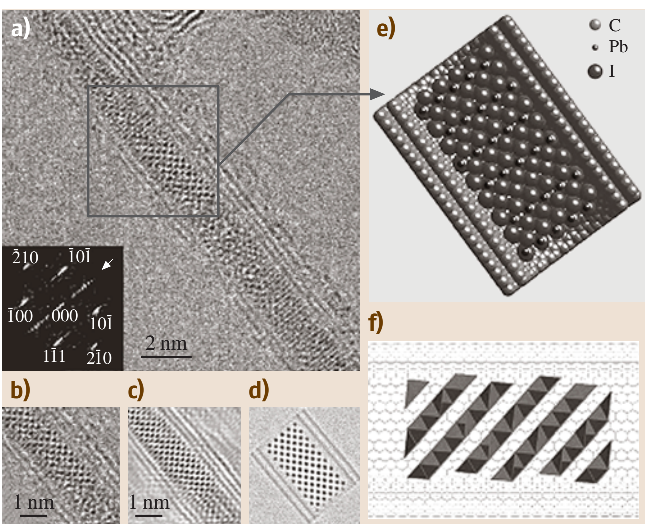

Fig. 3.25 HRTEM images (experimental and simulations), and corresponding structural model for a PbI_2 filled double-wall carbon nanotube (from [3.186])

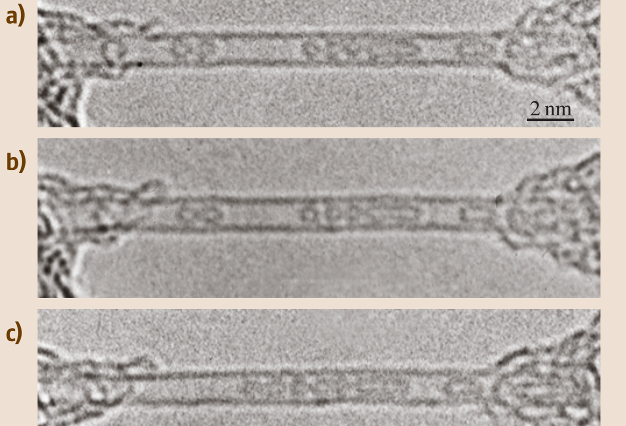

Fig. 3.26a–c HRTEM images of **(a)** example of five regular C_{60} molecules encapsulated together with two higher fullerenes (C_{120} and C_{180}) as distorted capsules (*on the right*) within a regular 1.4 nm diameter SWNT. **(a)–(c)** Example of the diffusion of the C_{60}-molecules along the SWNT cavity. The time between each image of the sequence is about 10 s. The fact that nothing occurs between **(a)** and **(b)** reveals the randomness of the ionisation events generated by the microscope electron beam and assumed to be responsible for the molecule displacement

3.5.3 Functionalized Nanotubes

Based on the reactivity of carbon nanotubes as discussed in Sect. 3.4.6, the functionalization reactions can be divided into two main groups. One is based on the chemical oxidation of the nanotubes (tips, structural defects) leading to carboxylic, carbonyl, and/or hydroxyl functions. These functions are then used for additional reactions, to attach oligomeric or polymeric functional entities. The second group is based on direct addition to the graphitic-like surface of the nanotubes (i. e. without any intermediate step). Examples of the latter reactions

include oxidation or fluorination (an important first step for further functionalization with other organic groups). Properties and applications of functionalized nanotubes have been reviewed recently [3.200].

Oxidation of Carbon Nanotubes

Carbon nanotubes are often oxidized and therefore opened before chemical functionalization to increase their chemical reactivity (creation of dangling bonds). Chemical oxidation of nanotubes is mainly achieved using either wet chemistry or gaseous oxidants such as oxygen (typically air) or CO_2. Depending on the synthesis process, the oxidation resistance of the nanotubes can vary. When oxidation is carried out through gas phases, thermo-gravimetric analysis (TGA) is of great use to determine at which temperature the treatment should be applied. It is important to know that TGA accuracy increases as the heating rate diminishes, while the literature often provides TGA analyses obtained in nonoptimized conditions, leading to overestimated oxidation temperatures. The presence of catalyst remnants (metals, more rarely oxides), the type of nanotubes (SWNTs, c-MWNTs, h-MWNTs), and the oxidizing agent (air, O_2 is an inert gas, CO_2, etc.) as well as the flow rate used make difficult the comparison of published results. It is generally agreed, however, that amorphous carbon burns first, followed by SWNTs and then multiwall materials (shells, MWNTs), even if TGA is often unfortunately not able to clearly separate the different oxidation steps. The more common method used for nanotube oxidation is that of aqueous solutions of oxidizing reagents. The main one is nitric acid, either concentrated or diluted (around 3 moles per liter in most cases), but oxidants such as potassium dichromate ($K_2Cr_2O_7$), hydrogen peroxide (H_2O_2), or potassium permanganate ($KMnO_4$) are very often used as well. HCl, like HF, do not damage nanotubes because these acids are not oxidizing.

Functionalization of Oxidized Carbon Nanotubes

Carboxylic groups located at the nanotube tips can be coupled with different chemical groups. Oxidized nanotubes are usually reacted with thionyl chloride ($SOCl_2$) to generate the acyl chloride, even if a direct reaction is theoretically possible with alcohols or amines, for example. Reaction of SWNTs with octadecylamine (ODA) was reported by *Chen* et al. [3.201] after reaction of oxidized SWNTs with $SOCl_2$. The functionalized SWNTs have substantial solubility in chloroform ($CHCl_3$), dichloromethane (CH_2Cl_2), aromatic solvents, and carbon bisulfide (CS_2). Many other reactions between functionalized nanotubes (after reaction with $SOCl_2$) and amines have been reported in the literature and will not be reviewed here. Noncovalent reactions between the carboxylic groups of oxidized nanotubes and octadecylammonium ions are possible [3.202], providing solubility in tetrahydrofuran (THF) and CH_2Cl_2. Functionalization by glucosamine using similar procedures [3.203] allowed the water solubilization of SWNTs, which is of special interest when considering biological applications of functionalized nanotubes. Functionalization with lipophilic and hydrophilic dendra (with long alkyl chains and oligomeric poly(ethyleneglycol) groups) has been achieved by amination and esterification reactions [3.204], leading to solubility of the functionalized nanotubes in hexane, chloroform, and water. It is interesting to note that in the latter case, the functional groups could be removed just by modifying the pH of the solution (base- and acid-catalyzed hydrolysis reaction conditions, [3.205]). A last example is the possible interconnection of nanotubes via chemical functionalization. This has been recently achieved by *Chiu* et al. [3.206] using the already detailed acyl chloride way and a bifunctionalized amine to link the nanotubes by the formation of amide bonds.

Sidewall Functionalization of Carbon Nanotubes

The covalent functionalization of the nanotube walls is possible by means of fluorination reactions. It was first reported by *Mickelson* et al. [3.207], with F_2 gas (the nanotubes can then be defluorinated, if required, with anhydrous hydrazine). As recently reviewed by *Khabashesku* et al. [3.208], it is then possible to use these fluorinated nanotubes to carry out subsequent derivatization reactions. Thus, sidewall-alkylated nanotubes can be prepared by nucleophilic substitution (Grignard synthesis or reaction with alkyllithium precursors [3.209]). These alkyl sidewall groups can be removed by air oxidation. Electrochemical addition of aryl radicals (from the reduction of aryl diazonium salts) to nanotubes has also been reported by *Bahr* et al. [3.210]. Functionalization of the nanotube external wall by cycloaddition of nitrenes, addition of nuclephilic carbenes, or addition of radicals has been described by *Holzinger* et al. [3.211]. Electrophilic addition of dichlorocarbene to SWNTs occurs by reaction with the deactivated double bonds in the nanotube wall [3.212]. Silanization reactions are another way to functionalize nanotubes, although only tested with MWNTs. *Velasco-Santos* et al. [3.213] have reacted oxidized MWNTs with an organosilane ($RsiR'_3$,

with R being an organo-functional group attached to silicon) and obtained organo-functional groups attached to the nanotubes by silanol groups.

Noncovalent sidewall functionalization of nanotubes is important because the covalent bonds are associated with changes from sp^2 to sp^3 in the hybridization of the carbon atoms involved, which corresponds to a loss of the graphite-like character. As a consequence, physical properties of functionalized nanotubes, specifically SWNTs, may be modified. One possibility for achieving noncovalent functionalization of nanotubes is to wrap the nanotubes in a polymer [3.214], which allows their solubilization (thus improving the processing possibilities) while preserving their physical properties.

Finally, it is worth keeping in mind that all these chemical reactions are not specific to nanotubes and may occur to most of the carbonaceous impurities present in the raw materials. This makes difficult the characterization of the functionalized samples and thus requires one to perform the experiments starting with very pure carbon nanotube samples, which is unfortunately not always the case for the results reported in the literature. On the other hand, purifying the nanotubes to start with may also bias the functionalization experiments since purification requires chemical treatments. But the demand for such products does exist already, and purified then fluorinated SWNTs can be found on the market at $ 900/g (Carbon Nanotechnologies Inc., 2003).

3.6 Applications of Carbon Nanotubes

Carbon nanotubes can be inert and can have a high aspect ratio, high tensile strength, low mass density, high heat conductivity, large surface area, and versatile electronic behavior including high electron conductivity. While these are the main characteristics of the properties for individual nanotubes, a large number of them can form secondary structures such as ropes, fibers, papers, thin films with aligned tubes, etc., with their own specific properties. The combination of these properties makes them ideal candidates for a large number of applications provided their cost is sufficiently low. The cost of carbon nanotubes depends strongly on both the quality and the production process. High quality single shell carbon nanotubes can cost 50–100 times more than gold. But synthesis of carbon nanotubes is constantly improving, and sale prizes fall by 50% per year. Application of carbon nanotubes is therefore a very fast moving area with new potential applications found every year, even several times per year. Making an exhaustive list is again a challenge we will not take. Below are listed applications considered "current" (Sect. 3.6.1) either because already marketed, or because up-scaling synthesis is being processed, or because prototypes are currently developed by profit-based companies. Other applications are said to be "expected" (Sect. 3.6.2).

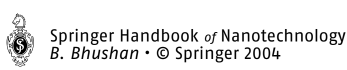
3.6.1 Current Applications

High mechanical strength of carbon nanotubes makes them a near to ideal force sensor in scanning probe microscopy (SPM) with a higher durability and the ability to image surfaces with a high lateral resolution, the latter being a typical limitation of conventional force sensors (ceramic tips). The idea was first proposed and experimented by Dai et al. [3.77] using c-MWNTs. It was extended to SWNTs by *Hafner* et al. [3.215], since small diameters of SWNTs were supposed to bring higher resolution than MWNTs due to the extremely short radius of curvature of the tube end. But commercial nanotube-based tips (e.g., Piezomax, Middleton, WI, USA) use MWNTs for processing convenience. It is also likely that the flexural modulus of SWNTs is too low and therefore induces artifacts affecting the lateral resolution when scanning a rough surface. On the other hand, the flexural modulus of c-MWNTs is supposed to increase with the number of walls, but the radius of curvature of the tip meanwhile increases.

Near-Field Microscope Probes

SWNT or MWNT, such nanotube-based SPM tips also offer the perspective of being functionalized, in the prospect of making selective images based on chemical discrimination by "chemical force microscopy" (CFM). Chemical function imaging using functionalized nanotubes represents a huge step forward in CFM because the tip can be functionalized very accurately (ideally at the very nanotube tip only, where the reactivity is the highest), increasing the spatial resolution. The interaction between chemical species present at the end of the nanotube tip and a surface containing chemical functions can be recorded with great sensitivity, allowing the chemical mapping of molecules [3.216, 217].

Today the cost of nanotube-based SPM tips is in the range of $ 200/tip. Such a high cost is explained both



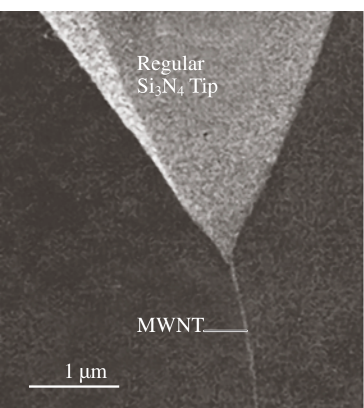


Fig. 3.27 Scanning electron microscopy image of a carbon nanotube (MWNT) mounted onto a regular ceramic tip as a probe for atomic force microscopy

by the processing difficulty, which ideally requires one to grow or mount a single MWNT in the appropriate direction at the tip of a regular SPM probe (Fig. 3.27), and by the need to individually control the tip quality. Such a market has been estimated at $\sim$ \$ 20 M/year.

Field Emission-Based Devices

Based on a pioneering work by *de Heer* et al. [3.218], carbon nanotubes have been demonstrated to be efficient field emitters and are currently being incorporated in several applications, including flat panel display for television sets or computers (whose a first prototype was exhibited by Samsung in 1999) or any devices requiring an electron producing cathode, such as X-ray sources. The principle of a field-emission-based screen is demonstrated in Fig. 3.28a. Briefly, a potential difference is brought between emitting tips and an extraction grid so that electrons are taking out from the tips and sent onto an electron sensitive screen layer. Replacing the glass support and protection of the screen by some polymer-based material will even allow the develope of flexible screens. As opposed to regular (metallic) electron emitting tips, the structural perfection of carbon nanotubes allows higher electron emission stability, higher mechanical resistance, and longer life time. First of all, it allows energy savings since it needs lower (or no) heating temperature of the tips and requires much lower threshold voltage. As an illustration for the latter, producing a current density of 1 mA/cm^2 is possible for a threshold voltage of 3 V/µm with nanotubes, while it requires 20 V/µm for graphite powder and 100 V/µm for regular Mo or Si tips. The subsequent reductions in cost and energy consumption are estimated at 1/3 and 1/10 respectively. Generally speaking, the maximum current density obtainable ranges between 10^6 A/cm^2 and 10^8 A/cm^2 depending on the nanotubes involved (e.g., SWNT or MWNT, opened or capped, aligned or not) [3.219–221]. Although nanotube side-walls seem to emit as well as nanotube tips, many works have dealt (and are still dealing) with growing nanotubes perpendicular to the substrate surface as regular arrays (Fig. 3.28b). Besides, using SWNTs instead of MWNTs does not appear necessary for many of these applications when they are used as bunches. On the other hand, when considering single, isolated nanotubes, SWNTs are generally less preferable since they allow much lower electron doses than do MWNTs, although they are likely meanwhile to provide an even higher coherent source (an useful feature for devices such as electron microscopes or X-ray generators).

The market associated with this application is huge. With such major companies involved as Motorola, NEC, NKK, Samsung, Thales, Toshiba, etc., the first commercial flat TV sets and computers using nanotube-based screens are about to be seen in stores, and companies such as Oxford Instruments and Medirad are about to commercialize miniature X-ray generators for medical applications on the basis of nanotube-based cold cathodes developed by Applied Nanotech Inc.

Chemical Sensors

The electrical conductance of semiconductor SWNTs was recently demonstrated to be highly sensitive to the change in the chemical composition of the surround-

ing atmosphere at room temperature, due to the charges transfer between the nanotubes and the molecules from the gases adsorbed onto the SWNT surface. It has also been shown that there is a linear dependence between the concentration of the adsorbed gas and the difference in electrical properties, and that the adsorption is reversible. First tries involved NO_2 or NH_3 [3.222] and O_2 [3.223]. SWNT-based chemical NO_2 and NH_3 sensors are characterized by extremely short response time (Fig. 3.29), thus being different from conventionally used sensors [3.222, 224]. High sensitivity toward water or ammonia vapors has been measured on SWNT-SiO_2 composite [3.225]. This study indicated the presence of p-type SWNTs dispersed among the predominant metallic SWNTs, and that chemisorption of gases on the surface of the semiconductor SWNTs is responsible for the sensing action. The determination of CO_2 and O_2 concentrations on SWNT-SiO_2 composite has also been reported [3.226]. By doping nanotubes with palladium nanoparticles, *Kong* et al. [3.227] have also shown that the modified material could reveal the presence of hydrogen up to 400 ppm whereas the as-grown material was totally ineffective.

Generally speaking, the sensitivity of the new nanotube-based sensors is three orders of magnitude higher than that of standard solid state devices. In addition, the interest in using nanotubes as opposed to current sensors is the simplicity and the very small size of the system in which they can be placed, the fact that they can operate at room temperature, and their selectivity, which allows a limited number of sensor device architectures to be built for a variety of industrial purposes, while the current technology requires a large diversity of devices based on mixed metal oxide, opto-mechanics, catalytic beads, electrochemistry, etc. The market opportunity is expected to be $ 1.6 billion by 2006, including both the biological area and the chemical industrial area. Nanotube-based sensors are currently developed in both large and small companies, such as Nanomix (USA), for example.

Catalyst Support

Carbon materials are attractive supports in heterogeneous catalytic processes due to their ability to be tailored to specific needs: indeed, activated carbons are already currently employed as catalyst supports because of their high surface area, their stability at high temperatures (under not oxidizing atmosphere), and the possibility of controlling both their porous structure and the chemical nature of their surface [3.228, 229]. The attention has been brought to nano-sized fibrous morphologies of carbon that appeared during the last decade, showing novel interesting potentialities as supports [3.230]. Carbon nanofibers (also improperly called graphite nanofibers) and carbon nanotubes have been used successfully and shown to present, as catalyst-supporting materials, properties superior to that of such other regular catalyst-supports as activated carbon, soot, or graphite [3.231]. The use of graphite nanofibers as a direct catalyst for oxidative dehydrogenation has also been reported [3.232].

The morphology and size of carbon nanotubes, especially since they do present huge lengths vs. diameters (= aspect ratio), can play a significant role in catalytic applications due to their ability to disperse catalytically active metal particles. Their electronic properties are also of primary importance [3.233] since this conductive support may be exerting electronic perturbation as well as geometric constraint on the dispersed metal particles. A recent comparison between the interaction of transition metal atoms with carbon nanotube walls

and that with graphite indicates major differences in bonding sites, magnetic moments, and charge-transfer direction [3.234]. Thus the possibility of strong metal-support interaction has to be taken into account. Their mechanical strength is also important and makes them resistant to attrition in view of recycling. Their external or internal surface presents strong hydrophobicity and strong adsorption ability toward organic molecules. Finally, for MWNT-based catalyst-supports, the relatively high surface area and the absence of microporosity (i. e., pores < 2 nm) associated with a high meso- and macropore volume (see Sect. 3.4.3) result in significant improvements of the catalytic activity, in the case of liquid-phase reactions when compared to catalysts supported on activated carbon. With nanotube supports, the mass transfer limitation of the reactants to the active sites is actually prevented due to the absence of microporosity, and the apparent contact time of the products with the catalyst is diminished, leading to more active and more selective catalytic effects.

The most widely used technique to prepare carbon nanotube-supported catalysts is the incipient wetness impregnation, in which the purified support is impregnated with a solution of the metal precursor, then dried, calcinated and/or reduced in order to obtain metal particles dispersed on the support. The chemical treatment and/or the modification of the carbon nanotube surface was found to be a useful tool to control its hydrophobic or hydrophilic character [3.236]. A strong metal/support interaction can thus be expected from the occurrence of functionalized groups created by the oxidation of the support surface, resulting in smaller particle sizes [3.237]. A more sophisticated technique to achieve the grafting of metal particles onto carbon nanotubes consists of functionalizing the outer surface of the tubes and then performing a chemical reaction with a metal complex, thus resulting in a good dispersion of the metallic particles (Fig. 3.30) [3.235].

Fig. 3.30 Transmission electron microscopy image showing rhodium nanoparticles supported on MWNT surface (from [3.235])

Selected examples of some carbon nanotube-based catalysts together with the related preparation routes and catalytic activities are listed in Table 3.4.

The market is huge for this application since it most often concerns the "heavy" chemical industry. It implies and requires mass production of low-cost nanotubes, processed by methods other than solid-carbon-source-based methods (see Sect. 3.2.1). Such an application also requires some surface reactivity, making the h-MWNT type nanotubes with a poor nanotexture (see Sect. 3.1.2) the most suitable starting material for preparing such catalyst supports. Catalysis-enhanced thermal cracking of gaseous carbon precursors is therefore preferred, and pilot plants are already being built by major chemical industrial companies (e.g., Ato-Fina, France).

3.6.2 Expected Applications Related to Adsorption

The adsorption and interaction of gases, liquids, or metal with carbon nanotubes has attracted much attention in the past several years. The applications resulting from the adsorption properties of carbon nanotubes can be arbitrarily divided into two groups. The first group is based on the consequences of molecule adsorption on nanotube electronic properties, whose main application is the chemical sensors (see Sect. 3.6.1). The second group includes gas storage, gas separation, or the use of carbon nanotubes as adsorbent and results from the morphological characteristics of carbon nanotubes (surface area, aspect ratio, and so forth). Among the three latter potential applications, the possibility of storing gases, and more particularly hydrogen, on carbon nanotubes has received most of the attention.

Table 3.4 Preparation and catalytic performances of some nanotube-supported catalysts

Catalyst	Preparation route	Catalytic reaction	Comments
Ru/MWNT+SWNT [3.230]	Liquid phase impregnation, no pretreatment of the tubes	Liquid phase cinnamaldehyde hydrogenation	Different kind of metal support interaction compared to activated carbon
Pt/MWNT electrodes [3.149]	Electrode-less plating with pre-functionalization of MWNT	Oxygen reduction for fuel cells applications	High electrocatalytic activity
Rh/MWNT [3.235]	Surface mediated organometallic synthesis, pre-functionalization of MWNT	Liquid phase hydroformylation and hydrogenation	Higher activity of Rh/MWNT compared to Rh/activated carbon
Ru-alkali/MWNT [3.238]	Liquid phase impregnation, no pretreatment of the tubes	Ammonia synthesis, gas phase reaction	Higher activity with MWNT than with graphite
Rh-phosphine/MWNT [3.239]	Liquid phase grafting from $[RhH(CO)(PPh_3)_3]$	Liquid phase hydroformylation	Highly active and regioselective catalyst

Gas Storage – Hydrogen

The development of lightweight and safe system for hydrogen storage is necessary for a wide use of highly efficient H_2-air fuel cells in transportation vehicles. The U.S. Department of Energy Hydrogen Plan has set a standard by providing a commercially significant benchmark for the amount of reversible hydrogen adsorption. This benchmark requires a system-weight efficiency (the ratio of H_2 weight to system weight) of 6.5 wt% hydrogen and a volumetric density of 63 kgH_2/m^3.

From now on, the failure to produce a practical storage system for hydrogen has prevented hydrogen from coming to the commercial forefront as a transportation fuel. The ideal hydrogen storage system needs to be light, compact, relatively inexpensive, safe, easy to use, and reusable without the need for regeneration. While research and development are continuing on such technologies as liquid hydrogen systems, compressed hydrogen systems, metal hydride systems, and superactivated carbon systems, all have serious disadvantages. For example, liquid hydrogen systems are very expensive, primarily because the hydrogen must be cooled to about −252 °C. For example, a liquid hydrogen system will cost about four times more than an equivalent amount of gasoline. Further, liquid hydrogen must be kept cooled to prevent it from boiling away, even when the vehicle is parked.

Compressed hydrogen is much cheaper than liquid hydrogen but also much bulkier.

Metal hydride systems store hydrogen as a solid in combination with other materials. For example, metal hydrides are produced by bathing a metal, such as palladium or magnesium, in hydrogen. The metal splits the dihydrogen gas molecules and binds the hydrogen atoms to the metal until released by heating. The disadvantages of a metal hydride system are its weight (typically about eight times more than an equivalent amount of liquid hydrogen or an equivalent amount of gasoline) and the need to warm it up to release the hydrogen.

Superactivated carbon is the basis of another system for storing hydrogen that initially showed commercial potential. Superactivated carbon is a material similar to the highly porous activated carbon used in water filters but can gently hold hydrogen molecules by physisorption at sub-zero temperatures. The colder the carbon, the less heat is needed to disturb the weak forces holding the carbon and hydrogen together. Again, a major disadvantage of such a system is that preventing the hydrogen from escaping requires it to constantly remain at very low temperatures, even when the vehicle is parked.

Consequently there still remains a great need for a material that can store hydrogen and is light, compact, relatively inexpensive, safe, easy to use, and reusable without regeneration. Recently some articles or patents concerning the very high, reversible adsorption of hydrogen in carbon nanotubes or platelet nanofibers have aroused tremendous interest in the research community, stimulating much experimental and theoretical works. Most of the works on hydrogen adsorption on carbon nanotubes have been recently reviewed [3.240–243].

A group from Northeastern University [3.132, 244] was the first to report the supposedly successful hydrogen storage in carbon layered nanostructures possessing some crystallinity. The authors claimed that, in platelet nanofibers (3–50 nm in width), hydrogen can be stored up to 75 wt%, meaning a C/H ratio of 1/9. Complete

hydrogen desorption occurs only at very high temperature. The same authors have recently pointed out the dramatic role of the treatment that has to be applied to the carbon nanofibers prior to H_2 adsorption [3.244]. This thermal treatment, though simple (1,000 °C in an inert gas), is a critical procedure in order to remove chemisorbed gases from the edge and step regions of the carbon structures. Failure to achieve this condition results in a dramatic decrease in the hydrogen adsorption performance of the materials. In this work, the authors have performed the experiments at room temperature, and 100 bar of H_2, hydrogen uptake between 20 and 40 wt% were recorded. The authors have also demonstrated by XRD measurements that structural perturbation of the material was produced following hydrogen treatment, and that it was manifested by an expansion of the graphitic interplane distance (from 0.34 before H_2 adsorption to 0.347 after H_2 uptake).

Hydrogen adsorption and desorption measurements on nanofibers similar to that used by *Rodriguez* et al. [3.19] were also performed by *Ahn* et al. [3.245]. The authors have measured a hydrogen uptake of 2.4 wt%. In fact, in their study, none of the graphite nanofiber material tested has indicated hydrogen storage abilities that exceed the values already reported for activated carbons.

Adsorption of H_2 on platelet nanofibers was computed by Monte Carlo simulations [3.246]. The graphene spacing was optimized to maximize the weight fraction of H_2 adsorbed. Given the results of their calculations, the authors concluded that no physically realistic graphite-hydrogen potential can account for the tremendous adsorption ability reported by the group from Penn State.

Rzepka et al. [3.247] have also used theoretical Monte Carlo calculation to calculate the amount of physically adsorbed hydrogen molecules in carbon slit pores of dimensions similar to that used by the Penn State group (i. e., 0.34 nm as the interplanar distance between graphenes in the nanofibers). They reached the conclusion that no hydrogen can be adsorbed at all. Even if the interplanar distance is assumed to expand during the adsorption process, the maximum calculated adsorption is 1 wt% for $d = 0.7$ nm. These authors concluded that the Penn State experimental results could not be attributed to some "abnormal capillary condensation effect" as initially claimed. Since then, nobody has been able to duplicate it experimentally.

Meanwhile, hydrogen storage experiments were also attempted on SWNTs. The first work was reported by *Dillon* et al. [3.248] who used temperature-programmed desorption measurements. A major drawback of their experimental procedure was that they used only 1 mg of *unpurified* soot containing 0.1% of SWNTs. They attributed the reversible hydrogen capacity of 0.01 wt% observed to the SWNTs only, therefore leading to a presumable capacity of 5–10 wt% for a pure nanotubes sample. TPD experiments shown H_2 desorption between −170 and +100 °C. Despite the weakness of the demonstration, the paper, which was published not much before that of Chambers et al. [3.132], has induced a worldwide excitement for the field.

Hydrogen adsorption measurements were also performed on SWNT samples of high purity [3.249]. At −193 °C, 160 bar of H_2 were admitted and the hydrogen adsorption was found to exceed 8 wt%. In this case, the authors proposed that hydrogen is first adsorbed on the outer surfaces of the crystalline material. But no data concerning H_2 desorption are given.

In recent reports, Dresselhaus and coworkers [3.240, 250] reported hydrogen storage in SWNTs (1.85 nm of average diameter) at room temperature. A hydrogen storage capacity of 4.2 wt% was achieved reproducibly under 100 bar for a SWNT-containing material of about 0.5 g that was previously soaked in hydrochloric acid and then heat-treated (500 °C) in vacuum. The purity of the sample was estimated from TGA and TEM observations to be about 50 to 60%. Moreover, 78% of the adsorbed hydrogen could be released under ambient pressure at room temperature, while the release of the residual stored hydrogen required some heating at 200 °C.

A valuable input to the topic was brought by *Hirscher* et al. [3.251], who demonstrated that several of the supposedly successful experiments regarding the storage of H_2 in SWNTs were actually misled by the hydrogen storage capacity of Ti nanoparticles originating from the sonoprobe frequently used at one step or another of the procedure, specifically when the SWNT material is previously purified.

Density functional theory (DFT) was used [3.252] to estimate H_2 adsorption in SWNTs. From their calculations, within the regime of operating conditions where adsorptive storage seems attractive, the storage properties of H_2 in a SWNT system appear to fall far short of the DOE target. In their model, rolling graphite into a cylindrical sheet does not significantly alter the nature of the carbon–H_2 interaction, in contradiction with the latest calculations, which indicate that the possibilities of physisorption increase as the radius of curvature of SWNTs decreases [3.253].

More recently, however, *Lee* et al. [3.254, 255] have also used DFT calculations to search for hydrogen ad-

sorption sites and predict maximum storage capacity in SWNTs. They have found two chemisorption sites, at the exterior and the interior of the tube wall. Thus they predict a maximum hydrogen storage capacity that can exceed 14 wt% (160 kgH_2/m^3). The authors have also considered H_2 adsorption in multiwall carbon nanotubes and have predicted lower storage capacities for the latter.

Calculations are constrained, however, by the starting hypotheses. While considering the same (10,10) SWNT, although calculations based on DFT predict a 14.3% storage [3.254], calculations based on a geometrical model predict 3.3% [3.240], and calculations based on quantum mechanical molecular dynamics model predict 0.47% [3.256].

In conclusion, neither the experimental results, obviously biased by some problem in the procedures, nor theoretical results are yet able to demonstrate that an efficient storage of H_2 is achievable for carbon nanotubes, whatever the type. But the definitive failure statement cannot yet be claimed. Further efforts have to be made to enhance H_2 adsorption of these materials, in particular (i) by adjusting the surface properties that can be modified by chemical or mechanical treatments, and (ii) by adjusting the material structure (pore size and curvature). Whether the best carbon material will then be nanotube-based is another story.

Gas Storage – Gases Other than Hydrogen

Encouraged by the potential applications related to hydrogen adsorption, several research groups have tried to use carbon nanotubes as a stocking and transporting mean for other gases such as: oxygen, nitrogen, noble gases (argon and xenon), and hydrocarbons (methane, ethane, and ethylene). These studies have shown that carbon nanotubes could become the world's smallest gas cylinders combining low weight, easy transportability, and safe use with acceptable adsorbed quantities. Thanks to their nano-sizes, nanotubes might also be used in medicine where physically confining special gases (like ^{133}Xe for instance) prior to injection would be extremely useful.

Kusnetzova et al. [3.257] have conducted experiments with xenon and found that a very significant enhancement (280 times more, up to a molar ratio $N_{Xe}/N_C = 0.045$) can be achieved by opening the SWNT bundles by thermal activation at 800 °C. With this treatment the gas can be adsorbed inside the nanotubes and the rates of adsorption are also increased.

The possibility of storing argon in carbon nanotubes has been studied with encouraging results by *Gadd* et al. [3.258]: their experiments show that large amounts of argon can be trapped into catalytically grown MWNTs (20–150 nm) by hot isostatic pressing (HIPing) for 48 hours at 650 °C under an argon pressure of 1,700 bar. Energy dispersive X-ray spectroscopy was used to determine that the gas was located inside the tubes and not on their walls. Further studies determined the argon pressure inside the tubes at room temperature. The authors estimated this feature to be around 600 bars, indicating that the equilibrium pressure was attained in the tubes during the HIP-ing and that MWNTs would be a convenient material for storing that gas.

Gas Separation

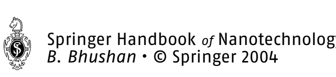
As SWNTs or MWNTs have regular geometries that can, to some extent, be controllable, they could be used to develop precise separation tools. If the sorption mechanisms are known, it should be possible to control sorption of various gases through combinations of temperature, pressure, and nanotube morphology. Since the large-scale production of nanotubes is now constantly progressing and may result in low costs, accurate separation methods based on carbon nanotubes have started to be investigated.

A theoretical study has aimed to determine the effect of different factors such as the diameter of the tubes, the density and the type of the gas used on the flow of molecules inside the nanotubes. An atomistic simulation with methane, ethane, and ethylene [3.259] has shown that the molecule mobility decreases with the decrease of the diameter of the tube for each of the three gases. Ethane and ethylene have a smaller mobility due to the stronger interaction they seem to have with the nanotube walls. In another theoretical study on the possibility of hydrocarbon mixture separation on SWNT bundles, the authors conclude on the possibility of using carbon nanotubes to separate methane/n-butane and methane/isobutene mixtures [3.260], with an efficiency that increases as the average tube diameter decreases. An experimental work was also performed by the same group on the sorption of butane on MWNTs [3.133].

Simulation by grand canonical Monte Carlo for separation of hydrogen and carbon monoxide by adsorption on SWNT has also been reported [3.261]. In most of the situations studied, SWNTs are found to adsorb more CO than H_2, and an excellent separation effect could probably be obtained, again, by varying the SWNT average diameter.

Adsorbents

Carbon nanotubes were recently found to be able to adsorb some toxic gases such as dioxins [3.262], fluo-



ride [3.263], lead [3.264], or alcohols [3.265] better than the materials used so far, such as activated carbon. These pioneering works opened a new field of applications as cleaning filters for many industrial processes having hazardous by-products. Adsorption of dioxins, which are very common and persistent carcinogenic by-products of many industrial processes, is a good example of the interest of nanotubes in this field. Ecological consciousness has imposed emission limits on dioxin-generating sources in many countries, but finding materials that can act as effective filters, even at extremely low concentrations, is a big issue. *Long* et al. [3.262] have found that nanotubes can attract and trap more dioxins than activated carbons or other polyaromatic materials that are currently used as filters. This improvement is probably due to the stronger interaction forces that exist between dioxin molecules and the nanotube curved surfaces compared to those for flat graphene sheets.

The adsorption capacity of Al_2O_3/MWNT for fluoride from water has been reported to be 13.5 times that of activated carbon and 4 times that of Al_2O_3 [3.263]. The same group has also reported an adsorption capacity of lead from water by MWNTs higher than that by activated carbon [3.264]. The possibility to using graphite nanofibers to purify water from alcohols has also been explored [3.265]. These experimental results suggest that carbon nanotubes may be promising adsorbents for the removal of polluting agents from water.

Bio-Sensors

Attaching molecules of biological interest to carbon nanotubes is an ideal way to realize nanometer-sized biosensors. Indeed, the electrical conductivity of such functionalized nanotubes would depend on modifications of the interaction of the probe with the studied media, because of chemical changes or as result of their interaction with target species. The science of attaching biomolecules to nanotubes is rather recent and was inspired by similar research in the fullerene area. Some results have already been patented, and what was looking like a dream a couple of years ago may become reality in the near future. The use of the internal cavity of nanotubes for drug delivery would be another amazing application, but little work has been carried out so far to investigate the harmfulness of nanotubes in the human body. MWNTs have been used by *Mattson* et al. [3.266] as a substrate for neuronal growth. They have compared the activity of untreated MWNTs with that of MWNTs coated with a bioactive molecule (4-hydroxynonenal) and observed that on these latter functionalized nanotubes, neurons elaborated multiple neurites. This is an important result illustrating the feasibility of using nanotubes as substrate for nerve cell growth.

Davis et al. [3.267] have immobilized different proteins (metallothionein, cytochrome c and c_3, β-lactamase I) in MWNTs and checked that these molecules were still catalytically active compared to the nonimmobilized ones. They have shown that confining a protein within a nanotube provides some protection toward the external environment. Protein immobilization via noncovalent sidewall functionalization was proposed by *Chen* et al. [3.268] by using a bifunctional molecule (1-pyrenebutanoic acid, succinimidyl ester). This molecule is maintained to the nanotube wall by the pyrenyl group, and amine groups or biological molecules can react with the ester function to form amid bonds. This method was also used to immobilize ferritin and streptavidin onto SWNTs. It has the main advantage of not modifying the SWNT wall and keeping unperturbed the sp^2 structure, maintaining the physical properties of the nanotubes. *Shim* et al. [3.269] have functionalized SWNTs with biotin and observed specific binding with streptavidin, illustrating biomolecular recognition possibilities. *Dwyer* et al. [3.270] have functionalized SWNTs by covalently coupling DNA strands to them using EDC(1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride) but did not test biomolecular recognition; other proteins such as bovine serum albumin (BSA) [3.271] have been attached to nanotubes using the same process (diimide-activated amidation with EDC) and most of the attached proteins remained bioactive. Instead of working with individual nanotubes (or more likely nanotube bundles in the case of SWNTs), *Nguyen* et al. [3.272] have functionalized nanotubes arrayed with a nucleic acid, still using EDC as the coupling agent, in order to facilitate the realization of biosensors based on protein-functionalized nanotubes. Recently *Azamian* et al. [3.273] have immobilized a series of biomolecules (cytochrome c, ferritin, and glucose oxydase) on SWNTs and observed that the use of EDC was not always necessary, indicating that the binding was predominantly noncovalent. In the case of glucose oxydase, they have tested the catalytic activity of functionalized nanotubes immobilized on a glassy carbon electrode and observed a tenfold greater catalytic response compared to that in the absence of modified SWNTs.

Functionalization of nanotubes with biomolecules is still in its infancy, and their use as biosensors may lead to practical applications earlier than expected. For example, functionalized nanotubes can be used as AFM tips (see Sect. 3.6.1) allowing to perform "chemical

force microscopy" (CFM), allowing single-molecule measurements. Even in the case of nonfunctionalized CNT-based tips, important improvements have been obtained for the characterization of biomolecules (see the review by [3.215]).

Composites

Because of their exceptional morphological, electrical, thermal, and mechanical characteristics, carbon nanotubes are particularly promising materials as reinforcement in composite materials with metal, ceramic, or polymer matrix. Key basic issues include the good dispersion of the nanotubes, the control of the nanotube/matrix bonding, the densification of bulk composites and thin films, and the possibility of aligning the nanotubes. In addition, the nanotube type (SWNT, c-MWNT, h-MWNT, etc.) and origin (arc, laser, CCVD, etc.) is also an important variable since determining the structural perfection, surface reactivity, and aspect ratio of the reinforcement.

Considering the major breakthrough that carbon nanotubes are expected to make in the field, the following will give an overview of the current work on metal-, ceramic- and polymer-matrix composites reinforced with nanotubes. We will not consider nanotubes merely coated with another material will not be considered here. We discussed filled nanotubes in Sect. 3.5.2. Applications involving the incorporation of nanotubes to materials for purposes other than structural will be mentioned in Sect. 3.6.2.

Metal Matrix Composites

Nanotube-metal matrix composites are still rarely studied. The materials are generally prepared by standard powder metallurgy techniques, but the dispersion of the nanotubes is not optimal. Thermal stability and electrical and mechanical properties of the composites are investigated. The room temperature electrical resistivity of hot-pressed CCVD MWNTs-Al composites increases slightly by increasing the MWNT volume fraction [3.274]. The tensile strength and elongation of nonpurified arc-discharge MWNT-Al composites are only slightly affected by annealing at 873 K in contrast to that of pure Al [3.275]. The Young's modulus of nonpurified arc-discharge MWNTs-Ti composites is about 1.7 times that of pure Ti [3.276]. The formation of TiC, probably resulting from the reaction between amorphous carbon and the matrix, was observed, but the MWNTs themselves were not damaged. An increase of the Vickers hardness by a factor 5.5 over that of pure Ti was associated with the suppression of coarsening of the Ti grains, the TiC formation, and the addition of MWNTs with an extremely high Young's modulus. CCVD MWNTs-Cu composites [3.277] also show a higher hardness and a lower friction coefficient and wear loss. A deformation of 50–60 % of the composites was observed. A MWNTs-metallic glass Fe82P18 composite [3.278] with a good dispersion of the MWNTS was prepared by the rapid solidification technique.

Ceramic Matrix Composites

Carbon nanotube-containing ceramic-matrix composites are a bit more frequently studied, most efforts made to obtain tougher ceramics [3.279]. Composites can be processed following the regular processing route, in which the nanotubes are usually mechanically mixed with the matrix (or a matrix precursor) then densified using hot-pressing sintering of the slurry or powders. *Zhan* et al. [3.280] ball-milled SWNT bundles (from the HiPCo technique) and nanometric alumina powders, producing a fairly homogeneous dispersion, supposedly without damaging the SWNTs. On the other hand, interesting results were obtained using the spark plasma sintering (SPS) technique, which was able to prepare fully dense composites without damage to the SWNTs [3.281]. Other original composite processing include sol-gel route, by which bulk and thin film composites were prepared [3.282], and in situ SWNT growth in ceramic foams, using procedures closely related to that described in Sect. 3.2.2 [3.283].

Ma et al. [3.284] prepared MWNT-SiC composites by hot-pressing mixtures of CCVD MWNTs and nano-SiC powders. They claimed that the presence of the MWNTs provides an increase of about 10% of both the bending strength and fracture toughness, but the dispersion of the MWNTs looks poor. Several detailed studies [3.82, 285–288] have dealt with the preparation of nanotube-Fe-Al_2O_3, nanotube-Co-MgO, and nanotube-Fe/Co-$MgAl_2O_4$ composites by hot-pressing of the corresponding composite powders. The nanotubes were grown in situ in the starting powders by a CCVD method [3.73, 80, 289–293] and thus are very homogeneously dispersed between the metal-oxide grains, in a way that could be impossible to achieve by mechanical mixing. The nanotubes (mostly SWNTs and DWNTs) gather in long, branched bundles smaller than 50 nm in diameter, which appear to be very flexible. Depending on the matrix and hot-pressing temperature, a fraction of the nanotubes seems to be destroyed during hot-pressing in a primary vacuum. The increase of the quantity of nanotubes (ca. 2–12 wt%) leads to a refinement of the microstructure but also to a strong decrease in rela-

tive density (70–93 %). Probably because of this, the fracture strength and the toughness of the nanotube-containing composites are generally lower than those of the nanotube-free metal-oxide composites and only marginally higher than those of the corresponding ceramics. SEM observations revealed both the trapping of some of the nanotubes within the matrix grains or at grain boundaries and a relatively good wetting in the case of alumina. Most nanotubes are cut near the fracture surface after some pull-out and could contribute to a mechanical reinforcement.

Siegel et al. [3.294] claimed that the fracture toughness of 10 vol.% MWNTs-alumina hot-pressed composites is increased by 24% (to 4.2 MPa $m^{1/2}$) over that of pure alumina. But the density and grain size are not reported, so it is difficult to consider this result as an evidence for the beneficial role of the MWNTs themselves. A confirmation could be found in the work by *Sun* et al. [3.281] who developed a colloidal route to coat the nanotubes with alumina particles prior to another mixing step with alumina particles then densification by SPS. A very large gain in fracture toughness (calculated from Vickers indentation) is reported (from 3.7 MPa $m^{1/2}$ for pure Al_2O_3 to 4.9 MPa $m^{1/2}$ for an addition of 0.1 wt% of SWNT nanotubes, and to 9.7 MPa $m^{1/2}$ for an addition of 10 wt%). But it is possible that the beneficial input of the nanotubes is due to the previous coating of the nanotubes before sintering, resulting in an improved bonding with the matrix.

Bulk properties other than mechanical are also worth being investigated. Interestingly, the presence of well dispersed nanotubes confers an electrical conductivity to the otherwise insulating ceramic-matrix composites. The percolation threshold is very low – in the range 0.2–0.6 wt% of carbon – due to the very high aspect ratio of nanotubes. Varying the nanotube quantity in the starting powders allows the electrical conductivity to be controlled in the range 0.01–10 S cm^{-1}. Moreover, the extrusion at high temperatures in vacuum allows the nanotubes to be aligned in the matrix, thus inducing an anisotropy in the electrical conductivity [3.295]. One of the early works involved MWNTs in a superconducting $Bi_2Sr_2CaCu_2O_{8+\delta}$ matrix [3.296]. The application of SWNTs for thermal management in partially stabilized zirconia [3.297] and of MWNTs-lanthanum cobaltate composites for application as an oxygen electrode in zinc/air [3.298] were reported more recently. The friction coefficient was also shown to increase and the wear loss to decrease upon the increase in nanotube volume fraction in carbon/carbon composites [3.299].

The latter is one of the few examples in which carbon has been considered as a matrix. Another one is the work reported by *Andrews* et al. [3.300], who introduced 5 wt% of SWNTs into a pitch material before spinning the whole as a SWNT-reinforced pitch-fiber. Subsequent carbonization transformed it into a SWNT-reinforced carbon fiber. Due to the contribution of the SWNTs, which were aligned by the spinning stresses, the resulting gain in tensile strength, modulus, and electrical conductivity with respect to the nonreinforced carbon fiber was claimed to be 90, 150, and 340%, respectively.

Polymer Matrix Composites

Nanotube-polymer composites, first reported by *Ajayan* et al. [3.301] are now intensively studied, notably epoxy- and polymethylmethacrylate (PMMA)-matrix composites. Regarding the mechanical characteristics, the three key issues affecting the performance of a fiber-polymer composite are the strength and toughness of the fibrous reinforcement, its orientation, and a good interfacial bonding crucial for the load transfer to occur [3.302]. The ability of the polymer to form large-diameter helices around individual nanotubes favors the formation of a strong bond with the matrix [3.302]. Isolated SWNTs may be more desirable than MWNTs or bundles for dispersion in a matrix because of the weak frictional interactions between layers of MWNTs and between SWNTs in bundles [3.302]. The main mechanisms of load transfer are micromechanical interlocking, chemical bonding, and van der Waals bonding between the nanotubes and the matrix. A high interfacial shear stress between the fiber and the matrix will transfer the applied load to the fiber over a short distance [3.303]. SWNTs longer than 10–100 μm would be needed for significant load-bearing ability in the case of nonbonded SWNT-matrix interactions, whereas the critical length for SWNTs cross-linked to the matrix is only 1 μm [3.304]. Defects are likely to limit the working length of SWNTs [3.305], however.

The load transfer to MWNTs dispersed in an epoxy resin was much higher in compression than in tension [3.303]. It was proposed that all the walls of the MWNTs are stressed in compression, whereas only the outer walls are stressed in tension because all the inner tubes are sliding within the outer. Mechanical tests performed on 5 wt% SWNT-epoxy composites [3.306] showed that SWNTs bundles were pulled out of the matrix during the deformation of the material. The influence of the nanotube/matrix interfacial interaction was evidenced by *Gong* et al. [3.307]. It was also reported that coating regular carbon fiber with MWNTs prior to their

dispersion into an epoxy matrix improves the interfacial load transfer, possibly by local stiffening of the matrix near interface [3.308].

As for ceramic matrix composites, the electrical characteristics of SWNT- and MWNT-epoxy composites are described with the percolation theory. Very low percolation threshold (below 1 wt%) is often reported [3.309–311]. Industrial epoxy loaded with 1 wt% unpurified CCVD-prepared SWNTs showed an increase in thermal conductivity of 70% and 125% at 40 K and at room temperature, respectively [3.309]. Also, the Vickers hardness rose with the SWNT loading up to a factor of 3.5 at 2 wt%. Thus both the thermal and mechanical properties of such composites are improved without the need to chemically functionalize the SWNTs.

Likewise, the conductivity of laser-prepared SWNT-PMMA composites increases with the load in SWNTs (1–8 wt% SWNTs) [3.302]. Thermogravimetric analysis shows that, compared to pure PMMA, the thermal degradation of PMMA films occurs at a slightly higher temperature when 26 wt% MWNTs are added [3.312]. Improving the wetting between the MWNTs and the PMMA by coating the MWNTs with poly(vinylidene fluoride) prior to melt-blending with PMMA resulted in an increased storage modulus [3.313]. The impact strength in aligned SWNT-PMMA composites was significantly increased with only 0.1 wt% of SWNTs, possibly because of a weak interfacial adhesion, and/or of the high flexibility of the SWNTs, and/or the pullout and sliding effects of individual SWNTs within bundles [3.314]. The transport properties of arc-discharge SWNTs-PMMA composite films (10 μm thick) were studied in great detail [3.315, 316]. The electrical conductivity increases by nine orders of magnitude from 0.1 to 8 wt% SWNTs. The room temperature conductivity is again well described with the standard percolation theory, confirming the good dispersion of the SWNTs in the matrix.

Polymer composites with other matrices include CCVD-prepared MWNT-polyvinyl alcohol [3.317], arc-prepared MWNT-polyhydroxyaminoether [3.318], arc-prepared MWNT-polyurethane acrylate [3.319, 320], SWNT-polyurethane acrylate [3.321], SWNT-polycarbonate [3.322], MWNT-polyaniline [3.323], MWNT-polystyrene [3.324], SWNT-polyethylene [3.325], CCVD-prepared MWNT-polyacrylonitrile. [3.326], MWNT-oxotitanium phthalocyanine [3.327], arc-prepared MWNT-poly(3-octylthiophene) [3.328], SWNT-poly(3-octylthiophene) [3.329], and CCVD MWNTs-poly(3-hexylthiophene) [3.330]. These works deal mainly with films 100–200 micrometer thick and aim to study the glass transition of the polymer, mechanical, and electrical characteristics as well as photoconductivity.

A great deal of work is also devoted to nano-tube-polymer composites for applications as materials for molecular optoelectronics, using primarily poly(m-phenylenevinylene-co-2,5-dioctoxy-p-phenylenevinylene) (PmPV) as the matrix. This conjugated polymer tends to coil, forming a helical structure. The electrical conductivity of the composite films (4–36 wt% MWNTs) is increased by eight orders of magnitude compared to that of PmPV [3.331]. Using the MWNT-PmPV composites as the electron-transport-layer in light-emitting diodes results in a significant increase in brightness [3.332]. The SWNTs act as a hole-trapping material blocking the holes in the composites, this being probably induced through long-range interactions within the matrix [3.333]. Similar investigations were carried out on arc-discharge SWNTs-polyethylene dioxythiophene (PEDOT) composite layers [3.334] and MWNTs-polyphenylenevinylene composites [3.335].

To conclude, two critical issues have to be considered for the application of nanotubes as reinforcement for advanced composites. One is to chose between SWNTs and MWNTs. The former seem more beneficial for the purpose of mechanical strengthening, provided they are isolated or arranged into cohesive yarns so that the load is able to be conveniently transferred from a SWNT to another. Unfortunately, despite recent advances [3.336–339], this is still a technical challenge. The other issue is to tailor the nanotube/matrix interface with respect to the matrix. This is a current topic for many laboratories involved in the field.

Multifunctional Materials

One of the major benefits expected from incorporating carbon nanotubes in other solid or liquid materials is bringing some electrical conductivity to them while not affecting the other properties or behaviors of these materials. As already mentioned in the previous section, the percolation threshold is reached at very low load with nanotubes. Tailoring the electrical conductivity of a bulk material is then achievable by adjusting the nanotube volume fraction in the formerly insulating material while not making this fraction too large anyway. As demonstrated by Maruyama [3.3], there are three regimes of interest regarding the electrical conductivity: (i) electrostatic discharge, e.g., to prevent fire or explosion hazard in combustible environments or perturbations in electronics, which requires electrical resistivity less than 10^{12} Ω cm; (ii) electrostatic painting, which requires

the material to be painted to be electrical conductive enough (electrical resistivity below $10^6\ \Omega$ cm) to prevent the charged paint droplets to be repelled; (iii) electromagnetic interference shielding, which is achieved for electrical resistivity lower than $10\ \Omega$ cm.

Materials are often asked to be multifunctional, e.g. having both high electrical conductivity and high toughness, or high thermal conductivity and high thermal stability, etc. The association of several materials, each of them bringing one of the desired features, therefore generally meets this need. Exceptional features and properties of carbon nanotubes make them likely to be a perfect multifunctional material in many cases. For instance, materials for satellites are often required to be electrical conductive, mechanically self-supporting, able to transport the excess heat away, sometimes be protected against electromagnetic interferences, etc., while exhibiting minimal weight and volume. All these properties should be possible with a single nanotube-containing composite material instead of complex multi-materials combining layers of polymers, aluminum, copper, etc. Table 3.5 provides an overview of various fields in which nanotube-based multifunctional materials should find an application.

Nano-Electronics

As reported in Sects. 3.1.1 and 3.4.4, SWNT nanotubes can be either metallic (with an electrical conductivity higher than that of copper), or semiconductor. This has inspired the design of several components for nanoelectronics. First, metallic SWNTs can be used as mere ballistic conductors. Moreover, as early as 1995,

realizing a rectifying diode by joining one metallic SWNT to one semiconductor SWNT (hetero-junction) was proposed by *Lambin* et al. [3.340], then later by *Chico* et al. [3.341] and *Yao* et al. [3.342]. Also, field-effect transistors (FET) can be built by the attachment of a semiconductor SWNT across two electrodes (source and drain) deposited on an insulating substrate that serves as a gate electrode [3.343, 344]. Recently the association of two such SWNT-based FETs has made a voltage inverter [3.345].

All the latter developments are fascinating and provide promising perspectives for nanotube-based electronics. But progress is obviously needed before making SWNT-based integrated circuits on a routine basis. A key point is the need to be able to prepare selectively either metallic or semiconductor nanotubes. Although a way has been proposed to destroy selectively metallic SWNTs from bundles of undifferentiated SWNTs [3.347], the method is not scalable and selective synthesis would be preferable. Also, defect-free nanotubes are required. Generally speaking, it relates to another major challenge, which is to be able to fabricate at industrial scale integrated circuits including nanometer-size components that only sophisticated imaging methods (AFM) are able to visualize.

Nano-Tools, Nano-Devices, Nano-Systems

Due to the ability of graphene to expand slightly when electrically charged, nanotubes have been found to act conveniently as actuators. *Kim* et al. [3.346] demonstrated it by designing "nano"-tweezers able to grab, manipulate, release nano-objects (the "nano"-bead having been handled for the demonstration was actually closer to micrometer than nanometer), and measure their electrical properties. This was made possible quite simply by depositing two non-interconnected gold coatings onto a pulled glass micropipette (Fig. 3.31), then attaching two MWNTs (or two SWNT-bundles) ~ 20–50 nm in diameter to each of the gold electrodes. Applying a voltage (0–8.5 V) between the two electrodes then makes the tube tips to open and close reversibly in a controlled manner.

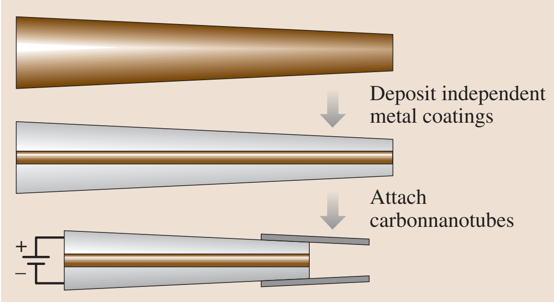

Fig. 3.31 Sketch explaining how the first nano-tweezers were designed. First is a glass micropipette (dark cone, *top*). Then two Au coatings (in grey, *middle*) are deposited so that they are not in contact. Then a voltage is applied to the electrodes (from [3.346])

A similar experiment, again rather simple, was proposed by *Baughman* et al. the same year (1999) [3.348], consisting in mounting two SWNT-based paper strips ("bucky-paper") on both sides of an insulating double-side tape. The two bucky-paper strips were previously loaded with Na^+ and Cl^-, respectively. When 1 V was applied between the two paper strips, both expand, but the strip loaded with Na^+ expands a bit more, forcing the whole system to bend. Though performed in a liquid environment, such a behavior has inspired the authors to predict a future for their system as "artificial muscles."

Another example of amazing nano-tools is the nano-thermometer proposed by *Gao* et al. [3.349]. A single MWNT was used, in that case, partially filled with liquid gallium. Upon the effect of temperature variations in the range 50–500 °C, the gallium goes up and down reversibly within the nanotube cavity at reproducible level with respect to the values of the temperature applied.

Of course, nano-tools such as nano-tweezers or nano-thermometers will hardly reach a commercial development so to justify industrial investments. But such experiments are more than amazing laboratory curiosities. They definitely demonstrate the ability of carbon nanotubes as parts for future nano-devices, including nanomechanics-based systems.

Supercapacitors

Supercapacitors include two electrodes immersed in an electrolyte (e.g., 6 M KOH), separated by an insulating ion-permeable membrane. Charging the capacitors is achieved by applying a potential between the two electrodes, making the cations and the anions moving toward the electrode oppositely charged. Suitable electrodes should exhibit a high electrical conductivity and a high surface area since the capacitance is proportional to it. Actually, the surface area should originate mainly from the appropriate combination of mesopores (to allow the electrolyte components to circulate well, which is related to the charging speed) and micropores (whose walls are the surface of attraction and fixation sites for the ions). Based on early works by

Niu et al. [3.350], such a combination was found to be reached with the specific architecture offered by packed and entangled h-MWNTs with a poor nanotexture (see Sect. 3.1.2). But, activation pre-treatments are necessary. For instance, a capacitor made from nanotubes with surface area $= 220\,m^2/g$ exhibited a capacitance of 20 F/g, which increased up to 100 F/g after an activation treatment was applied to the nanotubes so that their surface area reaches $880\,m^2/g$ [3.126]. Alternatively, again due to their specific architecture induced by their huge aspect ratio, nanotubes can also be used as supports for conductive polymer coatings, e.g., polypyrrole or polyaniline [3.351], which otherwise would make a too dense phase (i. e. not allowing an easy circulation and penetration of ions). Supercapacitors built from such composites can overcome more than 2,000 charging cycles, with current density as high as 350 mA/g [3.352]. Capacitors including nanotubes already have capacitance as high as 180–200 F/g, i. e. equivalent to that obtained with electrodes built from regular carbon materials, with the advantage of faster charging [3.126]. Current works will certainly lead to further optimization of both the nanotube material architecture and the nanotube-supported conductive polymers, giving reasonable perspectives for the commercial use of nanotubes as components for supercapacitors.

4. Nanowires

Nanowires are especially attractive for nanoscience studies as well as for nanotechnology applications. Nanowires, compared to other low dimensional systems, have two quantum confined directions while still leaving one unconfined direction for electrical conduction. This allows them to be used in applications which require electrical conduction, rather than tunneling transport. Because of their unique density of electronic states, nanowires in the limit of small diameters are expected to exhibit significantly different optical, electrical, and magnetic properties from their bulk 3-D crystalline counterparts. Increased surface area, very high density of electronic states and joint density of states near the energies of their van Hove singularities, enhanced exciton binding energy, diameter-dependent bandgap, and increased surface scattering for electrons and phonons are just some of the ways in which nanowires differ from their corresponding bulk materials. Yet the sizes of nanowires are typically large enough (>1 nm in the quantum confined direction) to have local crystal structures closely related to their parent materials, thereby allowing theoretical predictions about their properties to be made on the basis of an extensive literature relevant to their bulk properties.

Not only do nanowires exhibit many properties that are similar to, and others that are distinctly different from those of their bulk counterparts, nanowires have the advantage from an applications standpoint in that some of the materials parameters critical for certain properties can be independently controlled in nanowires but not in their bulk counterparts. Certain properties can also be enhanced nonlinearly in small diameter nanowires by exploiting the singular aspects of the 1-D electronic density of states. Furthermore, nanowires have been shown to provide a promising framework for applying the "bottom-up" approach [4.1] for the design of nanostructures for nanoscience investigations and for potential nanotechnology applications. Driven by: (1) these new research and development opportunities, (2) the smaller and smaller length scales now being used in the semiconductor, opto-electronics, and magnetics industries, and (3) the dramatic development of the biotechnology industry where the action is also at the nanoscale, the nanowire research field has developed with exceptional speed in the last few years. A review of the current status of nanowire research is therefore of significant broad interest at the present time. This review aims to focus on nanowire properties that differ from those of their parent crystalline bulk materials, with an eye toward possible applications that might emerge from the unique properties of nanowires and from future discoveries in this field.

References 138

For quick reference, examples of typical nanowires that have been synthesized and studied are listed in Table 4.1. Also of use to the reader are review articles that focus on a comparison between nanowire and nanotube properties [4.2] and the many reviews that have been written about carbon nanotubes [4.3–5], which can be considered as a model one-dimensional system.

4.1 Synthesis

In this section we survey the most common synthetic approaches that have successfully afforded high quality nanowires of a large variety of materials (see Table 4.1). In Sect. 4.1.1, we discuss methods that make use of various templates with nanochannels to confine the nanowire growth to two dimensions. In Sect. 4.1.2, we present the synthesis of nanowires by the vapor-liquid-solid mechanism and its many variations. In Sect. 4.1.3, we present examples of other synthetic methods of general applicability. The last part of this section (Sect. 4.1.4) features several approaches that have been developed to organize nanowires into simple architectures.

4.1.1 Template-Assisted Synthesis

The template-assisted synthesis of nanowires is a conceptually simple and intuitive way to fabricate nanostructures [4.7–10]. These templates contain very small cylindrical pores or voids within the host material, and the empty spaces are filled with the chosen material, which adopts the pore morphology, to form nanowires. In this section, we describe the templates first and then describe strategies for filling them to make nanowires.

Template Synthesis

In template-assisted synthesis of nanostructures, the chemical stability and mechanical properties of the template, as well as the diameter, uniformity, and density of the pores are important characteristics to consider. Templates frequently used for nanowire synthesis include anodic alumina (Al_2O_3), nano-channel glass, ion track-etched polymers, and mica films.

Porous anodic alumina templates are produced by anodizing pure Al films in various acids [4.11–13]. Under carefully chosen anodization conditions, the resulting oxide film possesses a regular hexagonal array of parallel and nearly cylindrical channels, as shown in Fig. 4.1a. The self-organization of the pore structure in an anodic alumina template involves two coupled processes: pore formation with uniform diameters and pore ordering. The pores form with uniform diameters because of a delicate balance between electric-field-enhanced diffusion, which determines the growth rate of the alumina, and dissolution of the alumina into the acidic electrolyte [4.12]. The pores are believed to self-order because of mechanical stress at the aluminum-alumina interface due to volume expansion during the anodization. This stress produces a repulsive force between the pores, causing them to arrange in a hexagonal lattice [4.14]. Depending on the anodization conditions, the pore diameter can be systematically varied from < 10 nm up to 200 nm with a pore density in the range of 10^9–10^{11} pores/cm^2 [4.11, 12, 15, 16]. Many groups have shown that the pore size distribution and the pore ordering of the anodic alumina templates can be significantly improved by a two-step anodization technique [4.6, 17, 18] in which the aluminum oxide layer is dissolved after the first anodization in an acidic solution followed by a second anodization under the same conditions.

Another type of porous template commonly used for nanowire synthesis is the template type fabricated by chemically etching particle tracks originating from ion bombardment [4.19], such as track-etched polycarbonate membranes (Fig. 4.1b) [4.7,20,21] and also mica films [4.22].

Other porous materials can be used as host templates for nanowire growth, as discussed by *Ozin* [4.8]. Nanochannel glass (NCG), for example, contains a regular hexagonal array of capillaries similar to the pore structure in anodic alumina with a packing density as high as 3×10^{10} pores/cm^2 [4.9]. Porous Vycor glass that contains an interconnected network of pores less than 10 nm was also employed for the early study of nanostructures [4.68]. Mesoporous molecular sieves [4.69], termed MCM-41, possess hexagonally packed pores with very small channel diameters that can be varied between 2 nm and 10 nm. Conducting organic filaments have been fabricated in the nanochannels of MCM-41 [4.70]. Recently the DNA molecule has also been used as a template for growing nanometer-sized wires [4.23].

Diblock copolymers, polymers that consist of two chain segments with different properties, have also been utilized as templates for nanowire growth. When the two segments are immiscible in each other, phase segregation occurs, and depending on their volume ratio, spheres, cylinders, and lamellae may self-assemble. To form self-assembled arrays of nanopores, copolymers composed of polystyrene and polymethylmethacrylate [P(S-b-MMA)] [4.71] were used. By applying an electric field while the copolymer was heated above the glass transition temperature of the two constituent polymers, the self-assembled cylinders of PMMA could be aligned with their main axis perpendicular to the film. Selective removal of the PMMA component afforded the preparation of 14-nm-diameter ordered pore arrays with a packing density of 1.9×10^{11} cm^{-3}.

Nanowire Template Assisted Growth by Pressure Injection

The pressure injection technique is often employed when fabricating highly crystalline nanowires from a low-melting point material and when using porous templates with robust mechanical strength. In the high-pressure injection method, the nanowires are formed by pressure injecting the desired material in liquid form into the evacuated pores of the template. Due to the heating and the pressurization processes, the templates used for the pressure injection method must be chemically stable and be able to maintain their structural integrity at high temperatures and high pressures. Anodic aluminum oxide films and nano-channel glass are two typical materials used as templates in conjunction with the pressure injection filling technique. Metal nanowires (Bi, In, Sn, and Al) and semiconductor nanowires (Se, Te, GaSb, and Bi_2Te_3) have been fabricated in anodic aluminum oxide templates using this method [4.32,58,67].

The pressure P required to overcome the surface tension for the liquid material to fill the pores with a diameter d_W is determined by the Washburn equation [4.72]:

$$d_W = -4\gamma\cos\theta/P\,, \qquad (4.1)$$

where γ is the surface tension of the liquid, and θ is the contact angle between the liquid and the template. To reduce the required pressure and to maximize the filling factor, some surfactants are used to decrease the surface tension and the contact angle. For example, the introduction of Cu in the Bi melt can facilitate filling the

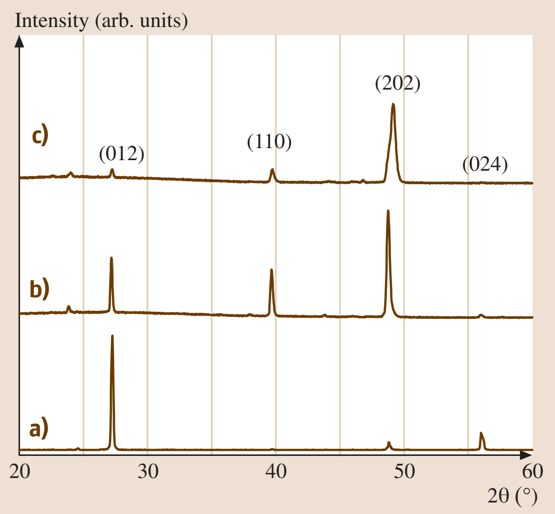

Fig. 4.2a–c XRD patterns of bismuth/anodic alumina nano-composites with average bismuth wire diameters of **(a)** 40 nm, **(b)** 52 nm, and **(c)** 95 nm [4.67]. The Miller indices corresponding to the lattice planes of bulk Bi are indicated above the individual peaks. The majority of the Bi nanowires are oriented along the $[10\bar{1}1]$ and $[01\bar{1}2]$ directions for $d_W \geq 60$ nm and $d_W \leq 50$ nm, respectively [4.16,67]. The existence of more than one dominant orientation in the 52-nm Bi nanowires is attributed to the transitional behavior of *intermediate*-diameter nanowires as the preferential growth orientation is shifted from $[10\bar{1}1]$ to $[01\bar{1}2]$ with decreasing d_W

pores in the anodic alumina template with liquid Bi and can increase the number of nanowires prepared [4.16]. But some of the surfactants might cause contamination problems and therefore should be avoided. Nanowires produced by the pressure injection technique usually possess high crystallinity and a preferred crystal orientation along the wire axis. For example, Fig. 4.2 shows the X-ray diffraction (XRD) patterns of Bi nanowire arrays of three different wire diameters with an injection pressure of $\sim 5{,}000$ psi [4.67], demonstrating that the major ($> 80\%$) crystal orientation of the wire axes in the 95-nm and 40-nm diameter Bi nanowire arrays are, respectively, normal to the (202) and (012) lattice planes. These are denoted by $[10\bar{1}1]$ and $[01\bar{1}2]$ when using a hexagonal unit cell, suggesting a wire-diameter-dependent crystal growth direction. On the other hand, 30 nm Bi nanowires produced using a much higher pressure of $> 20{,}000$ psi show a different crystal orientation of (001) along the wire axis [4.33], indicating that the preferred crystal orientation may also depend on the applied pressure, with the most dense packing direction along the wire axis for the highest applied pressure.

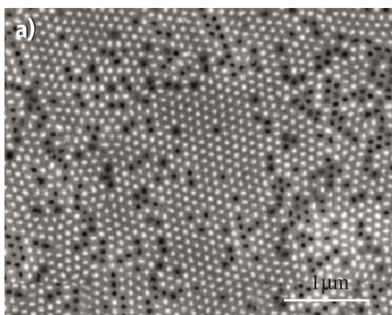
Electrochemical Deposition

The electrochemical deposition technique has attracted increasing attention as an alternative method for fabricating nanowires. Traditionally, electrochemistry has been used to grow thin films on conducting surfaces. Since electrochemical growth is usually controllable in the direction normal to the substrate surface, this method can be readily extended to fabricate 1-D or 0-D nanostructures, if the deposition is confined within the pores of an appropriate template. In the electrochemical methods, a thin conducting metal film is first coated on one side of the porous membrane to serve as the cathode for electroplating. The length of the deposited nanowires can be controlled by varying the duration of the electroplating process. This method has been used to synthesize a wide variety of nanowires e.g., metals (Bi [4.21, 29]; Co [4.73, 74]; Fe [4.15, 75]; Cu [4.20, 76]; Ni [4.22, 73]; Ag [4.24, 77]; Au [4.25, 26]); conducting polymers [4.7, 29]; superconductors (Pb [4.78]); semiconductors (CdS [4.37]); and even superlattice nanowires with A/B constituents (such as Cu/Co [4.20, 76]) have been synthesized electrochemically (see Table 4.1).

In the electrochemical deposition process, the chosen template has to be chemically stable in the electrolyte during the electrolysis process. Cracks and defects in the templates are detrimental to the nanowire growth, since the deposition processes primarily occur in the more accessible cracks, leaving most of the nanopores unfilled. Particle track-etched mica films or polymer membranes are typical templates used in the simple dc electrolysis. To use anodic aluminum oxide films in the dc electrochemical deposition, the insulating barrier layer that separates the pores from the bottom aluminum substrate has to be removed, and a metal film is then evaporated onto the back of the template membrane [4.79]. Compound nanowire arrays, such as Bi_2Te_3, have been fabricated in alumina templates with a high filling factor using the dc electrochemical deposition [4.34]. Figures 4.3a and b, respectively, show the top view and cross-sectional SEM images of a Bi_2Te_3 nanowire array [4.34]. The light areas are associated with Bi_2Te_3 nanowires, the dark regions denote empty pores, and the surrounding gray matrix is alumina.

Surfactants are also used with electrochemical deposition when necessary. For example, when using templates derived from PMMA/PS diblock copolymers (see above), methanol is used as a surfactant is used to facilitate pore filling [4.71], thereby achieving $\sim 100\%$ filling factor.

It is also possible to employ an ac electrodeposition method in anodic alumina templates without the removal of the barrier layer, by utilizing the rectifying



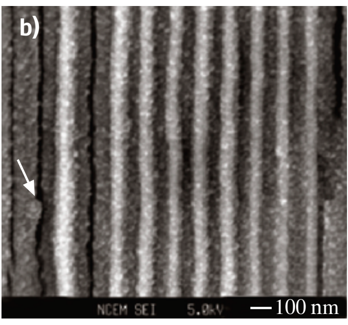


Fig. 4.3 (a) SEM image of a Bi_2Te_3 nanowire array in cross section showing a relatively high pore filling factor. **(b)** SEM image of a Bi_2Te_3 nanowire array composite along the wire axis [4.34]

properties of the oxide barrier. In ac electrochemical deposition, although the applied voltage is sinusoidal and symmetric, the current is greater during the cathodic half-cycles, making deposition dominant over the stripping, which occurs in the subsequent anodic half-cycles. Since no rectification occurs at defect sites, the deposition and stripping rates are equal, and no material is deposited. Hence, the difficulties associated with cracks are avoided. In this fashion, metals, such as Co [4.74] and Fe [4.15, 75], and semiconductors, such as CdS [4.37], have been deposited into the pores of anodic aluminum oxide templates without removing the barrier layer.

In contrast to nanowires synthesized by the pressure injection method, nanowires fabricated by the electrochemical process are usually polycrystalline, with no preferred crystal orientations, as observed by XRD studies. Some exceptions exist, however. For example, polycrystalline CdS nanowires, fabricated by an ac electrodeposition method in anodic alumina templates [4.37], possibly have a preferred wire growth orientation along the *c*-axis. In addition, *Xu* et al. have prepared a number of single-crystal II-VI semiconductor nanowires, including CdS, CdSe, and CdTe, by dc electrochemical deposition in anodic alumina templates with a nonaqueous electrolyte [4.36, 40]. Furthermore, single-crystal Pb nanowires can be formed by pulse electrodeposition under over-potential conditions, but no specific crystal orientation along the wire axis was observed [4.78]. The use of pulse currents is believed to be advantageous for the growth of crystalline wires because the metal ions in the solution can be regenerated between the electrical pulses and, therefore, uniform deposition conditions can be produced for each deposition pulse. Similarly, single crystal Ag nanowires were fabricated by pulsed electro-deposition [4.24].

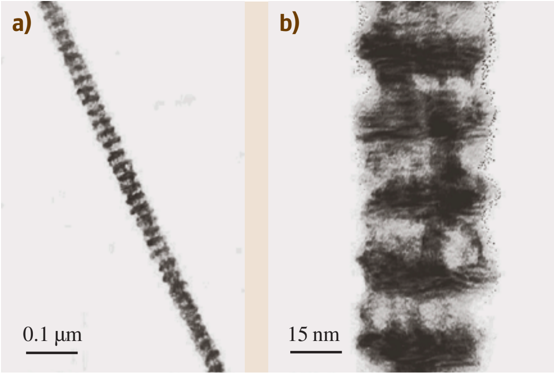

Fig. 4.4 **(a)** TEM image of a single Co(10 nm)/Cu(10 nm) multilayered nanowire. **(b)** A selected region of the sample at high magnification [4.76]

One advantage of the electrochemical deposition technique is the possibility of fabricating multilayered structures within nanowires. By varying the cathodic potentials in the electrolyte that contains two different kinds of ions, different metal layers can be controllably deposited. In this fashion, Co/Cu multilayered nanowires have been synthesized [4.20, 76]. Figure 4.4 shows TEM images of a single Co/Cu nanowire of about 40 nm in diameter [4.76]. The light bands represent Co-rich regions, and the dark bands represent Cu-rich layers. This electrodeposition method provides a low-cost approach to preparing multilayered 1-D nanostructures.

Vapor Deposition

Vapor deposition of nanowires includes physical vapor deposition (PVD) [4.28], chemical vapor deposition (CVD) [4.80], and metallorganic chemical vapor deposition (MOCVD) [4.48]. Like electrochemical deposition, vapor deposition is usually capable of preparing smaller-diameter (≤ 20 nm) nanowires than pressure injection methods, since it does not rely on the high pressure and surface tension involved to insert the material into the pores.

In the physical vapor deposition technique, the material to be filled is first heated to produce a vapor, which is then introduced through the pores of the template and cooled to solidify. Using an especially designed experimental setup [4.28], nearly single-crystal Bi nanowires in anodic aluminum templates with pore diameters as small as 7 nm have been synthesized, and these Bi nanowires were found to possess a preferred crystal growth orientation along the wire axis, similar to the Bi nanowires prepared by pressure injection [4.16, 28].

Compound materials that result from two reacting gases have also been prepared by the chemical vapor deposition (CVD) technique. For example, single-crystal GaN nanowires have been synthesized in anodic alumina templates through a gas reaction of Ga_2O vapor with a flowing ammonia atmosphere [4.45, 80]. A different liquid/gas phase approach has been used to prepare polycrystalline GaAs and InAs nanowires in a nanochannel glass array [4.48]. In this method, the nanochannels are filled with one liquid precursor (e.g., Me_3Ga or Et_3In) via a capillary effect, and the nanowires are formed within the template by reactions between the liquid precursor and the other gas reactant (e.g., AsH_3).

Nanotube Synthesis with Templates and as Templates

Recently carbon nanotubes, an important class of 1-D nanostructures, have been fabricated within the pores of anodic alumina templates using a chemical vapor deposition technique [4.81–84] to form highly ordered two-dimensional carbon nanotube arrays. A small amount of metal catalyst (e.g., Co) is first electrochemically deposited on the bottom of the pores. The templates are then placed in a furnace and heated to ∼ 700–800 °C with a flowing gas consisting of a mixture of N_2 and acetylene (C_2H_2) or ethylene (C_2H_4). The hydrocarbon molecules are pyrolyzed to form carbon nanotubes in the pores of the template with the help of the metal catalysts. Well-aligned nanotube arrays have stimulated much interest because of their great potential in various applications, such as cold-cathode flat panel displays. Of particular interest is the use of zeolite templates with very narrow pores (< 1 nm diameter) that permit the growth of carbon nanotubes with diameters of 0.42 nm, having only 10 carbon atoms around the circumference [4.85].

The hollow cores of carbon nanotubes have also been used to synthesize a variety of nanowires of very small diameter [4.86]. These very small diameter nanowires have been extensively studied by high resolution TEM but have not yet been characterized to the same degree regarding their physical properties.

4.1.2 VLS Method for Nanowire Synthesis

Some of the recent successful syntheses of semiconductor nanowires are based on the so-called vapor-liquid-solid (VLS) mechanism of anisotropic crystal growth. This mechanism was first proposed for the growth of single crystal silicon whiskers 100 nm to hundreds of microns in diameter [4.87]. The proposed growth mechanism (see Fig. 4.5) involves the absorption of source material from the gas phase into a liquid droplet of catalyst (a molten particle of gold on a silicon substrate in the original work [4.87]). Upon supersaturation of the liquid alloy, a nucleation event generates a solid precipitate of the source material. This seed serves as a preferred site for further deposition of material at the interface of the liquid droplet, promoting the elongation of the seed into a nanowire or a whisker, and suppressing further nucleation events on the same catalyst. Since the liquid droplet catalyzes the incorporation of material from the gas source to the growing crystal, the deposit grows anisotropically as a whisker whose diameter is dictated by the diameter of the liquid alloy

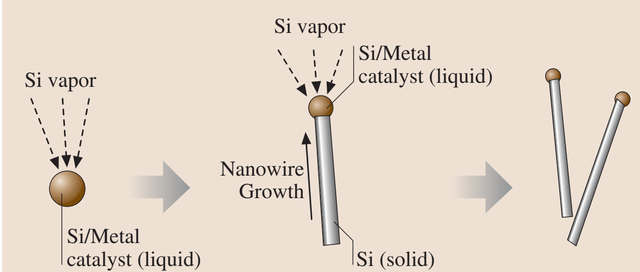

Fig. 4.5 Schematic diagram illustrating the growth of silicon nanowires by the VLS mechanism

droplet. The nanowires thus obtained are of high purity, except for the end containing the solidified catalyst as an alloy particle (see Figs. 4.5, 4.6a). Real-time observations of the alloying, nucleation, and elongation steps in the growth of germanium nanowires from gold nanoclusters by the VLS method were recorded by in situ TEM [4.88].

Reduction of the average wire diameter to the nanometer scale requires the generation of nanosized catalyst droplets. Due to the balance between the liquid-vapor surface free energy and the free energy of condensation, however, the size of a liquid droplet, in equilibrium with its vapor, is usually limited to the micrometer range. This obstacle was overcome in recent years by several new methodologies: 1) Advances in the synthesis of metal nanoclusters have made monodispersed nanoparticles commercially available. These can be dispersed on a solid substrate in high dilution so that when the temperature is raised above the melting point, the liquid clusters do not aggregate [4.59]. 2) Alternatively, metal islands of nanoscale sizes can self-form when a strained thin layer is grown or heat treated on a non-epitaxial substrate [4.50]. 3) Laser-assisted catalytic VLS growth is a method used to generate nanowires under nonequilibrium conditions. By laser ablation of a target containing both the catalyst and the source materials, a plasma is generated from which catalyst nanoclusters nucleate as the plasma cools down. Single crystal nanowires grow as long as the particle remains liquid [4.60]. 4) Interestingly, by optimization of the material properties of the catalyst-nanowire system, conditions can be achieved for which nanocrystals nucleate in a liquid catalyst pool supersaturated with the nanowire material, migrate to the surface due to a large surface tension, and continue growing as nanowires perpendicular to the liquid surface [4.62]. In this case, supersaturated nanodroplets are sustained on the outer

The crystalline Si core appears darker than the amorphous oxide surface layer. The inset shows the convergent beam electron diffraction pattern recorded perpendicular to the wire axis, confirming the nanowire crystallinity [4.60]. **(c)** STEM image of $Si/Si_{1-x}Ge_x$ superlattice nanowires in the bright field mode. The scale bar is 500 nm [4.90]

end of the nanowire due to the low solubility of the nanowire material in the liquid [4.89].

A wide variety of elemental, binary, and compound semiconductor nanowires has been synthesized by the VLS method, and relatively good control over the nanowire diameter and diameter distribution has been achieved. Researchers are currently focusing attention on the controlled variation of the materials properties along the nanowire axis. To this context, researchers have modified the VLS synthesis apparatus to generate compositionally modulated nanowires. GaAs/GaP modulated nanowires have been synthesized by alternately ablating targets of the corresponding materials in the presence of gold nanoparticles [4.92]. p-Si/n-Si nanowires were grown by chemical vapor deposition from alternating gaseous mixtures containing the appropriate dopant [4.92]. $Si/Si_{1-x}Ge_x$ nanowires were grown by combining silicon from a gaseous source with germanium from a periodically ablated target (see Fig. 4.6c) [4.90]. Finally, using an ultra-high vacuum chamber and molecular beams, InAs/InP nanowires with atomically sharp interfaces were obtained [4.93]. These compositionally modulated nanowires are expected to exhibit exciting electronic, photonic, and thermoelectric properties.

Silicon and germanium nanowires grown by the VLS method consist of a crystalline core coated by a relatively thick amorphous oxide layer (2–3 nm) (see Fig. 4.6b). These layers are too thick to be the result of ambient oxidation, and it has been shown that these oxides play an important role in the nanowire growth process [4.61, 91]. Silicon oxides were found to serve as a special and highly selective catalyst, that significantly enhances the yield of Si nanowires, without the need for metal catalyst particles [4.61, 91, 94]. A similar yield enhancement was also found in the synthesis of Ge nanowires from the laser ablation of Ge powder mixed with GeO_2 [4.51]. The Si and Ge nanowires produced from these metal-free targets generally grow along the [112] crystal direction [4.95] and have the benefit that no catalyst clusters are found on either ends of the nanowires. Based on these observations

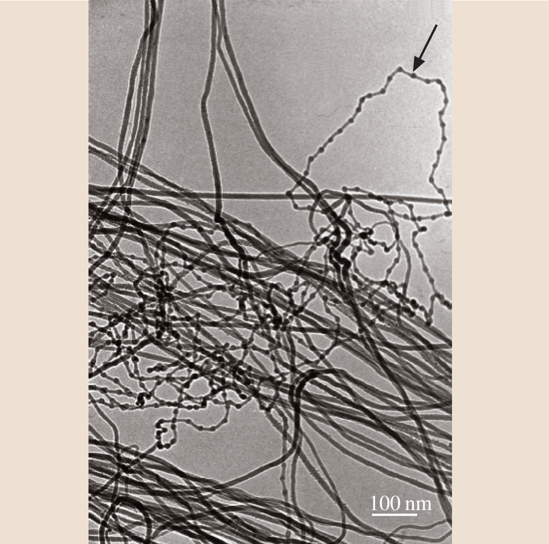

Fig. 4.7 TEM image showing the two major morphologies of Si nanowires prepared by the oxide assisted growth method [4.91]. Notice the absence of metal particles when compared to Fig. 4.6a. The *arrow* points at an oxide-linked chain of Si nanoparticles

and other TEM studies, an oxide-enhanced nanowire growth mechanism different from the classical VLS mechanism was proposed, in which no metal catalyst is required during the laser ablation-assisted synthesis [4.91]. It is postulated that the nanowire growth is dependent on the presence of SiO (or GeO) vapor. This decomposes in the nanowire tip region into Si (or Ge), which is incorporated into the crystalline phase, and SiO_2 (or GeO_2), which contributes to the outer coating. The initial nucleation events generate oxide-coated spherical nanocrystals. The [112] crystal faces have the fastest growth rate, and therefore the nanocrystals soon begin elongating along this direction to form one-dimensional structures. The Si_mO or Ge_mO ($m > 1$) layer on the nanowire tips may be at temperatures near their molten states, catalyzing the incorporation of gas molecules in a directional fashion [4.95]. Besides nanowires with smooth walls, a second morphology of chains of non-oriented nanocrystals linked by oxide necks is frequently observed (indicated by an arrow in Fig. 4.7). In addition, it was found by STM studies that about 1% of the wires consist of a regular array of two alternating segments, 10 nm and 5 nm in length, respectively [4.96]. The segments, whose junctions form an angle of 30°, are probably a result of alternating growth along different crystallographic orientations (see Sect. 4.2.1).

4.1.3 Other Synthesis Methods

In this section we review several other general procedures available for the synthesis of a variety of nanowires. We focus on "bottom-up" approaches, which afford many kinds of nanowires in large numbers and do not require highly sophisticated equipment (such as scanning microscopy or lithography based methods). We exclude cases for which the nanowires are not self sustained (such as in the case of atomic rows on the surface of crystals).

Gates et al. have demonstrated a solution-phase synthesis of nanowires with controllable diameters [4.57, 97], without the use of templates, catalysts, or surfactants. They make use of the anisotropy of the crystal structure of trigonal selenium and tellurium, which can be viewed as rows of 1-D helical atomic chains. They base their approach on the mass transfer of atoms during an aging step from a high free-energy solid phase (e.g., amorphous selenium) to a seed (e.g., trigonal selenium nanocrystal) that grows preferentially along one crystallographic axis. The lateral dimension of the seed, which dictates the diameter of the nanowire, can be controlled by the temperature of the nucleation step. Furthermore, Se/Te alloy nanowires were synthesized by this method, and Ag_2Se compound nanowires were obtained by treating selenium nanowires with $AgNO_3$ [4.98–100].

More often, however, the use of surfactants is necessary to promote the anisotropic 1-D growth of nanocrystals. Solution phase synthetic routes have been optimized to produce monodispersed quantum dots, i. e., zero-dimensional isotropic nanocrystals [4.101]. Surfactants are necessary in this case to stabilize the interfaces of the nanoparticles and retard oxidation and aggregation processes. Detailed studies on the effect of growth conditions revealed that they can be manipulated to induce a directional growth of the nanocrystals, usually generating nanorods (aspect ratio of ≈ 10), and in favorable cases, nanowires of high-aspect ratios. *Heath* and *LeGoues* [4.49] synthesized germanium nanowires by reducing a mixture of $GeCl_4$ and phenyl-$GeCl_3$ at high temperature and high pressure. The phenyl ligand was essential for the formation of high-aspect ratio nanowires [4.49]. In growing CdSe nanorods [4.38], Alivisatos et al. used a mixture of two surfactants, whose concentration ratio influenced the structure of the nanocrystal. It is believed that different surfactants have different affinities and different absorption rates for the different crystal faces of CdSe, thereby regulating the growth rate of these faces. A coordinating alkyl-diamine solvent was used to grow polycrystalline PbSe nanowires at low temperatures [4.55]. Here, the surfactant-induced directional growth is believed to occur, through the formation of organometallic complexes in which the bidentate ligand assumes the equatorial positions, thus hindering the ions from approaching each other in this plane. Additionally, the alkyl-amine molecules coat the external surface of the wire, preventing lateral growth. The aspect ratio of the wires increased as the temperature was lowered in the range $10 < T < 117$ °C. Ethylenediamine was used to grow CdS nanowires and tetrapods by a solvo-thermal recrystallization process starting with CdS nanocrystals or amorphous particles [4.35]. While the coordinating solvent was crucial for the nanowire growth, the researchers did not clarify its role in the shape and phase control.

Stress-induced crystalline bismuth nanowires have been grown from sputtered films of layers of Bi and CrN. The nanowires presumably grow from defects and cleavage fractures in the film and are up to several millimeter in lengths with diameters ranging from 30 to 200 nm [4.27]. While the exploration of this technique has only begun, stress-induced unidirectional

growth should be applicable to a variety of composite films.

Selective electrodeposition along the step edges in highly oriented pyrolytic graphite (HOPG) was used to obtain MoO_2 nanowires as shown in Fig. 4.8. The site-selectivity was achieved by applying a low overpotential to the electrochemical cell in which the HOPG served as cathode, thus minimizing the nucleation events on less favorable sites (i. e., plateaus). While these nanowires cannot be removed from the substrate, they can be reduced to metallic molybdenum nanowires, which can then be released as free-standing nanowires. Other metallic nanowires were also obtained by this method [4.53, 102]. In contrast to the template synthesis approaches described above, in this method the substrate defines only the position and orientation of the nanowire, not its diameter. In this context, other surface morphologies, such as self-assembled grooves in etched crystal planes, have been used to generate nanowire arrays via gas-phase shadow deposition (for example: Fe nanowires on (110)NaCl [4.44]). The cross-section of artificially prepared superlattice structures has also been used for site-selective electrodeposition of parallel and closely spaced nanowires [4.103]. Nanowires prepared on the above-mentioned substrates would have semicircular, rectangular, or other unconventional cross-sectional shapes.

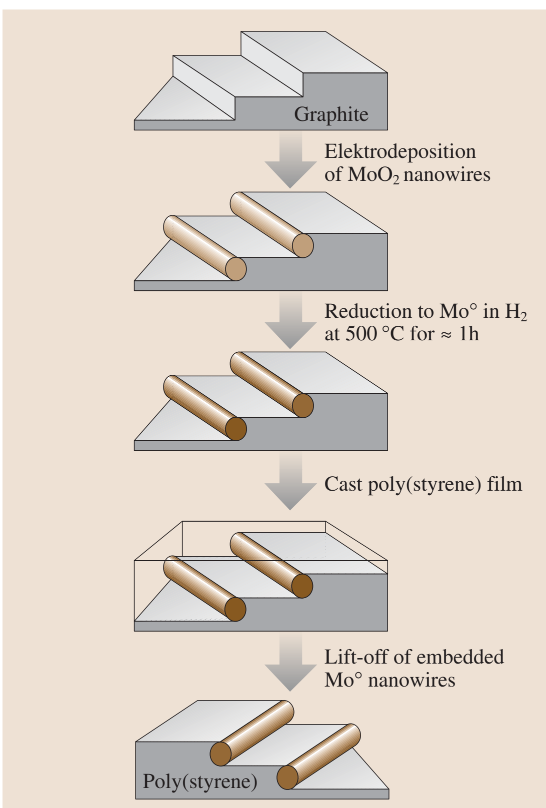

Fig. 4.8 Schematic of the electrodeposition step edge decoration of HOPG (highly oriented pyrolytic graphite) for the synthesis of molybdenum nanowires [4.53, 102]

4.1.4 Hierarchical Arrangement and Superstructures of Nanowires

Ordering nanowires into useful structures is another challenge to address in order to harness the full potential of nanowires for applications. We will first review examples of nanowires having a nontrivial structure and then proceed to describe methods to create assemblies of nanowires of a predetermined structure.

We have already mentioned in Sect. 4.1.2 that the preparation of nanowires with a graded composition or with a superlattice structure along their main axis was demonstrated by controlling the gas-phase chemistry as a function of time during the growth of the nanowires by the VLS method. Control of the composition along the axial dimension was also demonstrated by a template-assisted method, for example by the consecutive electrochemical deposition of different metals in the pores of an alumina template [4.104]. Alternatively, the composition can be varied along the radial dimension of the nanowire, for example, by first growing a nanowire by the VLS method and then switching the synthesis conditions to grow a different material on the surface of the nanowire by CVD. This technique was demonstrated for the synthesis of Si/Ge and Ge/Si coaxial (or core-shell) nanowires [4.105], and it was shown that by a thermal annealing process the outer shell can be formed epitaxially on the inner core. A different approach was adopted by *Wang* et al. who generated a mixture of coaxial and biaxial SiC-SiO_x nanowires by the catalyst-free high-temperature reaction of amorphous silica and a carbon/graphite mixture [4.106].

A different category of nontrivial nanowires is that of nanowires having a nonlinear structure, resulting from multiple one-dimensional growth steps. Members of this category are tetrapods, which were mentioned in the context of liquid-phase synthesis (Sect. 4.1.3). In this process, a tetrahedral quantum-dot core is first grown, and then the conditions are modified to induce a one-dimensional growth of a nanowire from each one of the facets of the tetrahedron. A similar process

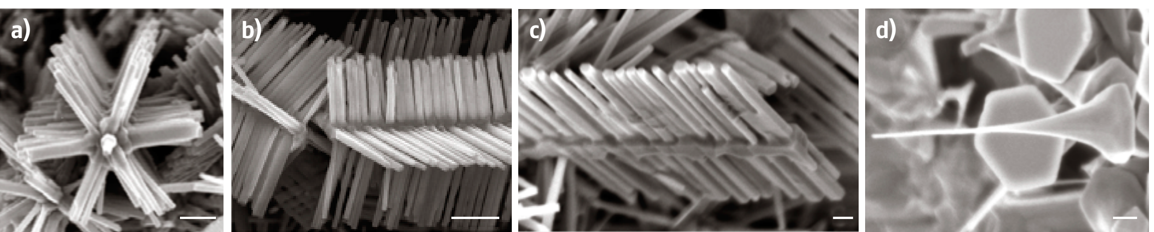

Fig. 4.9a–d SEM images of **(a)** 6-fold **(b)** 4-fold and **(c)** 2-fold symmetry nanobrushes made of an In_2O_3 core and ZnO nanowire brushes [4.107], and of **(d)** ZnO nanonails [4.108]

produced high-symmetry In_2O_3/ZnO hierarchical nanostructures. From a mixture of heat-treated In_2O_3, ZnO and graphite powders, faceted In_2O_3 nanowires were first obtained, on which oriented shorter ZnO nanowires crystallized [4.107]. Brush-like structures were obtained as a mixture of 11 structures of different symmetries. For example, two, four, or six rows of ZnO nanorods could be found on different core nanowires, depending on the crystallographic orientation of the main axis of the core nanowire, as shown in Fig. 4.9. Comb-like structures entirely made of ZnO were also reported [4.65].

Control of the position of a nanowire in the growth process is important for preparing devices or test structures containing nanowires, especially when involving a large array of nanowires. Post-synthesis methods to align and position nanowires include microfluidic channels [4.110], Langmuir–Blodgett assemblies [4.109], and electric-field assisted assembly [4.111]. The first method involves the orientation of the nanowires by the liquid flow direction when a nanowire solution is injected into a microfluidic channel assembly and by the interaction of the nanowires with the side walls of the channel. The second method involves the alignment of nanowires at a liquid-gas or liquid-liquid interface by the application of compressive forces on the interface (Fig. 4.10). The third technique is based on dielectrophoretic forces that pull polarizable nanowires toward regions of high field strength. The nanowires align between two isolated electrodes that are capacitatively coupled to a pair of buried electrodes biased with an AC voltage. Once a nanowire shorts the electrodes, the electric field is eliminated, preventing more nanowires from depositing. The above techniques have been successfully used to prepare electronic circuitry and optical devices out of nanowires (see Sects. 4.3.1 and 4.3.3). Alternatively, alignment and positioning of the nanowires can be specified and controlled during their growth by the proper design of the synthesis. For example, ZnO nanowires prepared by the VLS method were grown into an array in which both their position on the substrate and their growth direction and orientation were controlled [4.65]. The nanowire growth region was defined by patterning the gold film, which serves as a catalyst for the ZnO nanowire growth, employing soft-lithography, e-beam lithography, or photolithography. The orientation of the nanowires was achieved by selecting a substrate with a lattice structure matching that of the nanowire material to facilitate the epitaxial growth. These conditions result in an array of nanowire posts at predetermined positions, all vertically aligned with the same crystal growth orientation (see Fig. 4.11). A similar structure could be obtained by the template-mediated electrochemical synthesis of nanowires (see Sect. 4.1.1), particularly if anodic alumina with its parallel and ordered channels is used. The control over the

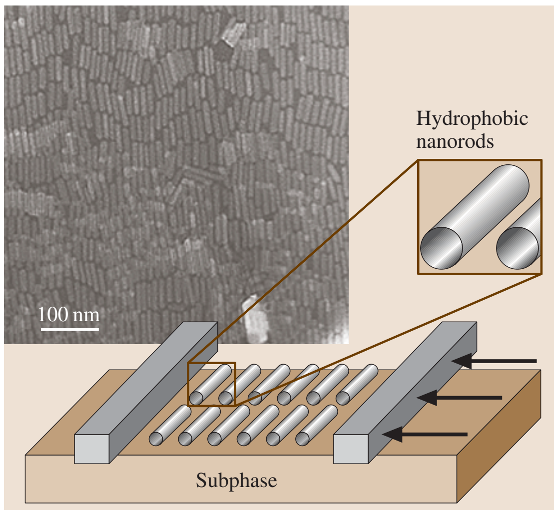

Fig. 4.10 A TEM image of a smectic phase of a $BaCrO_4$ nanorod film (*left inset*) achieved by the Langmuir–Blodgett technique, as depicted by the illustration [4.109]

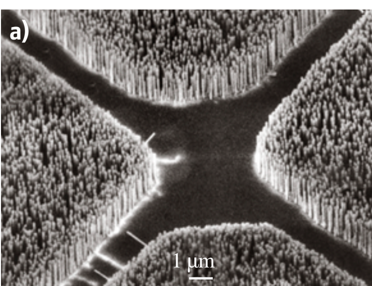

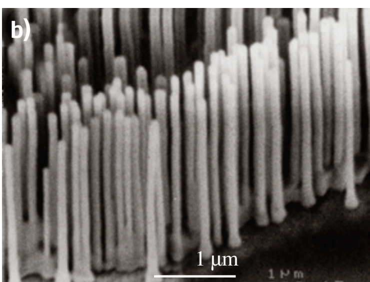

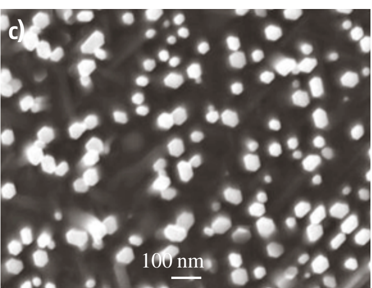

Fig. 4.11a–c SEM images of ZnO nanowire arrays grown on a sapphire substrate, where **(a)** shows patterned growth, **(b)** shows a higher resolution image of the parallel alignment of the nanowires, and **(c)** shows the faceted side-walls and the hexagonal cross section of the nanowires. For nanowire growth, the sapphire substrates were coated with a 1.0 to 3.5 nm thick patterned layer of Au as the catalyst, using a TEM grid as the shadow mask. These nanowires have been used for nanowire laser applications [4.115]

location of the nucleation of nanowires in the electrochemical deposition is determined by the pore positions and the back-electrode geometry. The pore positions can be precisely controlled by imprint lithography [4.112]. By growing the template on a patterned conductive substrate that serves as a back-electrode [4.113,114], different materials can be deposited in the pores at different regions of the template.

4.2 Characterization and Physical Properties of Nanowires

In this section we review the structure and properties of nanowires, and the interrelationship between the two. The discovery and investigation of nanostructures were galvanized by advances in various characterization and microscopy techniques that enable materials characterization to take place at smaller and smaller length scales, reaching down to individual atoms. For applications, characterization of the nanowire structural properties is especially important so that a reproducible relationship between their desired functionality and their geometrical and structural characteristics can be established. Due to the enhanced surface-to-volume ratio in nanowires, their properties may depend sensitively on their surface condition and geometrical configuration. Even nanowires made of the same material may possess dissimilar properties due to differences in their crystal phase, crystalline size, surface conditions, and aspect ratios, which depend on the synthesis methods and conditions used in their preparation.

4.2.1 Structural Characterization

Structural and geometric factors play an important role in determining the various attributes of nanowires, such as their electrical, optical and magnetic properties. Various novel tools, therefore, have been developed and employed to obtain this important structural information at the nanoscale. At the micron scale, optical techniques are extensively used for imaging structural features. Since the sizes of nanowires are usually comparable to or, in most cases, much smaller than the wavelength of visible light, traditional optical microscopy techniques are usually limited in characterizing the morphology and surface features of nanowires. Electron microscopy techniques, therefore, play a more dominant role at the nanoscale. Since electrons interact more strongly than photons, electron microscopy is particularly sensitive relative to X-rays for the analysis of tiny samples.

In this section we review and give examples of how scanning electron microscopy, transmission electron microscopy, scanning probe spectroscopies, and diffraction techniques are used to characterize the structure of nanowires. To provide the necessary basis for developing reliable structure-property relations, we apply multiple characterization tools to the same samples.

Scanning Electron Microscopy (SEM)

SEM usually produces images down to length scales of ~ 10 nm and provides valuable information regarding the structural arrangement, spatial distribution, wire density, and geometrical features of the nanowires. Examples of SEM micrographs shown in Figs. 4.1 and

4.3 indicate that structural features at the 10 nm to 10 μm length scales can be probed, providing information on the size, size distribution, shapes, spatial distributions, density, nanowire alignment, filling factors, granularity etc. As another example, Fig. 4.11a shows an SEM image of ZnO nanowire arrays grown on a sapphire substrate [4.115], which provides evidence for the nonuniform spatial distribution of the nanowires on the substrate. This distribution was attained by patterning the catalyst film to define high density growth regions and nanowire-free regions. Figure 4.11b, showing a higher magnification of the same system, indicates that these ZnO nanowires grow perpendicular to the substrate, are well aligned with approximately equal wire lengths, and have wire diameters in the range of $20 < d_W < 150$ nm. The SEM micrograph in Fig. 4.11c provides further information about the surface of the nanowires, showing it to be well-faceted and forming a hexagonal cross-section, indicative of nanowire growth along the ⟨0001⟩ direction. The uniformity of the nanowire size, its alignment perpendicular to the substrate, and its uniform growth direction, as suggested by the SEM data, are linked to the good epitaxial interface between the (0001) plane of the ZnO nanowire and the (110) plane of the sapphire substrate. (The crystal structures of ZnO and sapphire are essentially incommensurate, with the exception that the *a* axis of ZnO and the *c* axis of sapphire are related almost exactly by a factor of 4, with a mismatch of less than 0.08% at room temperature [4.115].) The well-faceted nature of these nanowires has important implications for their lasing action (see Sect. 4.3.2). Figure 4.12 shows an SEM image of GaN nanowires synthesized by a laser-assisted catalytic growth method [4.46], indicating a random spatial orientation of the nanowire axes and a wide diameter distribution for these nanowires, in contrast to the ZnO wires in Fig. 4.11 and to arrays of well-aligned nanowires prepared by template-assisted growth (see Fig. 4.3).

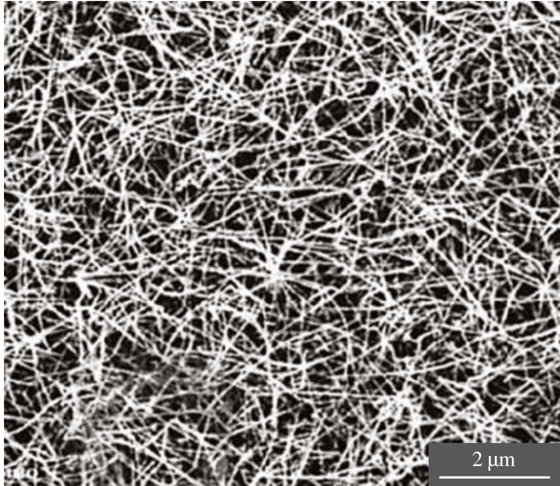

Fig. 4.12 SEM image of GaN nanowires in a mat arrangement synthesized by laser-assisted catalytic growth. The nanowires have diameters and lengths on the order of 10 nm and 10 μm, respectively [4.46]

Transmission Electron Microscopy (TEM)

TEM and high resolution transmission electron microscopy (HRTEM) are powerful imaging tools to study nanowires at the atomic scale, and they usually provide more detailed geometrical features than are seen in SEM images. TEM studies also yield information regarding the crystal structure, crystal quality, grain size, and crystal orientation of the nanowire axis. When operating in the diffraction mode, selected area electron diffraction (SAED) patterns can be made to determine the crystal structure of nanowires. As an example, the TEM images in Fig. 4.13 show four different morphologies for Si nanowires prepared by the laser ablation of a Si target [4.116]: (a) spring-shaped; (b) fishbone-shaped (indicated by solid arrow) and frog-egg-shaped (indicated by the hollow arrow), (c) pearl-shaped, while (d) shows the poly-sites of nanowire nucleation. The crystal quality of nanowires is revealed from high resolution TEM images with atomic resolution, along with selected area electron diffraction (SAED) patterns. For example, Fig. 4.14 shows a TEM image of one of the GaN nanowires from Fig. 4.12, indicating single crystallinity and showing (100) lattice planes, thus demonstrating the growth direction of the nanowire. This information is supplemented by the corresponding electron diffraction pattern in the upper right.

The high resolution of the TEM also allows for the investigation of the surface structure of the nanowires. In many cases the nanowires are sheathed with a native oxide layer or an amorphous oxide layer that forms during the growth process. This can be seen in Fig. 4.6b for silicon nanowires and in Fig. 4.15 for germanium nanowires [4.51], showing a mass-thickness contrast TEM image and a selected-area electron diffraction pattern of a Ge nanowire. The main TEM image shows that these Ge nanowires possess an amorphous GeO_2 sheath with a crystalline Ge core oriented in the [211] direction.

Dynamical processes of the surface layer of nanowires can be studied by using an in situ environ-

coating the nanowire (Fig. 4.16a) is removed by exposure to hydrogen gas within the environmental chamber of the TEM, as indicated in Fig. 4.16b.

By coupling the powerful imaging capabilities of TEM with other characterization tools, such as an electron energy loss spectrometer (EELS) or an energy dispersive X-ray spectrometer (EDS) within the TEM instrument, additional properties of the nanowires can be probed with high spatial resolution. With the EELS technique, the energy and momentum of the incident and scattered electrons are measured in an inelastic electron scattering process to provide information on the energy and momentum of the excitations in the nanowire sample. Fig. 4.17 shows the dependence on nanowire diameter of the electron energy loss spectra of Bi nanowires. The spectra were taken from the center of the nanowire, and the shift in the energy of the peak position (Fig. 4.17) indicates the effect of the nanowire diameter on the plasmon frequency in the nanowires. The results show changes in the electronic structure of Bi nanowires as the wire diameter decreases [4.118]. Such changes in electronic structure as a function of nanowire diameter are also observed in their transport (Sect. 4.2.2) and optical (Sect. 4.2.3) properties and are related to quantum confinement effects.

EDS measures the energy and intensity distribution of X-rays generated by the impact of the electron beam on the surface of the sample. The elemental composition within the probed area can be determined to a high degree of precision. The technique was particularly useful for the compositional characterization of superlattice

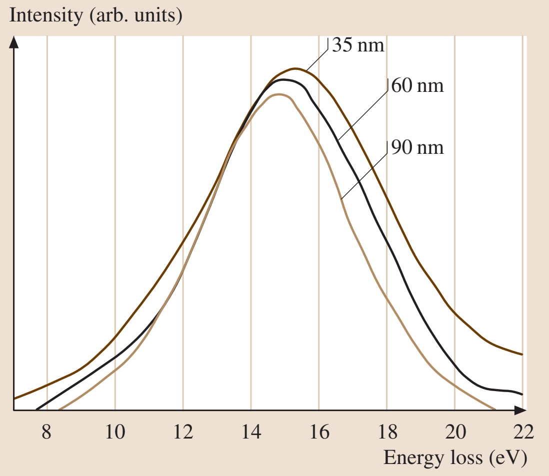

Fig. 4.17 Electron energy loss spectra (EELS) taken from the center of bismuth nanowires with diameters of 35, 60, and 90 nm. The shift in the volume plasmon peaks is due to the wire diameter effects on the electronic structure [4.118]

nanowires [4.90] and core-sheath nanowires [4.105] (see Sect. 4.1.2).

Scanning Tunneling Probes

Several scanning probe techniques [4.119], such as scanning tunneling microscopy (STM), electric field gradient microscopy (EFM) [4.16], magnetic field microscopy (MFM) [4.54], and scanning thermal microscopy (SThM) [4.120], combined with atomic force microscopy (AFM), have been employed to study the structural, electronic, magnetic, and thermal properties of nanowires. A scanning tunneling microscope can be employed to reveal both topographical structural information, such as that illustrated in Fig. 4.18, as well as information on the local electronic density of states of a nanowire, when used in the STS (scanning tunneling spectroscopy) mode. Figure 4.18 shows STM height images (taken in the constant current STM mode) of MoSe molecular wires deposited from a methanol or acetonitrile solution of $Li_2Mo_6Se_6$ on to Au substrates. The STM image of a single MoSe wire (Fig. 4.18a) exhibits a 0.45 nm lattice repeat distance in a MoSe molecular wire. When both STM and STS measurements are made on the same sample, the electronic and structural properties can be correlated, for example, as in the joint STM/STS studies on Si nanowires [4.96], showing alternating segments of a single nanowire identified with growth along [110] and [112] directions, and different I–V characteristics measured for the [110] segments as compared with the [112] segments.

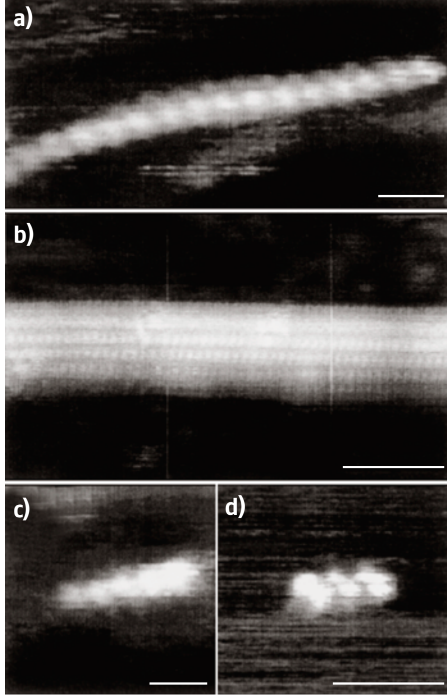

Fig. 4.18a–d STM height images, obtained in the constant current mode, of MoSe chains deposited on an Au(111) substrate. **(a)** A single chain image, and **(b)** a MoSe wire bundle. **(c)** and **(d)** Images of MoSe wire fragments containing 5 and 3 unit cells, respectively [4.119]. The scale bars are all 1 nm

Magnetic field microscopy (MFM) has been employed to study magnetic polarization of magnetic nanowires embedded in an insulating template, such as an anodic alumina template. For example, Fig. 4.19a shows the topographic image of an anodic alumina template filled with Ni nanowires, and Fig. 4.19b demonstrates the corresponding magnetic polarization of each nanowire in the template. This micrograph shows that a magnetic field microscopy probe can distinguish between spin-up and spin-down nanowires in the nanowire

array, thereby providing a method for measuring interwire magnetic dipolar interactions [4.54].

X-Ray Analysis

Other characterization techniques commonly used to study the crystal structure and chemical composition of nanowires include X-ray diffraction and X-ray energy dispersion analysis (EDAX). The peak positions in the X-ray diffraction pattern can be used to determine the chemical composition and the crystal phase structure of the nanowires. For example, Fig. 4.2 shows that Bi nanowires have the same crystal structure and lattice constants as bulk bismuth. Both the X-ray diffraction pattern (XRD) for an array of aligned Bi nanowires (Fig. 4.2) and the SAED pattern for individual Bi nanowires [4.16] suggest that the nanowires have a common axis of crystal orientation.

As another example of an XRD pattern for an array of aligned nanowires, Fig. 4.20 shows the X-ray diffraction pattern of the ZnO nanowires displayed in Fig. 4.11. Only (00ℓ) diffraction peaks are observed for these aligned ZnO nanowires, indicating that their preferred growth direction is (001) along the wire axis. A similar preferred growth orientation was also observed for Bi nanowires produced by high pressure injection (see Sect. 4.1.1), while the vapor phase and low pressure injection filling techniques give preferred alignment along lower symmetry axes (see Fig. 4.2).

EDAX has been used to determine the chemical composition, stoichiometry of compound nanowires, or the impurity content in the nanowires. But the results from EDAX analysis should be interpreted carefully to avoid systematic errors.

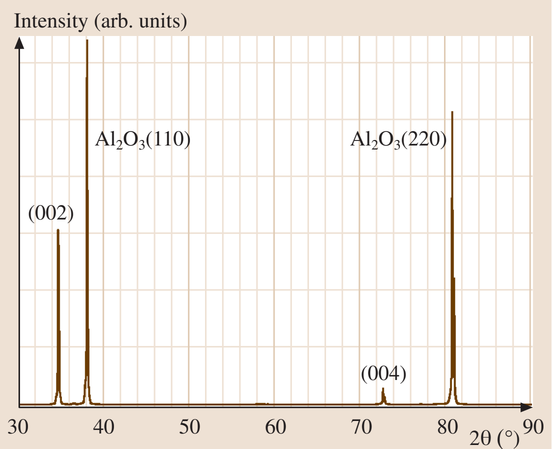

Fig. 4.20 X-ray diffraction pattern of aligned ZnO nanowires (see Fig. 4.11) grown on a sapphire substrate. Only [00ℓ] diffraction peaks are observed for the nanowires, owing to their well-oriented growth orientation. Strong diffraction peaks for the sapphire substrate are also found [4.115]

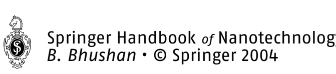
4.2.2 Transport Properties

The study of nanowire electrical transport properties is important for nanowire characterization, electronic device applications, and the investigation of unusual transport phenomena arising from one-dimensional quantum effects. Important factors that determine the transport properties of nanowires include the wire diameter (important for both classical and quantum size effects), material composition, surface conditions, crystal quality, and the crystallographic orientation along the wire axis, which is important for materials with anisotropic materials parameters, such as the effective mass tensor, the Fermi surface, or the carrier mobility.

Electronic transport phenomena in low-dimensional systems can be roughly divided into two categories: ballistic and diffusive transport. Ballistic transport phenomena occur when electrons travel across the nanowire without any scattering. In this case, the conduction is mainly determined by the contacts between the nanowire and the external circuit, and the conductance is quantized into an integral number of universal conductance units $G_0 = 2e^2/h$ [4.121, 122]. Ballistic transport phenomena are usually observed in very short quantum wires, such as those produced by using mechanically controlled break junctions (MCBJ) [4.123, 124] where the electron mean free path is much longer than the wire length, and the conduction is a pure quantum phenomenon. To observe ballistic transport, the thermal energy must also obey the relation $k_B T \ll \varepsilon_j - \varepsilon_{j-1}$, where $\varepsilon_j - \varepsilon_{j-1}$ is the energy separation between subband levels j and $j-1$. On the other hand, for nanowires with lengths much larger than the carrier mean free path, the electrons (or holes) undergo numerous scattering events when they travel along the wire. In this case, the transport is in the diffusive regime, and the conduction is dominated by carrier scattering within the wires due to phonons (lattice vibrations), boundary scattering, lattice and other structural defects, and impurity atoms.

Conductance Quantization in Metallic Nanowires

The ballistic transport of 1-D systems has been extensively studied since the discovery of quantized



conductance in 1-D systems in 1988 [4.121, 122]. The phenomena of conductance quantization occur when the diameter of the nanowire is comparable to the electron Fermi wavelength, which is on the order of 0.5 nm for most metals [4.125]. Most conductance quantization experiments up to the present were performed by joining and separating two metal electrodes. As the two metal electrodes are slowly separated, a nano-contact is formed before it breaks completely (see Fig. 4.21a), and conductance in integral multiple values of G_0 is observed through these nano-contacts. Fig. 4.21b shows the conductance histogram built with 18,000 contact breakage curves between two gold electrodes at room temperature [4.126], with the electrode separation up to ~ 1.8 nm. The conductance quantization behavior is found to be independent of the contact material and has been observed in various metals, such as Au [4.126], Ag, Na, Cu [4.127], and Hg [4.128]. For semimetals such as Bi, conductance quantization has also been observed for an electrode separation of as long as 100 nm at 4 K because of the long Fermi wavelength (~ 26 nm) [4.125], indicating that the conductance quantization may be due to the existence of well-defined quantum states localized at a constriction instead of resulting from the atom rearrangement as the electrodes separate. Since the conductance quantization is observed only in breaking contacts, or for very narrow and very short nanowires, most nanowires of practical interest (possessing lengths of several microns) lie in the diffusive transport regime, where the carrier scattering is significant and should be considered.

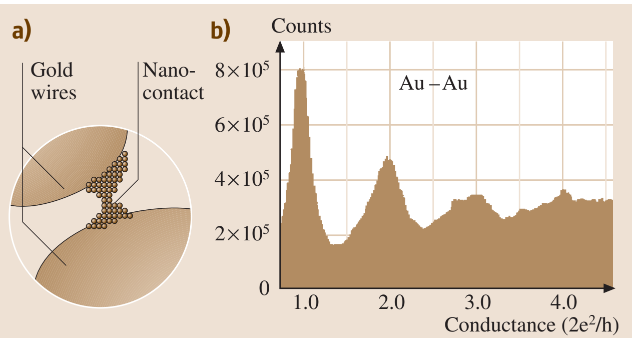


Fig. 4.21 **(a)** Schematic representation of the last stages of the contact breakage process [4.126]. **(b)** Histogram of conductance values built with 18,000 gold contact breakage experiments in air at room temperature, showing conductance peaks at integral values of G_0. In this experiment the gold electrodes approach and separate at 89,000 Å/s [4.126]

I–V Characterization of Semiconducting Nanowires

The electronic transport behavior of nanowires may be categorized based on the relative magnitude of three length scales: carrier mean free path ℓ_W, the de Broglie wavelength of electrons λ_e, and the wire diameter d_W. For wire diameters much larger than the carrier mean free path ($d_W \gg \ell_W$), the nanowires exhibit transport properties similar to bulk materials, which are independent of the wire diameter, since the scattering due to the wire boundary is negligible compared to other scattering mechanisms. For wire diameters comparable or smaller than the carrier mean free path ($d_W \sim \ell_W$ or $d_W < \ell_W$) but still much larger than the de Broglie wavelength of the electrons ($d_W \gg \lambda_e$), the transport in nanowires is in the classical finite size regime, in which the band structure of the nanowire is still similar to that of bulk while the scattering events at the wire boundary alter their transport behavior. For wire diameters comparable to the electronic wavelength $d_W \sim \lambda_e$, the electronic density of states is altered dramatically and quantum subbands are formed due to the quantum confinement effect at the wire boundary. In this regime, the transport properties are further influenced by the change in the band structure. Transport properties for nanowires in the classical finite size and quantum size regimes, therefore, are highly diameter-dependent.

Researchers have investigated the transport properties of various semiconducting nanowires and have demonstrated their potential for diverse electronic devices, such as for p-n diodes [4.129, 130], field effect transistors [4.129], memory cells, and switches [4.131] (see Sect. 4.3.1). The nanowires studied so far in this context have usually been made from conventional semiconducting materials, such as group IV and III-V compound semiconductors via the VLS growth method (see Sect. 4.1.2), and their nanowire properties have been compared to their well-established bulk properties. Interestingly, the physical principles for describing bulk semiconductor devices also hold for devices based on these semiconducting nanowires with wire diameters of tens of nanometers. For example, Fig. 4.22 shows the current–voltage (I–V) behavior of a 4-by-1 crossed p-Si/n-GaN junction array at room temperature [4.129]. The long horizontal wire in the figure is a p-Si nanowire (10–25 nm in diameter) and the four short vertical wires are n-GaN nanowires (10–30 nm in diameter). Each of the four nanoscale cross points independently forms a p-n junction with current rectification behavior, as shown by the I–V curves in Fig. 4.22, and the junction behavior (e.g., the turn-on voltage) can

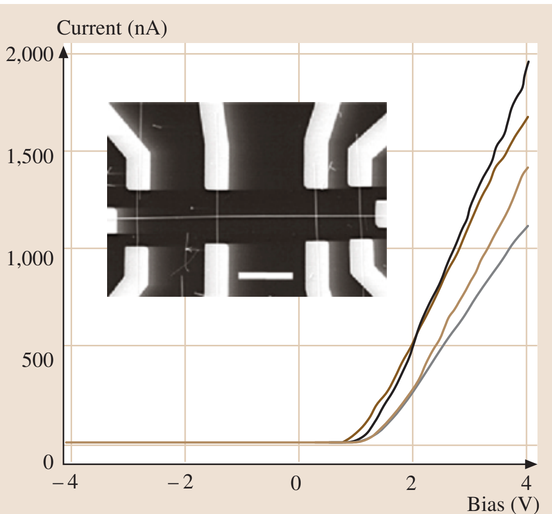

Fig. 4.22 I–V behavior for a 4(p) by 1(n) crossed p-Si/n-GaN junction array shown schematically in the inset. The four curves represent the I–V response for each of the four junctions, showing similar current rectifying characteristics in each case. The length scale bar between the two middle junctions is 2 μm [4.129]. The p-Si and n-GaN nanowires are 10–25 nm and 10–30 nm in diameter, respectively

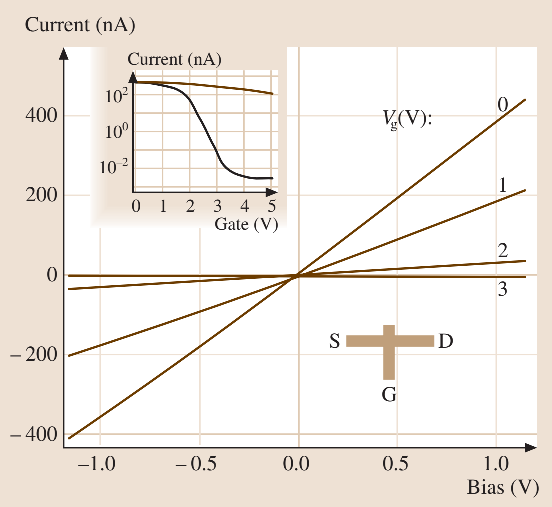

Fig. 4.23 Gate-dependent I–V characteristics of a crossed nanowire field-effect transistor (FET). The n-GaN nanowire is used as the nano-gate, with the gate voltage indicated (0, 1, 2, and 3 V). The inset shows the current vs. V_{gate} for a nanowire gate (*lower curve*) and for a global back-gate (*top curve*) when the bias voltage is set at 1 V [4.129]

be controlled by varying the oxide coating on these nanowires [4.129].

Huang et al. have demonstrated nanowire junction diodes with a high turn-on voltage (∼ 5 V) by increasing the oxide thickness at the junctions. The high turn-on voltage enables the use of the junction in a nanoscale FET as shown in Fig. 4.23 [4.129], where I–V data for a p-Si nanowire are presented, for which the n-GaN nanowire with a thick oxide coating is used as a nano-gate. By varying the nano-gate voltage, the conductance of the p-Si nanowire can be changed by more than a factor of 10^5 (lower curve in the inset), whereas the conductance changes by only a factor of ten when a global back-gate is used (top curve in the inset of Fig. 4.23). This behavior may be due to the thin gate dielectric between the crossed nanowires and the better control of the local carrier density through a nano-gate. Based on the gate-dependent I–V data of these p-Si nanowires, it is found that the mobility for holes in the p-Si nanowires may be higher than that for bulk p-Si, although further investigation is required for a complete understanding.

Because of the enhanced surface-to-volume ratio of nanowires, their transport behavior may be modified by changing their surface conditions. For example, researchers have found that by coating n-InP nanowires with a layer of redox molecules such as cobalt phthalocyanine, the conductance of the InP nanowires may change by orders of magnitude by altering the charge state of the redox molecules to provide bistable nanoscale switches [4.131]. The resistance (or conductance) of some nanowires (e.g., Pd nanowires) is also very sensitive to the presence of certain gases (e.g., H_2) [4.132, 133], and this property may be utilized for sensor applications to provide improved sensitivity compared to conventional sensors based on bulk material (see Sect. 4.3.4).

Although it remains unclear how the size may influence the transport properties and device performance of semiconducting nanowires, many of the larger diameter semiconducting nanowires are expected to be described by classical physics, since their quantization energies $\hbar^2/(2m_e d_W^2)$ are usually smaller than the thermal energy $k_B T$. By comparing the quantization energy with the thermal energy, the critical wire diameter below which quantum confinement effects become significant is estimated to be 1 nm for Si nanowires at room temperature, which is much smaller than the size of many of the semiconducting nanowires that have been investigated so far. By using material systems with much smaller effective carrier masses m_e (such as bismuth), the critical diam-

eter for which such quantum effects can be observed is increased, thereby facilitating the study of quantum confinement effects. It is for this reason that the bismuth nanowire system has been studied so extensively. Furthermore, since the crystal structure and lattice constants of bismuth nanowires are the same as for 3-D crystalline bismuth, it is possible to carry out detailed model calculations to guide and to interpret transport and optical experiments on bismuth nanowires. For these reasons, bismuth can be considered as a model system for studying 1-D effects in nanowires.

Temperature-Dependent Resistance Measurements

Although nanowires with electronic properties similar to their bulk counterparts are promising for constructing nano-devices based on well-established knowledge of their bulk counterparts, it is expected that quantum size effects in nanowires will likely be utilized to generate new phenomena absent in bulk materials and thus provide enhanced performance and novel functionality for certain applications. In this context, the transport properties of bismuth (Bi) nanowires have been extensively studied, both theoretically [4.134] and experimentally [4.28, 30, 67, 135–138] because of their promise for enhanced thermoelectric performance. Transport studies of ferromagnetic nanowire arrays, such as Ni or Fe, have also received much attention because of their potential for high-density magnetic storage applications.

The very small electron effective mass components and the long carrier mean free paths in Bi facilitate the study of quantum size effects in the transport properties of nanowires. Quantum size effects are expected to become significant in bismuth nanowires with diameters smaller than 50 nm [4.134], and the fabrication of crystalline nanowires of this diameter range is relatively easy.

Figure 4.24a shows the T dependence of the resistance $R(T)$ for Bi nanowires ($7 \leq d_W < 200$ nm) synthesized by vapor deposition and pressure injection [4.28], illustrating the quantum effects in their temperature-dependent resistance. In Fig. 4.24a, the $R(T)$ behavior of Bi nanowires is dramatically different from that of bulk Bi and is highly sensitive to the wire diameter. The $R(T)$ curves in Fig. 4.24a show a non-monotonic trend for larger-diameter (70 and 200 nm) nanowires, although $R(T)$ becomes monotonic with T for small-diameter (≤ 48 nm) nanowires. This dramatic change in the behavior of $R(T)$ as a function of d_W is attributed to a unique semimetal-semiconductor transition phenomena in Bi [4.139], induced by quantum size effects. Bi is a semimetal in bulk form, in which the T-point valence band overlaps with the L-point conduction band by 38 meV at 77 K. As the wire diameter decreases, the lowest conduction subband increases in energy, and the highest valence subband decreases in energy. Model calculations predict that the band overlap should vanish in Bi nanowires (with their wire axes along the trigonal direction) at a wire diameter ~ 50 nm [4.134].

The resistance of Bi nanowires is determined by two competing factors: the carrier density that increases with T, and the carrier mobility that decreases with T. The non-monotonic $R(T)$ for large-diameter Bi nanowires is due to a smaller carrier concentration variation at low temperature (≤ 100 K) in semimetals, so that the electrical resistance is dominated by the mobility factor in this temperature range. Based on the semiclassical transport model and the established band structure of Bi nanowires, the calculated $R(T)/R(300\,\text{K})$ for 36-nm and 70-nm Bi nanowires is shown by the solid curves in Fig. 4.24c to illustrate different $R(T)$ trends for semiconducting and semimetallic nanowires, respectively [4.67]. The curves in Fig. 4.24c exhibit trends consistent with experimental results. The condition for the semimetal–semiconductor transition in Bi nanowires can be experimentally determined, as shown by the measured resistance ratio $R(10\,\text{K})/R(100\,\text{K})$ of Bi nanowires as a function of wire diameter [4.140] in Fig. 4.25. The maximum in the resistance ratio $R(10\,\text{K})/R(100\,\text{K})$ at $d_W \sim 48$ nm indicates the wire diameter for the transition of Bi nanowires from a semimetallic phase to a semiconducting phase. The semimetal–semiconductor transition and the semiconducting phase in Bi nanowires are examples of new transport phenomena, resulting from low dimensionality and absent in the bulk 3-D phase, which further increase the possible benefits from the properties of nanowires for desired applications (see Sect. 4.3.2).

It should be noted that good crystal quality is essential for observing the quantum size effect in nanowires, as shown by the $R(T)$ plots in Fig. 4.24a. For example, Fig. 4.24b shows the normalized $R(T)$ measurements of Bi nanowires with larger diameters (200 nm–2 μm) prepared by electrochemical deposition [4.30], and these nanowires possess monotonic $R(T)$ behaviors, quite different from those of the corresponding nanowire diameters shown in Fig. 4.24a. The absence of the resistance maximum in Fig. 4.24b is due to the lower crystalline quality for nanowires prepared by electrochemical deposition, which tends to produce polycrystalline nanowires with a much lower

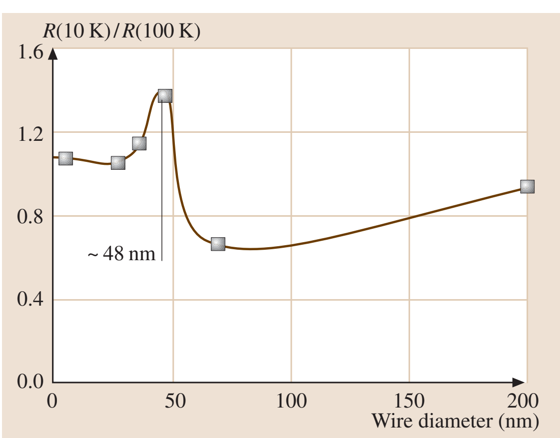

Fig. 4.25 Measured resistance ratio $R(10\,K)/R(100\,K)$ of Bi nanowires as a function of diameter. The peak indicates the transition from a semimetallic phase to a semiconducting phase as the wire diameter decreases [4.141]

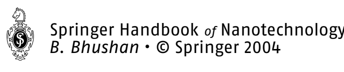

carrier mobility. This monotonic $R(T)$ for semimetallic Bi nanowires at a higher defect level is also confirmed by theoretical calculations, as shown by the dashed curve in Fig. 4.24c for 70-nm wires with increased grain boundary scattering [4.139].

The theoretical model developed for Bi nanowires not only provides good agreement with experimental results, but it also plays an essential role in understanding the influence of the quantum size effect, the boundary scattering, and the crystal quality on their electrical properties. The transport model has also been generalized to predict the transport properties of Te-doped Bi nanowires [4.67], Sb nanowires [4.142], and BiSb alloy nanowires [4.143], and good agreement between experiment and theory has also been obtained for these cases. While the electronic density of states may be significantly altered due to quantum confinement effects, various scattering mechanisms related to the transport properties of nanowires can be accounted for by Matthiessen's rule.

For nanowires with diameters comparable to the phase-breaking length, their transport properties may be further influenced by localization effects. It has been predicted that in disordered systems, the extended electronic wave functions become localized near defect sites, resulting in the trapping of carriers and giving rise to a different transport behavior. Localization effects are also expected to be more pronounced as dimensionality and sample size are reduced. Localization effects on the transport properties of nanowire systems have been studied on Bi nanowires [4.144] and, more recently, on Zn nanowires [4.63]. Figure 4.26 shows the measured $R(T)/R(300\,\mathrm{K})$ of Zn nanowires fabricated by vapor deposition in porous silica or alumina [4.63]. While 15 nm Zn nanowires exhibit an $R(T)$ behavior with a T^1 dependence as expected for a metallic wire, the $R(T)$ of 9 nm and 4 nm Zn nanowires exhibits a temperature dependence of $T^{-1/2}$ at low temperature, consistent with 1-D localization theory. Thus, due to this localization effect, the use of nanowires with very small diameters for transport applications may be limited.

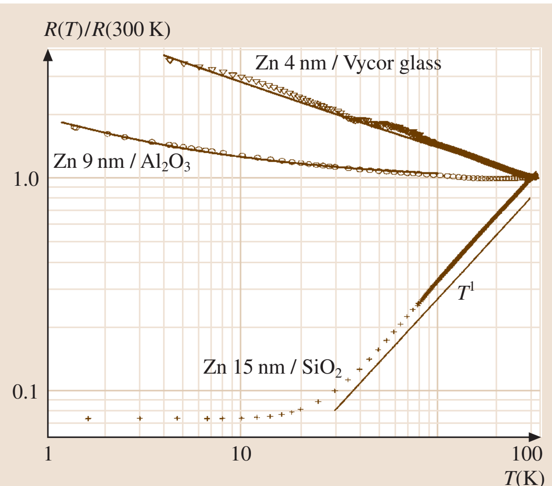

Fig. 4.26 Temperature dependence of the resistance of Zn nanowires synthesized by vapor deposition in various porous templates [4.63]. The data are given as points, the *full line* are fits to a T^1 law for 15 nm diameter Zn nanowires in an SiO_2 template, denoted by Zn/SiO_2. Fits to a combined T^1 and $T^{-1/2}$ law were made for the smaller nanowire diameter composite denoted by 9 nm Zn/Al_2O_3 and 4 nm Zn/Vycor glass

Magnetoresistance

Magnetoresistance (MR) measurements provide an informative technique for characterizing nanowires because these measurements yield a great deal of information about the electron scattering with wire boundaries, the effects of doping and annealing on scattering, and localization effects in the nanowires [4.137]. For example, at low fields the MR data show a quadratic dependence on the B field from which carrier mobility estimates can be made (see Fig. 4.27 at low B field).

Figure 4.27 shows the longitudinal magnetoresistance ($\boldsymbol{B}$ parallel to the wire axis) for 65 nm and 109 nm Bi nanowire samples (before thermal annealing) at 2 K. The MR maxima in Fig. 4.27a are due to the classical size effect, where the wire boundary scattering is reduced as the cyclotron radius becomes smaller than the wire radius in the high field limit, resulting in a decrease in the resistivity. This behavior is typical for the longitudinal MR of Bi nanowires in the diameter range of 45 nm to 200 nm [4.28, 136, 137, 145], and the peak position B_m moves to lower B field values as the wire diameter increases, as shown in Fig. 4.27c [4.145], in which B_m varies linearly with $1/d_\mathrm{W}$. The condition for the occurrance of B_m is approximately given by $B_\mathrm{m} \sim 2c\hbar k_\mathrm{F}/ed_\mathrm{W}$ where k_F is the wave vector at the Fermi energy. The peak position, B_m, is found to increase linearly with temperature in the range of 2 to 100 K, as shown in Fig. 4.27b [4.145]. As T is increased, phonon scattering becomes increasingly important, and therefore a higher magnetic field is required to reduce the resistivity associated with boundary scattering sufficiently to change the sign of the MR. Likewise, in-

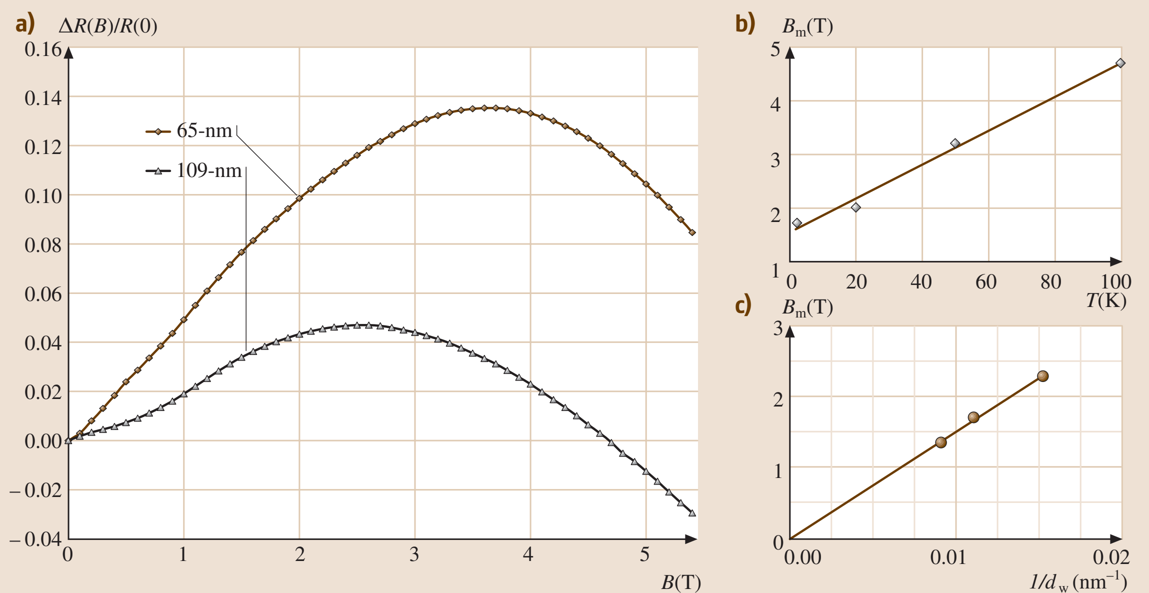

Fig. 4.27 **(a)** Longitudinal magnetoresistance, $\Delta R(B)/R(0)$, at 2 K as a function of B for Bi nanowire arrays with diameters 65 and 109 nm before thermal annealing. **(b)** The peak position B_m as a function of temperature for the 109 nm diameter Bi nanowire array after thermal annealing. **(c)** The peak position B_m of the longitudinal MR (after thermal annealing) at 2 K as a function of $1/d_W$, the reciprocal of the nanowire diameter [4.145]

creasing the grain boundary scattering is also expected to increase the value of B_m at a given T and wire diameter.

The presence of the peak in the longitudinal MR of nanowires requires a high crystal quality with long carrier mean free paths along the nanowire axis, so that most scattering events occur at the wire boundary instead of at a grain boundary, at impurity sites, or at defect sites within the nanowire. *Liu* et al. have investigated the MR of 400-nm Bi nanowires synthesized by electrochemical deposition [4.21], and no peak in the longitudinal MR is observed. The absence of a magnetoresistance peak may be attributed to a higher defect level in the nanowires produced electrochemically and to a large wire diameter, much longer than the carrier mean free path. The negative MR observed for the Bi nanowire arrays above B_m (see Fig. 4.27) shows that wire boundary scattering is a dominant scattering process for the longitudinal magnetoresistance, thereby establishing that the mean free path is larger than the wire diameter and that a ballistic transport behavior is indeed observed in the high field regime.

In addition to the longitudinal magnetoresistance measurements, transverse magnetoresistance measurements (**B** perpendicular to the wire axis) have also been performed on Bi nanowires array samples [4.28, 137, 145], where a monotonically increasing B^2 dependence over the entire range $0 \leq B \leq 5.5$ T is found for all Bi nanowires studied thus far. This is as expected, since the wire boundary scattering cannot be reduced by a magnetic field perpendicular to the wire axis. The transverse magnetoresistance is also found always to be larger than the longitudinal magnetoresistance in nanowire arrays.

By applying a magnetic field to nanowires at very low temperatures (≤ 5 K), one can induce a transition from a 1-D confined system at low magnetic fields to a 3-D confined system as the field strength increases, as shown in Fig. 4.28 for the longitudinal MR of Bi nanowire arrays of various nanowire diameters (28–70 nm) for $T < 5$ K [4.137]. In these curves, a subtle step-like feature is seen at low magnetic fields, which is found to depend only on the wire diameter, and is independent of temperature, the orientation of the magnetic field, and even on the nanowire material (e.g., in Sb nanowires [4.142]). The lack of a dependence of the magnetic field at which the step appears on temperature, field orientation, and material type indicates that

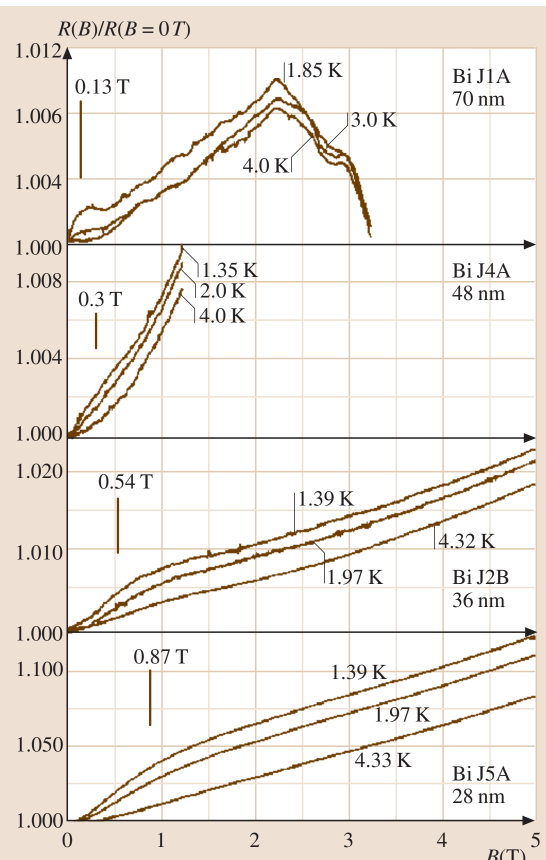

Fig. 4.28 Longitudinal magnetoresistance as a function of magnetic field for Bi nanowires of the diameters indicated. The vertical bars indicate the critical magnetic field B_c at which the magnetic length equals the nanowire diameter [4.137]

the phenomenon is related to the magnetic field length, $L_H = (\hbar/eB)^{1/2}$. The characteristic length L_H is the spatial extent of the wave function of electrons in the lowest Landau level, and L_H is independent of the carrier effective masses. Setting $L_H(B_c)$ equal to the diameter d_W of the nanowire defines a critical magnetic field strength, B_c, below which the wave function is confined by the nanowire boundary (the 1-D regime), and above which the wave function is confined by the magnetic field (the 3-D regime). The physical basis for this phenomenon is associated with confinement of a single magnetic flux quantum within the nanowire cross section [4.137]. This phenomenon, though independent of temperature, is observed for $T \leq 5$ K, since the phase breaking length has to be larger than the wire diameter. This calculated field strength, B_c, indicated in Fig. 4.28 by vertical lines for the appropriate nanowire diameters, provides a good fit to the step-like features in these MR curves.

The Shubnikov–de Haas (SdH) quantum oscillatory effect, which results from the passage of the quantized Landau levels through the Fermi energy as the field strength varies, should, in principle, provide the most direct measurement of the Fermi energy and carrier density. For example, *Heremans* et al. have demonstrated that SdH oscillations can be observed in Bi nanowire samples with diameters down to 200 nm [4.146] and have demonstrated that Te doping can be used to raise the Fermi energy in Bi nanowires. Such information on the Fermi energy is important because, for certain applications based on nanowires, it is necessary to place the Fermi energy near a subband edge where the density of states has a sharp feature. But due to the unusual 1-D geometry for nanowires, other characterization techniques commonly used in bulk materials to determine the Fermi energy and the carrier concentration (e.g., the Hall measurement) cannot be applied for nanowire systems. The observation of the SdH oscillatory effect requires very high crystal quality samples that allow carriers to execute a complete cyclotron orbit in the nanowire before they are scattered. For small nanowire diameters, large magnetic fields are required to produce cyclotron radii smaller than the wire radius. For some nanowire systems, all Landau levels may have passed through the Fermi level at such a high field strength, and in such a case, no oscillations can be observed. The localization effect may also prevent the observation of SdH oscillations for very small diameter (≤ 10 nm) nanowires. Observing SdH oscillations in highly doped samples (as may be required for certain applications) may be difficult because impurity scattering reduces the mean free path, requiring high $\boldsymbol{B}$ fields to satisfy the requirement that carriers complete a cyclotron orbit prior to scattering. Although SdH oscillations provide the most direct method of measuring the Fermi energy and carrier density of nanowire samples, this technique may not work, however, for smaller diameter nanowires, or for heavily doped nanowires.

Thermoelectric Properties

Nanowires are predicted to be promising for thermoelectric applications [4.134, 147], due to their novel band structure compared to their bulk counterparts and the expected reduction in thermal conductivity associated with enhanced boundary scattering (see Sect. 4.2.2). Due to the sharp density of states at the 1-D subband edges

(where the van Hove singularities occur), nanowires are expected to exhibit enhanced Seebeck coefficients compared to their bulk counterparts. Since the Seebeck coefficient measurement is independent of the number of nanowires contributing to the signal, the measurements on nanowire arrays of uniform wire diameter are, in principle, as informative as single-wire measurements. The major challenge in measuring the Seebeck coefficient of nanowires lies in the design of tiny temperature probes to determine accurately the temperature difference across the nanowire. Figure 4.29a shows the schematic experimental setup for the Seebeck coefficient measurement of nanowire arrays [4.148], where two thermocouples are placed on both faces of a nanowire array and a heater is attached on one face of the array to generate a temperature gradient along the nanowire axis. Ideally the size of the thermocouples should be much smaller than the thickness of the nanowire array template (i. e., the nanowire length) to minimize error. However, due to the thinness of most templates ($\leq 50\,\mu m$) and the large size of commercially available thermocouples ($\sim 12\,\mu m$), the measured Seebeck coefficient values are usually underestimated.

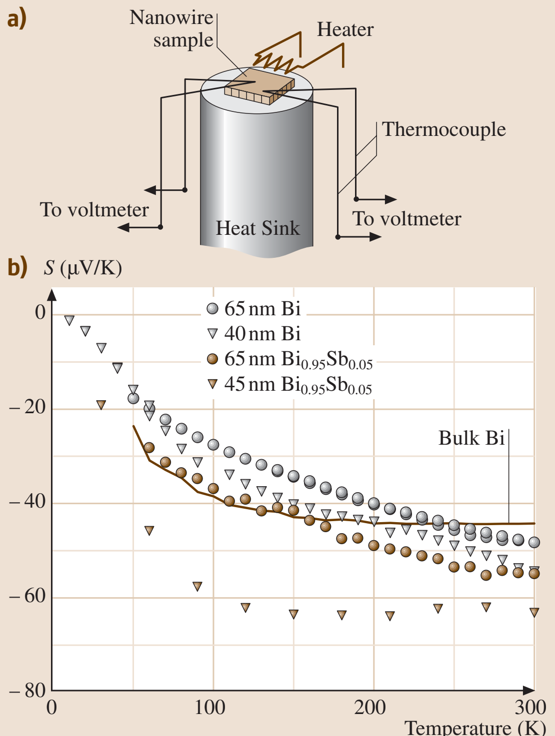

Fig. 4.29 **(a)** Experimental setup for the measurement of the Seebeck coefficient in nanowire arrays [4.148]. **(b)** Measured Seebeck coefficient as a function of temperature for Bi (○,▽) and $Bi_{0.95}Sb_{0.05}$ (●,▼) nanowires with different diameters. The *solid curve* denotes the Seebeck coefficient for bulk Bi [4.139]

The thermoelectric properties of Bi nanowire systems have been investigated extensively because of their potential as good thermoelectric materials. Figure 4.29b shows the measured Seebeck coefficient $S(T)$ as a function of temperature for nanowire arrays with diameters of 40 and 65 nm and different isoelectronic Sb alloy concentrations [4.139]; $S(T)$ results for bulk Bi are shown (*solid curve*) for comparison. Enhancement in the thermopower is observed in Fig. 4.29b as the wire diameter decreases and as the Sb content increases, which is attributed to the semimetal–semiconductor transition induced by quantum confinement and to Sb alloying effects in $Bi_{1-x}Sb_x$ nanowires. *Heremans* et al. have observed a substantial increase in the thermopower of Bi nanowires as the wire diameter further decreases, as shown in Fig. 4.30a for 15 nm Bi/silica and 9 nm Bi/alumina nanocomposites [4.63]. The enhancement is due to the sharp density of states near the Fermi energy in a 1-D system. Although the samples in Fig. 4.30a also possess very high electrical resistance ($\sim G\Omega$), the results for the 9 nm Bi/alumina samples show that the Seebeck coefficient can be enhanced by almost 1,000 times relative to bulk material. But for Bi nanowires with very small diameters (~ 4 nm), the localization effect becomes dominant, which compromises the thermopower enhancement. Therefore, for Bi nanowires, the optimal wire diameter range for the largest thermopower enhancement is found to be between 4 to 15 nm [4.63].

The effect of the nanowire diameter on the thermopower of nanowires has also been observed in Zn nanowires [4.63]. Figure 4.30b shows the Seebeck coefficient of 9 nm Zn/alumina and 4 nm Zn/Vycor glass nanocomposites, exhibiting enhanced thermopower as the wire diameter decreases. It is found that while 9 nm Zn nanowires still exhibit metallic behavior, the thermopower of 4 nm Zn nanowires shows a different temperature dependence, which may be due to the 1-D localization effect, although further investigation is required for a definitive identification of the conduction mechanism in such small nanowires.

Quantum Wire Superlattices

The *full line* on top of the figure is a fit to a T^{-1} law. The Seebeck coefficient of the 9 nm Bi/alumina composite is positive; the rest are negative. **(b)** The Seebeck coefficient of 9 nm Zn/Al_2O_3 and 4 nm Zn/Vycor glass nanocomposite samples in comparison to bulk Zn [4.63]

along the wire axis, have attracted much attention recently because of their promise in such applications as thermoelectrics (see Sect. 4.3.2) [4.149], nanobarcodes (see Sect. 4.3.3) [4.90], nanolasers (see Sect. 4.3.3) [4.92], one-dimensional waveguides, and resonant tunneling diodes [4.93, 150]. Figure 4.31a shows a schematic structure of a superlattice nanowire consisting of interlaced quantum dots of two different materials, as denoted by A and B. Various techniques have been developed to synthesize superlattice nanowire structures with different interface conditions, as mentioned in Sect. 4.1.1 and Sect. 4.1.2.

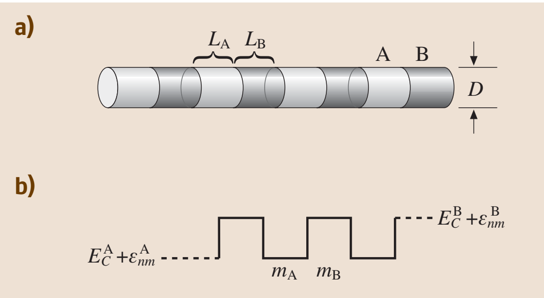

Fig. 4.31 **(a)** Schematic diagram of superlattice (segmented) nanowires consisting of interlaced nanodots A and B of the indicated length and wire diameter. **(b)** Schematic potential profile of the subbands in the superlattice nanowire [4.149]

In this superlattice (SL) nanowire structure, the electronic transport along the wire axis is made possible by the tunneling between adjacent quantum dots, while the uniqueness of each quantum dot and its 0-D characteristic behavior is maintained by the energy difference of the conduction or valence bands between quantum dots of different materials (see Fig. 4.31b), which provides some amount of quantum confinement. Recently *Björk* et al. have observed interesting nonlinear I–V characteristics with a negative differential resistance in one-dimensional heterogeneous structures made of InAs and InP, where InP serves as the potential barrier [4.93, 150]. The nonlinear I–V behavior is associated with the double barrier resonant tunneling in one-dimensional structures, demonstrating the capability of transport phenonema in superlattice nanowires via tunneling and the possibility of controlling the electronic band structure of the SL nanowires by carefully selecting the constituent materials. This kind of new structure is especially attractive for thermoelectric ap-

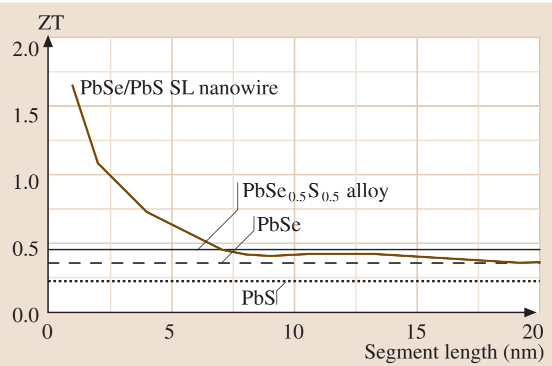

Fig. 4.32 Optimal ZT calculated as a function of segment length for 10-nm diameter PbSe/PbS nanowires at 77 K, where "optimal" refers to the placement of the Fermi level to optimize ZT. The optimal ZT for 10-nm diameter PbSe, PbS, and $PbSe_{0.5}S_{0.5}$ nanowires are 0.33, 0.22, and 0.48, respectively [4.141]

plications, because the interfaces between the nanodots can reduce the lattice thermal conductivity by blocking the phonon conduction along the wire axis, while electrical conduction may be sustained and even benefit from the unusual electronic band structures due to the periodic potential perturbation. For example, Fig. 4.32 shows the calculated dimensionless thermoelectric figure of merit $ZT = S^2\sigma T/\kappa$ (see Sect. 4.2.2) where κ is the total thermal conductivity (including both the lattice and electronic contribution) of 10-nm diameter PbS/PbSe superlattice nanowires as a function of the segment length. A higher thermoelectric performance than for $PbSe_{0.5}S_{0.5}$ alloy nanowires can be achieved for a 10 nm diameter superlattice nanowire with segment lengths ≤ 7 nm. But the localization effect, which may become important for very short segment lengths, may jeopardize this enhancement in the ZT of superlattice nanowires [4.141].

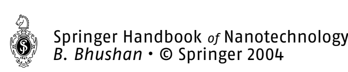
Thermal Conductivity of Nanowires

Experimental measurements of the temperature dependence of the thermal conductivity $\kappa(T)$ of individual suspended nanowires have been carried out to study the dependence of $\kappa(T)$ on the wire diameter. In this context, measurements have been made on nanowires down to only 22 nm in diameter [4.151]. Such measurements are very challenging and are now possible because of technological developments in fabricating and using nanometer size thermal scanning probes [4.120, 152, 153]. The experiments show that the thermal conductivity of small homogeneous nanowires may be more than one order of magnitude smaller than in the bulk, arising mainly from strong boundary scattering effects [4.154]. Phonon confinement effects may eventually become important at still smaller diameter nanowires (see Sect. 4.2.3). Measurements on mats of nanowires (see, for example, Fig. 4.12) do not generally give reliable results because the contact thermal resistance between adjacent nanowires tends to be high, which is in part due to the thin surface oxide coating that most nanowires have. This surface oxide coating may also be important for thermal conductivity measurements on individual suspended nanowires because of the relative importance of phonon scattering at the lateral walls of the nanowire.

The most extensive experimental thermal conductivity measurements have been done on Si nanowires [4.151] where $\kappa(T)$ measurements have been made on nanowires in the diameter range of $22 \leq d_W \leq 115$ nm. The results show a large decrease in the peak of $\kappa(T)$ associated with umklapp processes as d_W decreases, indicating a growing importance of boundary scattering and a corresponding decreasing importance of phonon–phonon scattering. At the smallest wire diameter of 22 nm, a linear $\kappa(T)$ dependence is found experimentally, consistent with a linear T dependence of the specific heat for a 1-D system and a temperature independent mean free path and velocity of sound.

Model calculations for $\kappa(T)$ based on a radiative heat transfer model have been carried out for Si nanowires [4.155]. These results show that the predicted $\kappa(T)$ behavior for Si nanowires is similar to that observed experimentally in the range of $37 \leq d_W \leq 115$ nm regarding both the functional form of $\kappa(T)$ and the magnitude of the relative decrease in the maximum thermal conductivity κ_{max} as a function of d_W. But the model calculations predict a substantially larger magnitude for $\kappa(T)$ (by 50% or more) than is observed experimentally. Furthermore, the model calculations (see Fig. 4.33) do not reproduce the experimentally observed linear T dependence for the 22 nm nanowires, but rather predict a 3-D behavior for both the density of states and the specific heat in 22 nm nanowires [4.155, 156].

Thermal conductance measurements on GaAs nanowires below 6 K show a power law dependence, but the T dependence becomes somewhat less pronounced below ~ 2.5 K [4.152]. This deviation from the power law temperature dependence led to a more detailed study of the quantum limit for the thermal conductance. To carry out these more detailed experiments, a mesoscopic phonon resonator and waveguide device were



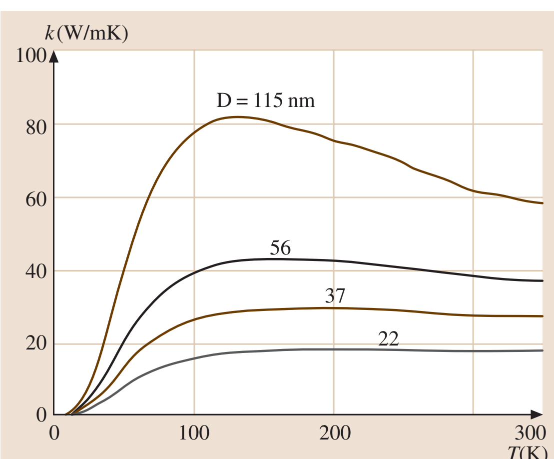


Fig. 4.33 Predicted thermal conductivity of Si nanowires of various diameters [4.155]

constructed that included four ∼ 200 nm wide and 85 nm thick silicon nitride nanowire-like nano-constrictions (see Fig. 4.34a) to establish the quantized thermal conductance limit of $g_0 = \pi^2 k_B^2 T/3h$ (see Fig. 4.34b) for ballistic phonon transport [4.157, 158]. For temperatures above 0.8 K, the thermal conductance in Fig. 4.34b follows a T^3 law, but as T is further reduced, a transition to a linear T dependence is observed, consistent with a phonon mean free path of ∼ 1 μm, and a thermal conductance value approaching $16g_0$, corresponding to four massless phonon modes per channel and four channels in their phonon waveguide structure (see Fig. 4.34a). Ballistic phonon transport occurs when the thermal phonon wavelength (380 nm for the experimental structure) is somewhat greater than the width of the phonon waveguide at its constriction.

4.2.3 Optical Properties

Optical methods provide an easy and sensitive tool for measuring the electronic structure of nanowires since optical measurements require minimal sample preparation (for example, contacts are not required) and the measurements are sensitive to quantum effects. Optical spectra of 1-D systems, such as carbon nanotubes, often show intense features at specific energies near singularities in the joint density of states formed under strong quantum confinement conditions. A variety of optical techniques have shown that the properties of nanowires are different from those of their bulk counterparts, and this section of the review focuses on these differences.

Although optical properties have been shown to provide an extremely important tool for the characterization of nanowires, the interpretation of these measurements is not always straightforward. The wavelength of light used to probe the sample is usually smaller than the wire length but larger than the wire diameter. Hence, the probe light used in an optical measurement cannot be focused solely onto the wire, and the wire and the substrate on which the wire rests (or host material, if the wires are embedded in a template) are simultaneously probed. For measurements, such as photo-luminescence

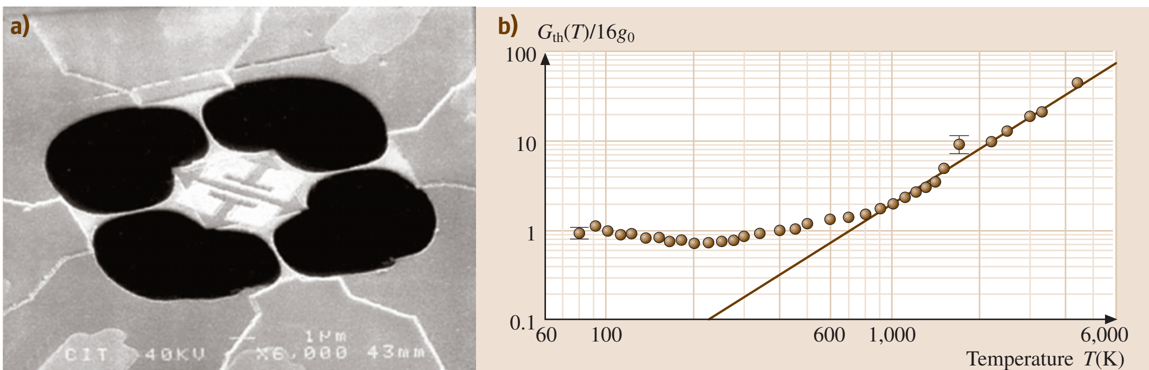

Fig. 4.34 **(a)** Suspended mesoscopic phonon device used to measure ballistic phonon transport. The device consists of an 4×4 μm "phonon cavity" (*center*) connected to four Si_3N_4 membranes, 60 nm thick and less than 200 nm wide. The two bright "C" shaped objects on the phonon cavity are thin film heating and sensing Cr/Au resistors, whereas the *dark regions* are empty space. **(b)** Log–log plot of the temperature dependence of the thermal conductance G_0 of the structure in **(a)** normalized to $16g_0$ (see text) [4.158]

(PL), if the substrate does not luminescence or absorb in the frequency range of the measurements, PL directly measures the luminescence of the nanowires and the substrate can be ignored. In reflection and transmission measurements, however, even a nonabsorbing substrate can modify the measured spectra of nanowires.

In this section, we discuss the determination of the dielectric function for nanowires in the context of effective medium theories. We then discuss various optical techniques with appropriate examples that sensitively differentiate nanowire properties from those also found in the parent bulk material, giving particular emphasis to electronic quantum confinement effects. Finally, we review phonon confinement effects.

The Dielectric Function

In this subsection we review the use of effective medium theory as a method to handle the optical properties of nanowires whose diameters are typically smaller than the wavelength of light, noting that observable optical properties of materials can be related to the complex dielectric function [4.159, 160]. Effective medium theories [4.161, 162] can be applied to model the nanowire and substrate as one continuous composite with a single complex dielectric function ($\epsilon_1 + i\epsilon_2$), where the real and imaginary parts of the dielectric function ϵ_1 and ϵ_2 are related to the index of refraction (n) and the absorption coefficient (K) by the relation $\epsilon_1 + i\epsilon_2 = (n + iK)^2$. Since photons at visible or infrared wavelengths "see" a dielectric function for the composite nanowire array/substrate system that is different from that of the nanowire itself, the optical transmission and reflection are different from what they would be if the light were focused only on the nanowire. One commonly observed consequence of effective medium theory is the shift in the plasma frequency in accordance with the percentage of nanowire material contained in the composite [4.163]. The plasma resonance occurs when $\epsilon_1(\omega)$ becomes zero, and the plasma frequency of the nanowire composite will shift to lower (higher) energies when the magnitude of the dielectric function of the host materials is larger (smaller) than that of the nanowire.

Although reflection and transmission measurements probe both the nanowire and the substrate, the optical properties of the nanowires can be independently determined. One technique for separating the dielectric function of the nanowires from the host is to use an effective medium theory in reverse. Since the dielectric function of the host material is often known, and since the dielectric function of the composite material can be measured by the standard method of using reflection and transmission measurements in combination with either the Kramer–Kronig relations or Maxwell's equations, the complex dielectric function of the nanowires can be deduced. This approach has been used successfully, for example, in determining the frequency dependence of the real and imaginary parts of the dielectric function $\epsilon_1(\omega)$ and $\epsilon_2(\omega)$ for a parallel array of bismuth nanowires filling the pores of an alumina template [4.164].

Optical Properties Characteristic of Nanowires

A wide range of optical techniques are available for the characterization of nanowires to distinguish their properties from those of their parent bulk materials. Some differences in properties are geometric, such as the small diameter size and the large length-to-diameter ratio (also called the aspect ratio), while other differences focus on quantum confinement issues.

Probably the most basic optical technique is to measure the reflection and/or transmission of a nanowire to determine the frequency-dependent real and imaginary parts of the dielectric function. This technique has been used, for example, to study the band gap and its temperature dependence in gallium nitride nanowires in the 10–50 nm range in comparison to bulk values [4.165]. The plasma frequency, free carrier density, and donor impurity concentration as a function of temperature were also determined from the infrared spectra, which is especially useful for nanowire research since Hall effect measurements cannot be made on nanowires.

Photo-luminescence (PL) or fluorescence spectroscopy is a common method to study nanowires. Emission techniques probe the nanowires directly, and the effect of the host material does not have to be considered. This characterization method has been used to study many properties of nanowires, such as the optical gap behavior, oxygen vacancies in ZnO nanowires [4.66], strain in Si nanowires [4.166], and quantum confinement effects in InP nanowires [4.92]. Figure 4.35 shows the photo-luminescence of InP nanowires as a function of wire diameter, thereby providing direct information on the effective band gap. As the wire diameter of an InP nanowire is decreased so that it becomes smaller than the bulk exciton diameter of 19 nm, quantum confinement effects set in, and the band gap is increased. This results in an increase in the PL peak energy because of the stronger electron–hole Coulomb binding energy within the quantum-confined nanowires as the wire radius gets smaller than the effective Bohr radius for the exciton for bulk InP. The smaller the effective mass, the larger the quantum con-

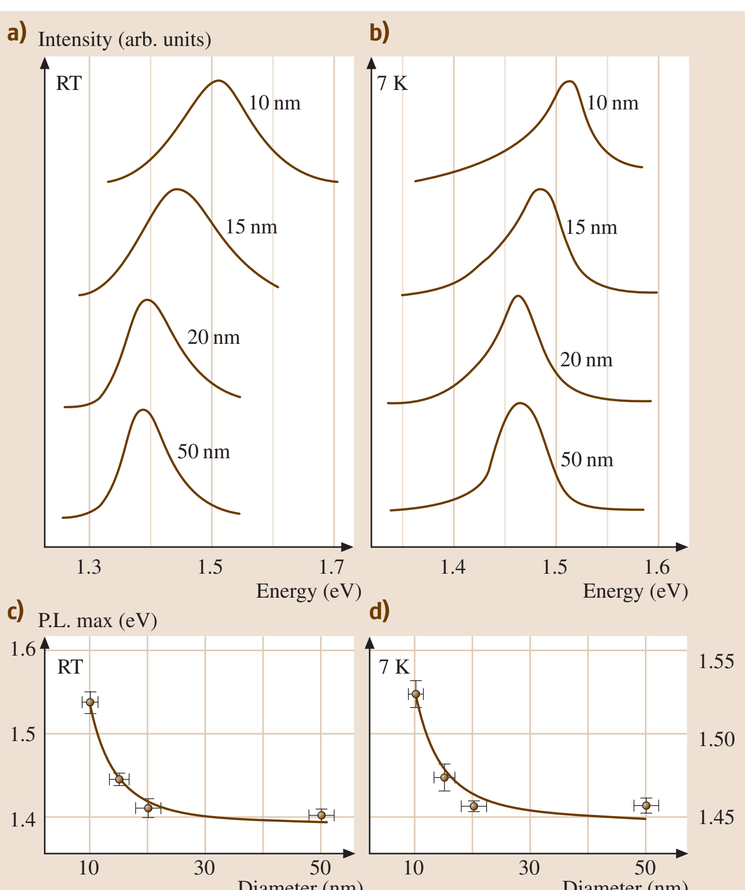

Fig. 4.35a–d Photo-luminescence of InP nanowires of varying diameters at 7 K ((**b**) and (**d**)) and room temperature ((**a**) and (**c**)), showing quantum confinement effects of the exciton for wire diameters less than 20 nm [4.92]

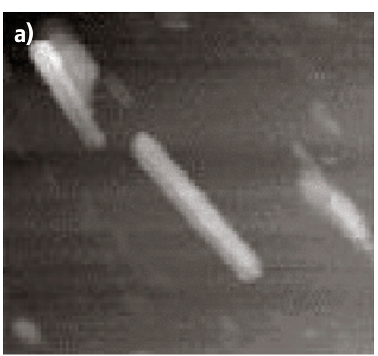
finement effects. When the shift in the peak energy as a function of nanowire diameter (Fig. 4.35a) is analyzed using an effective mass model, the reduced effective mass of the exciton is deduced to be $0.052m_0$, which agrees quite well with the literature value of $0.065m_0$ for bulk InP. Although the line widths of the PL peak for the small diameter nanowires (10 nm) are smaller at low temperature (7 K), the observation of strong quantum confinement and band gap tunability effects at room temperature are significant for photonics applications of nanowires (see Sect. 4.3.3).

The resolution of photo-luminescence (PL) optical imaging of a nanowire is, in general, limited by the wavelength of light. But when a sample is placed very close to the detector, the light is not given a chance to diffract, and so samples much smaller than the wavelength of light can be resolved. This technique is known as near-field scanning optical microscopy (NSOM) and has been used successfully [4.167] to image nanowires. For example, Fig. 4.36 shows the topographical (a) and PL (b) NSOM images of a single ZnO nanowire.

Magneto-optics can be used to measure the electronic band structure of nanowires. For example, magneto-optics in conjunction with photo-conductance has been proposed [4.168] as a tool to determine band parameters for nanowires, such as the Fermi energy, electron effective masses, and the number of subbands to be considered [4.168]. Since different nanowire subbands have different electrical transmission properties, the electrical conductivity changes when light is used to excite electrons to higher subbands, thereby providing a method for studying the electronic structure of nanowires optically. Magneto-optics can also be used to study the magnetic properties of nanowires in relation to bulk properties [4.44, 169]. For example, the surface magneto-optical Kerr effect has been used to measure



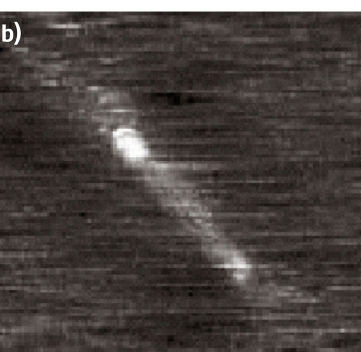


Fig. 4.36 **(a)** Topographical and **(b)** photoluminescence (PL) near-field scanning optical microscopy (NSOM) images of a single ZnO nanowire waveguide [4.167]

the dependence of the magnetic ordering temperature of Fe-Co alloy nanowires on the relative concentration of Fe and Co [4.169], and it was used to find that, unlike the case of bulk Fe-Co alloys, cobalt in nanowires inhibits magnetic ordering.

Nonlinear optical properties of nanowires have received particular attention since the nonlinear behavior is often enhanced over that in bulk materials and since the nonlinear effects can be utilized for many applications. One such study measured the second harmonic generation (SHG) and third harmonic generation (THG) in a single nanowire by using near-field optical microscopy [4.170]. ZnO nanowires were shown to have strong SHG and THG effects that are highly polarization-sensitive, and this polarization sensitivity can be explained on the basis of optical and geometrical considerations. Some components of the second harmonic polarization tensor are found to be enhanced in nanowires while others are suppressed as the wire diameter is decreased, and such effects could be of interest for device applications. The authors also showed that the second-order nonlinearities are mostly wavelength independent for $\lambda < 400$ nm, which is in the transparent regime for ZnO, below the onset of band gap absorption; this observation is also of interest for device applications.

Reflectivity and transmission measurements have also been used to study the effects of quantum confinement and surface effects on the low energy indirect transition in bismuth nanowires [4.171]. *Black* et al. [4.171] investigated an intense and sharp absorption peak in bismuth nanowires, which is not observed in bulk bismuth. The energy position E_p of this strong absorption peak increases with decreasing diameter. But the rate of increase in energy with decreasing diameter $|\partial E_p/\partial d_W|$ is an order of magnitude less than that predicted for either a direct interband transition or for intersubband transitions in bismuth nanowires. On the other hand, the magnitude of $|\partial E_p/\partial d_W|$ agrees well with that predicted for an indirect L-point valence to T-point valence band transition (see Fig. 4.37). Since both the initial and final states for the indirect L-T point valence band transition downshift in energy as the wire diameter d_W is decreased, the shift in the absorption peak results from a *difference* between the effective masses and not from the actual value of either of the masses. Hence the diameter dependence of the absorption peak energy is an order of magnitude less for a valence to valence band indirect transition than for a direct interband L-point transition. Furthermore, the band-tracking effect for the indirect transition gives rise to a large value for the joint density of states, thus accounting for the high intensity of this feature. The enhanced coupling of this indirect transition to an applied optical field arises through the gradient of the dielectric function, which is large at the bismuth-air or bismuth-alumina interfaces. It should be noted that, in contrast to the surface effect for bulk samples, the whole nanowire contributes to the optical absorption due to the spatial variation in the dielectric function, since the penetration depth is larger than or comparable to the wire diameter. In addition, the intensity can be quite significant because abundant initial state electrons, final state holes, and appropriate phonons exist for making an indirect L-T point valence band transition at room temperature. Interestingly, the polarization dependence of this absorption peak is such that the strong absorption is present when the electric field is perpendicular to the wire axis but is absent when the electric field is parallel to the wire axis; this is contrary to a traditional polarizer, such as a carbon nanotube in which the optical E field is polarized by the nanotube itself to be aligned along the carbon nanotube axis. The observed polarization dependence for bismuth nanowires is consistent

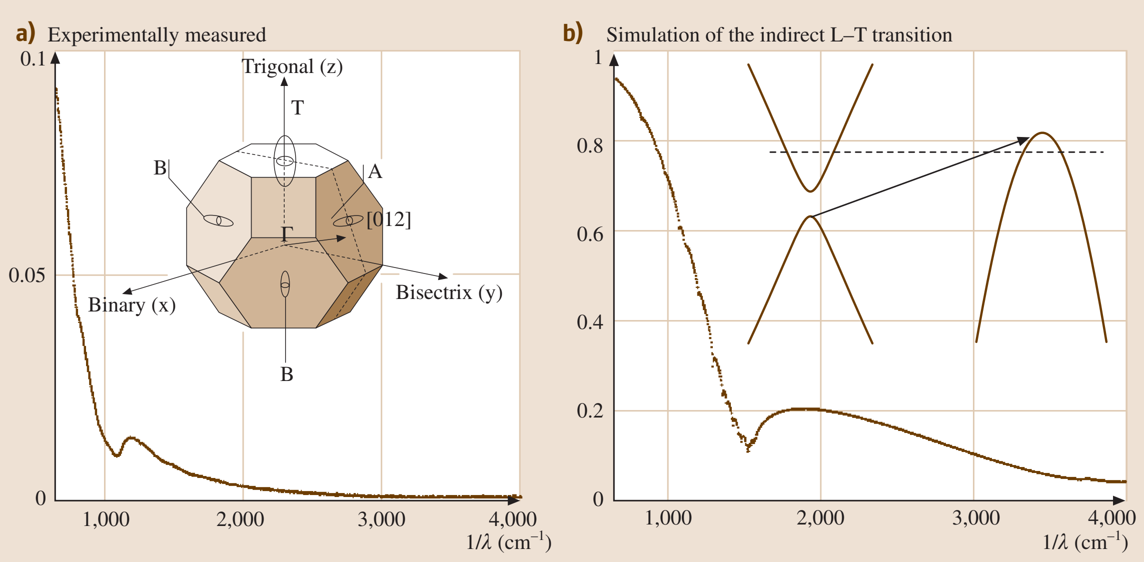

Fig. 4.37 **(a)** The measured optical transmission spectra as a function of wavenumber ($1/\lambda$) of a ~ 45 nm diameter bismuth nanowire array. **(b)** The simulated optical transmission spectrum resulting from an indirect transition of an L point electron to a T point valence subband state. The insert in **(a)** shows the bismuth Brillouin zone, and the location of the T-point hole and of the three L-point electron pockets, including the nondegenerate A, and the doubly degenerate B pockets. The insert in **(b)** shows the indirect L to T point electronic transition induced by a photon with an energy equal to the energy difference between the initial and final states minus the phonon energy (about 100 cm^{-1}) needed to satisfy conservation of energy in a Stokes process [4.171]

with a surface-induced effect that increases the coupling between the L-point and T-point bands throughout the full volume of the nanowire. Figure 4.37 shows the experimentally observed transmission spectrum in bismuth nanowires of ~ 45 nm diameter (a), and for comparison, the simulated optical transmission from an indirect transition in bismuth nanowires of ~ 45 nm diameter is also shown in (b). The indirect L to T point valence band transition mechanism [4.171] is also consistent with observations of the effect on the optical spectra of a decrease in the nanowire diameter and of n-type doping of bismuth nanowires with Te.

Phonon Confinement Effects

Phonons in nanowires are spatially confined by the nanowire cross-sectional area, crystalline boundaries and surface disorder. These finite size effects give rise to phonon confinement, causing an uncertainty in the phonon wave vector, which typically gives rise to a frequency shift and a lineshape broadening. Since zone center phonons tend to correspond to maxima in the phonon dispersion curves, the inclusion of contributions from a broader range of phonon wave vectors results in both a downshift in frequency and an asymmetric broadening of the Raman line that developes a low frequency tail. These phonon confinement effects have been theoretically predicted [4.173,174] and experimentally observed in GaN [4.172], as shown in Fig. 4.38 for GaN nanowires with diameters in the range 10–50 nm. The application of these theoretical models indicates that broadening effects should be noticeable as the wire diameter in GaN nanowires decreases to ~ 20 nm. When the wire diameter further decreases to ~ 10 nm, the frequency downshift and asymmetric Raman line broadening effects should become observable in the Raman spectra for the GaN nanowires but are not found in the corresponding spectra for bulk GaN.

The experimental spectra in Fig. 4.38 show the four $A_1 + E_1 + 2E_2$ modes expected from symmetry considerations for bulk GaN crystals. Two types of quantum confinement effects are observed. The first type is the observation of the downshift and asymmetric broadening effects discussed above. Observations of such downshifts and asymmetric broadening have also been recently reported in 7 nm diameter Si nanowires [4.175]. A second type of confinement effect found in Fig. 4.38 for GaN nanowires is the appearance of additional Raman features not found in the corresponding bulk spectra and associated with combination modes and a zone boundary mode. Resonant enhancement effects were also observed for the A_1(LO) phonon at 728 cm^{-1} (see Fig. 4.38) at higher laser excitation energies [4.172].

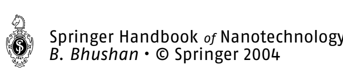
4.3 Applications

In the preceding sections we have reviewed many of the central characteristics that make nanowires in some cases similar and in some cases very different from their parent materials. We have also shown that some properties are diameter dependent and are therefore tunable during synthesis. Thus it is of great interest to find applications for nanowires that could benefit in unprecedented ways from both the unique and tunable properties of nanowires and the small size of these nanostructures, for use in the miniaturization of conventional devices. As the synthetic methods for the production of nanowires are maturing (Sect. 4.1), and nanowires can be made in reproducible and cost-effective ways, it is only a matter of time before applications will be explored seriously. This is a timely development, as the semiconductor industry will soon be reaching what seems to be its limit in feature-size reduction and approaching a classical-to-quantum size transition. At the same time the field of biotechnology is expanding through the availability of tremendous genome information and innovative screening assays. Since nanowires are the size of the shrinking electronic components and of cellular biomolecules, it is only natural for nanowires to be good candidates for applications in these fields. Commercialization of nanowire devices, however, will require reliable mass-production, effective assembly techniques, and quality-control methods.

In this section, we discuss applications of nanowires to electronics (Sect. 4.3.1), thermoelectrics (Sect. 4.3.2), optics (Sect. 4.3.3), chemical and biological sensing (Sect. 4.3.4), and magnetic media (Sect. 4.3.5).

4.3.1 Electrical Applications

The microelectronics industry continues to face technology (e.g., lithography) and economic challenges as the device feature size is decreased, especially below 100 nm. The self-assembly of nanowires might present a way to construct unconventional devices that do not



rely on improvements in photo-lithography and, therefore, do not necessarily imply increasing fabrication costs. Devices made from nanowires have several advantages over those made by photolithography. A variety of approaches has been devised to organize nanowires via self-assembly (see Sect. 4.1.4), thus eliminating the need for the expensive lithographic techniques normally required to produce devices the size of typical nanowires, which we discuss earlier (see Sect. 4.1). In addition, unlike traditional silicon processing, different semiconductors can be simultaneously used in nanowire devices to produce diverse functionalities. Not only can wires of different materials be combined, but a single wire can be made of different materials. For example, junctions of GaAs and GaP show rectifying behavior [4.92], thus demonstrating that good electronic interfaces between two different semiconductors can be achieved in the synthesis of multicomponent nanowires. Transistors made from nanowires could also have advantages because of their unique morphology. For example, in bulk field effect transistors (FETs), the depletion layer formed below the source and drain region results in a source-drain capacitance that limits the operation speed. In nanowires, however, the conductor is surrounded by an oxide and thus the depletion layer cannot be formed. Depending on the device design, the source-drain capacitance in nanowires could be greatly minimized and possibly eliminated.

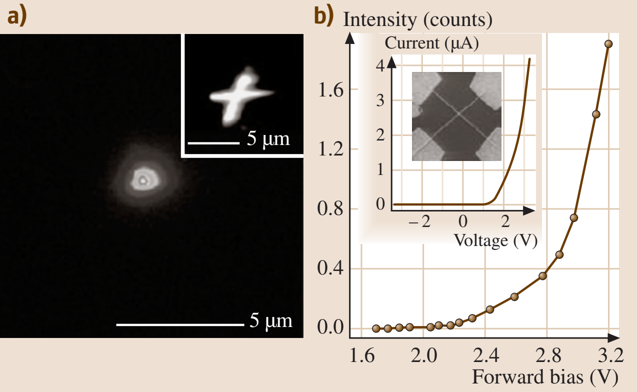


Fig. 4.39a,b Optoelectrical characterization of a crossed nanowire junction formed between 65-nm n-type and 68-nm p-type InP nanowires. **(a)** Electroluminescence (EL) image of the light emitted from a forward-biased nanowire p-n junction at 2.5 V. *Inset*, photoluminescence (PL) image of the junction. **(b)** EL intensity as a function of operation voltage. *Inset*, the SEM image and the I–V characteristics of the junction [4.52]. The scale bar in the *inset* is 5 µm

Device functionalities common in conventional semiconductor technologies, such the p-n junction diodes [4.129], field-effect transistors [4.131], logic gates [4.129], and light-emitting diodes [4.52, 92], have been recently demonstrated in nanowires, showing their promise as the building blocks for the construction of complex integrated circuits by employing the "bottom-up" paradigm. Several approaches have been investigated to form nanowire diodes (see Sect. 4.2.2). For example, Schottky diodes can be formed by contacting a GaN nanowire with Al electrodes [4.130]. Furthermore, p-n junction diodes can be formed at the crossing of two nanowires, such as the crossing of n and p-type InP nanowires doped by Te and Zn, respectively [4.52], or Si nanowires doped by phosphorus (n-type) and boron (p-type) [4.176]. In addition to the crossing of two distinctive nanowires, heterogeneous junctions have also been constructed inside a single wire, either along the wire axis in the form of a nanowire superlattice [4.92] or perpendicular to the wire axis by forming a core-shell structure of silicon and germanium [4.105]. These various nanowire junctions not only possess similar current rectifying properties (see Fig. 4.22) as expected for bulk semiconductor devices, but they also exhibit electro-luminescence (EL) that may be interesting for optoelectronic applications, as shown in Fig. 4.39 for the electroluminescence of a crossed junction of n and p-type InP nanowires [4.52] (see Sect. 4.3.3).

In addition to the two-terminal nanowire devices, such as the p-n junctions described above, it is found that the conductance of a semiconductor nanowire can be significantly modified by applying voltage at a third gate terminal, implying the utilization of nanowires as a field-effect transistor (FET). This gate terminal can either be the substrate [4.46, 47], a separate metal contact located close to the nanowire [4.177], or another nanowire with a thick oxide coating in the crossed nanowire junction configuration [4.129]. We discuss the operation principles of these nanowire-based FETs in Sect. 4.2.2. Various logic devices performing basic logic functions have been demonstrated using nanowire junctions [4.129], as shown in Fig. 4.40 for the OR and AND logic gates constructed from 2-by-1 and 1-by-3 nanowire p-n junctions, respectively. By functionalizing nanowires with redox active molecules to store charges, the nanowire FETs can exhibit bi-stable logic *on* or *off* states [4.131], which may be used for nonvolatile memory or as switches.

The *inset* shows the SEM image (*bar:* 1 μm) of an assembled AND gate and the symbolic electronic circuit. **(d)** The output voltage of the circuit in **(c)** versus the four possible logic address level inputs [4.129]

Nanowires have also been proposed for applications associated with electron field emission [4.178], such as flat panel displays, because of their small diameter and large curvature at the nanowire tip, which may reduce the threshold voltage for the electron emission [4.179]. In this connection, the demonstration of very high field emission currents from the sharp tip (~ 10 nm radius) of a Si cone [4.178] and from carbon nanotubes [4.180] stimulates interest in this potential application opportunity for nanowires.

The concept of constructing electronic devices based on nanowires has already been demonstrated, and the next step for electronic applications would be to devise a feasible method for integration and mass production. We expect that in order to maintain the growing rate of device density and functionality in the existing electronics industry, new kinds of complementary electronic devices will emerge from this "bottom-up" scheme for nanowire electronics, different from what has been produced by the traditional "top-down" approach pursued by conventional electronics.

4.3.2 Thermoelectric Applications

One proposed application for nanowires is for thermoelectric cooling and for the conversion between thermal and electrical energy [4.156, 181]. The efficiency of a thermoelectric device is measured in terms of a dimensionless figure of merit ZT, where Z is defined as

$$Z = \frac{\sigma S^2}{\kappa}, \quad (4.2)$$

in which σ is the electrical conductivity, S is the Seebeck coefficient, κ is the thermal conductivity, and T is the temperature. In order to achieve a high ZT and therefore efficient thermoelectric performance, a high electrical conductivity, a high Seebeck coefficient, and a low thermal conductivity are required. In 3-D systems, the electronic contribution to κ is proportional to σ in accordance with the Wiedemann–Franz law, and normally materials with high S have a low σ. Hence an increase in the electrical conductivity (e.g., by electron donor doping) results in an adverse variation in both the Seebeck coefficient (decreasing) and the thermal conductivity (increasing). These two trade-offs set the upper limit for increasing ZT in bulk materials, with the maximum ZT remaining at ~ 1 at room temperature for the 1960–1995 time frame.

The high electronic density of states in quantum-confined structures is proposed as a promising possibility to bypass the Seebeck/electrical conductivity trade-off and to control each thermoelectric-related variable independently, thereby allowing for an increased electrical conductivity, a relatively low thermal

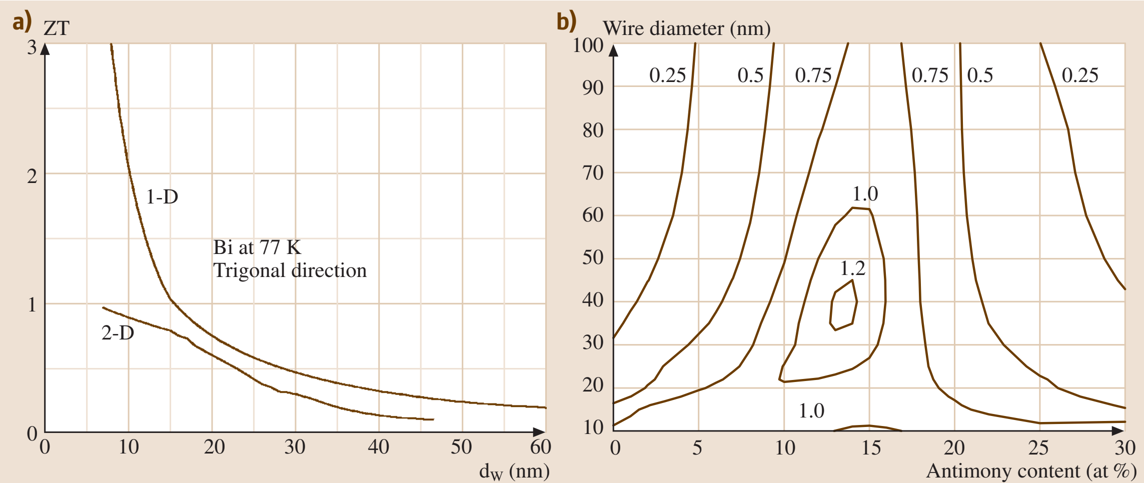

Fig. 4.41 (a) Calculated ZT of 1-D(nanowire) and 2-D(quantum well) bismuth systems at 77 K as a function of d_W, denoting the wire diameter or film thickness. The thermoelectric performance (i. e., ZT) is expected to improve greatly when the wire diameter is small enough so that the nanowire become a one-dimensional system. **(b)** Contour plot of optimal ZT values for p-type $Bi_{1-x}Sb_x$ nanowires vs. wire diameter and antimony concentration calculated at 77 K [4.183]

conductivity, and a large Seebeck coefficient simultaneously [4.182]. For example, Figs. 4.29b and 4.30a in Sect. 4.2.2 show an enhancement in S for bismuth an dbismuth-antimony nanowires as the wire diameter decreases. In addition to alleviating the undesired connections between σ, S, and the electronic contribution to the thermal conductivity, nanowires also have the advantage that the phonon contribution to the thermal conductivity is greatly reduced because of boundary scattering (see Sect. 4.2.2), thereby achieving a high ZT. Figure 4.41a shows the theoretical values for ZT vs. sample size for both bismuth thin films (2-D) and nanowires (1-D) in the quantum confined regime, exhibiting a rapidly increasing ZT as the quantum size effect becomes more and more important [4.182]. In addition, the quantum size effect in nanowires can be combined with other parameters to tailor the band structure and electronic transport behavior (e.g., Sb alloying in Bi) to further optimize ZT. For example, Fig. 4.41b shows the predicted ZT for p-type $Bi_{1-x}Sb_x$ alloy nanowires as a function of wire diameter and Sb content x [4.183]. The occurrence of a local ZT maxima in the vicinity of $x \sim 0.13$ and $d_W \sim 45$ nm is due to the coalesce of ten valence bands in the nanowire and the resulting unusual high density of states for holes, which is a phenomenon absent in bulk $Bi_{1-x}Sb_x$ alloys. For nanowires with very small diameters, it is speculated that localization effects will eventually limit the enhancement of ZT. But in bismuth nanowires, localization effects are not significant for wires with diameters larger than 9 nm [4.63]. In addition to 1-D nanowires, ZT values as high as ~ 2 have also been experimentally demonstrated in macroscopic samples containing PbSe quantum dots (0-D) [4.184] and stacked 2-D films [4.154].

Although the application of nanowires to thermoelectrics seems very promising, these materials are still in the research phase of the development cycle and quite far from being commercialized. One challenge for thermoelectric devices based on nanowires lies in finding a suitable host material that will not reduce ZT too much due to the unwanted heat conduction through the host material. The host material should, therefore, have a low thermal conductivity and occupy as low a volume percentage in the composite material as possible while still providing the quantum confinement and the support for the nanowires.

4.3.3 Optical Applications

Nanowires also hold promise for optical applications. One-dimensional systems exhibit a singularity in their joint density of states, allowing quantum effects in nanowires to be optically observable, sometimes, even at room temperature. Since the density of states of a nanowire in the quantum limit (small wire diameter)

is highly localized in energy, the available states quickly fill up with electrons as the intensity of the incident light is increased. This filling up of the subbands, as well as other effects unique to low-dimensional materials, lead to strong optical nonlinearities in quantum wires. Quantum wires may thus yield optical switches with a lower switching energy and increased switching speed compared to currently available optical switches.

Light emission from nanowires can be achieved by photo-luminescence (PL) or electro-luminescence (EL), distinguished by whether the electronic excitation is achieved by optical illumination or by electrical stimulation across a p-n junction, respectively. PL is often used for optical properties characterization, as described in Sect. 4.2.3, but from the applications point of view, EL is a more convenient excitation method. Light emitting diodes (LEDs) have been achieved in junctions between a p-type and an n-type nanowire (Fig. 4.39) [4.52] and in superlattice nanowires with p-type and n-type segments [4.92]. The light emission was localized to the junction area and was polarized in the superlattice nanowire.

Light emission from quantum wire p-n junctions is especially interesting for laser applications, because quantum wires can form lasers with lower excitation thresholds compared to their bulk counterparts, and they also exhibit a decreased temperature sensitivity in their performance [4.185]. Furthermore, the emission wavelength can be tuned for a given material composition by only altering the geometry of the wire.

Lasing action has been reported in ZnO nanowires with wire diameters much smaller than the wavelength of the light emitted ($\lambda = 385$ nm) [4.115] (see Fig. 4.42). Since the edge and lateral surface of ZnO nanowires are faceted (see Sect. 4.2.1), they form optical cavities that sustain desired cavity modes. Compared to conventional semiconductor lasers, the exciton laser action employed in zinc oxide nanowire lasers exhibits a lower lasing threshold ($\sim 40\,\mathrm{kW/cm^2}$) than their 3-D counterparts ($\sim 300\,\mathrm{kW/cm^2}$). In order to utilize exciton confinement effects in the lasing action, the exciton binding energy (~ 60 meV in ZnO) must be greater than the thermal energy (~ 26 meV at 300 K). Decreasing the wire diameter increases the excitation binding energy and lowers the threshold for lasing. PL NSOM imaging confirmed the waveguiding properties of the anisotropic and well-faceted structure of ZnO nanowires, limiting the emission to the tips of the ZnO nanowires [4.167].

Laser action has been also observed in GaN nanowires [4.186]. Unlike ZnO, GaN has a small exciton binding energy, of only ~ 25 meV. Furthermore, since the wire radii used in this study (15–75 nm) [4.186] are larger than the Bohr radius of excitons in GaN (11 nm), the exciton binding energy is not expected to increase in these GaN wires and quantum confinement effects such as shown in Fig. 4.35 for InP are not expected. Some tunability of the center of the spectral intensity, however, was achieved by increasing the intensity of the pump power, causing a redshift in the laser emission, which is explained as a band gap renormalization as a result of the formation of an electron-hole plasma. Heating effects were excluded as the source of the spectral shift.

Nanowire photodetectors were also proposed. ZnO nanowires were found to display a strong photocurrent response to UV light irradiation [4.187]. The con-

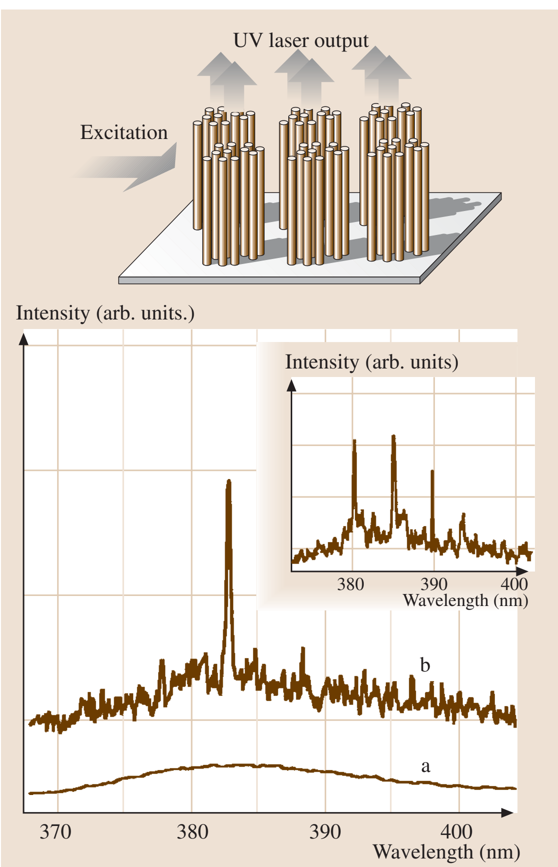

Fig. 4.42 A schematic of lasing in ZnO nanowires and the PL spectra of ZnO nanowires at two excitation intensities. One PL spectra is taken below the lasing threshold, and the other above it [4.115]

Part A | 4.3

ductivity of the nanowire increased by four orders of magnitude compared to the dark state. The response of the nanowire was reversible and selective to photon energies above the band gap, suggesting that ZnO nanowires could be a good candidate for optoelectronic switches.

Nanowires have also been proposed for another type of optical switching. Light with its electric field normal to the wire axis excites a transverse free carrier resonance inside the wire, while light with its electric field parallel to the wire axis excites a longitudinal free carrier resonance inside the wire. Since nanowires are highly anisotropic, these two resonances occur at two different wavelengths and thus result in absorption peaks at two different energies. Gold nanowires dispersed in an aqueous solution align along the electric field when a DC voltage is applied. The energy of the absorption peak can be toggled between the transverse and longitudinal resonance energies by changing the alignment of the nanowires under polarized light illumination using an electric field [4.188, 189]. Thus, electro-optical modulation is achieved.

Nanowires may also be used as barcode tags for optical read out. Nanowires containing gold, silver, nickel, palladium, and platinum were fabricated [4.104] by electrochemical filling of porous anodic alumina, so that each nanowire consisted of segments of various metal constituents. Thus many types of nanowires can be made from a handful of materials and identified by the order of the metal segments along their main axis and the length of each segment. Barcode read out is possible by reflectance optical microscopy. The segment length is limited by the Rayleigh diffraction limit and not by synthesis limitations; thus it can be as small as 145 nm. Figure 4.43a shows an optical image of many Au-Ag-Au-Ag bar-coded wires, where the silver segments show higher reflectivity. Figure 4.43b is a backscattering mode FE-SEM image of a single nanowire, highlighting the composition and segment length variations along the nanowire.

Both the large surface area and the high conductivity along the length of nanowires are favorable for their use in inorganic-organic solar cells [4.190], which offer promise from a manufacture-ability and cost effective standpoint. In a hybrid nanocrystal-organic solar cell, the incident light forms bound electron–hole pairs (excitons) in both the inorganic nanocrystal and in the surrounding organic medium. These excitons diffuse to the inorganic–organic interface and disassociate to form an electron and a hole. Since conjugated polymers usually have poor electron mobilities, the inorganic phase is chosen to have a higher electron affinity than the organic phase so that the organic phase carries the holes and the semiconductor carries the electrons. The separated electrons and holes drift to the external electrodes through the inorganic and organic materials, respectively. But only those excitons formed within an exciton diffusion length from an interface can disassociate before recombining, and therefore the distance between the dissociation sites limits the efficiency of a solar cell. A solar cell prepared from a composite of CdSe nanorods inside poly (3-ethylthiophene) [4.190] yielded 6.9% monochromatic power efficiencies and 1.7% power conversion efficiencies under A.M. 1.5 illumination (equal to solar irradiance through 1.5 times the air mass of the earth at direct normal incidence). The nanorods provide a large surface area with good chemical bonding to the polymer for efficient charge transfer and exciton dissociation. Furthermore, they provide a good conduction path for the electrons to reach the electrode. Their enhanced absorption coefficient and their tunable band gap are also characteristics that can be used to enhance the energy conversion efficiency of solar cells.

4.3.4 Chemical and Biochemical Sensing Devices

Sensors for chemical and biochemical substances with nanowires as the sensing probe are a very attractive application area. Nanowire sensors will potentially be smaller, more sensitive, demand less power, and react faster than their macroscopic counterparts. Arrays of nanowire sensors could, in principle, achieve nanometer scale spatial resolution and therefore provide accurate real-time information regarding not only the concentration of a specific analyte but also its spatial distribution. Such arrays, for example, could be very useful for dynamic studies on the effects of chemical gradients on biological cells. The operation of sensors made with nanowires, nanotubes, or nano-contacts is based mostly on the reversible change in the conductance of the nanostructure upon absorption of the agent to be detected, but other detection methods, such as mechanical and optical detection, are conceptually plausible. The increased sensitivity and faster response time of nanowires are a result of the large surface-to-volume ratio and the small cross-section available for conduction channels. In the bulk, on the other hand, the abundance of charges can effectively shield external fields, and the abundance of material can afford many alternative conduction channels. Therefore a stronger chemical stimulus and longer response time are necessary to observe changes in the physical properties of a 3-D sensor in comparison to a nanowire.

Cui et al. placed silicon nanowires made by the VLS method (Sect. 4.1.2) between two metal electrodes and modified the silicon oxide coating of the wire by the addition of molecules sensitive to the analyte to be detected [4.191]. For example, a pH sensor was made by covalently linking an amine containing silane to the surface of the nanowire. Variations in the pH of the solution into which the nanowire was immersed caused protonation and deprotonation of the $-NH_2$ and the $-SiOH$ groups on the surface of the nanowire. The variation in surface charge densities regulates the conductance of the nanowire; due to the p-type characteristics of a silicon wire, the conductance increases with the addition of negative surface charge. The combined acid and base behavior of the surface groups results in an approximately linear dependence of the conductance on pH in the pH range 2 to 9, thus leading to a direct readout pH meter. This same type of approach was used for the detection of the binding of biomolecules, such as streptavidin using biotin-modified nanowires (see Fig. 4.44). This nanowire-based device has high sensitivity and could detect streptavidin binding down to a 10 pM (10^{-12} mole) concentration. The chemical detection devices were made in a field-effect transistor geometry, so that the back-gate potential could be used to regulate the conductance in conjugation with the chemical detection and to provide a real time direct read out [4.191]. The extension of this device to detect multiple analytes, using multiple nanowires each sensitized to a different analyte, could provide for fast, sensitive and in-situ screening procedures.

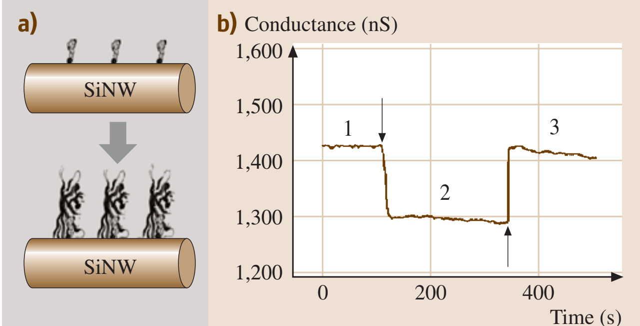

Fig. 4.44 (a) Streptavidin molecules bind to a silicon nanowire functionalized with biotin. The binding of streptavidin to biotin causes the nanowire to change its resistance. **(b)** The conductance of a biotin-modified silicon nanowire exposed to streptavidin in a buffer solution (regions 1 and 3) and with the introduction of a solution of antibiotin monoclonal antibody (region 2) [4.191]

Favier et al. used a similar approach, making a nanosensor for the detection of hydrogen out of an array of palladium nanowires between two metal contacts [4.56]. They demonstrated that nanogaps were present in their nanowire structure, and upon absorption of H_2 and formation of Pd hydride, the nanogap structure would close and improve the electrical contact, thereby increasing the conductance of the nanowire array. The response time of these sensors was 75 msec, and they could operate in the range of 0.5 to 5% H_2 before saturation occurred.

4.3.5 Magnetic Applications

It has been demonstrated that arrays of single domain magnetic nanowires can be prepared with controlled nanowire diameter and length, aligned along a common direction and arranged in a close-packed ordered array (see Sect. 4.1.1), and that the magnetic properties (coercivity, remanence, and dipolar magnetic interwire interaction) can be controlled to achieve a variety of magnetic applications [4.54, 71].

Magnetic information storage is the most interesting of these applications. The large nanowire aspect ratio (length/diameter) prevents the onset of the "superparamagnetic" limit at which the magnetization direction in the magnetic grains can be reversed by the thermal energy $k_B T$, thereby resulting in loss of recorded data in the magnetic recording medium. The magnetic energy in a grain can be increased by increasing either the volume or the anisotropy of the grain. If the volume is increased, the particle size increases, and thus, the resolution is decreased. For spherical magnetized grains, the superparamagnetic limit at room temperature is reached at 70 Gbit/in^2. In nanowires, the anisotropy is very large and yet the wire diameters are small, so the magnetostatic switching energy can easily be above the thermal energy while the spatial resolution is large. For magnetic data storage applications, a large aspect ratio is needed for the nanowires to maintain a high coercivity, and a sufficient separation between nanowires is needed to suppress inter-wire magnetic dipolar coupling (see Sect. 4.2.1). Thus nanowires can form stable and highly dense magnetic memory arrays with packing densities in excess of 10^{11} wires/cm^2.

The onset of superparamagnetism can be prevented in the single domain magnetic nanowire arrays that have already been fabricated either using porous alumina templates to make Ni nanowires with 35 nm diameters [4.54] or diblock copolymer templates [4.71] to make Co nanowires, with mean diameters of 14 nm and 100% filling of the template pores (see Sect. 4.1.1). Ordered magnetic nanowire arrays that have already been demonstrated offer the exciting promise for achieving systems permitting 10^{12} bits/in^2 data storage.

4.4 Concluding Remarks

A review has been presented of synthesis, characterization, and physical properties of nanowires, with particular reference to nanowire properties that differ from those of their bulk counterparts and to potential applications that might result from the special structure and properties of nanowires. We have shown in this chapter that the emerging field of nanowire research has developed rapidly over the past few years, driven by the development of a variety of complementary nanowire synthesis methods and of effective tools to measure both their structure and properties, as reviewed, respectively, in Sect. 4.1 and Sect. 4.2. At present, much of the progress is at the demonstration-of-concept level, with many gaps in knowledge remaining to be elucidated, theoretical models to be developed, and new nanowire systems to be explored. Having demonstrated that many of the most interesting discoveries to date relate to nanowire properties not present in their bulk material counterparts, we can expect future research emphasis to be focused increasingly on smaller diameter nanowires, where new unexplored physical phenomena related to quantum confinement effects are more likely to be found. We can also expect the development of applications to soon follow. Many promising applications are now at the early demonstration stage (see Sect. 4.3), but are moving ahead rapidly because of their promise for new functionality, not previously available, to the fields of electronics, opto-electronics, biotechnology, magnetics, and energy conversion and generation, among others. Many exciting challenges remain in advancing both the nanoscience and the nano-technological promise already demonstrated by the nanowire research described in this review.

5. Introduction to Micro/Nanofabrication

In this chapter, we discuss various *micro/nanofabrication* techniques used to manufacture structures in a wide range of dimensions (mm–nm). Starting with some of the most common microfabrication techniques (lithography, deposition, and etching), we present an array of *micromachining* and *MEMS* technologies that can be used to fabricate microstructures down to ∼1 μm. These techniques have attained an adequate level of maturity to allow for a variety of MEMS-based commercial products (pressure sensors, accelerometers, gyroscopes, etc.). More recently, nanometer-sized structures have attracted an enormous amount of interest. This is mainly due to their unique electrical, magnetic, optical, thermal, and mechanical properties. These could lead to a variety of electronic, photonic, and sensing devices with a superior performance compared to their macro counterparts. Subsequent to our discussion on MEMS and micromachining, we present several important *nanofabrication* techniques currently under intense investigation. Although e-beam and other high resolution lithographies can be used to fabricate nanometer-sized structures, their serial nature and/or cost preclude their widespread application. This has forced investigators to explore alternative and potentially superior techniques such as *strain engineering*, *self-assembly*, and *nano-imprint* lithography. Among these, self-assembly is the most promising method, due to its low cost and the ability to produce nanostructures at different length scales.

References 180

Recent innovations in the area of *micro/nanofabrication* have created a unique opportunity for manufacturing structures in the nanometer–millimeter range. The available six orders of magnitude dimensional span can be used to fabricate novel electronic, optical, magnetic, mechanical, and chemical/biological devices with applications ranging from sensors to computation and control. In this chapter, we will introduce major micro/nanofabrication techniques currently used to fabricate structures in the nanometer to several hundred micrometer range. We will focus mainly on the most important and widely used techniques and will not discuss specialized methods. After a brief introduction to basic microfabrication, we will discuss *MEMS*-fabrication techniques used to build microstructures down to about 1 μm in dimensions. Following this, we will discuss several major top-down and bottom-up nanofabrication methods that have shown great promise in manufacturing *nanostructures* (dimensions < 1 μm).

5.1 Basic Microfabrication Techniques

Most micro/nanofabrication techniques have their roots in the standard fabrication methods developed for the semiconductor industry [5.1–3]. Therefore, a clear understanding of these techniques is necessary for anyone embarking on a research and development path in the micro/nano area. In this section, we will discuss major microfabrication techniques used most frequently in the manufacturing of micro/nanostructures. Some of these techniques such as thin-film deposition and etching are common between the micro/nano and VLSI microchip fabrication disciplines. However, several other techniques that are more specific to the micro/nanofabrication area will also be discussed in this section.

5.1.1 Lithography

Lithography is the technique used to transfer a computer generated pattern onto a substrate (silicon, glass, GaAs, etc.). This pattern is subsequently used to etch an underlying thin film (oxide, nitride, etc.) for various purposes (doping, etching, etc.). Although photolithography, i. e., the lithography using a UV light source, is by far the most widely used lithography technique in microelectronic fabrication, electron-beam (e-beam) and X-ray lithography are two other alternatives that have attracted considerable attention in the MEMS and nanofabrication areas. We will discuss photolithography in this section and postpone the discussion of e-beam and X-ray techniques to the subsequent sections dealing with MEMS and nanofabrication.

The starting point following the creation of the computer layout for a specific fabrication sequence is the generation of a photomask. This involves a sequence of photographic processes (using optical or e-beam pattern generators) that results in a glass plate having the desired pattern in the form of a thin (∼ 100 nm) chromium layer. Following the generation of photomask, the lithography process can proceed as shown in Fig. 5.1. This sequence demonstrates the pattern transfer onto a substrate coated with silicon dioxide. However, the same technique is applicable to other materials. After depositing the desired material on the substrate, the photolithography process starts with spin coating the substrate with a photoresist. This is a polymeric photosensitive material that can be spun onto the wafer in liquid form (usually an adhesion promoter such as hexamethyldisilazane HMDS is used prior to the application of the resist). The spinning speed and photoresist viscosity will determine the final resist thickness, which is typically between 0.5–2.5 μm. Two different kinds of photoresist are available: positive and negative. In the positive resist, the UV-exposed areas will be dissolved in the subsequent development stage, whereas in the negative photoresist, the exposed areas will remain intact after the development. Due to its better performance with regard to the process control in small geometries, the positive resist is the most extensively used photoresist in the VLSI processes. After spinning the photoresist on the wafer, the substrate is soft baked (5–30 min at 60–100 °C) in order to remove the solvents from the resist and improve the adhesion. Subsequently, the mask is aligned to the wafer and the photoresist is exposed to a UV source.

Depending on the separation between the mask and the wafer, three different exposure systems are available: 1) contact, 2) proximity, and 3) projection. Although contact printing gives better resolution compared to the proximity technique, the constant contact of the mask with photoresist reduces the process yield and can damage the mask. Projection printing uses a dual-lens optical system to project the mask image onto the wafer. Since only one die at a time can be exposed, this requires a step-and-repeat system to totally cover the wafer area. Projection printing is by far the most widely used system in microfabrication and can yield superior resolutions compared to contact and proximity methods. The exposure source for photolithography depends on the resolution. Above 0.25 μm minimum line width, high pressure mercury lamp is adequate (436 nm g-line and 365 nm i-line). However, between 0.25 and 0.13 μm, deep UV sources such as excimer lasers (248 nm KrF and 193 nm ArF) are required. Although there has been extensive competition for the below 0.13 μm regime (including e-beam and X-ray), extreme UV (EUV) with

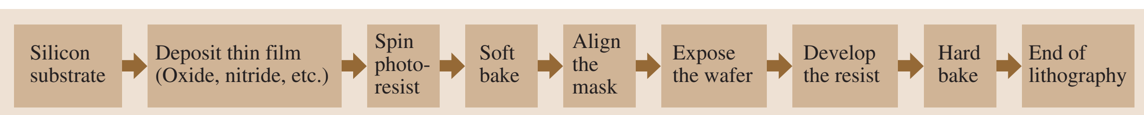

Fig. 5.1 Lithography process flow

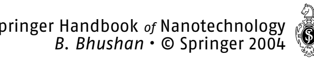

a wavelength of 10–14 nm seems to be the preferred technique [5.4].

After exposure, the photoresist is developed in a process similar to the development of photographic film. The resist is subsequently hard baked (20–30 min at 120–180 °C) in order to further improve the adhesion. The hard bake step concludes the photolithography sequence by creating the desired pattern on the wafer. Next, the underlying thin film is etched, and the photoresist is stripped in acetone or other organic removal solvents. Figure 5.2 shows schematic drawing of photolithography steps with a positive photoresist.

5.1.2 Thin Film Deposition and Doping

Thin-film deposition and doping are used extensively in micro/nanofabrication technologies. Most of the fabricated micro/nanostructures contain materials other than that of the substrate, which are obtained by various deposition techniques, or by modification of the substrate. The following is a list of a few typical applications for the deposited and/or doped materials used in micro/nanofabrication that gives an idea of the required properties:

- Mechanical structure
- Electrical isolation
- Electrical connection
- Sensing or actuating
- Mask for etching and doping
- Support or mold during deposition of other materials (sacrificial materials)
- Passivation

Most of the deposited thin films have different properties than those of their corresponding "bulk" forms (for example, metals show higher resistivities as thin films). In addition, the techniques utilized to deposit these materials have a great impact on their final properties. For instance, internal stress (compressive or tensile) in a film is strongly process-dependent. Excessive stress may crack or detach the film from the substrate and therefore must be minimized, although it may also be useful for certain applications. Adhesion is another important issue that needs to be taken into account when depositing thin films. In some cases such as the deposition of noble metals (e.g., gold) an intermediate layer (chromium or titanium) may be needed to improve the adhesion. Finally, step coverage and conformality are two properties that can also influence the choice of deposition technique. Figure 5.3 illustrates these concepts.

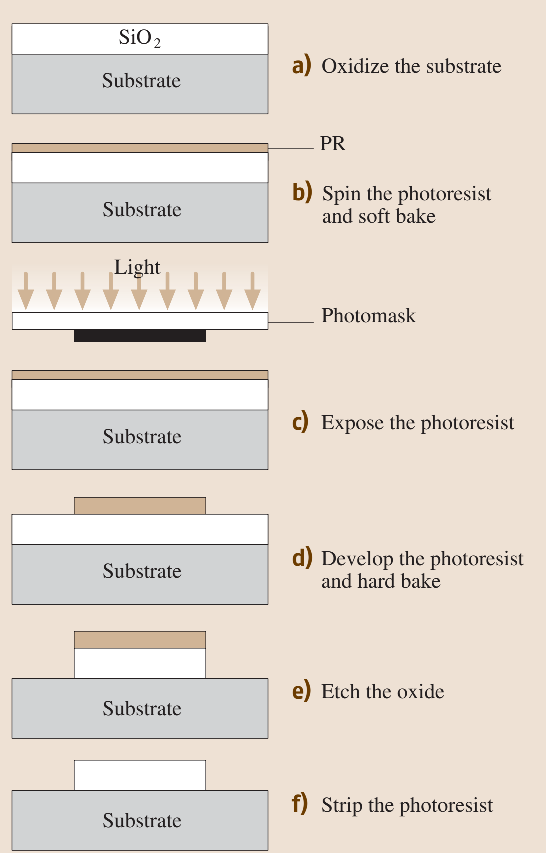

Fig. 5.2 Schematic drawing of the photolithographic steps with a positive photoresist (PR)

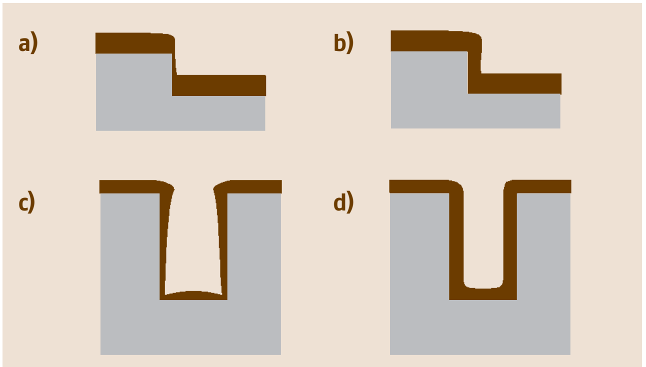

Fig. 5.3a–d Step coverage and conformality: **(a)** poor step coverage, **(b)** good step coverage, **(c)** nonconformal layer, and **(d)** conformal layer

Oxidation

Oxidation of silicon is a process used to obtain a thin film of SiO_2 of excellent quality (very low density of defects) and thickness homogeneity. Although it is not properly a deposition, the result is the same, i.e., a thin layer of a new material covering the surface is produced. The oxidation process is typically carried out at temperatures in the range of 900 °C to 1,200 °C in the presence of O_2 (dry oxidation) or H_2O (wet oxidation). The reactions for oxide formation are:

$$Si_{(solid)} + O_{2(gas)} \Rightarrow SiO_{2(solid)}$$

and

$$Si_{(solid)} + 2H_2O_{(steam)} \Rightarrow SiO_{2(solid)} + 2H_{2(gas)} \ .$$

Although the rate of the oxide growth is higher for wet oxidation, it is achieved at the expense of a lower oxide quality (density). Since silicon atoms from the substrate participate in the reaction, the substrate is consumed as the oxide grows ($\sim$ 44% of the total thickness lies above the line of the original silicon surface). The oxidation of silicon also occurs at room temperature, however, a layer of about 20 Å (native oxide) is enough to passivate the surface and prevent further oxidation. To grow thicker oxides, wafers are introduced into an electric resistance furnace such as the one represented in Fig. 5.4. Tens of wafers can be processed in a single batch in such equipment. By strictly controlling the timing, temperature, and gas flow entering the quartz tube, the desired thickness can be achieved with a high accuracy. Thicknesses ranging from a few tens of Angstroms to 2 µm can be obtained in reasonable times. Despite the good quality of the SiO_2 obtained by silicon oxidation (also called *thermal oxide*), the use of this process is often limited to the early stages of fabrication, since some of the materials added during the formation of structures may not withstand the high temperatures. The contamination of the furnace when the substrates have been previously in contact with certain etchants such as KOH, or when materials such as metals have been deposited also pose limitations in most of the cases.

Doping

The introduction of certain impurities in a semiconductor can change its electrical, chemical, and even mechanical properties. Typical impurities, or *dopants*, used in silicon include boron (to form p-type regions) and phosphorous or arsenic (to form n-type regions). Doping is the main process used in the microelectronic industry to fabricate major components such as diodes and transistors. In micro/nanofabrication technologies doping has additional applications such as the formation of piezoresistors for mechanical transducers and the creation of etch stop layers. Two different techniques are used to introduce the impurities into a semiconductor substrate: diffusion and ion implantation.

Diffusion is the process that became dominant in the initial years following the invention of the integrated circuit to form n- and p-type regions in the silicon. The diffusion of impurities into the silicon occurs only at high temperatures (above 800 °C). Furnaces used to carry out this process are similar to the oxidation ones. The dopants are introduced into the furnace's gaseous atmosphere from liquid or solid sources. Figure 5.5 illustrates the process of creating an n-type region by diffusion of phosphor from the surface into a p-type substrate. A masking material is previously deposited and patterned on the surface to define the areas to be doped. However, because diffusion is an isotropic process, the doped area will also extend underneath the mask. In microfabrication, diffusion is mainly used for the formation of very highly doped boron regions (p^{++}), which are usually used as an etch stop in bulk *micromachining*.

Ion implantation allows a more precise control of the dose (total amount of impurities introduced per area unit)

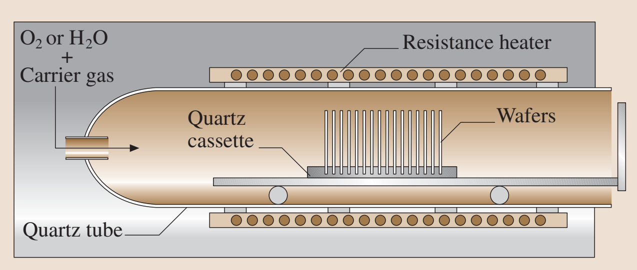

Fig. 5.4 Schematic representation of a typical oxidation furnace

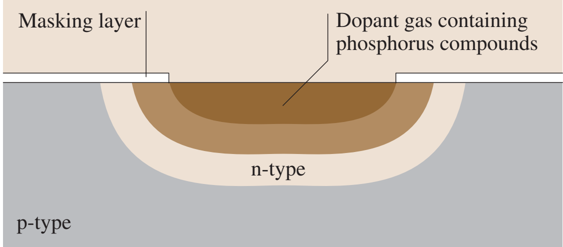

Fig. 5.5 Formation of an n-type region on a p-type silicon substrate by diffusion of phosphorous

and the impurity profile (concentration versus depth). In ion implantation, the impurities are ionized and accelerated toward the semiconductor surface. The penetration of impurities in the material follows a Gaussian distribution. After implantation, an annealing process is needed to activate the impurities and repair the damage in the crystal structure produced by the ion collisions. A *drive-in* process to redistribute the impurities performed in a standard furnace such as the ones used for oxidation or diffusion may be required as well.

Chemical Vapor Deposition and Epitaxy

As its name suggests, chemical vapor deposition (CVD) includes all the deposition techniques using the reaction of chemicals in a gas phase to form the deposited thin film. The energy needed for the chemical reaction to occur is usually supplied by maintaining the substrate at elevated temperatures. Other alternative energy sources such as plasma or optical excitation are also used, with the advantage of requiring a lower temperature at the substrate. The most common CVD processes in microfabrication are LPCVD (low pressure CVD) and PECVD (plasma enhanced CVD).

The LPCVD process is typically carried out in electrically heated tubes, similar to the oxidation tubes, equipped with pumping capabilities to achieve the needed low pressures (0.1 to 1.0 torr). A large number of wafers can be processed simultaneously, and the material is deposited in both sides of the wafers. The process temperatures depend on the material to be deposited, but generally are in the range of 550 to 900 °C. As in the oxidation, high temperatures and contamination issues can restrict the type of processes used prior to the LPCVD. Typical materials deposited by LPCVD include silicon oxide (e.g., $SiCl_2H_2 + 2N_2O \Rightarrow SiO_2 + 2N_2 + 2HCl$ at 900 °C), silicon nitride (e.g., $3SiH_4 + 4NH_3 \Rightarrow Si_3N_4 + 12H_2$ at 700–900 °C), and polysilicon (e.g., $SiH_4 \Rightarrow Si + 2H_2$ at 600 °C). Due to its faster etch rate in HF, in situ phosphorous-doped LPCVD oxide (phosphosilicate glass or PSG) is used extensively as the sacrificial layer in surface micromachining. Conformality in this process is excellent, even for very high-aspect-ratio structures. Mechanical properties of LPCVD materials are good compared to others such as PECVD, and LPCVD materials often used as structural materials in microfabricated devices. Stress in the deposited layers depends on the material, deposition conditions, and subsequent thermal history (e.g., post-deposition anneal). Typical values are: 100–300 MPa (compressive) for oxide, ∼ 1 GPa (tensile) for stoichiometric nitride, and ∼ 200–300 MPa (tensile) for polysilicon. The stress in nitride layers can be reduced to nearly zero by using a silicon-rich composition. Since the stress values can vary over a wide range, one has to measure and characterize the internal stress of deposited thin films for any specific equipment and deposition conditions.

The PECVD process is performed in plasma systems such as the one represented in Fig. 5.6. The use of RF energy to create highly reactive species in the plasma allows for the use of lower temperatures at the substrates (150 to 350 °C). Parallel-plate plasma reactors normally used in microfabrication can only process a limited number of wafers per batch. The wafers are positioned horizontally on top of the lower electrode, so only one side gets deposited. Typical materials deposited with PECVD include silicon oxide, nitride, and amorphous silicon. Conformality is good for low-aspect-ratio structures, but becomes very poor for deep trenches (20% of the surface thickness inside through-wafer holes with aspect ratio of ten). Stress depends on deposition parameters and can be either compressive or tensile. PECVD nitrides are typically non-stoichiometric (Si_xN_y) and are much less resistant to etchants in masking applications.

Another interesting type of CVD is epitaxial growth. In this process, a single crystalline material is grown as an extension of the crystal structure of the substrate. It is possible to grow dissimilar materials if the crystal structures are somehow similar (lattice-matched). Silicon-on-sapphire (SOS) substrates and some heterostructures are fabricated in this way. However, most

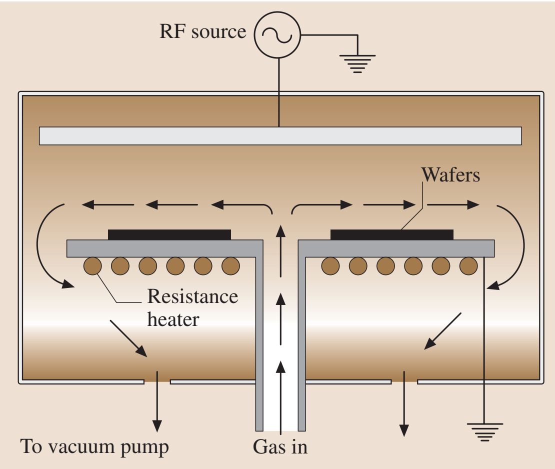

Fig. 5.6 Schematic representation of a typical PECVD system

common in microfabrication is the growth of silicon on another silicon substrate. Of particular interest for the formation of microstructures is the selective epitaxial growth. In this process the silicon crystal is allowed to grow only in windows patterned on a masking material. Many CVD techniques have been used to produce epitaxial growth. The most common for silicon is thermal chemical vapor deposition or *vapor phase epitaxy* (VPE). *Metallorganic chemical vapor deposition* (MOCVD) and *molecular beam epitaxy* (MBE) are the most common for growing high quality III-V compound layers with nearly atomic abrupt interfaces. The former uses vapors of organic compounds with group III atoms such as trimethylgallium [$Ga(CH_3)_3$] and group V hydrides such as AsH_3 in a CVD chamber with fast gas switching capabilities. The latter typically uses molecular beams from thermally evaporated elemental sources aiming at the substrate in an ultrahigh vacuum chamber. In this case, rapid on/off control of the beams is achieved by using shutters in front of the sources. Finally, it should be mentioned that many metals (molybdenum, tantalum, titanium, and tungsten) can also be deposited using LPCVD. These are attractive for their low resistivities and their ability to form silicides with silicon. Due to its application in the new interconnect technologies, copper CVD is an active area of research.

Physical Vapor Deposition (Evaporation and Sputtering)

In physical deposition systems the material to be deposited is transported from a source to the wafers, both being in the same chamber. Two physical principles are used to do so: evaporation and sputtering.

In evaporation, the source is placed in a small container with tapered walls, called a crucible, and heated up to a temperature at which evaporation occurs. Various techniques are utilized to reach the high temperatures needed, including the induction of high currents with coils wound around the crucible and the bombardment of the material surface with an electron beam (e-beam evaporators). This process is mainly used to deposit metals, although dielectrics can also be evaporated. In a typical system, the crucible is located at the bottom of a vacuum chamber, whereas the wafers are placed lining the dome-shaped ceiling of the chamber, Fig. 5.7. The main characteristic of this process is very poor step coverage, including shadow effects, as illustrated in Fig. 5.8. As will be explained in subsequent sections, some microfabrication techniques utilize these effects to pattern the deposited layer. One way to improve the step coverage is by rotating and/or heating the wafers during the deposition.

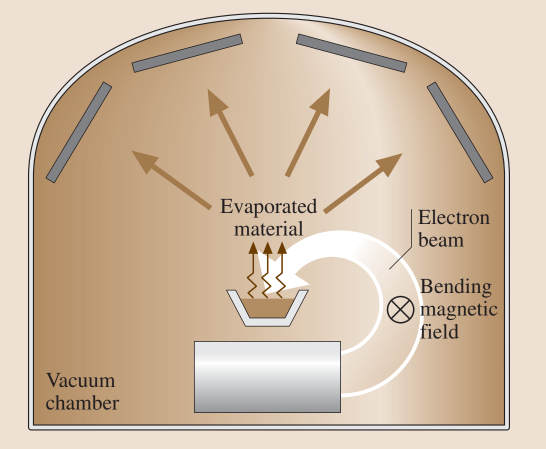

Fig. 5.7 Schematic representation of an electron-beam deposition system

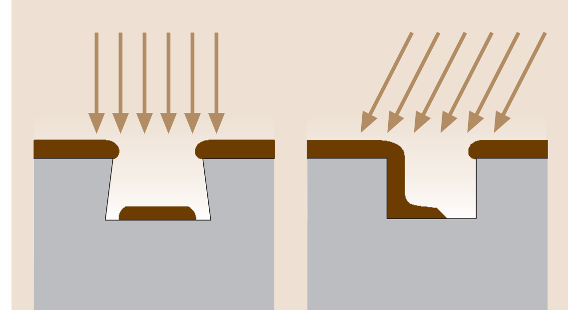

Fig. 5.8 Shadow effects observed in evaporated films. *Arrows* show the trajectory of the material atoms being deposited

In sputtering, a target of the material to be deposited is bombarded with high-energy inert ions (usually argon). The outcome of the bombardment is that individual atoms or clusters are removed from the surface and ejected toward the wafer. The physical nature of this process allows its use with virtually any existing material. Examples of interesting materials for microfabrication that are frequently sputtered include metals, dielectrics, alloys (such as shape memory alloys), and all kinds of compounds (for example, piezoelectric PZT). The inert ions bombarding the target are produced in DC or RF plasma. In a simple parallel-plate system, the top electrode is the target and the wafers are placed horizontally on top of the bottom electrode. In spite of its lower deposition rate, step coverage in sputtering is much better than in evaporation. Yet, the films obtained

Part A | 5.1

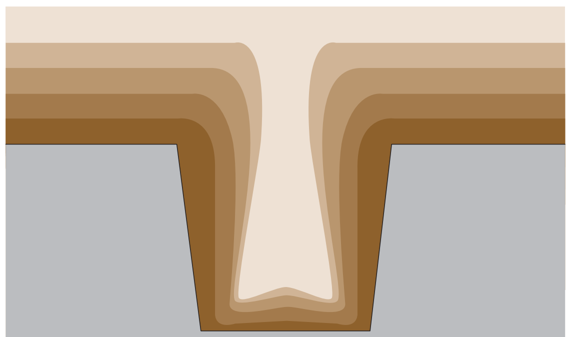

Fig. 5.9 Typical cross section evolution of a trench while being filled with sputter deposition

with this deposition process are nonconformal. Figure 5.9 illustrates successive sputtering profiles in a trench.

Both evaporation and sputtering systems are often capable of depositing more than one material simultaneously or sequentially. This capability is very useful in obtaining alloys and multilayers (e.g., multilayer magnetic recording heads are sputtered). For certain low reactivity metals such as Au and Pt, the previous deposition of a thin layer of another metal is needed to improve the adhesion. Ti and Cr are two frequently used adhesion promoters. Stress in evaporated or sputtered layers is typically tensile. The deposition rates are much higher than most CVD techniques. However, due to stress accumulation and cracking, a thickness beyond 2 µm is rarely deposited with these processes. For thicker depositions a technique described in the next section is sometimes used.

Electroplating

Electroplating (or electrodeposition) is a process typically used to obtain thick (tens of micrometers) metal structures. The sample to be electroplated is introduced in a solution containing a reducible form of the ion of the desired metal and is maintained at a negative potential (cathode) relative to a counter electrode (anode). The ions are reduced at the sample surface and the insoluble metal atoms are incorporated into the surface. As an example, copper electrodeposition is frequently done in copper sulfide-based solutions. The reaction taking place at the surface is $Cu^{2+} + 2e^- \rightarrow Cu_{(s)}$. Recommended current densities for electrodeposition processes are on the order of 5 to 100 mA/cm^2.

As can be deduced from the process mechanism, the surface to be electroplated has to be electrically conductive and preferably of the same material as the deposited one if a good adhesion is desired. In order to electrodeposit metals on top of an insulator (the most common case) a thin film of the same metal, called the seed layer, is previously deposited on the surface. Masking of the seed layer with a resist permits selective electroplatingat the patterned areas. Figure 5.10 illustrates a typical sequence of the steps required to obtain isolated metal structures.

5.1.3 Etching and Substrate Removal

Thin film and bulk substrate etching is another fabrication step that is of fundamental importance to both VLSI processes and micro/nanofabrication. In the VLSI area, various conducting and dielectric thin films deposited for passivation or masking purposes must be removed at some point or another. In micro/nanofabrication, in addition to thin film etching, very often the substrate (silicon, glass, GaAs, etc.) also needs to be removed in order to create various mechanical micro-/nanostructures (beams, plates, etc.). Two important figures of merit for any etching process are selectivity and directionality. Selectivity is the degree to which the etchant can differentiate between the masking layer and the layer to be

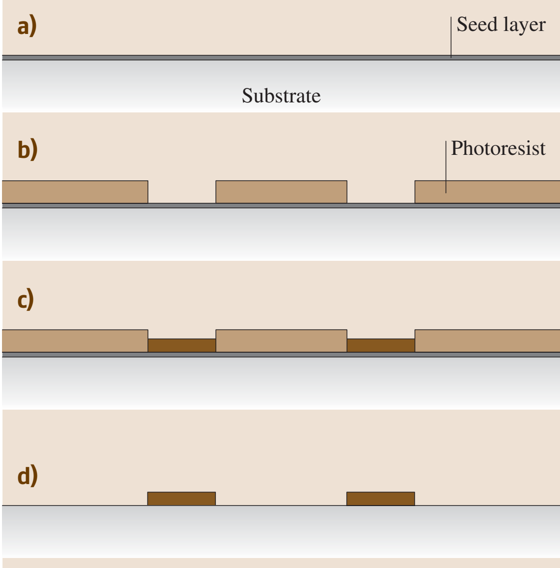

Fig. 5.10a–d Formation of isolated metal structures by electroplating through a mask: **(a)** seed layer deposition, **(b)** photoresist spinning and patterning, **(c)** electroplating, **(d)** photoresist and seed layer stripping

etched. Directionality has to do with the etch profile under the mask. In an isotropic etch, the etchant attacks the material in all directions at the same rate, creating a semicircular profile under the mask, Fig. 5.11a. In an anisotropic etch, the dissolution rate depends on specific directions, and one can obtain straight sidewalls or other noncircular profiles, Fig. 5.11b. One can also divide the various etching techniques into wet and dry categories. In this chapter, we will use this classification and discuss different wet etchants, followed by the dry etching techniques used most often in micro/nanofabrication.

Wet Etching

Historically, wet etching techniques preceded the dry ones. These still constitute an important group of etchants for micro/nanofabrication, in spite of their less frequent application in the VLSI processes. Wet etchants are by and large isotropic and show superior selectivity to the masking layer compared to various dry techniques. In addition, due to the lateral undercut, the minimum feature achievable with wet etchants is limited to $> 3\,\mu m$. Silicon dioxide is commonly etched in a dilute (6:1, 10:1, or 20:1 by volume) or buffered HF (BHF, $HF + NH_4F$) solutions (etch rate of $\sim 1{,}000\,Å/min$ in BHF). Photoresist and silicon nitride are the two most common masking materials for the wet oxide etch. The wet etchant for silicon nitride is hot (140–200 °C) phosphoric acid with silicon oxide as the masking material. Nitride wet etch is not very common (except for blanket etch), due to the masking difficulty and unrepeatable etch rates. Metals can be etched using various combinations of acids and base solutions. There are also many commercially available etchant formulations for aluminum, chromium, and gold that can be used easily. A comprehensive table of various metal etchants can be found in [5.5].

Anisotropic and isotropic wet etching of crystalline (silicon and gallium arsenide) and non-crystalline (glass) substrates are important topics in micro/nanofabrication [5.6–10]. In particular, the realization of the possibility of anisotropic wet etching of silicon is considered the beginning of the micromachining and MEMS discipline. Isotropic etching of silicon using $HF/HNO_3/CH_3COOH$ (various different formulations have been used) dates back to the 1950s and is still frequently used to thin down the silicon wafer. The etch mechanism for this combination has been elucidated and is as follows: HNO_3 is used to oxidize the silicon, which is subsequently dissolved away in the HF. The acetic acid is used to prevent the dissociation of HNO_3 (the etch works as well without the acetic acid). For short etch times, silicon dioxide can be used as the masking material However, one needs to use silicon nitride if a longer etch time is desired. This etch also shows dopant selectivity with the etch rate dropping at lower doping concentrations ($< 10^{17}\,cm^{-3}$ n- or p-type). Although this effect can potentially be used as an etch stop mechanism in order to fabricate microstructures, the difficulty in masking has prevented a widespread application of this approach. Glass can also be isotropically etched using the HF/HNO_3 combination with the etch surfaces showing considerable roughness. This has been used extensively in fabricating microfluidic components (mainly channels). Although Cr/Au is usually used as the masking layer, long etch times require a more robust mask (bonded silicon has been used for this purpose).

Silicon anisotropic wet etch constitutes an important technique in bulk micromachining. The three most important silicon etchants in this category are potassium hydroxide (KOH), ethylene diamine pyrochatechol (EDP), and tetramethyl ammonium hydroxide (TMAH). These are all anisotropic etchants that attack silicon along preferred crystallographic directions. In addition, they all show a marked reduction in the etch rate in heavily doped ($> 5 \times 10^{19}\,cm^{-3}$) boron ($p^{++}$) regions. The chemistry behind the action of these etchants is not yet very clear, but it seems that silicon atom oxidation at the surface and its reaction with hydroxyl ions (OH^-) are responsible for the formation of a soluble silicon complex ($SiO_2(OH)^{2-}$). The etch rate depends on the concentration and temperature and is usually around $1\,\mu m/min$ at temperatures of 85–115 °C. Common masking materials for anisotropic wet etchants are silicon dioxide and nitride, the latter being superior for longer etch times. The crystallographic plane which shows the slowest etch rate is the (111) plane. Although the lower atomic concentration along these planes have been speculated as the reason for this phenomenon, the evidence is inconclusive, and other factors must be included to account for this remarkable etch stop property. The anisotropic behavior of these etchants with respect to the (111) planes have been used extensively to create

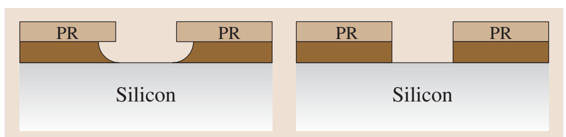

Fig. 5.11a,b Profile for isotropic **(a)** and anisotropic **(b)** etch through a photoresist (PR) mask

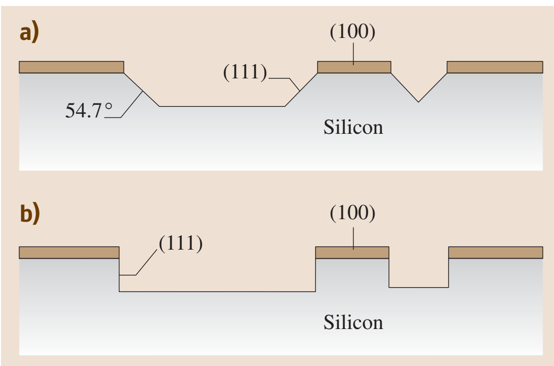

Fig. 5.12a,b Anisotropic etch profiles for: **(a)** (100) and **(b)** (110) silicon wafers

beams, membranes, and other mechanical and structural components. Figure 5.12 shows the typical cross sections of (100) and (110) silicon wafers etched with an anisotropic wet etchant. As can be seen, the (111) slow planes are exposed in both situations, one creating 54.7° sloped sidewalls in the (100) wafer and the other creating vertical sidewalls in the (110) wafer. Depending on the dimensions of the mask opening, a V-groove or a trapezoidal trench is formed in the (100) wafer. A large enough opening will allow the silicon to be etched all the way through the wafer, thus creating a thin dielectric membrane of the other side. It should be mentioned that exposed convex corners have a higher etch rate than the concave ones, resulting in an undercut that can be used to create dielectric (e.g., nitride) cantilever beams. Figure 5.13 shows a cantilever beam fabricated using the convex corner undercut on a (100) wafer.

The three above mentioned etchants show different directional and dopant selectivities. KOH has the best (111) selectivity (400/1) followed by TMAH and EDP. However, EDP has the highest selectivity with respect to the deep boron diffusion regions. Safety and CMOS compatibility are other important criteria for choosing a particular anisotropic etchant. Among the three mentioned etchants TMAH is the most benign, whereas EDP is extremely corrosive and carcinogenic. Silicon can be dissolved in TMAH in order to improve its selectivity with respect to aluminum. This property has made TMAH very appealing for post-CMOS micromachining for which aluminum lines have to be protected. Finally, it should be mentioned that one can modulate the etch rate using a reverse biased p–n junction (electrochemical etch stop). Figure 5.14 shows the setup commonly used to perform electrochemical etching. The silicon wafer under etch consists of an n-epi region on a p-type substrate. Upon the application of a reverse bias voltage to the structure (p-substrate is in contact with the solution and n-epi is protected using a water tight fixture), the p-substrate is etched away. When the n-epi regions are exposed to the solution, an oxide passivation layer is formed and etch is stopped. This technique can be used to fabricate single-crystalline silicon membranes for pressure sensors and other mechanical transducers.

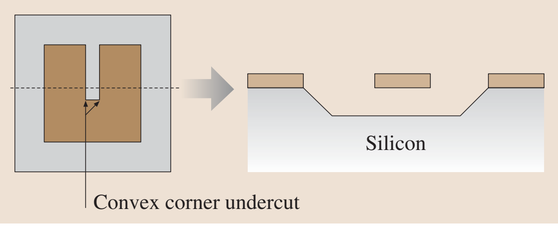

Fig. 5.13 Top view and cross section of a dielectric cantilever beam fabricated using convex corner undercut

Dry Etching

Most dry etching techniques are plasma-based. They have several advantages compared with wet etching. These include smaller undercut (allowing smaller lines to be patterned) and higher anisotropicity (allowing high-aspect-ratio vertical structures). However, the selectivity of dry etching techniques is lower than the wet etchants, and one must take into account the finite etch rate of the masking materials. The three basic dry etching techniques, namely, high-pressure plasma etching, reactive ion etching (RIE), and ion milling utilize different mechanisms to obtain directionality.

Ion milling is a purely physical process that utilizes accelerated inert ions (e.g., Ar^{+}) striking perpendic-

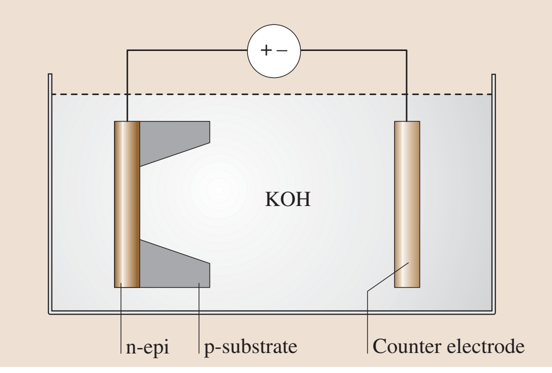

Fig. 5.14 Electrochemical etch setup

Part A | 5.1

ular to the surface to remove the material (pressure $\sim 10^{-4}$–10^{-3} torr), Fig. 5.15a. The main characteristics of this technique are very low etch rates (on the order of a few nanometers per minute) and poor selectivity (close to 1:1 for most materials); hence it is generally used to etch very thin layers. In high-pressure (10^{-1}–5 torr) plasma etchers, highly reactive species are created that react with the material to be etched. The products of the reaction are volatile, so that they diffuse away and new material is exposed to the reactive species. Directionality can be achieved, if desired, with the sidewall passivation technique (Fig. 5.15b). In this technique, nonvolatile species produced in the chamber deposit and passivate the surfaces. The deposit can only be removed by physical collision with incident ions. Because the movement of the ions has a vertical directionality, the deposit is removed mainly at the horizontal surfaces, while the vertical walls remain passivated. In this fashion, the vertical etch rate becomes much higher than the lateral one.

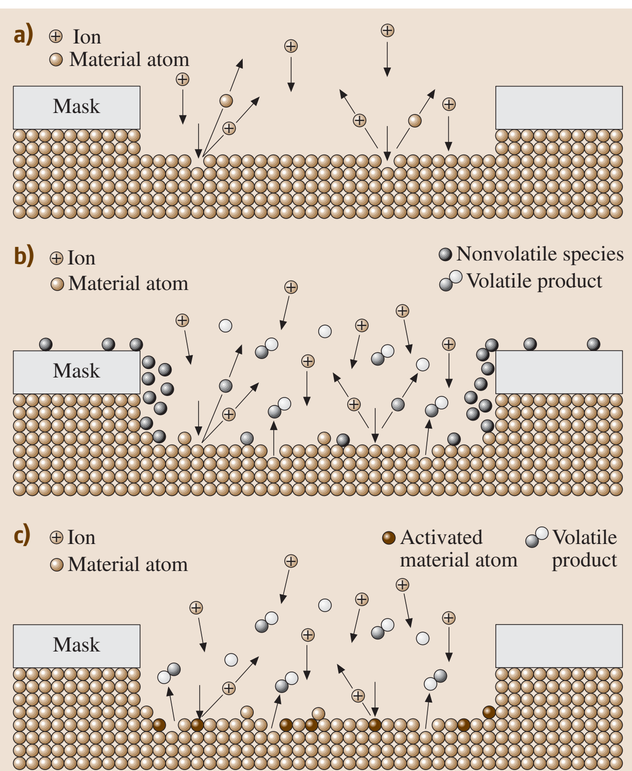

Fig. 5.15a–c Simplified representation of etching mechanisms for **(a)** ion milling, **(b)** high-pressure plasma etching, and **(c)** RIE

The RIE etching, also called ion-assisted etching, is a combination of physical and chemical processes. In this technique, the reactive species react with the material only when the surfaces are "activated" by the collision of incident ions from the plasma (e.g., by breaking bonds at the surface). As in the previous technique, the directionality of the ion's velocity produces many more collisions in the horizontal surfaces than in the walls, thus generating faster etching rates in the vertical direction (Fig. 5.15c). To further increase the etch anisotropy, sidewall passivation methods in some cases, are also used. An interesting case is the *deep reactive ion etching* (DRIE) technique, capable of achieving aspect ratios of 30:1 and silicon etching rates of 2 to 3 μm/min (through-wafer etch is possible). In this technique, the passivation deposition and etching steps are performed sequentially in a two-step cycle, as shown in Fig. 5.16. In commercial silicon DRIE etchers, SF_6/Ar is typically used for the etching step and a combination of Ar and a fluoropolymer ($n CF_2$) for the passivation step. A Teflon-like polymer about 50 nm thick is deposited during the latter step, covering only the sidewalls (Ar^+ ion bombardment removes the Teflon on the horizontal surfaces). Due to the cyclic nature of this process, the sidewalls of the etched features show a periodic "wave-shape" roughness in the range of 50 to 400 nm.

Dry etching can also be performed in non-plasma equipment if the etching gases are reactive enough. The so-called vapor phase etching (VPE) processes can be carried out in a simple chamber with gas feeding and pumping capabilities. Two examples of VPE are xenon difluoride (XeF_2) etching of silicon and HF-vapor etching of silicon dioxide. Due to its isotropic nature, these processes are typically used for etching sacrificial layers and releasing structures while avoiding stiction problems (see Sects. 5.2.1 and 5.2.2).

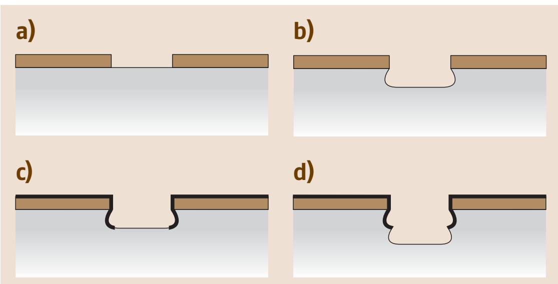

Fig. 5.16a–d DRIE cyclic process: **(a)** photoresist patterning, **(b)** etch step, **(c)** passivation step, and **(d)** etch step

Table 5.1 Typical dry etch chemistries

Si	CF_4/O_2, CF_2Cl_2, CF_3Cl, $SF_6/O_2/Cl_2$, $Cl_2/H_2/C_2F_6/CCl_4$, C_2ClF_5/O_2, Br_2, SiF_4/O_2, NF_3, ClF_3, CCl_4, CCl_3F_5, C_2ClF_5/SF_6, C_2F_6/CF_3Cl, CF_3Cl/Br_2
SiO_2	CF_4/H_2, C_2F_6, C_3F_8, CHF_3/O_2
Si_3N_4	$CF_4/O_2/H_2$, C_2F_6, C_3F_8, CHF_3
Organics	O_2, CF_4/O_2, SF_6/O_2
Al	BCl_3, BCl_3/Cl_2, $CCl_4/Cl_2/BCl_3$, $SiCl_4/Cl_2$
Silicides	CF_4/O_2, NF_3, SF_6/Cl_2, CF_4/Cl_2
Refractories	CF_4/O_2, NF_3/H_2, SF_6/O_2
GaAs	BCl_3/Ar, $Cl_2/O_2/H_2$, $CClH_3/H_2$ H_2, CH_4/H_2, $CCl_2F_2/O_2/Ar/He$
InP	CH_4/H_2, C_2H_6/H_2, Cl_2/Ar
Au	$C_2Cl_2F_4$, Cl_2, $CClF_3$

Most importantly, materials can be etched with the aforementioned techniques, and for each material a variety of chemistries is available. Table 5.1 lists some of the most common materials along with selected etch recipes [5.11]. For each chemistry, the etch rate, directionality, and selectivity with respect to the mask materials depend on parameters such as the flow/rates of the gases entering the chamber, the working pressure, and the RF power applied to the plasma.

5.1.4 Substrate Bonding

Substrate (wafer) bonding (silicon-silicon, silicon-glass, and glass-glass) is among the most important fabrication techniques in microsystem technology [5.12, 13]. It is frequently used to fabricate complex 3-D structures both as a functional unit and as part of the final microsystem package and encapsulation. The two most important bonding techniques are silicon-silicon fusion (or silicon direct bonding) and silicon-glass electrostatic (or anodic) bonding. In addition to these techniques, several other alternative methods that utilize an intermediate layer (eutectic, adhesive, and glass frit) have also been investigated. All these techniques can be used to bond the substrates at the wafer level. In this chapter, we will only discuss wafer-level techniques and will not treat the device level bonding methods (e.g., e-beam and laser welding).

Silicon Direct Bonding

Direct silicon, or fusion bonding, is used in the fabrication of micromechanical devices and silicon-on-insulator (SOI) substrates. Although it is mostly used to bond two silicon wafers with or without an oxide layer, it has also been used to bond different semiconductors such as GaAs and InP [5.13]. One main requirement for a successful bond is sufficient planarity (< 10 Å surface roughness and < 5 µm bow across a 4" wafer) and cleanliness of the surfaces. In addition, thermal expansion mismatch also needs to be considered if bonding of two dissimilar materials is contemplated. The bonding procedure is as follows: The silicon- or oxide-coated silicon wafers are first thoroughly cleaned. Subsequently, the surfaces are hydrated (activated) in HF or boiling nitric acid (RCA clean also works). This renders the surfaces hydrophilic by creating an abundance of hydroxyl ions. Then the substrates are brought together in close proximity (starting from the center to avoid the void formation). The close approximation of the bonding surfaces allows the short-range attractive van der Waals forces to bring the surfaces into intimate contact on an atomic scale. Following this step, a hydrogen bond between the two hydroxyl-coated silicon wafers bonds the substrates together. These steps can be performed at room temperatures; however, in order to increase the bond strength a high temperature (800–1,200 °C) anneal is usually required. A big advantage of silicon fusion bonding is the thermal matching of the substrates.

Anodic Bonding

Silicon-glass anodic (electrostatic) bonding is another major substrate joining technique that has been used extensively for microsensor packaging and device fabrication. The main advantage of this technique is its lower bonding temperature, which is around 300–400 °C. Figure 5.17 shows the bonding setup. A glass wafer (usually Pyrex 7740 for its thermal expansion match to silicon)

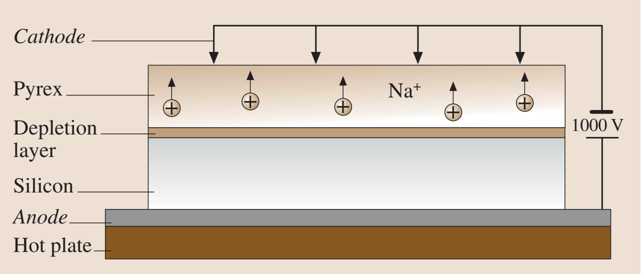

Fig. 5.17 Glass-to-silicon anodic bonding setup

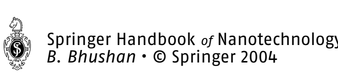

is placed on top of a silicon wafer, and the sandwich is heated to 300–400 °C. Subsequently, a voltage of ∼ 1,000 V is applied to the glass-silicon sandwich with the glass connected to the cathode. The bond starts immediately after the application of the voltage and spreads outward from the cathode contact point. The bond can be visually observed as a dark greyish front that expands throughout the wafer.

The bonding mechanism is as follows: During the heating period, glass sodium ions move toward the cathode and create a depletion layer at the silicon-glass interface. A strong electrostatic force is therefore created at the interface that pulls the substrates into intimate contact. The exact chemical reaction responsible for anodic bonding is not yet clear, but covalent silicon oxygen bond at the interface seems to be responsible for the bond. Silicon-to-silicon anodic bonding using sputtered or evaporated glass interlayer is also possible.

Bonding with Intermediate Layers

Various other wafer bonding techniques utilizing an intermediate layer have also been investigated [5.13]. Among the most important ones are adhesive, eutectic, and glass frit bonds. Adhesive bond using a polymer (e.g., polyimides, epoxies, thermoplast adhesives, and photoresists) in between the wafers has been used to join different wafer substrates [5.14]. Complete curing (in an oven or using dielectric heating) of the polymer before or during the bonding process prevents subsequent solvent outgas and void formation. Although reasonably high bonding strengths can be obtained, these bonds are non-hermetic and unstable over time.

In the eutectic bonding process, gold-coated silicon wafers are bonded together at temperatures greater than the silicon-gold eutectic point (363 °C, 2.85% silicon and 97.1% Au) [5.15]. This process can achieve high bonding strength and good stability at relatively low temperatures. For good bond uniformity, silicon dioxide must be removed from the silicon surface prior to the deposition of the gold. In addition, all organic contaminants on the gold surface must be removed (using UV light) prior to the bond. Pressure should also be applied in order to achieve a better contact. Although eutectic bond can be accomplished at low temperatures, achieving uniformity over large areas has proven to be challenging. More recently, localized silicon-gold eutectic bonding has been reported. In this technique, a silicon cap is bonded to another silicon wafer having a gold micro-heater (0.27 Å current for a bonding temperature of about 800 °C), Fig. 5.18 [5.16].

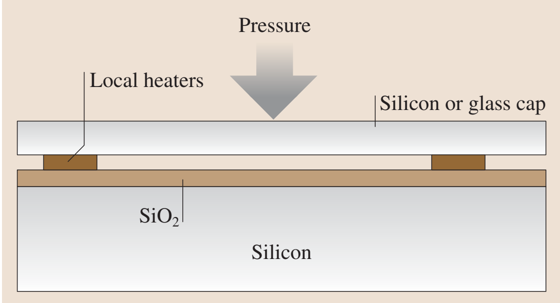

Fig. 5.18 Eutectic bonding with localized heating

Glass frit can also be used as an interlayer in substrate bonding. In this technique, first a thin layer of glass is deposited and pre-glazed. The glass-coated substrates are then brought into contact, and the sandwich is heated to above the glass melting temperature (typically < 600 °C). Like in the eutectic process, pressure must be applied for adequate contact [5.17].

Bond Characterization

Two major characterization techniques for substrate bonding evaluation are: 1) visual inspection and 2) blade test [5.12]. Once the bond has been completed, the bonding surfaces can be visually inspected for the presence of voids, cracks, and nonuniformity. The silicon-glass anodic bond interface does not require any particular imaging instrument and can be inspected with an unaided eye or under a light microscope. However, infrared imaging, X-ray photography, and ultrasonic methods are necessary for opaque substrates (mainly silicon-silicon). Although infrared transmission has some resolution limits due to its wavelength, it

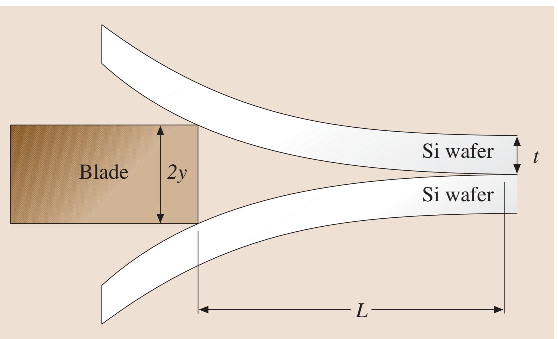

Fig. 5.19 Blade test technique for the measurement of bond strength

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

is the most common tool in bond inspection and offers a quality technique with a simple IR source and a CCD camera.

The blade test is often performed in order to estimate the specific surface energy (and hence bond strength), Fig. 5.19. In this test, a blade is inserted between the bonded substrates and a crack is induced. The length of the crack is then measured and the specific surface energy is calculated using the following equation [5.18]:

$$g = \frac{3Et^3y^2}{8L^4} ,$$

where g is the surface energy (erg/cm^2), E is the Young's modulus of substrate (dyne/cm^2), t is the thickness of the wafer, y is the half-thickness of the blade, and L is the crack length. The crack length is usually measured using the interference fringes parallel to theblade edge under an IR light source. A semi-quantitative technique for evaluation of the bond strength is the pull test. This technique is based on using a test fixture (or tensometer) for measuring the force required to pull two bonded substrates apart. The pull test is more effective on small samples and can be used to compare different bonding techniques without the need to accurately measure the surface energy.

5.2 MEMS Fabrication Techniques

In this section, we will discuss various important MEMS fabrication techniques commonly used to build various microdevices (microsensors and microactuators) [5.6–10]. The dimensional spectrum of the microstructures that can be fabricated using these techniques span from 1 mm to 1 µm. As mentioned in the introduction, we will mostly emphasize the more important techniques and will not discuss specialized methods.

5.2.1 Bulk Micromachining

Bulk micromachining is the oldest MEMS technology and hence probably one of the more mature ones [5.8, 9]. It is currently by far the most commercially successful one, helping manufacture devices such as pressure sensors and ink-jet print heads. Although there are many different variations, the basic concept behind bulk micromachining is selective removal of the substrate (silicon, glass, GaAs, etc.). This allows the creation of various micromechanical components such as beams, plates, and membranes that can be used to fabricate a variety of sensors and actuators. The most important microfabrication techniques used in bulk micromachining are wet and dry etch and substrate bonding. Although one can use different criteria in dividing the bulk micromachining techniques into separate categories, we will use a historical time line for this purpose. Starting with the more traditional wet etching techniques, we will proceed to the more recent ones that use deep RIE and wafer bonding.

Bulk Micromachining Using Wet Etch and Wafer Bonding

The use of anisotropic wet etchants to remove silicon can be regarded as the beginning of the micromachining era. Back side etch was used to create movable structures such as beams, membranes, and plates, Fig. 5.20. Initially, the etching was timed to create a specified thickness. However, this technique proved inadequate in creating thin structures (< 20 µm). Subsequent use of various etch stop techniques allowed the creation of thinner membranes in a more controlled fashion. As mentioned in Sect. 5.1.3, heavily doped boron regions and electrochemical bias can be used to drastically slow down the etch process and hence create controllable thickness microstructures. Figure 5.21a,b show the cross section of two piezoresistive pressure sensors fabricated using electrochemical and P^{++} etch stop techniques. The use of the P^{++} method requires the epitaxial growth of a lightly doped region on top of a P^{++} etch stop layer.

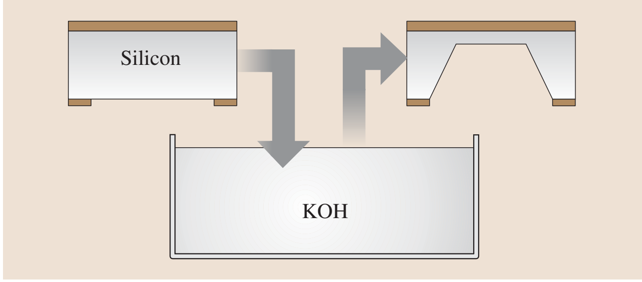

Fig. 5.20 Wet anisotropic silicon back side etch

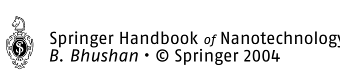
Part A | 5.2



This layer is subsequently used for the placement of piezoresistors. However, if no active component is required, one can simply use the P^{++} region to create a thin membrane, Fig. 5.21c.

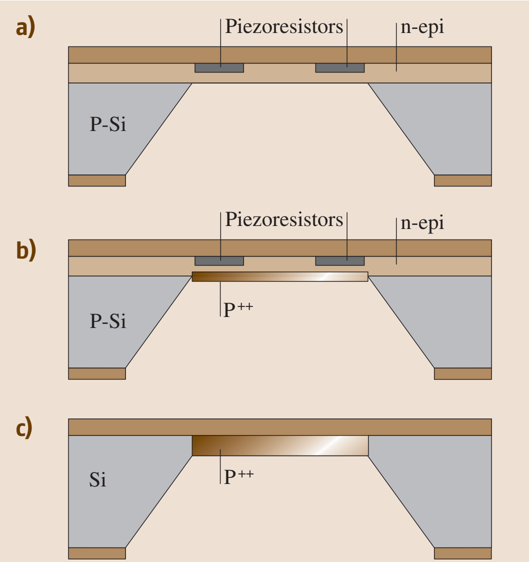


Fig. 5.21a–c Wet micromachining etch stop techniques: **(a)** electrochemical with n-epi on p substrate, **(b)** P^{++} etch stop with n-epi, and **(c)** P^{++} etch stop without n-epi

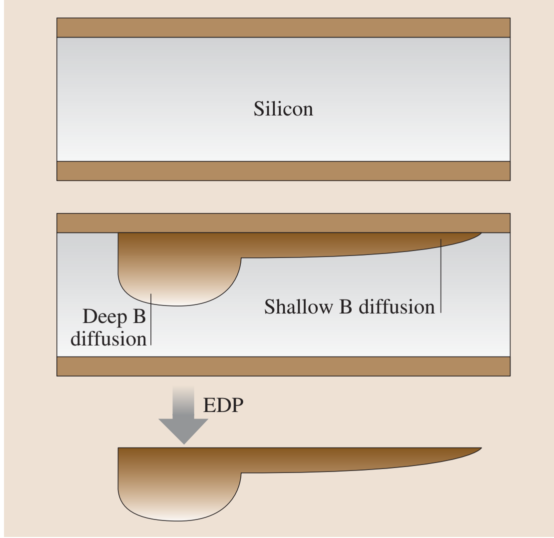

Fig. 5.22 Freestanding microstructure fabrication using deep and shallow boron diffusions and EDP release

The P^{++} etch stop technique can also be used to create isolated thin silicon structures through the dissolution of the entire lightly doped region [5.19]. This technique was successfully used to fabricate silicon recording and stimulate electrodes for biomedical applications. Figure 5.22 shows the cross section of such a process that relies on deep (15–20 μm) and shallow boron (2–5 μm) diffusion steps to create microelectrodes with flexible connecting ribbon cables. An extension of this process that uses a combination of P^{++} etch stop layers and silicon-glass anodic bonding has also been developed. This process is commonly known as the dissolved wafer process and has been used to fabricate a variety of microsensors and microactuators [5.20]. Figure 5.23 shows the cross section of this process. Figure 5.24 shows an SEM photograph of a micro-accelerometer fabricated using the dissolved wafer process.

It is also possible to merge wet bulk micromachining and microelectronics fabrication processes to build mi-

cromechanical components on the same substrate as the integrated circuits (CMOS, Bipolar, or BiCMOS) [5.21]. This is very appealing since it allows the integration of interface and signal processing circuitry with MEMS structures on a single chip. However, important fabrication issues such as process compatibility and yield have to be carefully considered. Among the most popular techniques in this category is the post-processing of the CMOS integrated circuits by front side etching in TMAH solutions. As mentioned previously, silicon-rich TMAH does not attack aluminum and therefore can be used to undercut microstructures in an already processed CMOS chip. Figure 5.25 shows a schematic of such a process in which front side wet etch and electrochemical etch stop have been used to produce suspended beams. This technique has been used extensively to fabricate a variety of microsensors (e.g., humidity, gas, chemical, and pressure). Figure 5.26 shows a photograph of a post-CMOS processed chemical sensor.

Bulk Micromachining Using Dry Etch

Bulk silicon micromachining using dry etch is a very attractive alternative to the wet techniques described in the previous section. These techniques were developed in the mid-1990s, following the successful efforts to develop processes for anisotropic dry silicon etch. More recent advances in deep silicon RIE and the availability of SOI wafers with a thick top silicon layer have increased the application of these techniques. These techniques allow the fabrication of high-aspect-ratio vertical structures in isolation or along with on-chip electronics. Process compatibility with active microelectronics is less of a concern in dry methods, since many of them do not damage the circuit or its interconnect.

The most simple dry bulk micromachining technique relies on the front side undercut of microstructures using XeF_2 vapor phase etch [5.22]. As mentioned before, this, however, is an isotropic etch and, therefore, has a limited application. A combination of isotropic/anisotropic dry etch is more useful and can be used to create a variety of interesting structures. Two successful techniques using this combination are single-crystal reactive etching and metallization (SCREAM) [5.23] and post-CMOS dry release using aluminum/silicon dioxide laminate [5.24]. The first technique relies on the combination of isotropic/anisotropic dry etch to create single crystalline suspended structures. Figure 5.27 shows the cross section of the process. It starts with an anisotropic (Cl_2/BCl_3) silicon etch using an oxide mask (Fig. 5.27b). This is followed by a conformal PECVD oxide deposition (Fig. 5.27c). Subsequently, an anisotropic oxide etch is used to remove the oxide at the bottom of the

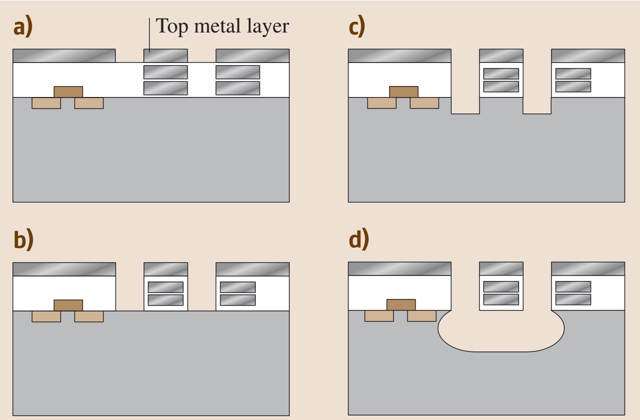

Fig. 5.29 Cross section of the process flow for the post-CMOS dry microstructure fabrication

trenches leaving the sidewall oxide intact (Fig. 5.27d). At this stage, an isotropic silicon etch (SF_6) is performed that results in undercut and release of the silicon structures (Fig. 5.27e). Finally, if electrostatic actuation is desired, a metal can be sputtered to cover the top and sidewall of the microstructure and the bottom of the cavity formed below it (Fig. 5.27f). Figure 5.28 shows an SEM photograph of a comb-drive actuator fabricated using SCREAM technology.

The second dry release technique relies on the masking capability of aluminum interconnect lines in a CMOS integrated circuit to create suspended microstructures. Figure 5.29 shows the cross section of this process. As can be seen, the third level Al of a prefabricated CMOS chip is used as a mask to anisotropically etch the underlying oxide layers all the way to the silicon (CHF_3/O_2), Fig. 5.29b. This is followed by an anisotropic silicon etch to create a recess in the silicon, which will be used in the final step to facilitate the undercut and release, Fig. 5.29c. Finally, an isotropic silicon etch is used to undercut and release the structures, Fig. 5.29d. Figure 5.30 shows an SEM photograph of a comb-drive actuator fabricated using this technology.

In addition to the methods described above, recent advancements in the development of deep reactive ion etching of silicon (DRIE, see Sect. 5.1.3) have created new opportunities for dry bulk micromachining techniques (see Sect. 5.2.3). One of the most important ones uses thick silicon SOI wafers that are commercially available in various top silicon thicknesses [5.26]. Figure 5.31 shows the cross section of a typical process using DRIE and SOI wafers. The top silicon layer is patterned and etched all the way to the buried oxide, Fig. 5.31b. The oxide is subsequently removed in HF, releasing suspended single crystalline microstructures, Fig. 5.31c. In a modification of this process, the substrate can also be removed from the back side, allowing

easy access from both sides (this allows an easier release and prevents stiction), Fig. 5.31d.

5.2.2 Surface Micromachining

Surface micromachining is another important MEMS microfabrication technique that can be used to create movable microstructures on top of a silicon substrate [5.28]. This technique relies on the deposition of structural thin films on a sacrificial layer that is subsequently etched away, resulting in movable micromechanical structures (beams, membranes, plates, etc.). The main advantage of surface micromachining is that extremely small sizes can be obtained. In addition, it is relatively easy to integrate the micromachined structures with on-chip electronics for increased functionality. However, due to the increased surface nonplanarity with any additional layer, there is a limit to the number of layers that can be deposited. Although one of the earliest reported MEMS structures was a surface micromachined resonant gate transistor [5.29], material-related difficulties resulted in the termination of efforts in this area. In the mid-1980s, improvements in the field of thin film deposition rekindled interest in surface micromachining [5.30]. Later in the same decade, polysilicon surface micromachining was introduced, which opened the door to the fabrication of a variety of microsensors (accelerometers, gyroscopes, etc.) and microactuators (micromirrors, RF switches, etc.). In this section, we will concentrate on the key process steps involved in surface micromachining fabrication and the various materials used in the surface micromachining process. In addition, monolithic integration of CMOS with MEMS structures and 3-D surface micromachining are also discussed.

Basic Surface Micromachining Processes

The basic surface micromachining process is illustrated in Fig. 5.32. The process begins with a silicon substrate on top of which a sacrificial layer is grown and patterned, Fig. 5.32a. Subsequently, the structural material is deposited and patterned, Fig. 5.32b. As can be seen, the structural material is anchored to the substrate through the openings created in the sacrificial layer during the previous step. Finally, the sacrificial layer is removed, resulting in the release of the microstructures Fig. 5.32c. In wide structures, it is usually necessary to provide access holes in the structural layer for a fast sacrificial layer removal. It is also possible to seal microcavities cre-

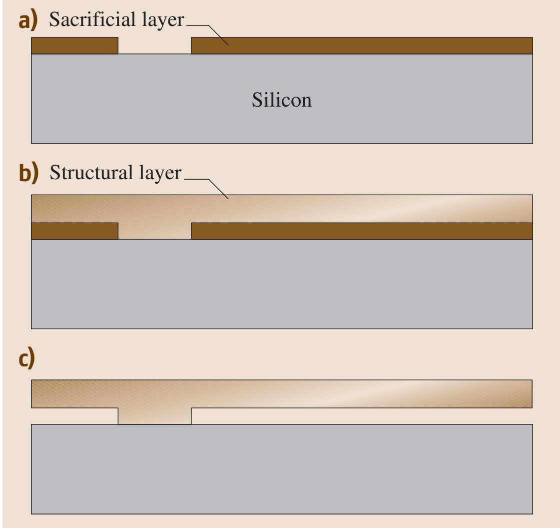

Fig. 5.32 Basic surface micromachining fabrication process

ated by the surface micromachining technique [5.8, 9]. This can be done at the wafer level and is a big advantage in applications such as pressure sensors that require a sealed cavity. Figure 5.33 shows two different techniques that can be used for this purpose. In the first, following the etching of the sacrificial layer, a LPCVD dielectric layer (oxide or nitride) is deposited to cover and seal the etch holes in the structural material, Fig. 5.33a. Since the LPCVD deposition is performed at reduced pressures, a sub-atmospheric pill-box microcavity can be created. In the second technique, also called reactive sealing, the polysilicon structural material is oxidized following the sacrificial layer removal, Fig. 5.33b. If access holes are small enough, the grown oxide can seal the cavity. Due to the consumption of the oxygen during the growth process, the cavity is sub-atmospheric.

The most common sacrificial and structural materials are phosphosilicate glass (PSG) and polysilicon, respectively (low temperature oxide, or LTO, is also frequently used as the sacrificial layer). However, there are several other sacrificial/structural combinations that have been used to create a variety of surface micromachined structures. Important design issues related to the choice of the sacrificial layer are: 1) quality (pinholes, etc.), 2) ease of deposition, 3) deposition rate, 4) deposition temperature, and 5) etch difficulty and selectivity (sacrificial layer etchant should not attack the structural layer). The particular choice of material for structural layers depends on the desired properties and the specific application. Several important requirements are: 1) ease of deposition, 2) deposition rate, 3) step coverage, 4) mechanical properties (internal stress, stress gradient, Young's modulus, fracture strength, and internal damping), 5) etch selectivity, 6) thermal budget and history, 7) electrical conductivity, and 8) optical reflectivity. Two examples from the commercially available surface micromachined devices illustrate various successful sacrificial/structural combinations. Texas Instruments's deformable mirror display (DMD) spatial light modulator uses aluminum as the structural material (good optical reflectivity) and photoresist as the sacrificial layer (easy dry etch and low processing temperatures, allowing easy post-IC integration with CMOS) [5.32], Fig. 5.34. In contrast, Analog Devices's microgyroscope uses polysilicon structural material and a PSG sacrificial layer, Fig. 5.35. Two recent additions to the collection of available structural layers are poly-silicon-germanium and poly-germanium [5.33, 34]. These are intended to be a substitute for polysilicon in applications where the high polysilicon deposition temperature (around 600 °C) is forbidding (e.g., CMOS integration).

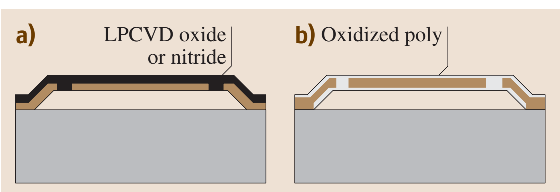

Fig. 5.33 Two sealing techniques for surface micromachined created cavities

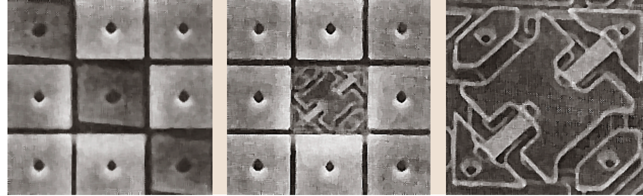

Fig. 5.34 SEM photographs of Texas Instrument micromirror array [5.28]

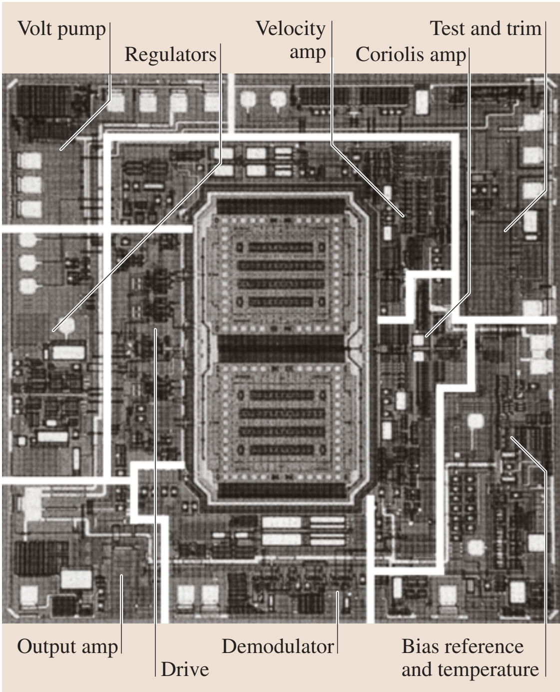

Fig. 5.35 SEM photograph of Analog Devices gyroscope [5.31]

Table 5.2 Several important surface micromachined sacrificial/structural combinations

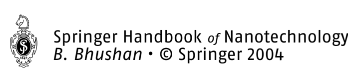
System	Sacrificial layer	Structural layer	Structural layer etchant	Sacrificial layer etchant
1	PSG or LTO	Poly-Si	RIE	Wet or vapor HF
2	Photoresist, polyimide	Metals (Al, Ni, Co, Ni-Fe)	Various metal etchants	Organic solvents, plasma O_2
3	Poly-Si	Nitride	RIE	KOH
4	PSG or LTO	Poly-Ge	H_2O_2 or RCA1	Wet or vapor HF
5	PSG or LTO	Poly-Si-Ge	H_2O_2 or RCA1	Wet or vapor HF

Unlike LPCVD polysilicon, poly-germanium (poly-Ge) and poly-silicon-germanium (poly-$Si_{1-x}Ge_x$) can be deposited at temperatures as low as 350 °C (poly-Ge deposition temperature is usually lower than poly-SiGe). Table 5.2 summarizes important surface micromachined sacrificial/structural combinations.

An important consideration in the design and processing of surface micromachined structures is the issue of stiction [5.8, 9, 35, 36]. This can happen during the release step if a wet etchant is used to remove the sacrificial layer, or during the device lifetime. The reason for stiction during release is the surface tension of the liquid etchant, which can hold the microstructure down and cause stiction. This usually happens when the structure is compliant and does not possess enough spring constant to overcome the surface tension force of the rinsing liquid (i. e., water). There are several ways one can alleviate the release-related stiction problem. These include: 1) the use of dry or vapor phase etchant, 2) the use of solvents with lower surface tension, 3) geometrical modifications, 4) CO_2 critical drying, 5) freeze drying, and 6) *self-assembled monolayer* (SAM) or organic thin-film surface modification. The first technique prevents stiction by not using a wet etchant, although in the case of vapor phase release, the condensation possibility is existent and can cause some stiction. The second method uses rinsing solvents such as methanol with a lower surface tension than water. This is usually followed by a rapid evaporation of the solvent on a hot plate. However, this technique is not optimum, and many structures still stick. The third technique is geometrical, which provides dimples in the structural layer in order to reduce the contact surface area and hence reduce the attractive force. The fourth and fifth techniques rely on the phase change (in one case CO_2 and the other butyl-alcohol), which avoids the liquid phase altogether by directly going to the gas phase. The last technique uses self-assembled monolayers or organic thin films to coat the surfaces with a hydrophobic layer. The stiction that occurs during the operating lifetime of the device (in-use stiction) is due to the condensation of moisture on the surfaces, electrostatic charge accumulation, or direct chemical bonding. Surface passivation using self-assembled monolayers or organic thin films can be used to reduce the surface energy and reduce or eliminate the capillary forces and direct chemical bonding. These organic coatings also reduce electrostatic forces if a thin layer is applied directly to the semiconductor (without the intervening oxide layer). Commonly used organic coatings include fluorinated fatty acids (Texas Instruments aluminum micromirrors), silicone polymeric layers (Analog Devices accelerometers), and siloxane self-assembled monolayers.

Surface Micromachining Integration with Active Electronics

Integration of surface micromachined structures with on-chip circuitry can increase performance and simplify packaging. However, issues related to process compatibility and yield must be carefully considered. The two most common techniques are MEMS-first and MEMS-last techniques. In the MEMS-last technique, the integrated circuit is first fabricated and surface micromachined structures are subsequently built on top of the silicon wafer. An aluminum structural layer with a photoresist sacrificial layer is an attractive combination due to the low thermal budget of the process (Texeas Instruments micromirror array). However, in applications where mechanical properties of Al are not adequate, polysilicon structural material with LTO or PSG sacrificial layer must be used. Due to the rather high deposition temperature of polysilicon, this combination requires special attention with regard to the thermal budget. For example, aluminum metallization must be avoided and substituted with refractory metals such as tungsten. This can only be achieved at a greater process complexity and lower transistor performance.



MEMS-first technique alleviates these difficulties by fabricating the microstructures at the very beginning of the process. But if the microstructures are processed first, they have to be buried in a sealed trench to eliminate the interference of microstructures with subsequent CMOS processes. Figure 5.36 shows a cross section of a MEMS-first fabrication process developed at the Sandia National Laboratory [5.37]. The process starts with a shallow anisotropic etching of trenches in a silicon substrate to accommodate the height of the polysilicon structures fabricated later on. A silicon nitride layer is then deposited to provide isolation at the bottom of the trenches. Next, several layers of polysilicon and sacrificial oxide are deposited and patterned in a standard surface micromachining process. Subsequently, the trenches are completely filled with sacrificial oxide and the wafers are planarized with chemical-mechanical polishing (this avoids complication in the following lithographic steps). After an annealing step, the trenches are sealed with a nitride cap. At this point, a standard CMOS fabrication process is performed. At the end of the CMOS process, the nitride cap is etched and the buried structures released by etching the sacrificial oxide.

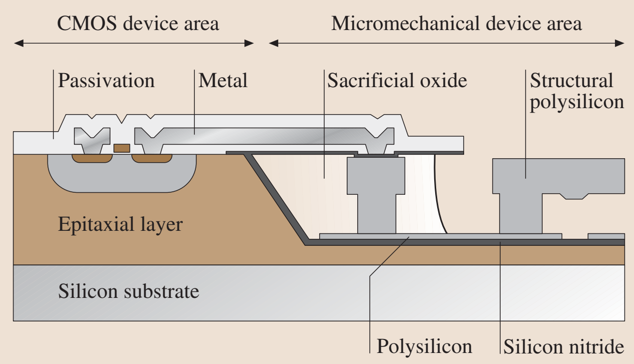


Fig. 5.36 Cross section of the Sandia MEMS-first integrated fabrication process

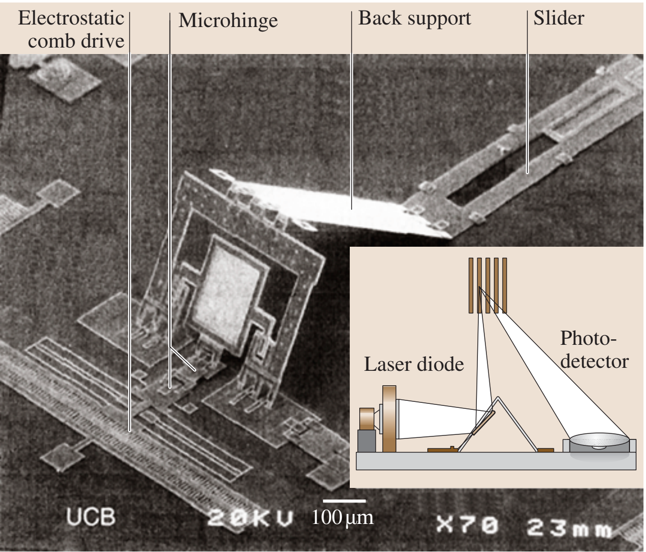

Fig. 5.37 Silicon pin-and-sample hinge scanner with 3-D surface micromachined structures [5.38]

3-D Microstructures Using Surface Micromachining

Three-dimensional surface microstructures can be fabricated using surface micromachining. The fabrication of hinges for the vertical assembly of MEMS was a major advance toward achieving 3-D microstructures [5.39]. Optical microsytems have greatly benefited from surface micromachined 3-D structures. These microstructures are used as passive or active components (micromirror, Fresnel lens, optical cavity, etc.) on a silicon optical bench (silicon microphotonics). An example is the Fresnel lens that has been surface micromachined in polysilicon and then erected using hinge structures and locked in place using micromachined tabs, thus liberating the structure from the horizontal plane of the wafer [5.38, 40]. Various microactuators (e.g., comb drive and vibromotors) have been used to move these structures out of the silicon plane and into position. Figure 5.37 shows an SEM photograph of a bar-code micro-scanner using a silicon optical microbench with 3-D surface micromachined structures.

5.2.3 High-Aspect-Ratio Micromachining

The bulk and surface micromachining technologies presented in the previous sections fulfill the requirements of a large group of applications. Certain applications, however, require the fabrication of high-aspect-ratio structures, which is not possible with the aforementioned technologies. In this section, we describe three technologies, LIGA, HEXSIL, and HARPSS, capable of producing structures with vertical dimensions much larger than the lateral dimensions by means of X-ray lithography (LIGA) and DRIE etching (HEXSIL and HARPSS).

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

LIGA

LIGA is a high-aspect-ratio micromachining process that relies on X-ray lithography and electroplating (in German: *LI*thographie *G*lvanoformung *A*bformung) [5.41, 42]. We already introduced the concept of the plating-through-mask technique in Sect. 5.1.2 (see Fig. 5.10). With standard UV photolithography and photoresists, the maximum thickness achievable is on the order of a few tens of microns and the resulting metal structures show tapered walls. LIGA is a technology based on the same plating-through-mask idea, but can be used to fabricate metal structures of thicknesses ranging from a few microns to a few millimeters with almost vertical sidewalls. This is achieved using X-ray lithography and special photoresists. Due to their short wavelength, X-rays are capable of penetrating a thick photoresist layer with no scattering and defining features with lateral dimensions down to 0.2 μm (aspect ratio > 100 : 1).

The photoresists used in LIGA should comply with certain requirements, including sensitivity to X-rays, resistance to electroplating chemicals, and good adhesion to the substrate. Based on such requirements Poly-(methylmethacrylate) (PMMA) is considered an optimal choice for the LIGA process. Application of the thick photoresist on top of the substrate can be performed by various techniques such as multiple spin coating, pre-cast PMMA sheets, and plasma polymerization coating. The mask structure and materials for X-ray lithography must also comply with certain requirements. The traditional masks based on

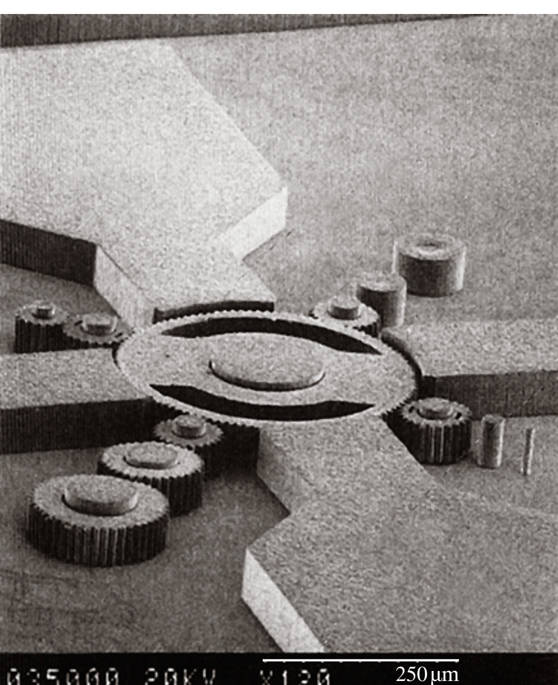

Fig. 5.38 SEM of assembled LIGA-fabricated nickel structures [5.41]

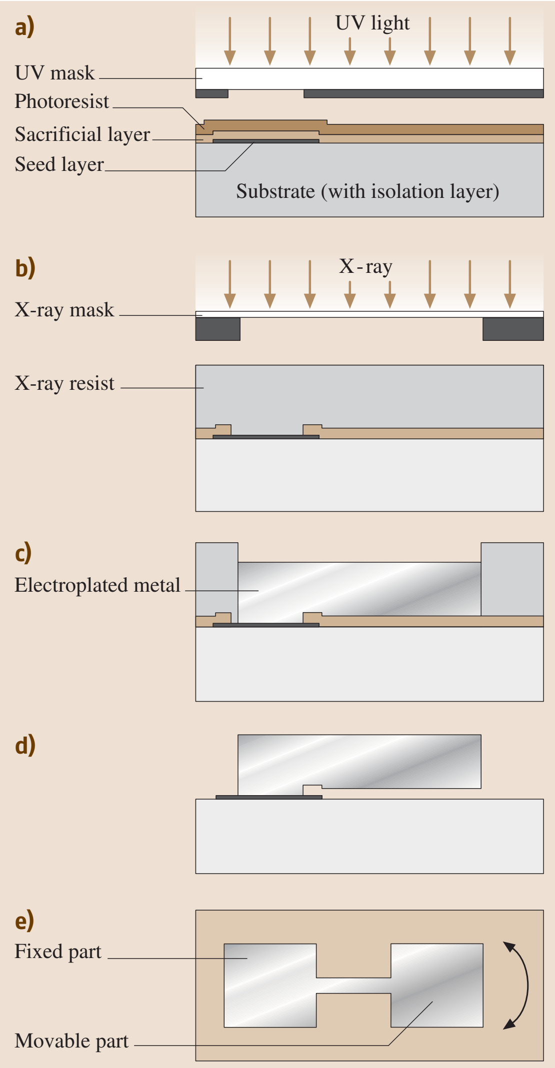

Fig. 5.39a–e Sacrificial LIGA process: **(a)** UV lithography for sacrificial layer patterning, **(b)** X-ray lithography, **(c)** electroplating, **(d)** structure releasing, **(e)** top view of the movable structure

Part A | 5.2

glass plates with a patterned chrome thin layer are not suitable, because X-rays are not absorbed in the chromium layer and the glass plate is not transparent enough. Instead, X-ray lithography uses a silicon nitride mask with gold as the absorber material (typically formed by electroplating gold to a thickness of 10–20 µm). The nitride membrane is supported by a silicon frame, which can be fabricated using bulk micromachining techniques. Once the photoresist is exposed to the X-rays and developed, the process proceeds with the electroplating of the desired metal. Ni is the most common, although other metals and metallic compounds such as Cu, Au, NiFe, and NiW are also electroplated in LIGA processes. A good agitation of the plating solution is the key in obtaining a uniform and repeatable result during this step. A paddle plating cell, based on a windshield wiper-like device moving only 1 mm away from the substrate surface, provides extremely reproducible agitation. Figure 5.38 shows an SEM of a LIGA microstructure fabricated by electroplating nickel.

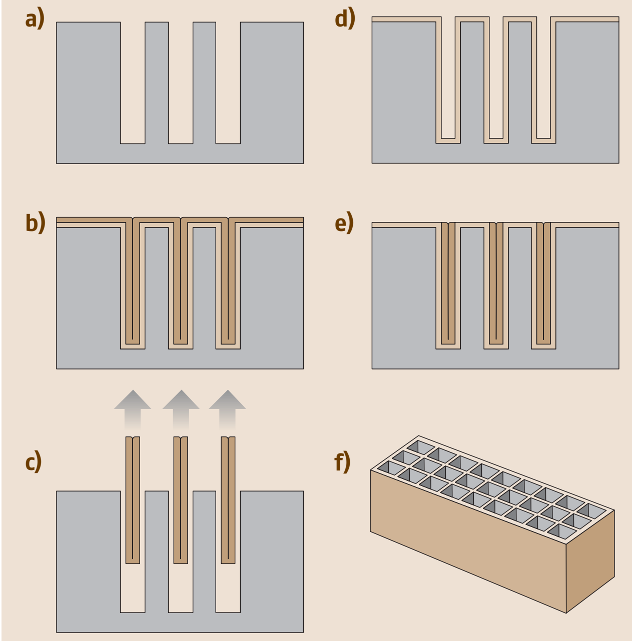

Fig. 5.40a–f HEXSIL process flow: **(a)** DRIE, **(b)** sacrificial layer deposition, **(c)** structural material deposition and trench filling, **(d)** etch structural layer from the surface, **(e)** etch sacrificial layer and pulling out of the structure, **(f)** example of a HEXSIL fabricated structure

Due to the high cost of the X-ray sources (synchrotron radiation), the LIGA technology was initially intended for the fabrication of molds that could be used many times in hot embossing or injection molding processes. However, it has been also used in many applications to directly form high-aspect-ratio metal structures on top of a substrate. A cheaper alternative to the LIGA process (with somewhat poorer qualities) called UV-LIGA, or "poor man's LIGA", has been proposed [5.43, 44]. This process uses SU-8 negative photoresists (available for spin coating at various thicknesses ranging from 1 to 500 µm) and standard contact lithography equipment. Using this technique, aspect ratios larger than 20:1 have been demonstrated. A major problem of this alternative is the removal of the SU-8 photoresist after plating. Various methods with different degrees of success have been proposed. These include: wet etching with special solvents, burning at high temperatures (600 °C), dry etching, use of a release layer, and high-pressure water jet etching.

A variation of the basic LIGA process, shown in Fig. 5.39, permits the fabrication of electrically isolated movable structures, and thus opens more possibilities for sensor and actuator design using this technology [5.45]. The so-called sacrificial LIGA (SLIGA) starts with the patterning of the seed layer. Subsequently, a sacrificial layer (e.g., titanium) is deposited and patterned. The process then proceeds as usual in standard LIGA until the last step when the sacrificial layer is removed. The electroplated structures that overlap with the sacrificial layer are released in this step.

HEXSIL

The second method for fabricating high-aspect-ratio structures, which is based on a template replication technology, is *HEXSIL* (*HEX*agonal honeycomb poly*SIL*icon) [5.46]. Figure 5.40 shows a simplified process flow. A high-aspect-ratio template is first formed in a silicon substrate using DRIE. Next, a sacrificial multilayer is deposited to allow the final release of the structures. The multilayer is composed of one or more PSG nonconformal layers to provide fast etch release (∼ 20 µm/min in 49% HF) alternated with conformal layers of either oxide or nitride to provide enough thickness for proper release of the structures. The total thickness of the sacrificial layer has to be larger than the shrinkage or elongation of the structures caused by the relaxation of the internal stress (compressive or tensile) during the release step. Otherwise, the structures will clamp themselves to the walls of the template and their retrieval will not be possible. Any material

that can be conformally deposited and yet not damaged during the HF release step is suitable for the structural layer. Structures made of polysilicon, nitride, and electroless nickel [5.47] have been reported. Nickel can only be deposited in combination with polysilicon since a conductive surface is needed for the deposition to occur. After deposition of structural materials, a blanket etch (poly or nitride) or a mechanical lapping (nickel) is performed to remove the excess materials from the surface. Finally, a 49% HF with surfactant is used to dissolve the sacrificial layers. The process can be repeated many times using the same template, thus considerably lowering the fabrication costs. Figure 5.41 shows an SEM photograph of a microactuator fabricated using the HEXSIL process.

HARPSS

The *h*igh *a*spect *r*atio combined with *p*oly and *s*ingle-crystal *s*ilicon (*HARPSS*) technology is another technique capable of producing high-aspect-ratio, electrically isolated polycrystalline and single-crystal silicon microstructures with capacitive air gaps ranging from submicrometer to tens of micrometers [5.50]. The structures, tens to hundreds of micrometers thick, are defined by trenches etched with DRIE and filled with oxide and poly layers. The release of the microstructures is done at the end by means of a directional silicon etch followed by an isotropic etch. The small, vertical gaps and thick structures possible with this technology can be applied to the fabrication of a variety of MEMS devices, particularly inertial sensors [5.51] and RF beam resonators [5.52]. Figure 5.42 shows the process flow at the cross section of a single-crystal silicon beam resonator. The HARPSS process starts with the deposition and patterning of a silicon nitride layer that will be used to isolate the poly structure's connection pads from the substrate. High-aspect-ratio trenches (∼ 5 µm wide) are then etched into the substrate using a DRIE etcher. Next, a conformal oxide layer (LPCVD) is deposited. This layer has two functions: 1) to protect the structures during the dry etch release and 2) to define the submicrometer gap between silicon and polysilicon structures. Following the oxide deposition, the trenches are completely filled with LPCVD polysilicon. The polysilicon

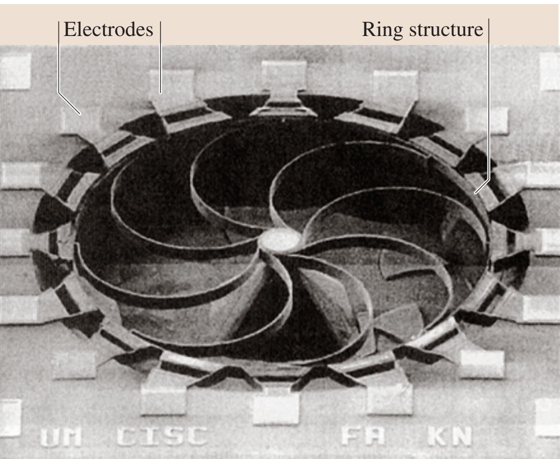

Fig. 5.43 SEM photograph of a micro-gyroscope fabricated using HARPSS process [5.49]

is etched back, and the underneath oxide is patterned to provide anchor points for the structures. A second layer of polysilicon is then deposited and patterned. Finally, the structures are released using a DRIE step followed by an isotropic silicon etch through a photoresist mask that exposes only the areas of silicon substrate surrounding the structures. It should be noted that single-crystal silicon structures are not protected at the bottom during the isotropic etch. This causes the single-crystal silicon structures to be etched vertically from the bottom, and thus be shorter than the polysilicon structures. Figure 5.43 shows an SEM photograph of a micro-gyroscope fabricated using the HARPSS process.

5.3 Nanofabrication Techniques

The microfabrication techniques discussed so far were mostly geared toward fabricating devices in the 1 mm to 1 μm dimensional range (submicron dimensions being possible in certain techniques such as *HARPSS* using a dielectric sacrificial layer). Recent years have witnessed a tremendous surge of interest in fabricating sub-micro (1 μm–100 nm) and nanostructures (1–100 nm range) [5.53]. This interest arises from both practical and fundamental view points. At the more scientific and fundamental level, nanostructures provide an interesting tool in studying electrical, magnetic, optical, thermal, and mechanical properties of matter at the nanometer scale. These include important quantum mechanical phenomena (e.g., conductance quantization, band-gap modification, coulomb blockade, etc.) arising from the confinement of charged carriers in structures such as quantum wells, wires, and dots, Fig. 5.44. On the practical side, nanostructures can provide significant improvements in the performance of electronic/optical devices and sensors. In the device area, investigators have been mostly interested in fabricating nanometer-sized transistors in anticipation of technical difficulties forecasted in extending Moore's law beyond 100 nm resolution. In addition, optical sources and detectors having nanometer-sized dimensions exhibit improved characteristics unachievable in larger devices (e.g., lower threshold current, improved dynamic behavior, and improved emission line-width in quantum dot lasers). These improvements create novel possibilities for next-generation computation and communication devices. In the sensors area, shrinking dimensions beyond conventional optical lithography can provide major improvements in sensitivity and selectivity.

One can broadly divide various nanofabrication techniques into top-down and bottom-up categories. The first approach starts with a bulk or thin film material and removes selective regions to fabricate nanostructures (similar to micromachining techniques). The second method relies on molecular recognition and self-assembly to fabricate nanostructures out of smaller building blocks (molecules, colloids, and clusters). The top-down approach is an offshoot of standard lithography and micromachining techniques. On the other hand, the bottom-up approach has more of a chemical engineering and material science flavor and relies on fundamentally different principles. In this chapter, we will discuss four major nano-fabrication techniques. These include: i) e-beam and *nano-imprint* fabrication, ii) *epitaxy* and *strain engineering*, iii) scanned probe techniques, and iv) *self-assembly* and *template manufacturing*.

5.3.1 E-Beam and Nano-Imprint Fabrication

In previous sections, we discussed several important lithography techniques used commonly in MEMS and microfabrication. These include various forms of UV (regular, deep, and extreme) and X-ray lithographies. However, due to the lack of resolution (in the case of the UV), or the difficulty in manufacturing mask and radiation sources (X-ray), these techniques are not suitable for nanometer-scale fabrication. E-beam lithography is an attractive alternative technique for fabricating nanostructures [5.54]. It uses an electron beam to expose an electron-sensitive resist such as polymethyl methacrylate (PMMA) dissolved in trichlorobenzene (positive) or poly chloromethylstyrene (negative) [5.55]. The e-beam gun is usually part of a scanning electron microscope (SEM), although transmission electron microscopes (TEM) can also be used. Although electron wavelengths on the order of 1 Å can be easily achieved, electron scattering in the resist limits the attainable resolutions to > 10 nm. The beam control and pattern generation are achieved through a computer interface. E-beam lithography is serial and, hence, it has a low throughput. Although this is not a major concern in fabricating devices used in studying fundamental microphysics, it severely limits large scale nanofabrication. E-beam lithography, in conjunction with such processes as lift-off, etching, and electro-deposition, can be used to fabricate various nanostructures.

An interesting new technique that circumvents the serial and low throughput limitations of the e-beam lithography for fabricating nanostructures is the nano-imprint technology [5.56]. This technique uses an e-beam fabricated hard material master (or mold) to stamp and deform a polymeric resist. This is usually followed by a reactive ion etching step to transfer the stamped pattern to the substrate. This technique is economically superior, since a single stamp can be used repeatedly to fabricate a large number of nanostructures. Figure 5.45 shows a schematic illustration of nano-imprint fabrication. First, a hard material (e.g., silicon or SiO_2) stamp is created using e-beam lithography and reactive ion etching. Then, a resist-coated substrate is stamped, and, finally, an anisotropic RIE is performed to remove the resist residue in the stamped area. At this stage, the process is complete and one can either etch the substrate or, if metallic nanostructures are desired, evaporate the metal and perform a lift off. The resist used in nano-imprint technology can be thermal plastic, UV-curable, or thermal-curable polymer. For a thermal plastic resist (e.g., PMMA), the substrate is heated to above the glass transition temperature (T_g) of the polymer before stamping and is cooled to below T_g before the stamp is removed. Similarly, the UV and thermal-curable resists are fully cured before the stamp is separated. Nano-imprint technology resolution is limited by the mold and polymer strengths and can be as small as 10 nm. More recently, the nano-imprint technique has been used to stamp a silicon substrate in less than 250 ns using a XeCl excimer laser (308 nm) and a quartz mask (laser assisted direct imprint, LADI), Fig. 5.46 [5.57].

5.3.2 Epitaxy and Strain Engineering

Atomic precision deposition techniques such as molecular beam epitaxy (MBE) and metallo-organic chemical vapor deposition (MOCVD) have proven to be effective tools in fabricating a variety of quantum confinement structures and devices (quantum well lasers, photodetectors, resonant tunneling diodes, etc.) [5.58–60]. Although quantum wells and superlattices are the structures that lend themselves most easily to these techniques (see Fig. 5.44a), quantum wires and dots have also been fabricated by adding subsequent steps such as etching and selective growth. Fabrication of quantum well and superlattice structures using epitaxial growth is a mature and well developed field and, therefore, will not be discussed in this chapter. Instead, we will concentrate on quantum wire and dot nanostructure fabrication using basic epitaxial techniques [5.61, 62].

Quantum Structure Nanofabrication Using Epitaxy on Patterned Substrates

There have been several different approaches to the fabrication of quantum wires and dots using epitaxial layers. The most straight forward technique involves e-beam lithography and etching of an epitaxial grown layer (e.g., InGaAs on GaAs substrate) [5.63]. However, due to the damage and/or contamination during lithography, this method is not very suitable for active device fabrication (e.g., quantum dot lasers). Several other methods involving regrowth of epitaxial layers over nonplanar surfaces such as step-edge, cleaved-edge, and patterned substrate have been used to fabricate quantum wires and dots without the need for lithography and etching of the quantum confined structure [5.62, 64]. These nonplanar surface templates can be fabricated in a variety of ways such as etching through a mask or cleavage along crystallographic planes. Subsequent epitaxial growth on top of these structures results in a set of planes with different growth rates depending on the geometry or surface diffusion and adsorption effects. These effects can significantly enhance or limit the growth rate on certain planes, resulting in lateral patterning and confinement of deposited epitaxial layers and formation of quantum wires (in V grooves) and dots (in inverted pyramids). Figure 5.48a shows a schematic cross section of an InGaAs quantum wire fabricated in a V-groove InP. As can be seen, the growth rate on the sidewalls is lower than that of the top and bottom surfaces. Therefore, the thicker InGaAs layer at the bottom of the V-groove forms a quantum wire confined from the sides by a thinner layer with a wider bandgap. Figure 5.48b shows a quantum wire formed using epitaxial growth over a dielectric pat-

B. Bhushan • © Springer 2004

terned planar substrate. In both of these techniques, it is relatively easy to create quantum wells. However, in order to create quantum wires and dots one still needs e-beam lithography to pattern the groove and window templates.

Quantum Structure Nanofabrication Using Strain-Induced Self-Assembly

A more recent technique for fabricating quantum wires and dots involves strain-induced *self-assembly* [5.62, 65]. The term *self-assembly* represents a process whereby a strained 2-D system reduces its energy by a transition into a 3-D morphology. The most commonly used material combination for this technique is the $In_xGa_{1-x}As/GaAs$ system, which offers a large lattice mismatch (7.2% between InAs and GaAs) [5.66,67], although recently Ge dots on Si substrate have also attracted considerable attention [5.68]. This method relies on lattice mismatch between an epitaxial grown layer and its substrate to form an array of quantum dots or wires. Figure 5.49 shows a schematic of the strain-induced self-assembly process. When the lattice constants of the substrate and the epitaxial layer differ considerably, only the first few deposited monolayers crystallize in the form of an epitaxial strained layer in which the lattice constants are equal. When a critical thickness is exceeded, a significant strain in the layer leads to the breakdown of this ordered structure and the spontaneous formation of randomly distributed islets of regular shape and similar size (usually < 30 nm in diameter). This mode of growth is usually referred to as the Stranski-Krastanow mode. The quantum dot size, separation, and height depend on the deposition parameters (i. e., total deposited material, growth rate, and temperature) and material combinations. As can be seen, this is a very convenient method to grow perfect crystalline nanostructures over a large area without any lithography and etching. One major drawback of this technique is the randomness of the quantum dot distribution. It should be mentioned that this technique can also be used to fabricate quantum wires by strain relaxation bunching at the step edges.

5.3.3 Scanned Probe Techniques

The invention of scanned probe microscopes in the 1980s revolutionized atomic-scale imaging and spectroscopy. In particular, scanning tunneling and atomic force microscopes (STM and AFM) have found widespread applications in physics, chemistry, material science, and biology. The possibility of atomic-scale manipulation, lithography, and nanomachining using such probes was considered from the beginning and has matured considerably over the past decade. In this section, after a brief introduction to scanned probe microscopes, we will discuss several important nano-lithography and machining techniques that have been used to create nanometer-sized structures.

The scanning probe microscopy (SPM) systems are capable of controlling the movement of an atomically sharp tip in close proximity to or in contact with a surface with subnanometer accuracy. Piezoelectric positioners are typically used to achieve such accuracy. High resolution images can be acquired by raster scanning the tips over a surface while simultaneously monitoring the interaction of the tip with the surface. In scanning tunneling microscope systems, a bias voltage is applied to the sample and the tip is positioned close enough to the surface, so that a tunneling current develops through the gap (Fig. 5.50a). Because this current is extremely sensitive to the distance between the tip and the surface, scanning the tip in the x-y plane while recording the tunnel current permits the mapping of the surface topography with resolution on the atomic scale. In a more common mode of operation, the amplified current signal is connected to the z-axis piezoelectric positioner through

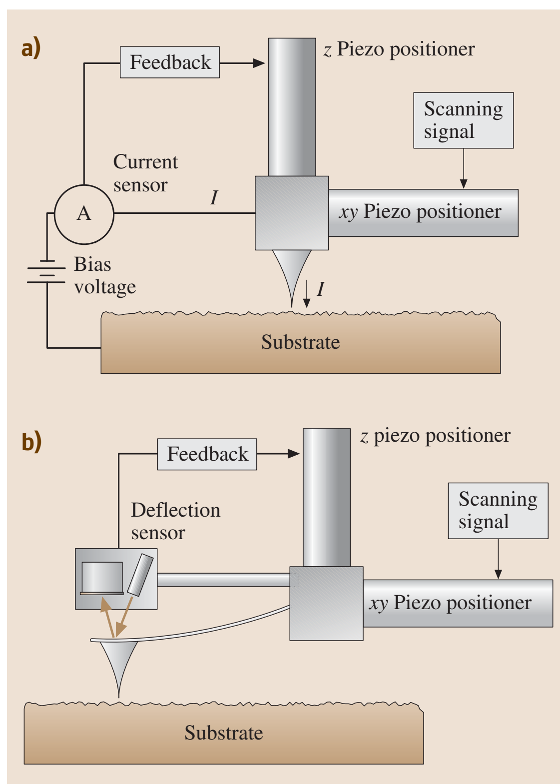

Fig. 5.50a,b Scanning probe systems: **(a)** STM and **(b)** AFM

a feedback loop, so that the current and, therefore, the distance are kept constant throughout the scanning. In this configuration the picture of the surface topography is obtained by recording the vertical position of the tip at each x-y position.

The STM system only works for conductive surfaces because of the need to establish a tunneling current. The atomic force microscopy was developed as an alternative for imaging either conducting or nonconducting surfaces. In AFM, the tip is attached to a flexible cantilever and is brought in contact with the surface (Fig. 5.50b). The force between the tip and the surface is detected by sensing the cantilever deflection. A topographic image of the surface is obtained by plotting the deflection as a function of the x-y position. In a more common mode of operation, a feedback loop is used to maintain a constant deflection, while the topographic information is obtained from the cantilever vertical displacement. Some scanning probe systems use a combination of the AFM and STM modes, i. e., the tip is mounted in a cantilever with an electrical connection, so both the surface forces and the tunneling currents can be controlled or monitored. STM systems can be operated in ultrahigh vacuum (UHV STM) or in air, whereas *AFM* systems are typically operated in air. When a scanning probe system is operated in air, water adsorbed onto the sample surface accumulates underneath the tip, forming a meniscus between the tip and the surface. This water meniscus plays an important role in some of the scanning probe techniques described below.

Scanning Probe Induced Oxidation

Nanometer-scale local oxidation of various materials can be achieved using scanning probes operated in air and biased at a sufficiently high voltage, Fig. 5.51. Tip bias of −2 to −10 V is normally used with writing speeds of 0.1–100 μm/s in an ambient humidity of 20–40 %. It is believed that the water meniscus formed at the contact point serves as an electrolyte such that the biased tip anodically oxidizes a small region of the surface [5.70]. The most common application of this principle is the oxidation of hydrogen-passivated silicon. A dip in HF solution is typically used to passivate the silicon surfaces with hydrogen atoms. Patterns of oxide "written" on a silicon surface can be used as a mask for wet or dry etching. Ten-nm line width patterns have been successfully transferred to a silicon substrate in this fashion [5.71]. Various metals have also been locally anodized using this approach such as alu-

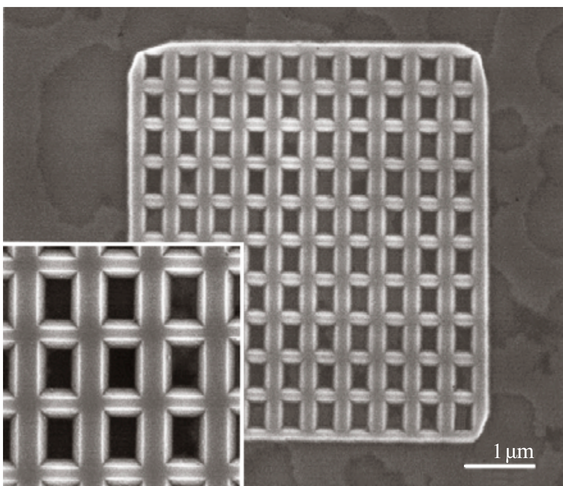

Fig. 5.51 SEM image of an inverted, truncated pyramid array fabricated on a silicon SOI wafer by SPM oxidation and subsequent etch in TMAH (pitch is 500 nm) [5.69]

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

minum or titanium [5.72]. An interesting variation of this process is the anodization of deposited amorphous silicon [5.73]. Amorphous silicon can be deposited at low temperature on top of many materials. The deposited silicon layer can be patterned and used as, for example, the gate of a 0.1 µm CMOS transistor [5.74], or it can be used as a mask to pattern an underlying film. The major drawback of this technique is poor reproducibility due to tip wear during the anodization. However, using AFM in noncontact mode has overcome this problem [5.70].

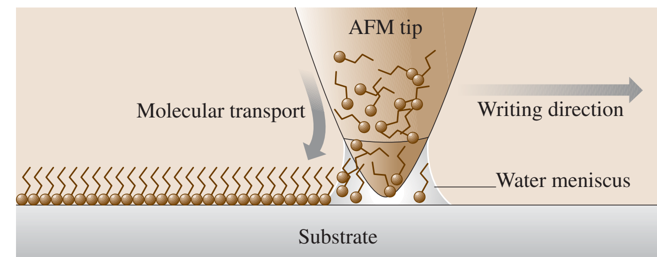

Fig. 5.53 Schematic representation of the dip-pen nanolithography working principle

Scanning Probe Resist Exposure and Lithography

Electrons emitted from a biased SPM tip can be used to expose a resist the same way e-beam lithography does (Fig. 5.52) [5.74]. Various systems have been used for this lithographic technique. These include constant current STM, noncontact AFM, and AFM with constant tip-resist force and constant current. The systems using AFM cantilevers have the advantage of performing imaging and alignment tasks without exposing the resist. Resists well characterized for e-beam lithography (e.g., PMMA or SAL601) have been used with scanning probe lithography to achieve reliable sub-100-nm lithography. The procedure for this process is as follows. The wafers are cleaned and the native oxide (in the case of silicon or poly) is removed with a HF dip. Subsequently, 35–100 nm-thick resist is spin-coated on top of the surface. The exposure is done by moving the SPM tip over the surface while applying a bias voltage high enough to produce an emission of electrons from the tip (a few tens of volts). Development of the resist is performed in standard solutions following the exposure. Features below 50 nm in width have been achieved with this procedure.

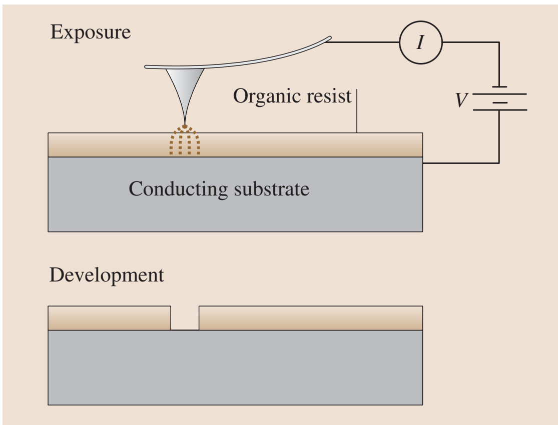

Fig. 5.52 Scanning probe lithography with organic resist

Dip-Pen Nanolithography

In dip-pen nanolithography (DPN), the tip of an AFM operated in air is "inked" with a chemical of interest and brought into contact with a surface. The ink molecules flow from the tip onto the surface as with a fountain pen. The water meniscus that naturally forms between the tip and the surface enables the diffusion and transport of the molecules, as shown in Fig. 5.53. Inking can be done by dipping the tip in a solution containing a small concentration of the molecules followed by a drying step (e.g., blowing dry with compressed difluoroethane). Line widths down to 12 nm with spatial resolution of 5 nm have been demonstrated with this technique [5.75]. Species patterned with DPN include conducting polymers, gold, dendrimers, DNA, organic dyes, antibodies, and alkanethiols. Alkanethiols have also been used as an organic monolayer mask to etch a gold layer and subsequently etch the exposed silicon substrate.

Other Scanning Probe Nanofabrication Techniques

A great variety of nanofabrication techniques using scanning probe systems have been demonstrated. Some of these are proof of concept demonstrations, and their utility as a viable and repeatable fabrication process has yet to be evaluated. For example, a substrate can be mechanically machined using STM/AFM tips acting as plows or engraving tools [5.76]. This can be used to directly create structures in the substrate, although it is more commonly used to pattern a resist for a subsequent etch, liftoff, or electro-deposition step. Mechanical nanomachining with SPM probes can be fa-

cilitated by heating the tip above the glass transition of a polymeric substrate material. This approach has been applied to SPM-based high-density data storage in polycarbonate substrates [5.77].

Electric fields strong enough to induce the emission of atoms from the tip can be easily generated by applying voltage pulses above 3 V. This phenomenon has been used to transfer material from the tip to the surface and vice versa. Ten- to 20-nm mounds of metals such as Au, Ag, or Pt have been deposited or removed from a surface in this fashion [5.78]. The same approach has been used to extract single atoms from a semiconductor surface and re-deposit them elsewhere [5.79]. Manipulation of nanoparticles, molecules, and single atoms on top of a surface has also been achieved by simply pushing or sliding them with the SPM tip [5.80]. Metals can also be locally deposited by the STM chemical vapor deposition technique [5.81]. In this technique, a precursor organometallic gas is introduced in the STM chamber. A voltage pulse applied between the tip and the surface dissociates the precursor gas into a thin layer of metal. Local electro-chemical etch [5.82] and electro-deposition [5.83] are also possible using SPM systems. A droplet of suitable solution is first placed on the substrate. Then the STM tip is immersed into the droplet and a voltage is applied. In order to reduce Faradaic currents the tip is coated with wax such that only the very end is exposed to the solution. Sub-100-nm feature size has been achieved using this technique.

Using a single tip to serially produce the desired modification in a surface leads to very slow fabrication processes that are impractical for mass production. Many of the scanning probe techniques developed thus far, however, could also be performed by an array of tips, which would increase their throughput and make them more competitive compared with other parallel nanofabrication processes. This approach has been demonstrated for imaging, lithography [5.84], and data storage [5.85] using both 1-D and 2-D arrays of scanning probes. With the development of larger arrays with individual control of force, vertical position, and current advances, we might see these techniques become standard fabrication processes in the industry.

5.3.4 Self-Assembly and Template Manufacturing

Self-assembly is a nanofabrication technique that involves aggregation of colloidal nano-particles into the final desired structure [5.86]. This aggregation can be either spontaneous (entropic) and due to the thermodynamic minima (energy minimization) constraints, or chemical and due to the complementary binding of organic molecules and supramolecules (molecular self-assembly) [5.87]. Molecular self-assembly is one of the most important techniques used in biology for the development of complex functional structures. Since these techniques require that the target structures be thermodynamically stable, they tend to produce structures that are relatively defect-free and self-healing. Self-assembly is by no means limited to molecules or the nano-domain and can be carried out on just about any scale, making it a powerful bottom-up assembly and manufacturing method (multiscale ordering). Another attractive feature of this technique relates to the possibility of combining self-assembly properties of organic molecules with the electronic, magnetic, and photonic properties of inorganic components. *Template manufacturing* is another bottom-up technique that utilizes material deposition (electroplating, CVD, etc.) in nano-templates in order to fabricate nanostructures. The nano-templates used in this technique are usually prepared using self-assembly techniques. In the following sections, we will discuss various important self-assembly and template manufacturing techniques currently under heavy investigation.

Physical and Chemical Self-Assembly

The central theme behind the self-assembly process is spontaneous (physical) or chemical aggregation of colloidal nano-particles [5.88]. Spontaneous self-assembly exploits the tendency of mono-dispersed nano- or sub-micro colloidal spheres to organize into a face-centered cubic (FCC) lattice. The force driving this process is the desire of the system to achieve a thermodynamically stable state (minimum free energy). In addition to spontaneous thermal self-assembly, gravitational, convective, and electrohydrodynamic forces can also be used to induce aggregation into complex 3-D structures. Chemical self-assembly requires the attachment of a single molecular organic layer (*self-assembled monolayer*, or *SAM*) to the colloidal particles (organic or inorganic) and subsequent self-assembly of these components into a complex structure using molecular recognition and binding.

Physical Self-Assembly. This is an entropic-driven method that relies on the spontaneous organization of colloidal particles into a relatively stable structure through non-covalent interactions. For example, colloidal polystyrene spheres can be assembled into a 3-D structure on a substrate that is held vertically in the colloidal solution, Fig. 5.54 [5.89, 90]. Upon the

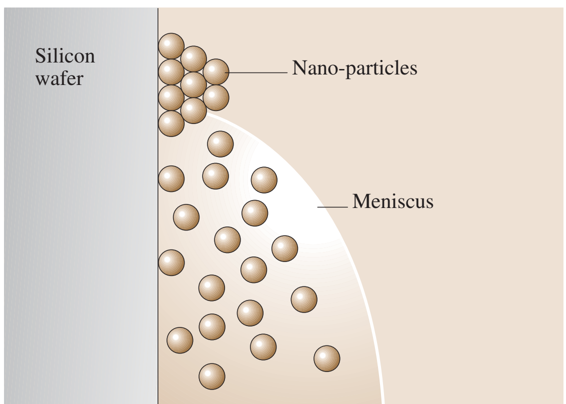

Fig. 5.54 Colloidal particle self-assembly onto solid substrates upon drying in vertical position

Fig. 5.55 Cross-sectional SEM image of a thin planar opal silica template (spheres 855 nm in diameter) assembled directly on a Si wafer [5.89]

evaporation of the solvent, the spheres aggregate into a hexagonal close packed (HCP) structure. The interstitial pore size and density are determined by the polymer sphere size. The polymer spheres can be etched into smaller sizes after forming the HCP arrays, thereby altering the template pore separations [5.91]. This technique can fabricate large patterned areas in a quick, simple, and cost-effective way. A classic example is the natural assembly of on-chip silicon photonic bandgap crystals [5.89], which are capable of reflecting the light arriving from any direction in a certain wavelength range [5.92]. In this method, a thin layer of silica colloidal spheres is assembled on a silicon substrate. This is achieved by placing a silicon wafer vertically in a vial containing an ethanolic suspension of silica spheres. A temperature gradient across the vial aids the flow of silica spheres. Figure 5.55 shows the cross-sectional SEM image of a thin planar opal template assembled directly on a Si wafer from 855 nm spheres. Once such a template is prepared, LPCVD can be used to fill the interstitial spaces with Si, so that the high refractive index of silicon provides the necessary bandgap.

One can also deposit colloidal particles into a patterned substrate (template-assisted self-assembly, TASA) [5.93, 94]. This method is based on the principle that when aqueous dispersion of colloidal particles is allowed to dewet from a solid surface that is already patterned, the colloidal particles are trapped by the recessed regions and assembled into aggregates of shapes and sizes determined by the geometric confinement provided by the template. The patterned arrays of templates can be fabricated using conventional contact-mode photolithography, which gives control over the shape and dimensions of the templates, thereby allowing the assembly of complex structures from colloidal particles. The cross-sectional view of a fluidic cell used in TASA is shown in Fig. 5.56. The fluidic cell has two parallel glass substrates to confine the aqueous dispersion of the colloidal particles. The surface of the bottom substrate is patterned with a 2-D array of templates. When the aqueous dispersion is allowed to slowly dewet across the cell, the capillary force exerted on the liquid pushes the colloidal spheres across the surface of the bottom substrate until they are physically trapped by the templates. If the concentration of the colloidal dispersion is high enough, the template will be filled by the maximum number of colloidal particles determined by the geometrical confinement. This method can be used to fabricate a variety of polygonal and polyhedral aggregates that are difficult to generate [5.95].

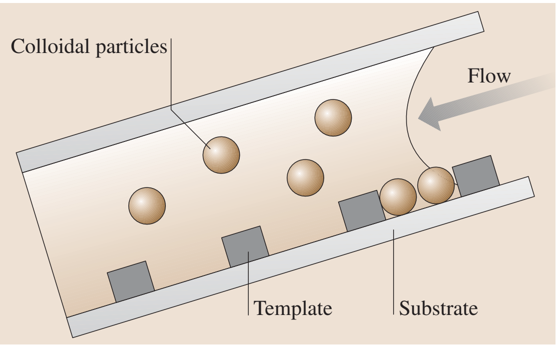

Fig. 5.56 A cross-sectional view of the fluidic cell used for template-assisted self-assembly

Chemical Self-Assembly. Organic and supramolecular SAMs play a critical role in colloidal particle self-assembly. SAMs are robust organic molecules that are chemically adsorbed onto solid substrates [5.96]. Most often, they have a hydrophilic (polar) head that can be bonded to various solid surfaces and a long, hydrophobic (nonpolar) tail that extends outward. SAMs are formed by the immersion of a substrate in a dilute solution of the molecule in an organic solvent. The resulting film is a dense organization of molecules arranged to expose the end group. The durability of a SAM is highly dependent on the effectiveness of the anchoring to the surface of the substrate. SAMs have been widely studied, because the end group can be functionalized to form precisely arranged molecular arrays for various applications ranging from simple, ultrathin insulators and lubricants to complex biological sensors. Chemical self-assembly uses organic or supramolecular SAMs as the binding and recognition sites for fabricating complex 3-D structures from colloidal nano-particles. Most commonly used organic monolayers include: 1) organosilicon compounds on glass and native surface oxide layer of silicon, 2) alkanethiols, dialkyl disulfides, and dialkyl sulfides on gold, 3) fatty acids on alumina and other metal oxides, and 4) DNA.

Octadecyltrichlorosilane (OTS) is the most common organosilane used in the formation of SAMs, mainly because of the fact that it is simple, readily available, and forms good, dense layers [5.97, 98]. Alkyltrichlorosilane monolayers can be prepared on clean silicon wafers whose surface is SiO_2 (with almost 5×10^{14} SiOHgroups/cm^2). Figure 5.57 shows the schematic representation of the formation of alkylsiloxane monolayers by adsorption of alkyltrichlorosilanes from solution onto Si/SiO_2 substrates. Since the silicon-chloride bond is susceptible to hydrolysis, a limited amount of water has to be present in the system in order to obtain good quality monolayers. Monolayers made of methyl- and vinyl-terminated alkylsilanes are autophobic to the hydrocarbon solution and hence emerge uniformly dry from the solution, whereas monolayers made of ester-terminated alkylsilanes emerge wet from the solution used in their formation. The disadvantage of this method is that if the alkyltrichlorosilane in the solvent adhering to the substrate is exposed to water, a cloudy film is deposited on the surface due to formation of a gel of polymeric siloxane.

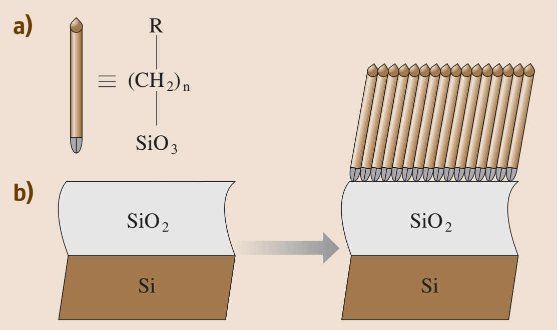

Fig. 5.57 (a) Alkylsiloxane formed from the adsorption of alkyltrichlorosilane on Si/SiO_2 substrates. **(b)** Schematic representation of the process

Another important organic SAM system is the alkanethiols ($X(CH_2)_nSH$, where X is the endgroup) on gold [5.96, 99–101]. A major advantage of using gold as the substrate material is that it does not have a stable oxide, and thus it can be handled in ambient conditions. When a fresh, clean, hydrophilic gold substrate is immersed (several minutes to several hours) into a dilute solution (10^{-3} M) of the organic sulfur compound (alkanethiols) in an inorganic solvent, a close-packed, oriented monolayer can be obtained. Sulfur is used as the head group, because of its strong interaction with gold substrate (44 kcal/mol), resulting in the formation of a close-packed, ordered monolayer. The end group of alkanethiol can be modified to render hydrophobic or hydrophilic properties to the adsorbed layer. Another method for depositing alkanethiol SAM is soft-lithography. This technique is based on inking a PDMS stamp with alkanethiol and its subsequent transfer to planar and nonplanar substrates. Alkanethiol functionalized surfaces (planar, nonplanar, spherical) can also be used to self-assemble a variety of intricate 3-D structures [5.102].

Carboxylic acid derivatives self-assemble on surfaces (e.g., glass, Al_2O_3, and Ag_2O) through an acid-base reaction, giving rise to monolayers of fatty acids [5.103]. The time required for the formation of a complete monolayer increases with decreased concentration. A higher concentration of carboxylic acid is required to form a monolayer on gold compared to Al_2O_3. This is due to differences in the affinity of the COOH groups (more affinity to Al_2O_3 and glass than gold) and also the surface concentration of the salt-forming oxides in the two substrates. In the case of amorphous metal oxide surfaces, the chemisorption of alkanoic acids is not unique. For example, on Ag_2O the carboxylate two oxygen atoms bind to the substrate in a nearly symmetrical manner, resulting in ordered monolayers with a chain tilt angle from the surface normally

of 15° to 25°. But on CuO and Al_2O_3, the oxygen atoms bind themselves symmetrically and the chain tilt angle is close to 0°. The structure of the monolayers is thus a balance of the various interactions taking place in the polymer chains.

Deoxyribonucleic acid (DNA), the framework on which all life is built, can be used to self-assemble nanomaterials into useful macroscopic aggregates that display a number of desired physical properties [5.104]. DNA consists of two strands, which are coiled around each other to form a double helix. When the two strands are uncoiled, singular strands of nucleotides are left. These nucleotides consist of a sugar (pentose ring) a phosphate (PO_4), and a nitrogenous base. The order and architecture of these components are essential for the proper structure of a nucleotide. There are typically four nucleotides found in DNA: Adenine (A), Guanine (G), Cytosine (C), and Thyamine (T). A key property of the DNA structure is that the described nucleotides bind specifically to another nucleotide when arranged in the two-strand double helix (A to T and C to G). This specific bonding capability can be used to assemble nanophase material and nano-structures [5.105]. For example, nucleotide functionalized nano-gold particles have been assembled into complex 3-D structures by attaching DNA strands to the gold via an enabler or linker [5.106]. In a separate work, DNA was used to assemble nanoparticles into macroscopic materials. This method uses alkane dithiol as the linker molecule to connect the DNA template to the nanoparticle. The thiol groups at each end of the linker molecule covalently attach themselves to the colloidal particles to form aggregate structures [5.107].

Template Manufacturing

Template manufacturing refers to a set of techniques that can be used to fabricate 3-D organic or inorganic structures from a nano-template. These templates differ in material, pattern, feature size, overall template size, and periodicity. Although nano-templates can be fabricated using e-beam lithography, the serial nature of this technique prohibits its widespread application. Self-assembly is the preferred technique that can produce large-area nano-templates in a massively parallel fashion. Several nano-templates have been investigated for use in template manufacturing. These include polymer colloidal spheres, alumina membranes, and nuclear-track etched membranes. Colloidal spheres can be deposited in a regular 3-D array using the techniques described in the previous section (see Figs. 5.54–5.56). Porous aluminum oxide membranes can be fabricated by the anodic oxidation of aluminum [5.108]. The oxidized film consists of columnar arrays of hexagonal, close-packed pores with a separation comparable to the pore size. By controlling the electrolyte species, temperature, anodizing voltage and time, different pore sizes, density and height can be obtained. The pore size and depth can further be adjusted by etching the oxide in an appropriate acid. Templates of porous polycarbonate or mica membranes can be fabricated by nuclear-track etched membranes [5.109]. This technique is based on the passage of high-energy decay fragments from a radioactive source through a dielectric material. The particles leave behind chemically active damaged tracks that subsequently can be etched to create pores throughout the thickness of the membrane [5.110, 111]. Unlike the other methods, the pore separation and, hence, the pore density are independent of the pore size. The pore density is only determined by the irradiation process.

Following template fabrication, the interstitial spaces (in the case of colloidal spheres) or pores (in the case of alumina and polycarbonate membranes) in the template are filled with the desired material [5.91, 112]. This can be done using a variety of deposition techniques such as electroplating and CVD. The final structure can be a composite of nano-template and deposited mater-

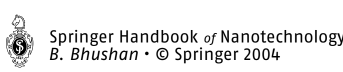

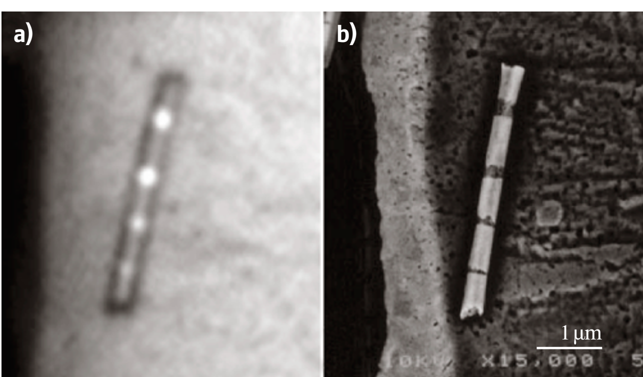

Fig. 5.59 **(a)** Optical and **(b)** FE-SEM images of Au-Ag multistripe particle 5.116

ial, or the template can be selectively etched, resulting in an air-filled 3-D complex structure. For example, nickel [5.111], iron [5.113], and cobalt [5.114] nanowires have been electrochemically grown into porous template matrices. Three-dimensional photonic crystals have been fabricated by electrochemical deposition of CdSe and silicon into polystyrene and silica colloidal assembly templates [5.89, 115]. An interesting example of template-assisted manufacturing is the synthesis of nanometer metallic bar codes [5.116]. These nano-bar codes are prepared by the electrochemical reduction of metallic ions into the pores of an aluminum oxide membrane followed by their release through etching of the template [5.117–119]. This procedure is schematically illustrated in Fig. 5.58. A back-side silver film is used as the working electrode for the reduction of metallic ions (silver and gold in this case) from solution. Up to seven different metallic segments as short as 10 nm and as long as several micrometers with 13 distinguishable stripes have been fabricated using this technique. Optical reflectivity is used to read out the striping pattern encoded in the metal particles [5.116]. Figure 5.59 shows optical and field emission scanning electron microscope images of a Au-Ag multistripe nano-bar code (Ag stripes ranging in length from 60 to 240 nm separated by Au segments of 550 nm). These coded nano-particles can be used in fluorescence and mass-spectrometry-based assays, enabling a wide variety of bioanalytical measurements.

6. Stamping Techniques for Micro and Nanofabrication: Methods and Applications

This chapter highlights some recent advances in high resolution printing methods, in which a "stamp" forms a pattern of "ink" on the surface it contacts. It focuses on two approaches whose capabilities, level of development, and demonstrated applications indicate a strong potential for widespread use, especially in areas where conventional methods are unsuitable. The first of these, known as microcontact printing, uses a high resolution rubber stamp to print patterns of chemical inks, mainly those that lead to the formation of organic self-assembled monolayers (SAMs). These printed SAMs can be used either as resists in selective wet etching, or as templates in selective deposition to form structures of a variety of materials. The other approach, referred to as nanotransfer printing, uses similar high resolution stamps, but ones inked with solid thin film materials. In this case, SAMs, or other types of surface chemistries, bond these films to a substrate that the stamp contacts. The material transfer that results upon removal of the stamp forms a pattern in the geometry of the relief features, in a purely additive fashion. In addition to providing detailed descriptions of these micro/nanoprinting techniques, this chapter illustrates their use in some areas where these methods may provide attractive alternatives to more established lithographic methods.

The demonstrator applications span fields as diverse as biotechnology (intravascular stents), fiber optics (tunable fiber devices), nanoanalytical chemistry (high resolution nuclear magnetic resonance), plastic electronics (paper-like displays), and integrated optics (distributed feedback lasers). The growing interest in nanoscience and nanotechnology motivates research and the development of new methods that can be used for nanofabricating the relevant test structures or devices. The attractive capabilities of the techniques described here, together with the interesting and subtle materials science, chemistry, and physics associated with them, make this a promising area for basic and applied study.

There is considerable interest in methods for building structures that have micron or nanometer dimensions. Historically, research and development in this area has been driven mainly by the needs of the microelectronics industry. The spectacularly successful techniques that have emerged from those efforts – photolithography, electron beam lithography, etc. – are extremely well suited to the tasks for which they were principally designed: forming structures of radiation sensitive materials (e.g., photoresists or electron beam resists) on ultra-flat glass or semiconductor surfaces. Significant challenges exist in adapting these methods for new emerging applications and areas of research that require patterning of unusual systems and materials (e.g., those in biotechnology, plastic electronics, etc.), structures with nanometer dimensions (i. e., below 50–100 nm), large areas in a single step (i. e., larger than a few square centimeters), or non-planar (i. e., rough or curved) surfaces. These established techniques also have the disadvantage of high capital and operational costs. As a result, some of the oldest and conceptually simplest forms of lithography – embossing, molding, stamping, writing, etc. – are now being re-examined for their potential to serve as the basis for nanofabrica-

tion techniques that can avoid these limitations [6.1]. Considerable progress has been made in the last few years, mainly by combining these approaches or variants of them with new materials, chemistries, and processing techniques. This chapter highlights some recent advances in high resolution printing methods, in which a "stamp" forms a pattern of "ink" on a surface that it contacts. It focuses on approaches whose capabilities, level of development, and demonstrated applications indicate a strong potential for widespread use, especially in areas where conventional methods are unsuitable.

Contact printing involves the use of an element with surface relief (i. e., the stamp) for transferring material applied to its surface (i. e. the ink) to locations on a substrate that it contacts. The printing press, one of the earliest manufacturable implementations of this approach, was introduced by Gutenberg in the fifteenth century. The general approach has since been used almost exclusively for producing printed text or images with features that are one hundred microns or larger in their minimum dimension. The resolution is determined by the nature of the ink and its interaction with the stamp and/or substrate, the resolution of the stamp, and the processing conditions that are used for printing or converting the pattern of ink into a pattern of functional material. This chapter focuses on (1) printing techniques that are capable of micron and nanometer resolution, and (2) their use for fabricating key elements of active electronic or optical devices and subsystems. It begins with an overview of some methods for fabricating high resolution stamps and then illustrates two different ways that these stamps can be used to print patterns of functional materials. Applications that highlight the capabilities of these techniques and the performance of systems that are constructed with them are also presented.

6.1 High Resolution Stamps

The printing process can be separated into two parts: fabrication of the stamp and the use of this stamp to pattern features defined by the relief on its surface. These two processes are typically quite different, although it is possible in some cases to use patterns generated by a stamp to produce a replica of that stamp. The structure from which the stamp is derived, which is known as the "master", can be fabricated with any technique that is capable of producing well-defined structures of relief on a surface. This master can then be used directly as the stamp, or to produce stamps via molding or printing procedures. It is important to note that the technique for producing the master does not need to be fast or low in cost. It also does not need to possess many other characteristics that might be desirable for a given patterning task: It is used just once to produce a master, which is directly or indirectly used to fabricate stamps. Each one of these stamps can then be used many times for printing.

In a common approach for the high resolution techniques that are the focus of this chapter, an established lithographic technique, such as one of those developed for the microelectronics industry, defines the master. Figure 6.1 schematically illustrates typical processes. Here, photolithography patterns a thin layer of resist on a silicon wafer. Stamps are generated from this structure in one of two ways: By casting against this master, or by etching the substrate with the patterned resist as a mask. In the first approach, the master itself can be used multiple times to produce many stamps, typically using a light or heat-curable prepolymer. In the second, the etched substrate serves as the stamp. Additional stamps can be generated either by repeating the lithography and etching, or by using the original stamp to print replica stamps. For minimum lateral feature sizes greater than $\sim 1-2$ microns, contact or proximity mode photolithography with a mask produced by direct write photolithography represents a convenient method to fabricate the master. For features smaller than ~ 2 microns, several different techniques can be used [6.2], including: (1) projection mode photolithography [6.3], (2) direct write electron beam (or focused ion beam) lithography [6.4, 5], (3) scanning probe lithography [6.6–9] or (4) laser interference lithography [6.10]. The first approach requires a photomask generated by some other method, such as direct write photolithography or electron beam lithography. The reduction (typically 4×) provided by the projection optics relaxes the resolution requirements on the mask and enables features as small as ~ 90 nm when deep ultraviolet radiation and phase shifting masks are used. The costs for these systems are, however, very high and their availability for general research purposes is limited. The second method is flexible in the geometry of patterns that can be produced, and the writing sys-

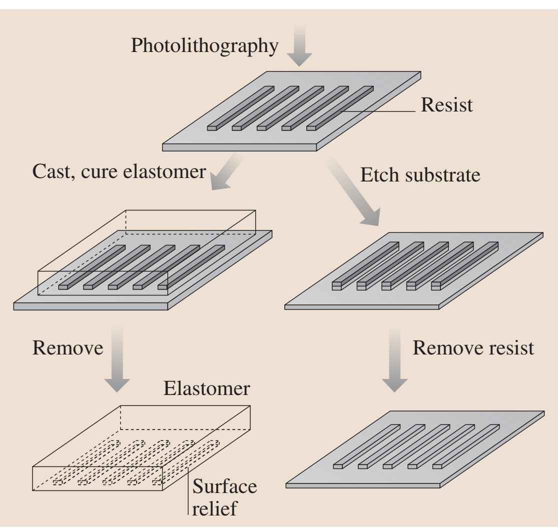

Fig. 6.1 Schematic illustration of two methods for producing high resolution stamps. The first step involves patterning a thin layer of some radiation sensitive material, known as the resist, on a flat substrate, such as a silicon wafer. It is convenient to use an established technique, such as photolithography or electron beam lithography, for this purpose. This structure, known as the master, is converted to a stamp either by etching or molding. In the first case, the resist acts as a mask for etching the underlying substrate. Removing the resist yields a stamp. This structure can be used directly as a stamp to print patterns, or to produce additional stamps. In the molding approach, a prepolymer is cast against the relief structure formed by the patterned resist on the substrate. Curing (thermally or optically) and then peeling the resulting polymer away from the substrate yields a stamp. In this approach, many stamps can be made with a single master, and each stamp can be used many times

tems are highly developed: 30–50 nm features can be achieved with commercial systems [6.11], and <10 nm features are possible with research tools, as first demonstrated more than 25 years ago by *Broers* [6.12]. The main drawbacks of this method are that it is relatively slow and it is difficult to pattern large areas. Like projection mode photolithography, it can be expensive. The third method, scanning probe lithography, is quite powerful in principle, but the tools are not as well established as those for other approaches. This technique has atomic resolution, but its writing speed can be lower and the areas that can be patterned are smaller than electron beam systems. Interference lithography provides a powerful, low cost tool for generating periodic arrays of features with dimensions down to 100–200 nm; smaller sizes demand ultraviolet lasers, and patterns with aperiodic or non-regular features are difficult to produce.

6.2 Microcontact Printing

Microcontact printing (μCP) [6.13] is one of several soft lithographic techniques – replica molding, micromolding in capillaries, microtransfer molding, near-field conformal photolithography using an elastomeric phase-shifting mask, etc. – that have been developed as alternatives to established methods for micro- and nanofabrication [6.14–18]. μCP uses an elastomeric element (usually polydimethylsiloxane – PDMS) with high resolution features of relief as a stamp to print patterns of chemical inks. It was mainly developed for use with inks that form self-assembled monolayers (SAMs) of alkanethiolates on gold and silver. The procedure for carrying out μCP in these systems is remarkably simple: A stamp, inked with a solution of alkanethiol, is brought into contact with the surface of a substrate to transfer ink molecules to regions where the stamp and substrate contact. The resolution and effectiveness of μCP rely on conformal contact between the stamp and the surface of the substrate, rapid formation of highly ordered monolayers [6.19], and autophobicity of the SAM, which effectively blocks the reactive spreading of the ink across the surface [6.20]. It can pattern SAMs over relatively large areas (∼ up to 0.25 ft^2 have been demonstrated in prototype electronic devices) in a single impression [6.21]. The edge resolution of SAMs printed onto thermally evaporated gold films is on the order of 50 nm, as determined by lateral force microscopy [6.22]. Microcontact printing has been used with a range of different SAMs on various substrates [6.14]. Of these, alkanethiolates on gold, silver, and palladium [6.23] presently give the highest resolution. In many cases, the mechanical properties of the stamp limit the sizes of the smallest features that can be achieved: The most commonly used elastomer (Sylgard 184, Dow Corning) has a low modulus, which can lead to mechanical collapse or sagging for features of relief with aspect

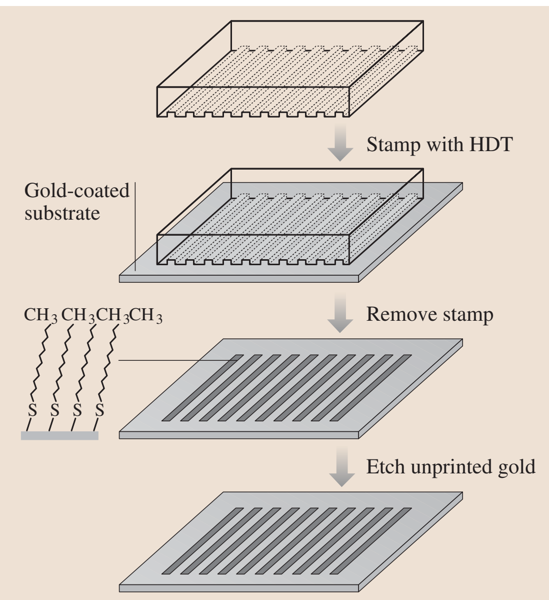

Fig. 6.2 Schematic illustration of microcontact printing. The first step involves inking a stamp with a solution of a material that is capable of forming a self-assembled monolayer (SAM) on a substrate that will be printed. In the case illustrated here, the ink is a millimolar concentration of hexadecanethiol (HDT) in ethanol. Directly applying the ink to the surface of the stamp with a pipette prepares the stamp for printing. Blowing the surface of the stamp dry and placing it on a substrate delivers the ink to areas where the stamp contacts the substrate. The substrate consists of a thin layer of Au on a flat support. Removing the stamp after a few seconds of contact leaves a patterned SAM of HDT on the surface of the Au film. The printed SAM can act as a resist for the aqueous-based wet etching of the exposed regions of the Au. The resulting pattern of conducting gold can be used to build devices of various types

ratios greater than ~ 2 or less than ~ 0.05. Stamps fabricated with high modulus elastomers avoid some of these problems [6.24, 25]. Conventional stamps are also susceptible to in-plane mechanical strains that can cause distortions in the printed patterns. Composite stamps that use thin elastomer layers on stiff supports are effective at minimizing this source of distortion [6.26]. Methods for printing that avoid direct mechanical manipulation of the stamp can reduce distortions with conventional and composite stamps [6.21]. This approach has proven effective in large area flexible circuit applications that require accurate multilevel registration.

The patterned SAM can be used either as a resist in selective wet etching or as a template in selective deposition to form structures of a variety of materials: metals, silicon, liquids, organic polymers, and even biological species. Figure 6.2 schematically illustrates the use of μCP and wet etching to pattern a thin film of Au. Figure 6.3 shows SEM images of nanostructures of gold (20 nm thick, thermally evaporated with a 2.5 nm layer of Ti as an adhesion promoter) and silver (~ 100 nm thick formed by electroless deposition using commercially available plating baths) [6.27] that were fabricated using this approach. In the first and second examples, the masters for the stamps consisted of photoresist patterned on silicon wafers with projection and contact mode photolithography, respectively. Placing these masters in a desiccator for ~ 1 h with a few drops of tridecafluoro-1,1,2,2-tetrahydrooctyl-1-trichlorosilane forms a silane monolayer on the exposed native oxide of the silicon. This monolayer prevents adhesion of the master to PDMS (Sylgard 184), which is cast and cured from a 10:1 mixture of prepolymer and curing agent. Placing a few drops of a ~ 1 mM solution of hexadecanethiol (HDT) in ethanol on the surface of the stamps, and then blowing them dry with a stream of nitrogen prepares them for printing. Contacting the metal film for a few seconds with the stamp produces a patterned self-assembled monolayer (SAM) of HDT. An aqueous etchant (1 mM $K_4Fe(CN)_6$, 10 mM $K_3Fe(CN)_6$, and 0.1 M $Na_2S_2O_3$) removes the unprinted regions of the silver [6.28]. A similar solution (1 mM $K_4Fe(CN)_6$, 10 mM $K_3Fe(CN)_6$, 1.0 M KOH, and 0.1 M $Na_2S_2O_3$)

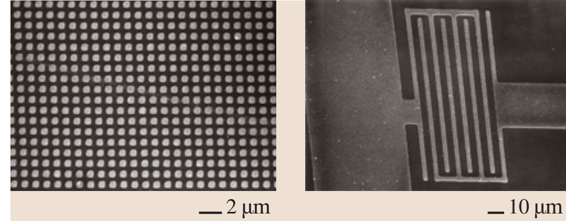

Fig. 6.3 Scanning electron micrographs of typical structures formed by microcontact printing a self-assembled monolayer ink of hexadecanethiol onto a thin metal film followed by etching of the unprinted areas of the film. The *left frame* shows an array of Au (20 nm-thick) dots with ~ 500 nm diameters. The *right frame* shows a printed structure of Ag (100 nm thick) in the geometry of interdigitated source/drain electrodes for a transistor in a simple inverter circuit. The edge resolution of patterns that can be easily achieved with microcontact printing is ~ 50–100 nm

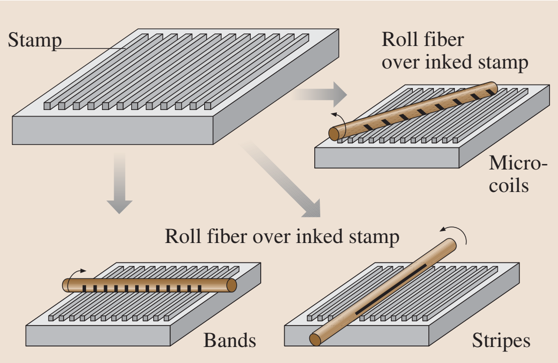

Fig. 6.4 Schematic illustration of a simple method to print lines on the surfaces of optical fibers. Rolling a fiber over the inked stamp prints a pattern onto the fiber surface. Depending on the orientation of the fiber axis with the line stamp illustrated here, it is possible in a single rotation of the fiber to produce a continuous microcoil, or arrays of bands or stripes

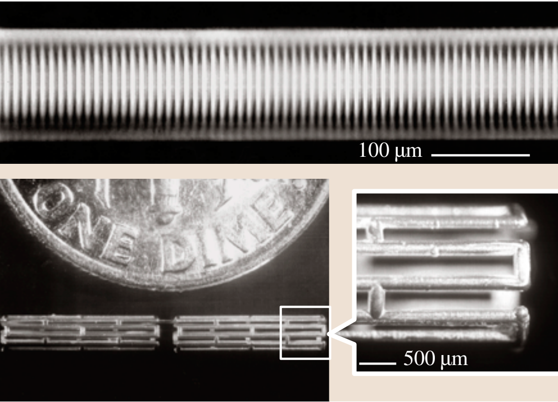

Fig. 6.5 Optical micrographs of some three-dimensional microstructures formed by microcontact printing on curved surfaces. The *top frame* shows an array of 3-micron lines of Au (20 nm)/Ti (1.5 nm) printed onto the surface of an optical fiber. This type of structure can be used as an integrated photomask for producing mode-coupling gratings in the core of the fiber. The *bottom frames* show a freestanding metallic microstructure formed by (1) microcontact printing and etching a thin (100 nm-thick) film of Ag on the surface of a glass microcapillary tube, (2) electroplating the Ag to increase its thickness (to tens of microns) and (3) etching away the glass microcapillary with concentrated hydrofluoric acid. The structure shown here has the geometry and mechanical properties of an intravascular stent, which is a biomedical device commonly used in balloon angioplasty

can be used for etching the bare gold [6.29]. The results of Fig. 6.3 show that the roughness on the edges of the patterns is ∼ 50–100 nm. The resolution is determined by the grain size of the metal films, the isotropic etching process, slight reactive spreading of the inks, and edge disorder in the patterned SAMs.

The structures of Fig. 6.3 were formed on the flat surfaces of silicon wafers (left image) and glass slides (right image). An attractive feature of μCP and certain other contact printing techniques is their ability to pattern features with high resolution on highly curved or rough surfaces [6.18, 30, 31]. This type of patterning task is difficult or impossible to accomplish with photolithography due to its limited depth of focus and the difficulty of casting uniform films of photoresist on non-flat surfaces. Figure 6.4 shows, as an example, a straightforward approach for high resolution printing on the highly curved surfaces of optical fibers. Here, simply rolling the fiber over an inked stamp prints a pattern on the entire outer surface of the fiber. Simple staging systems allow alignment of features to the fiber axis; they also ensure registration of the pattern from one side of the fiber to the other [6.16]. Figure 6.5 shows 3 micron-wide lines and spaces printed onto the surface of a single mode optical fiber (diameter 125 μm). The bottom frame shows a freestanding metallic structure with the geometry and mechanical properties of an intravascular stent, which is a biomedical device that is commonly used in balloon angioplasty procedures. In this latter case μCP followed by electroplating generated the Ag microstructure on a sacrificial glass cylinder that was subsequently etched away with concentrated hydrofluoric acid [6.32]. Other examples of microcontact printing on non-flat surfaces (i. e., low cost plastic sheets and optical ridge waveguides) appear in the applications section of this chapter.

6.3 Nanotransfer Printing

Nanotransfer printing (nTP) is a more recent high resolution printing technique, which uses surface chemistries as interfacial "glues" and "release" layers (rather than "inks", as in μCP) to control the transfer of solid material layers from relief features on a stamp to a substrate [6.33–35]. This approach is purely additive (i. e., material is only deposited in locations where it is needed), and it can generate complex patterns of single or multiple layers of materials with nanometer resolution over large areas in a single process step. It does not suffer from surface diffusion or edge disorder in the patterned inks of μCP, nor does it require post-printing etching or deposition steps to produce structures of functional materials. The method involves four components: (1) a stamp (rigid, flexible, or elastomeric) with relief features in the geometry of the desired pattern, (2) a method for depositing a thin layer of solid material onto the raised features of this stamp, (3) a means of bringing the stamp into intimate physical contact with a substrate, and (4) surface chemistries that prevent adhesion of the deposited material to the stamp and promote its strong adhesion to the substrate. nTP has been demonstrated with SAMs and other surface chemistries for printing onto flexible and rigid substrates with hard inorganic and soft polymer stamps. Figure 6.6 presents a set of procedures for using nTP to pattern a thin metal bilayer of Au/Ti with a surface transfer chemistry that relies on a dehydration reaction [6.33]. The process begins with fabrication of a suitable stamp. Elastomeric stamps can be built using the same casting and curing procedures described for μCP. Rigid stamps can be fabricated by (1) patterning resist (e.g., electron beam resist or photoresist) on a substrate (e.g., Si or GaAs), (2) etching the exposed regions of the substrate with an anisotropic reactive ion etch, and (3) removing the resist, as illustrated in Fig. 6.1. For both types of stamps, careful control of the lithography and the etching steps yields features of relief with nearly vertical or slightly re-entrant sidewalls. The stamps typically have depths of relief $> 0.2\,\mu$m for patterning metal films with thicknesses < 50 nm.

Electron beam evaporation of Au (20 nm; 1 nm/s) and Ti (5 nm; 0.3 nm/s) generates uniform metal bilayers on the surfaces of the stamp. A vertical, collimated flux of metal from the source ensures uniform deposition only on the raised and recessed regions of relief. The gold adheres poorly to the surfaces of stamps made of GaAs, PDMS, glass, or Si. In the process of Fig. 6.6, a fluorinated silane monolayer acts to reduce further the adhesion when a Si stamp (with native oxide) is used. The Ti layer serves two purposes: (1) it promotes adhesion between the Au layer and the substrate after pattern

Fig. 6.6 Schematic illustration of nanotransfer printing procedures. Here, interfacial dehydration chemistries control the transfer of a thin metal film from a hard inorganic stamp to a conformable elastomeric substrate (thin film of polydimethylsiloxane (PDMS) on a plastic sheet). The process begins with the fabrication of a silicon stamp (by conventional lithography and etching) followed by surface functionalization of the native oxide with a fluorinated silane monolayer. This layer ensures poor adhesion between the stamp and a bilayer metal film (Au and Ti) deposited by electron beam evaporation. A collimated flux of metal oriented perpendicular to the surface of the stamp avoids deposition on the sidewalls of relief. Exposing the surface Ti layer to an oxygen plasma produces titanol groups. A similar exposure for the PDMS produces silanol groups. Contacting the metal-coated stamp to the PDMS results in a dehydration reaction that links the metal to the PDMS. Removing the stamp leaves a pattern of metal in the geometry of the relief features

transfer, and (2) it readily forms a ∼ 3 nm oxide layer at ambient conditions, which provides a surface where the dehydration reaction can take place. Exposing the titanium oxide (TiO_x) surface to an oxygen plasma breaks bridging oxygen bonds, thus creating defect sites where water molecules can adsorb. The result is a titanium oxide surface with some fractional coverage of hydroxyl (−OH) groups (titanol).

In the case of Fig. 6.6, the substrate is a thin film of PDMS (10–50 µm thick) cast onto a sheet of poly(ethylene terephthalate) (PET; 175 µm thick). Exposing the PDMS to an oxygen plasma produces surface (−OH) groups (silanol). Placing the plasma oxidized, Au/Ti-coated stamp on top of these substrates leads to intimate, conformal contact between the raised regions of the stamp and the substrate, without the application of any external pressure. (The soft, conformable PDMS is important in this regard.) It is likely that a dehydration reaction takes place at the (−OH)-bearing interfaces during contact; this reaction results in permanent Ti−O−Si bonds that produce strong adhesion between the two surfaces. Peeling the substrate and stamp apart transfers the Au/Ti bilayer from the raised regions of the stamp (to which the metal has extremely poor adhesion) to the substrate. Complete pattern transfer from an elastomeric stamp to a thin elastomeric substrate occurs readily at room temperature in open air with contact times of less than 15 seconds. When a rigid stamp is employed, slight heating is needed to induce transfer. While the origin of this difference is unclear, it may reflect the comparatively poor contact when rigid stamps are used; similar differences are also observed in cold welding of gold films [6.36].

Figure 6.7 shows scanning electron micrographs of a pattern produced using a GaAs stamp generated by electron beam lithography and etching. The frames on the right show images of the metal-coated stamp before printing (top) and the transferred pattern (bottom). The resolution appears to be limited only by the resolution of the stamp itself, and perhaps by the grain size of the metal films. Although the accuracy in multilevel registration that is possible with nTP has not yet been quantified, its performance is likely similar to that of embossing techniques when rigid stamps are used [6.37].

A wide range of surface chemistries can be used for the transfer. SAMs are particularly attractive due to their chemical flexibility. Figure 6.8 illustrates the use of a thiol terminated SAM and nTP for forming patterns of Au on a silicon wafer [6.34]. Here, the vapor phase co-condensation of the methoxy groups of molecules of 3-mercaptopropyltrimethoxysilane (MPTMS) with the

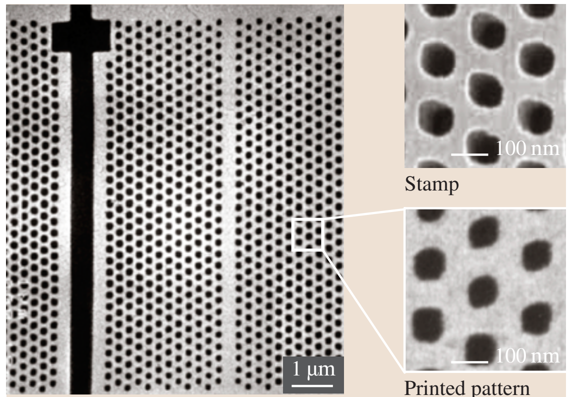

Fig. 6.7 Scanning electron micrograph (SEM) of a pattern produced by nanotransfer printing. The structure consists of a bilayer of Au (20 nm)/Ti (1 nm) (*white*) in the geometry of a photonic bandgap waveguide printed onto a thin layer of polydimethylsiloxane on a sheet of plastic (*black*). Electron beam lithography and etching of a GaAs wafer produced the stamp that was used in this case. The transfer chemistry relied on condensation reactions between titanol groups on the surface of the Ti and silanol groups on the surface of the PDMS. The *frames on the right* show SEMs of the Au/Ti-coated stamp (*top*) before printing and on the substrate (*bottom*) after printing. The electron beam lithography and etching used to fabricate the stamp limit the minimum feature size (∼ 70 nm) and the edge resolution (∼ 5–10 nm) of this pattern

−OH terminated surface of the wafer produces a SAM of MPTMS with exposed thiol (−SH) groups. PDMS stamps can be prepared for printing on this surface by coating them with a thin film (∼ 15 nm) of Au using conditions (thermal evaporation 1.0 nm/s; ∼ 10^{-7} torr base pressure) that yield optically smooth, uniform films without the buckling that has been observed in the past with similar systems [6.38]. Nanocracking that sometimes occurs in the films deposited in this way can be reduced or eliminated by evaporating a small amount of Ti onto the PDMS before Au deposition and/or by exposing the PDMS surface briefly to an oxygen plasma. Bringing this coated stamp into contact with the MPTMS SAM leads to the formation of sulfur–gold bonds in the regions of contact. Removing the stamp after a few seconds efficiently transfers the gold from the raised regions of the stamp (Au does not adhere to the PDMS) to the substrate. Covalent bonding of the SAM glue to both the substrate and the gold leads to good adhesion of the printed patterns: They easily pass Scotch

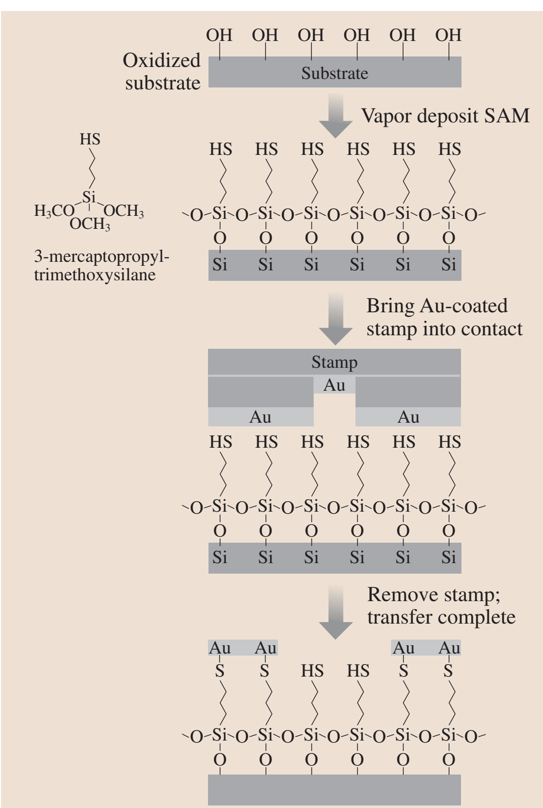

Fig. 6.8 Schematic illustration of steps for nanotransfer printing a pattern of a thin layer of Au onto a silicon wafer using a self-assembled monolayer (SAM) surface chemistry. Plasma oxidizing the surface of the wafer generates −OH groups. Solution or vapor phase exposure of the wafer to 3-mercaptopropyl-trimethoxysilane yields a SAM with exposed thiol groups. Contacting an Au-coated stamp to this surface produces thiol linkages that bond the gold to the substrate. Removing the stamp completes the transfer printing process

tape adhesion tests. Similar results can be obtained with other substrates containing surface −OH groups. For example, Au patterns can be printed onto ∼ 250 μm-thick sheets of poly(ethylene terephthalate) (PET) by first spin casting and curing (130 °C for 24 h) a thin film of an organosilsesquioxane on the PET. Exposing the cured film (∼ 1 μm thick) to an oxygen plasma and then to air produces the necessary surface (−OH) groups. Figure 6.9 shows some optical micrographs of typical printed patterns in this case [6.34].

Similar surface chemistries can guide transfer to other substrates. Alkanedithiols, for example, are useful

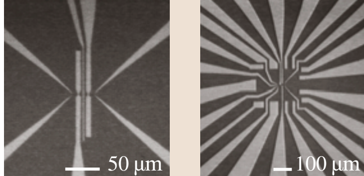

Fig. 6.9 Optical micrographs of patterns of Au (15 nm thick) formed on plastic (*left frame*) and silicon (*right frame*) substrates with nanotransfer printing. The transfer chemistries in both cases rely on self-assembled monolayers with exposed thiol groups. The minimum feature sizes and the edge resolution are both limited by the photolithography used to fabricate the stamps

for printing Au onto GaAs wafers [6.35]. Immersing these substrates (freshly etched with 37% HCl for ∼ 2 min to remove the surface oxide) in a 0.05 M solution of 1,8-octanedithiol in ethanol for 3 h produces a monolayer of dithiol on the surface. Although the chemistry of this system is not completely clear, it is generally believed that the thiol end groups bond chemically to the surface. Surface spectroscopy suggests the formation of Ga−S and As−S bonds. Contacting an Au-coated PDMS stamp with the treated substrate causes the exposed thiol endgroups to react with Au in the regions of contact. This reaction produces permanent Au−S bonds at the stamp/substrate interface (see insets in Fig. 6.2 for idealized chemical reaction schemes). Figure 6.10 illustrates a representative optical micrograph of an Au pattern generated by nTP on GaAs.

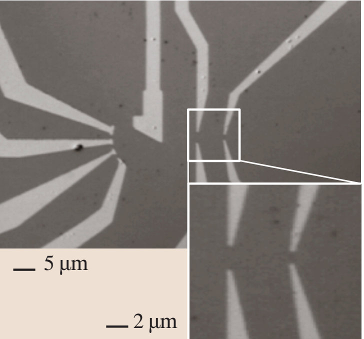

Fig. 6.10 Optical micrograph of a pattern of Au (15 nm thick) formed on a GaAs substrate using nanotransfer printing. The transfer chemistry in this case relies on a dithiol layer formed on the substrate. The minimum feature sizes and the edge resolution are both limited by the photolithography used to fabricate the stamps

6.4 Applications

Promising potential applications for the types of printing techniques described in the previous sections include those where the patterning requirements cannot be met with existing tools or those where the costs of these conventional methods are prohibitively high.We have focused our efforts partly on unusual electronic systems such as flexible plastic circuits and devices that rely on electrodes patterned on curved objects such as microcapillaries and optical fibers. We have also explored photonic systems such as distributed feedback structures for lasers and other integrated optical elements that demand sub-micron features.The sections below highlight several examples in each of these areas.

6.4.1 Unconventional Electronic Systems

A relatively new direction in electronics research seeks to establish low cost plastic materials, substrates, and printing techniques for large area flexible electronic devices, such as paper-like displays. These types of novel devices can complement those (e.g., high density memories, high speed microprocessors, etc.) that are well suited to existing inorganic (e.g., silicon) electronics technologies. High resolution patterning methods for defining the separation between the source and drain electrodes (i. e., channel length) of transistors in these plastic circuits are particularly important because this dimension determines current output and other important characteristics [6.39].

Although conventional patterning techniques, such as photolithography or electron beam lithography, have the required resolution, they are not appropriate because they are expensive and generally require multiple processing steps with resists, solvents, and developers, which can be difficult to use with organic active materials and plastic substrates. Microcontact and nanotransfer printing are both particularly well suited for this application. They can be combined and matched with other techniques, such as ink jet or screen printing, to form a complete system for patterning all layers in practical plastic electronic devices [6.40].

Figure 6.11 illustrates schematically a cross-sectional view of a typical organic transistor. The frame on the right shows the electrical switching characteristics of a device that uses source/drain electrodes of Au patterned by μCP, a dielectric layer of an organosilsesquioxane, a gate of indium tin oxide (ITO), and a PET substrate. The effective semiconductor mobility extracted from these data is comparable to those

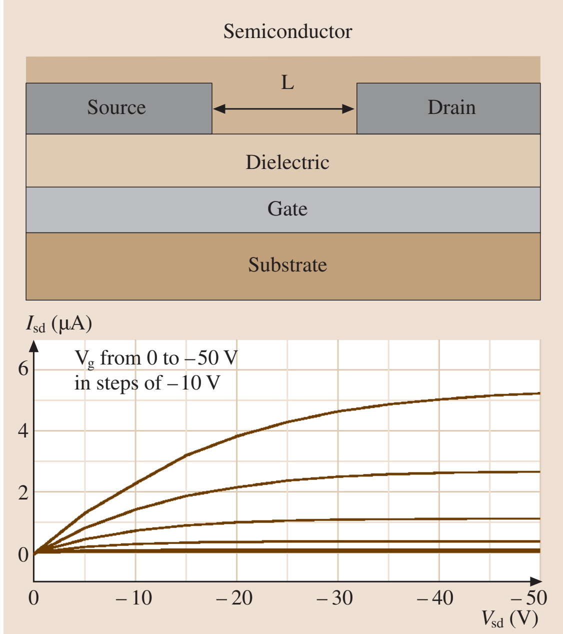

Fig. 6.11 Schematic cross-sectional view (*top*) and electrical performance (*bottom*) of an organic thin film transistor with microcontact printed source and drain electrodes. The structure consists of a substrate (PET), a gate electrode (indium tin oxide), a gate dielectric (spin cast layer of organosilsesquioxane), source and drain electrodes (20 nm Au and 1.5 nm Ti), and a layer of the organic semiconductor pentacene. The electrical properties of this device are comparable to or better than those that use pentacene with photolithographically defined source/drain electrodes and inorganic dielectrics, gates, and substrates

measured in devices that use the same semiconductor (pentacene in this case) with inorganic substrates and dielectrics, and gold source/drain electrodes defined by photolithography. Our recent work [6.1,27,41]with μCP in the area of plastic electronics demonstrates: (1) methods for using cylindrical "roller" stamps mounted on fixed axles for printing in a continuous reel-to-reel fashion, high resolution source/drain electrodes in ultrathin gold and silver deposited from solution at room temperature using electroless deposition, (2) techniques for performing registration and alignment of the printed features with other elements of a circuit over large areas, (3) strategies for achieving densities of defects that are as good as those observed with photolithography when the

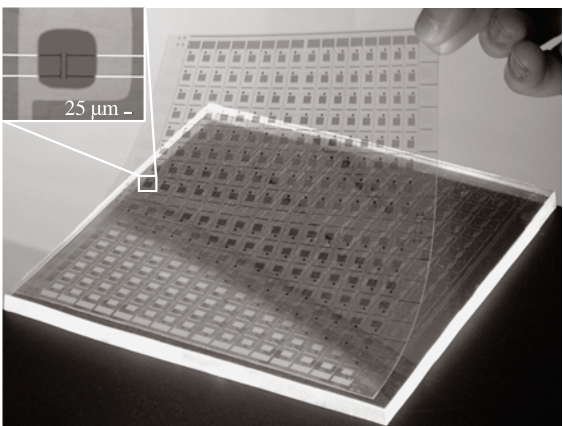

Fig. 6.12 Image of a flexible plastic active matrix backplane circuit whose finest features (transistor source/drain electrodes, and related interconnects) are patterned by microcontact printing. The circuit rests partly on the elastomeric stamp that was used for printing. The circuit consists of a square array of interconnected organic transistors, each of which acts locally as a voltage-controlled switch to control the color of an element in the display. The *inset* shows an optical micrograph of one of the transistors

patterning is performed outside of clean room facilities, (4) methods for removing the printed SAMs to allow good electrical contact of the electrodes with organic semiconductors deposited on top of them, and (5) materials and fabrication sequences that can efficiently exploit these printed electrodes for working organic TFTs in large scale circuits.

Figure 6.12 provides an image of a large area plastic circuit with critical features defined by µCP. This circuit is a flexible active matrix backplane for a display. It consists of a square array of interconnected transistors, each of which serves as a switching element that controls the color of a display pixel [6.21,42]. The transistors themselves have the layout illustrated in Fig. 6.11, and they use similar materials. The semiconductor in this image is blue (pentacene), the source/drain level is Au, the ITO appears green in the optical micrograph in the inset. Part of the circuit rests on the stamp that was used for µCP. The smallest features are the source and drain electrodes ($\sim 15\,\mu m$ lines), the interconnecting lines ($\sim 15\,\mu m$ lines), and the channel length of the transistor ($\sim 15\,\mu m$). This circuit incorporates five layers of material patterned with good registration of the source/drain, gate, and semiconductor levels. The simple printing approach is illustrated in Fig. 6.13 [6.21]. Just before use, the surface of the stamp is cleaned using a conventional adhesive roller lint remover; this procedure removes dust from the stamp in a manner that does

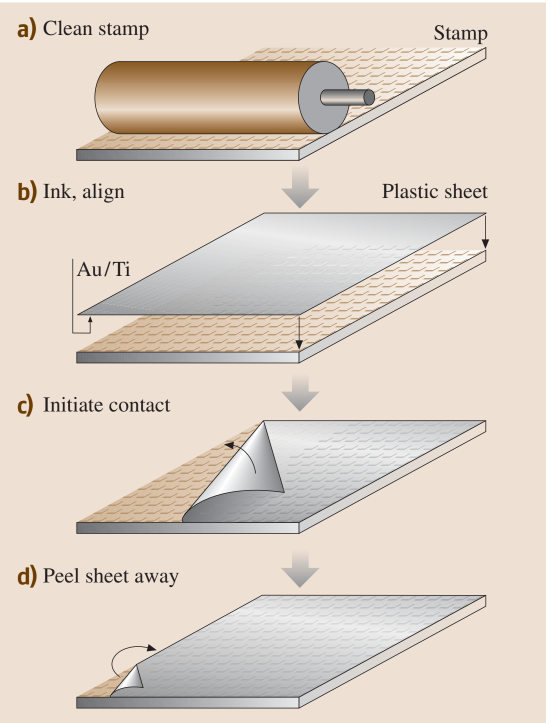

Fig. 6.13 Schematic illustration of fabrication steps for microcontact printing onto large areas of plastic sheets. The process begins with cleaning the stamp using a conventional adhesive roller lint remover. This procedure effectively removes dust particles. To minimize distortions, the stamp rests face up on a flat surface and is not manipulated directly during the printing. Alignment and registration are achieved with alignment marks on one side of the substrate and the stamp. By bending the plastic sheet, contact is initiated on one side of the stamp. The contact line is then allowed to progress gradually across the stamp. This approach avoids the formation of air bubbles that can frustrate good contact. After the substrate is in contact with the stamp for a few seconds, the plastic substrate is separated from the stamp by peeling it away, beginning in one corner. Good registration (maximum cumulative distortions less than 50 microns over an area of 0.25 square feet) and low density of defects can be achieved with this simple approach. It is also well suited for use with rigid composite stamps designed to even further reduce the level of distortion

not contaminate or damage its surface. Inking the stamp and placing it face up on a flat surface prepares it for printing. Matching the cross hair alignment marks on the corners of one edge of the stamp with those patterned in the ITO brings the substrate into registration with the stamp. During this alignment, features on the stamp are viewed directly through the semitransparent substrate. By bending the PET sheet, contact with the stamp is initiated on the edge of the substrate that contains the cross hair marks. Gradually unbending the sheet allows contact to progress across the rest of the surface. This printing procedure is attractive because it avoids distortions that can arise when directly manipulating the flexible rubber stamp. It also minimizes the number and size of trapped air pockets that can form between the stamp and substrate. Careful measurements performed after etching the unprinted areas of the gold show that over the entire 6"×6" area of the circuit, (1) the overall alignment accuracy for positioning the stamp relative to the substrate (i.e., the offset of the center of the distribution of registration errors) is ∼50–100 μm, even with the simple approach used here, and (2) the distortion in the positions of features in the source/drain level, when referenced to the gate level, can be as small as ∼50 μm (i.e., the full width at half maximum of the distribution of registration errors). These distortions represent the cumulative effects of deformations in the stamp and distortions in the gate and column electrodes that may arise during the patterning and processing of the flexible PET sheet. The density of defects in the printed patterns is comparable to (or smaller than) that in resist patterned by contact mode photolithography when both procedures are performed outside of a clean-room facility (i.e., when dust is the dominant source of defects).

Figure 6.14 shows an "exploded" view of a paper-like display that consists of a printed flexible plastic backplane circuit, like the one illustrated in Fig. 6.13, laminated against a thin layer of "electronic ink" [6.21, 43]. The electronic ink is composed of a monolayer of transparent polymer microcapsules that contain a suspension of charged white pigment particles suspended in a black liquid. The printed transistors in the backplane circuit act as local switches, which control electric fields that drive the pigments to the front or back of the display. When the particles flow to the front of a microcapsule, it appears white; when they flow to the back, it appears black. Figure 6.15 shows a working sheet of active matrix electronic paper that uses this design. This prototype display has several hundred pixels and an optical contrast that is both independent of the viewing angle and significantly better than newsprint. The device is ∼1 mm thick, is mechanically flexible, and weighs ∼80% less than a conventional liquid crystal display of similar size. Although these displays have only a relatively coarse resolution, all of the processing techniques, the μCP method, the materials, and the electronic inks are suitable for the large numbers of

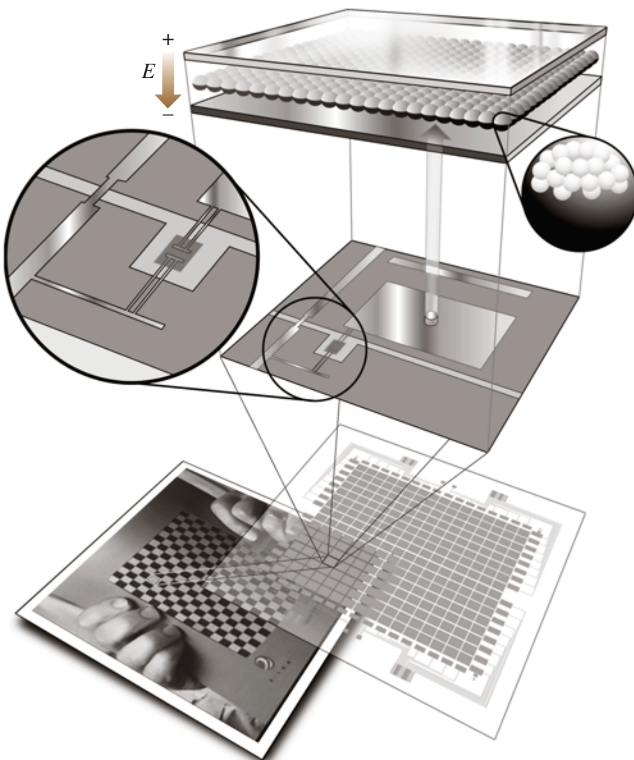

Fig. 6.14 Schematic exploded view of the components of a pixel in an electronic paper-like display (*bottom frame*) that uses a microcontact printed flexible active matrix backplane circuit (*illustration near the bottom frame*). The circuit is laminated against an unpatterned thin sheet of electronic ink (*top frame*) that consists of a monolayer of transparent polymer microcapsules (diameter ∼100 microns). These capsules contain a heavily dyed black fluid and a suspension of charged white pigment particles (see *right inset*). When one of the transistors turns on, electric fields develop between an unpatterned transparent frontplane electrode (indium tin oxide) and a backplane electrode that connects to the transistor. Electrophoretic flow drives the pigment particles to the front or the back of the display, depending on the polarity of the field. This flow changes the color of the pixel, as viewed from the front of the display, from black to white or vice versa

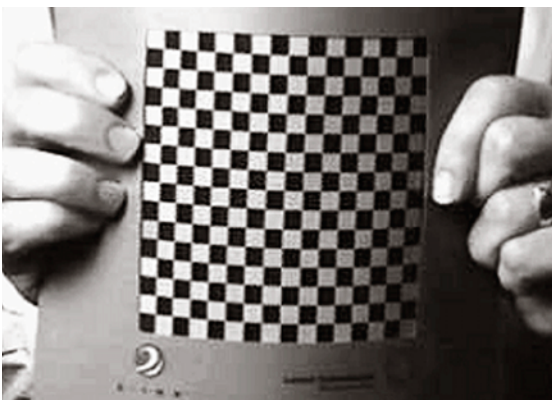

Fig. 6.15 Electronic paper-like display showing two different images. The device consists of several hundred pixels controlled by a flexible active matrix backplane circuit formed by microcontact printing. The relatively coarse resolution of the display is not limited by material properties or by the printing techniques. Instead, it is set by practical considerations for achieving high pixel yields in the relatively uncontrolled environment of the chemistry laboratory in which the circuits were fabricated

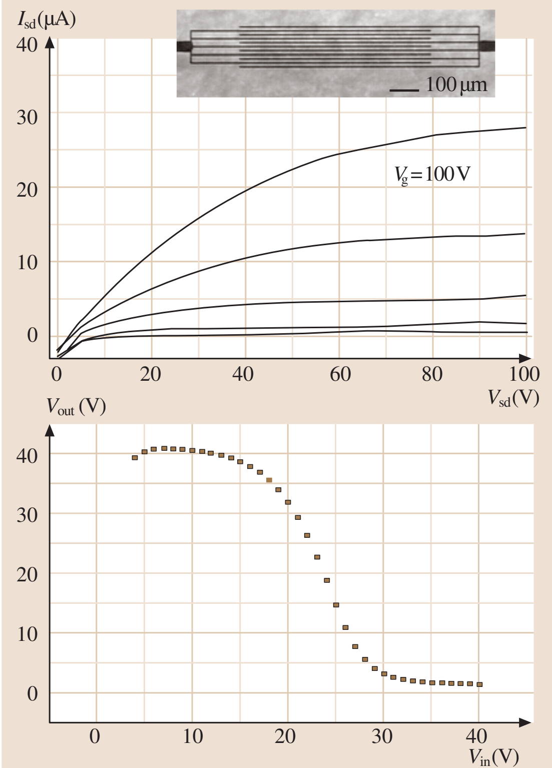

Fig. 6.16 The *top frame* shows current-voltage characteristics of an n-channel transistor formed with electrodes patterned by nanotransfer printing that are laminated against a substrate that supports an organic semiconductor, a gate dielectric, and a gate. The *inset* shows an optical micrograph of the interdigitated electrodes. The *bottom frame* on the right shows the transfer characteristics of a simple CMOS inverter circuit that uses this device and a similar one for the p-channel transistor

pixels required for high information content electronic newspapers and other systems.

Like μCP, nTP is well suited to forming high resolution source/drain electrodes for plastic electronics. nTP of Au/Ti features in the geometry of the drain and source level of organic transistors and with appropriate interconnects on a thin layer of PDMS on PET yields a substrate that can be used in an unusual but powerful way for building circuits: Soft, room temperature lamination of such a structure against a plastic substrate that supports the semiconductor, gate dielectric, and gate levels yields a high performance circuit embedded between two plastic sheets [6.33,44]. (Details of this lamination procedure are presented elsewhere.) The left frame of Fig. 6.16 shows the current-voltage characteristics of a laminated n-channel transistor that uses the organic semiconductor copper hexadecafluorophthalocyanine (n-type) and source/drain electrodes patterned with nTP. The inset shows an optical micrograph of the printed interdigitated source/drain electrodes of this device. The bottom frame of Fig. 6.16 shows the transfer characteristics of a laminated complementary organic inverter circuit whose electrodes and connecting lines are

defined by nTP. The p-channel transistor in this circuit used pentacene for the semiconductor [6.33].

In addition to high resolution source/drain electrodes, it is possible to use nTP to form complex multilayer devices with electrical functionality on plastic substrates [6.34]. Figure 6.17 shows a metal/insulator/metal (MIM) structure of Au (50 nm), SiN_x (100 nm; by plasma enhanced vapor deposition, PECVD), Ti (5 nm), and Au (50 nm) formed by transfer printing with a silicon stamp that is coated sequentially with these layers. In this case, a short reactive ion etch (with CF_4), after the second Au deposition, removes the SiN_x from the sidewalls of the stamp. nTP transfers these layers in a patterned geometry to a substrate of Au(15 nm)/Ti(1 nm)-coated PDMS(50 μm)/PET(250 μm). Interfacial cold welding between the Au on the surfaces of the stamp and substrate bonds the multilayers to the substrate. Figure 6.3 illustrates the procedures, the structures (lateral dimensions of 250 μm × 250 μm, for ease of electrical probing), and their electrical characteristics. These MIM capacitors have performance similar to devices fabricated on silicon wafers by photolithography and lift-off. This example illustrates the ability of nTP to print patterns of materials whose growth conditions (high temperature SiN_x by PECVD, in this case) prevent their direct deposition or processing on the substrate of interest (PET, in this case). The cold welding transfer approach has also been exploited in other ways for patterning components for plastic electronics [6.45,46].

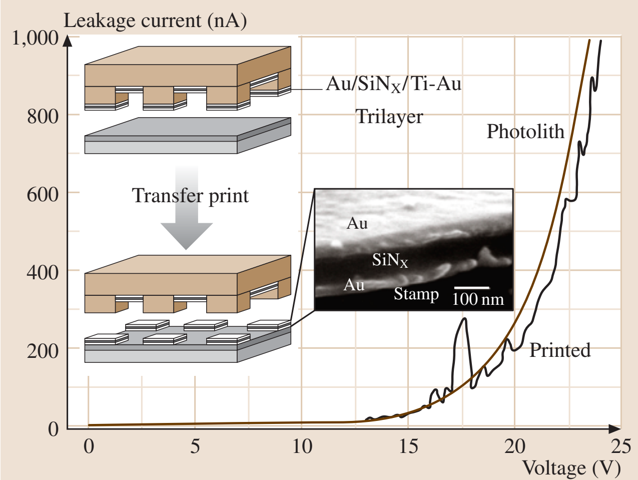

Fig. 6.17 Multilayer thin film capacitor structure printed in a single step onto a plastic substrate using the nanotransfer printing technique. A multilayer of Au/SiN_x/Ti/Au was first deposited onto a silicon stamp formed by photolithography and etching. Contacting this stamp to a substrate of Au/PDMS/PET forms a cold weld that bonds the exposed Au on the stamp to the Au coating on the substrate. Removing the stamp produces arrays of square (250 μm × 250 μm) metal/insulator/metal capacitors on the plastic support. The *black line* shows the measured current–voltage characteristics of one of these printed capacitors. The *brown line* corresponds to a similar structure formed on a rigid glass substrate using conventional photolithographic procedures. The characteristics are the same for these two cases. The slightly higher level of noise in the printed devices results, at least partly, from the difficulty in making good electrical contacts to structures on the flexible plastic substrate

Another class of unusual electronic/optoelectronic devices relies on circuits or circuit elements on curved surfaces. This emerging area of research was stimulated primarily by the ability of μCP to print high resolution features on fibers and cylinders. Figure 6.18 shows a conducting microcoil printed with μCP on a microcapillary tube using the approach illustrated in Fig. 6.4. The coil serves as the excitation and detection element for high resolution proton nuclear magnetic resonance of nanoliter volumes of fluid that are housed in the bore of the microcapillary [6.47]. The high fill factor and other considerations lead to extremely high sensitivity with such printed coils. The bottom frame of Fig. 6.18 shows the spectrum of an ∼ 8 nL volume of ethylbenzene. The narrow lines demonstrate the high resolution that is possible with this approach. Similar coils can be used as magnets [6.48], springs [6.32], and electrical transformers [6.49]. Figure 6.19 shows an optical micrograph and the electrical measurements from a concentric cylindrical microtransformer that uses a microcoil printed on a microcapillary tube with a ferromagnetic wire threaded through its core. Inserting this

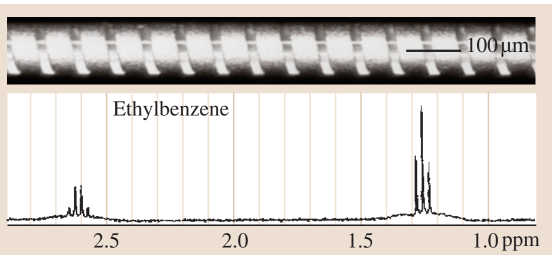

Fig. 6.18 The *top frame* shows an optical micrograph of a continuous conducting microcoil formed by microcontact printing onto a microcapillary tube. This type of printed microcoil is well suited for excitation and detection of nuclear magnetic resonance spectra from nanoliter volumes of fluid housed in the bore of the microcapillary. The *bottom frame* shows a spectra trace collected from an ∼ 8 nL volume of ethyl benzene using a structure similar to the one shown in the top frame

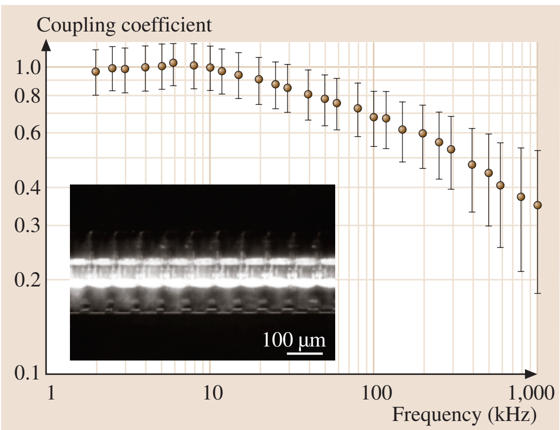

Fig. 6.19 The *inset* shows a concentric microtransformer formed using microcoils printed onto two different microcapillary tubes. The smaller of the tubes (outer diameter 135 microns) has a ferromagnetic wire threaded through its core. The larger one (outer diameter 350 microns) has the smaller tube threaded through its core. The resulting structure is a microtransformer that shows good coupling coefficients at frequencies up to ∼ 1 MHz. The graph shows its performance

Fig. 6.21 ▶ Schematic illustrations and lasing spectra of plastic lasers that use microcontact printed resonators based on surface relief distributed Bragg reflectors (DBRs) and distributed feedback gratings (DFBs) on glass substrates. The grating periods are ∼ 600 nm in both cases. The lasers use thin film plastic gain media deposited onto the printed gratings. The laser shows emission in a narrow wavelength range, with a width that is limited by the resolution of the spectrometer used to characterize the output. In both cases, the emission profiles, the lasing thresholds and other characteristics of the devices are comparable to similar lasers that use resonators formed by high resolution projection mode photolithography

structure into the core of a larger microcapillary that also supports a printed microcoil completes the transformer [6.49]. This type of device shows good coupling coefficients up to relatively high frequencies. Examples of other optoelectronic components appear in fiber optics where microfabricated on-fiber structures serve as integrated photomasks [6.16] and distributed thermal actuators [6.18].

6.4.2 Lasers and Waveguide Structures

In addition to integral components of unconventional electronic systems, useful structures for integrated optics can be built by using µCP and nTP to print sacrificial resist layers for etching glass waveguides. These printing techniques offer the most significant potential value for this area when they are used to pattern fea-

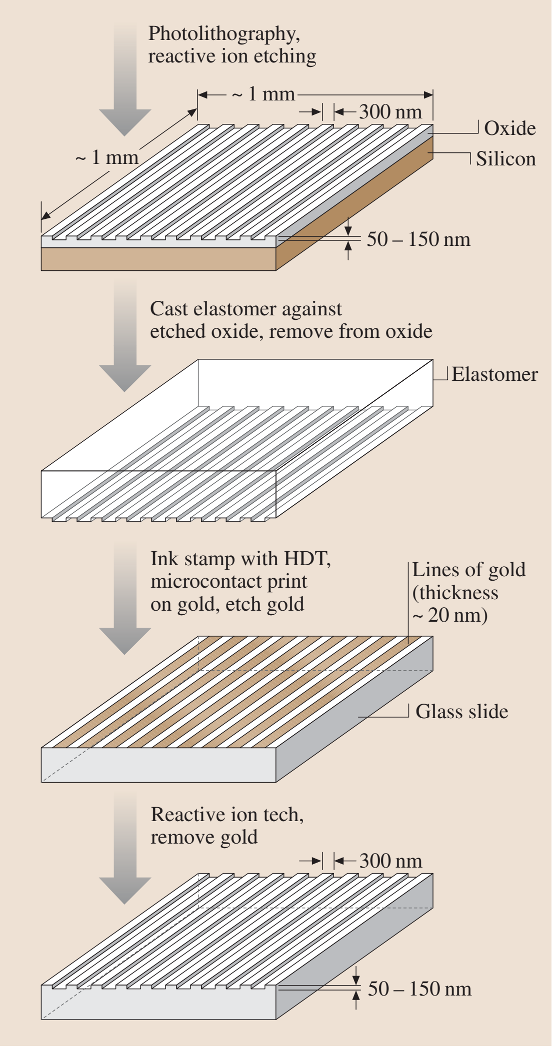

Fig. 6.20 ▶ Schematic illustration of the use of microcontact printing (µCP) for fabricating high resolution gratings that can be incorporated into distributed planar laser structures or other components for integrated optics. The geometries illustrated here are suitable for 3rd order distributed feedback (DFB) lasers that operate in the red

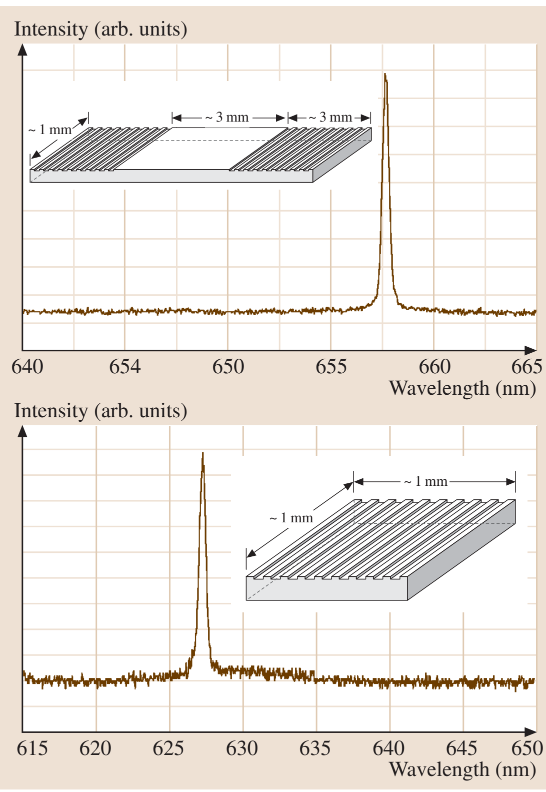

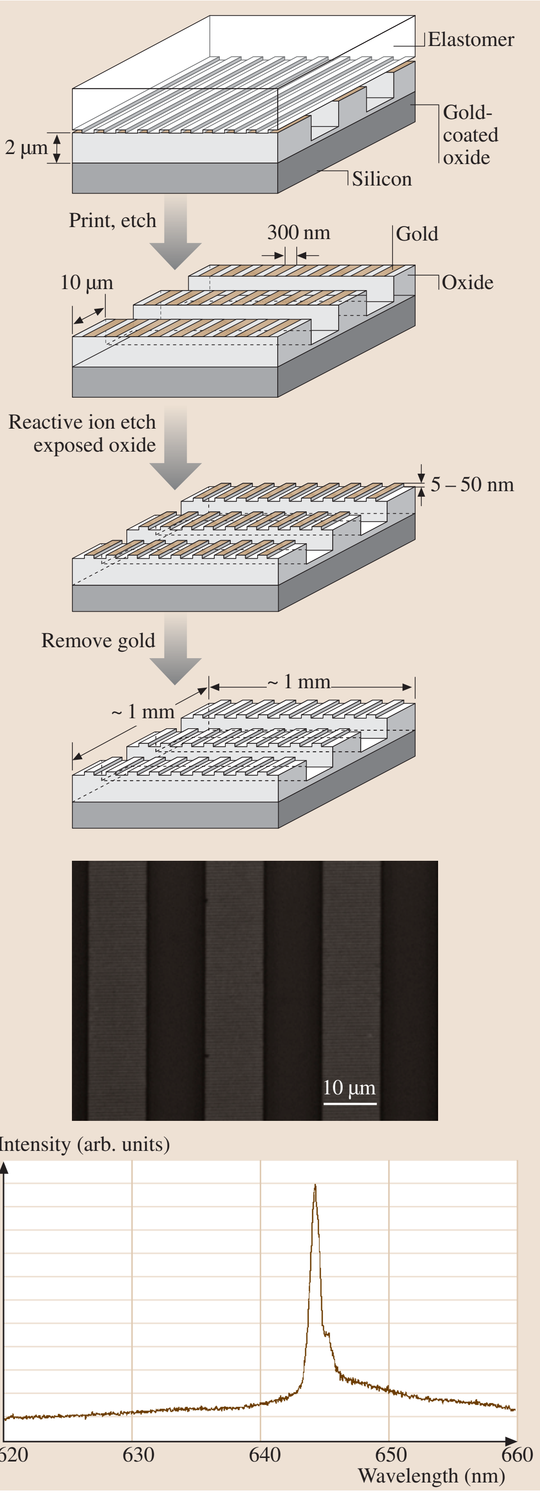

tures that are smaller than those that can be achieved with contact mode photolithography. Mode coupling gratings and distributed laser resonators are two such classes of structures. We have demonstrated µCP for forming distributed feedback (DFB) and distributed Bragg reflector (DBR) lasers that have narrow emission line widths [6.50]. This challenging fabrication

Fig. 6.22 The *top frames* gives a schematic illustration of steps for microcontact printing high resolution gratings directly onto the top surfaces of ridge waveguides. The printing defines a sacrificial etch mask of gold that is subsequently removed. Producing this type of structure with photolithography is difficult because of severe thickness nonuniformities that appear in photoresist spin cast on this type of non-planar substrate. The *upper bottom frame* shows a top view optical micrograph of printed gold lines on the ridge waveguides. The *lower bottom frame* shows the emission output of a plastic photopumped laser that uses the printed structure and a thin evaporated layer of gain media

demonstrates the suitability of μCP for building structures that have (1) feature sizes significantly less than one micron (∼ 300 nm), *and* (2) long-range spatial coherence (∼ 1 mm). The lasers employ optically pumped gain material deposited onto DFB or DBR resonators formed from periodic relief on a transparent substrate. The gain media confines light to the surface of the structure; its thickness is chosen to support a single transverse mode. To generate the required relief, lines of gold formed by μCP on a glass slide act as resists for reactive ion etching of the glass. Removing the gold leaves a periodic pattern of relief (600 nm period, 50 nm depth) on the surface of the glass (see Fig. 6.20). Figure 6.21 shows the performance of plastic lasers that use printed DFB and DBR resonators with gain media consisting of thin films of PBD doped with 1% by weight of coumarin 490 and DCMII, photopumped with 2 ns pulses from a nitrogen laser with intensities $> 5\,\mathrm{kW/cm^2}$ [6.50]. Multimode lasing at resolution-limited line widths was observed at wavelengths corresponding to the third harmonic of the gratings. These characteristics are similar to those observed in lasers that use resonators generated with photolithography and better than those that use imprinted polymers [6.51].

Contact printing not only provides a route to low cost equivalents of gratings fabricated with other approaches, but also allows the fabrication of structures that would be difficult or impossible to generate with photolithography. For example, μCP can be used to form DFB resonators directly on the top surfaces of ridge waveguides [6.52]. Figure 6.22 illustrates the procedures. The bottom left frame shows an optical micrograph of the printed gold lines. Sublimation of a ∼ 200 nm film of tris(8-hydroxyquinoline) aluminum (Alq) doped with 0.5–5.0 weight percent of the laser dye DCMII onto the resonators produces waveguide DFB lasers. The layer of gain material itself provides a planar waveguide with air and polymer as the cladding layers. The relief waveguide provides lateral confinement of the light. Photopumping these devices with the output of a pulsed nitrogen laser (∼ 2 ns, 337 nm) causes lasing due to Bragg reflections induced by the DFB structures on the top surfaces of the ridge waveguides. Some of the laser emission scatters out of the plane of the waveguide at an angle allowed by phase matching conditions. In this way, the grating also functions as an output coupler and offers a convenient way to characterize the laser emission. The bottom right frame of Fig. 6.22 shows the emission profile.

6.5 Conclusions

This chapter provides an overview of two contact printing techniques that are capable of micron and submicron resolution. It also illustrates some applications of these methods that may provide attractive alternatives to more established lithographic methods. The growing interest in nanoscience and technology makes crucial the development of new methods for fabricating the relevant test structures and devices. The simplicity of the techniques described here, together with the interesting and subtle materials science, chemistry, and physics associated with them, make this a promising area for basic and applied study.

7. Materials Aspects of Micro- and Nanoelectromechanical Systems

Two of the more significant technological achievements during the last 20 years have been the development of MEMS and its new offshoot, NEMS. These developments were made possible in large measure by significant advancements in the materials and processes used in the fabrication of MEMS and NEMS devices. And while initial developments capitalized on a mature Si infrastructure, recent advances have used materials and processes not associated with IC fabrication, a trend that is likely to continue as new application areas are identified.

A well-rounded understanding of MEMS and NEMS requires a basic knowledge of the materials used to construct the devices, since material properties often govern device performance. An understanding of the materials used in MEMS and NEMS is really an understanding of material systems. Devices are rarely constructed of a single material, but rather a collection of materials, each providing a critical function and often working in conjunction with each other. It is from this perspective that the following chapter is constructed. A preview of the materials selected for inclusion is presented in Table 7.1. From this table it is easy to see that this chapter is not a summary of all materials used in MEMS and NEMS, as such a work would itself constitute a text of significant size. It does, however, present a selection of some of the more important material systems, including examples that illustrate the importance of viewing MEMS and NEMS in terms of material systems.

7.1 Silicon

Use of silicon (Si) as a material for microfabricated sensors dates back to the 1950s when *C. S. Smith* published a paper describing the piezoresistive effect in germanium (Ge) and Si [7.1]. *Smith* found that the piezoresistive coefficients of Si were significantly higher than those associated with conventional metal strain gauges, a finding that led to the development of Si strain gauges in the early 1960s. Throughout the 1960s and early 1970s, various Si bulk micromachining techniques were developed, which ultimately led to the commercial production of piezoresistive Si pressure sensors during this period. The subsequent development of surface micromachining techniques for Si, along with the recognition that micromachined Si structures could potentially be integrated with Si IC devices, marked the advent of MEMS and positioned Si as the primary MEMS material.

Table 7.1 Distinguishing characteristics and application examples of selected materials for MEMS and NEMS

Material	Distinguishing Characteristics	Application Examples
Single crystal Silicon (Si)	High quality electronic material, selective anisotropic etching	Bulk micromachining, piezoresistive sensing
Polycrystalline Si (polysilicon)	Doped Si films on sacrificial layers	Surface micromachining, electrostatic actuation
Silicon Dioxide (SiO_2)	Insulating, etched by HF, compatible with polysilicon	Sacrificial layer in polysilicon surface micromachining, passivation layer for devices
Silicon Nitride (Si_3N_4, Si_xN_y)	Insulating, chemically resistant, mechanically durable	Isolation layer for electrostatic devices, membrane and bridge material
Polycrystalline Germanium (poly Ge), Polycrystalline Silicon-Germanium (poly Si-Ge)	Deposited at low temperatures	Integrated surface micromachined MEMS
Gold (Au), Aluminum (Al)	Conductive thin films, flexible deposition techniques	Innerconnect layers, masking layers, electromechanical switches
Nickel-Iron (NiFe)	Magnetic alloy	Magnetic actuation
Titanium-Nickel (TiNi)	Shape-memory alloy	Thermal actuation
Silicon Carbide (SiC) Diamond	Electrically and mechanically stable at high temperatures, chemically inert, high Young's modulus to density ratio	Harsh environment MEMS, high frequency MEMS/NEMS
Gallium Arsenide (GaAs), Indium Phosphide (InP), Indium Arsenide (InAs), and related materials	Wide bandgap, epitaxial growth on related ternary compounds	RF MEMS, optoelectronic devices, single crystal bulk and surface micromachining
Lead Zirconate Titanate (PZT)	Piezoelectric material	Mechanical sensors and actuators
Polyimide	Chemically resistant, high temperature polymer	Mechanically flexible MEMS, bioMEMS
SU-8	Thick, photo-definable resist	Micromolding, high-aspect-ratio structures
Parylene	Biocompatible polymer, deposited at room temperature by CVD	Protective coatings, molded polymer structures

7.1.1 Single Crystal Silicon

For MEMS applications, single crystal Si serves several key functions. It is one of the most versatile materials for bulk micromachining, due to the availability of anisotropic etching processes in conjunction with good mechanical properties. Having a Young's modulus of about 190 GPa, Si compares favorably, from a mechanical perspective, with steel, which has a Young's modulus of about 210 GPa. Favorable mechanical properties enable Si to be used as a material for membranes, beams, and other such structures. For surface micromachining applications, single crystal Si substrates are used primarily as mechanical platforms on which Si and non-Si device structures can be fabricated. Use of high-quality single crystal wafers enables the fabrication of integrated MEMS devices, at least for materials and processes that are compatible with Si ICs.

Bulk micromachining is a process whereby etching techniques are used in conjunction with etch masks and etch stops to selectively sculpt micromechanical structures from a bulk substrate. From the materials perspective, single crystal Si is a relatively easy material to bulk micromachine, due to the availability of anisotropic etchants, such as potassium hydroxide (KOH) and tetramethyl-aluminum hydroxide (TMAH), that attack the (100) and (110) Si crystal planes significantly faster than the (111) crystal planes. For example, the etching rate ratio of (100) to (111) planes in Si is about 400:1 for a typical KOH/water etch solution. Silicon dioxide (SiO_2), silicon nitride (Si_3N_4), and some metallic thin films (e.g., Cr, Au, etc.) provide good etch masks for most Si anisotropic etchants.

In contrast to anisotropic etching, isotropic etching exhibits no selectivity to the various crystal planes. From a processing perspective, isotropic etching of Si is commonly used for removal of work-damaged surfaces, creation of structures in single-crystal slices, and patterning single-crystal or polycrystalline films. The most commonly used isotropic Si etchants are mixtures of hydrofluoric (HF) and nitric (HNO_3) acid in water or acetic acid (CH_3COOH), with the etch rate dependent on the ratio of HF to HNO_3.

In terms of etch stops, boron-doped Si is effective for some liquid reagents. Boron-doped etch stops are often less than 10 μm thick, since the boron concentration in Si must exceed $7\times10^{19}\,cm^3$ for the etch stop to be effective, and the doping is done by diffusion. It is possible to create a boron-doped etch stop below an undoped Si layer using ion implantation; however, the practical implant depth is limited to a few microns.

Well-established dry etching processes are available to pattern single crystal Si. The process spectrum ranges from physical mechanisms such as sputtering and ion milling to chemical mechanisms such as plasma etching. Reactive ion etching (RIE) is the most commonly used dry etching technique to etch Si. By combining both physical and chemical processes, RIE is a highly effective anisotropic Si etching technique that is independent of crystalline orientation. Fluorinated compounds such as CF_4, SF_6, and NF_3, or chlorinated compounds such as CCl_4 or Cl_2, sometimes mixed with He, O_2, or H_2, are commonly used in Si RIE. The RIE process is highly directional, which enables direct pattern transfer from an overlying masking material to the etched Si surface. SiO_2 thin films are often used as a masking material, owing to its chemical durability and ease in patterning. Process limitations (i. e., etch rates) restrict the etch depths of Si RIE to less than 10 microns. However, a process called deep reactive ion etching (DRIE) has extended the use of anisotropic dry etching to depths well beyond several hundred microns.

Using the aforementioned processes and techniques, a wide variety of microfabricated devices have been made from single crystal Si, such as piezoresistive pressure sensors, accelerometers, and mechanical resonators, to name a few. Using nearly the same approaches but on a smaller scale, top-down nanomachining techniques have been used to fabricate nanoelectromechanical devices from single crystal Si. Single crystal Si is particularly well-suited for nanofabrication, because high crystal quality substrates with very smooth surfaces are readily available. By coupling electron-beam (e-beam) lithographic techniques with conventional Si etching, device structures with submicron dimensions have been fabricated. Submicron, single crystal Si nanomechanical structures have been successfully micromachined from bulk Si wafers [7.2] and silicon-on-insulator (SOI) wafers [7.3]. In the former case, an isotropic Si etch was performed to release the device structures, whereas in the latter, the 50 nm to 200 nm structures were released by dissolving the underlying oxide layer in HF. An example of nanoelectromechanical beam structures fabricated from a single crystal Si substrate is shown in Fig. 7.1.

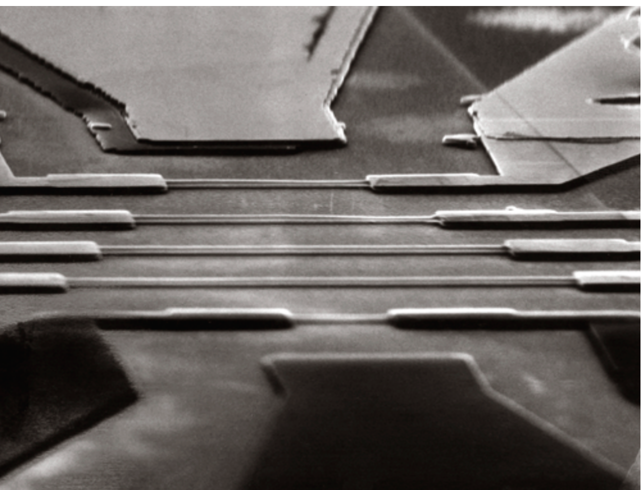

Fig. 7.1 A collection of Si nanoelectromechanical beam resonators fabricated from a single-crystal Si substrate (courtesy M. Roukes, Caltech)

7.1.2 Polysilicon

Surface micromachining is a process whereby a sequence of thin films, often of different materials, is deposited and selectively etched to form the desired micromechanical (or microelectromechanical) structure. In contrast to bulk micromachining, the substrate serves primarily as a platform to support the device. For Si-based surface micromachined MEMS, polycrystalline Si (polysilicon) is most often used as the structural material, silicon dioxide (SiO_2) as the sacrificial material, silicon nitride (Si_3N_4) for electrical isolation of device structures, and single crystal Si as the substrate. Like single crystal Si, polysilicon can be doped during or after film deposition. SiO_2 can be thermally grown or deposited on Si over a broad temperature range (e.g., 200 °C to 1,150 °C) to meet various process and material

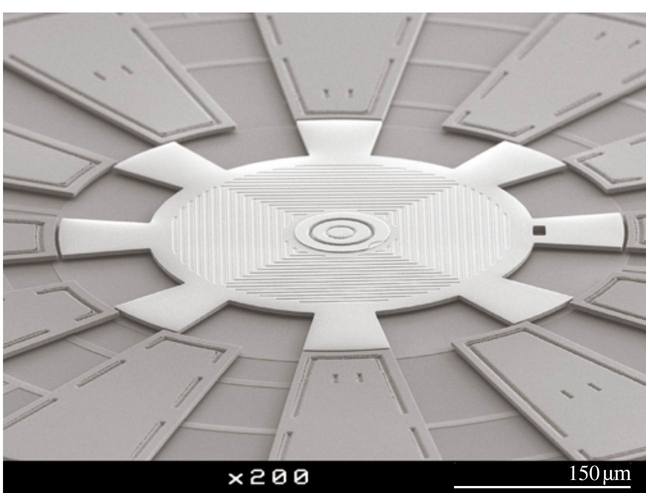

Fig. 7.2 SEM micrograph of a surface-micromachined polysilicon micromotor fabricated using a SiO_2 sacrificial layer

requirements. SiO_2 is readily dissolvable in hydrofluoric acid (HF), which does not etch polysilicon and, thus, can be used to dissolve SiO_2 sacrificial layers. Si_3N_4 is an insulating film that is highly resistant to oxide etchants. The polysilicon micromotor shown in Fig. 7.2 was surface micromachined using a process that included these materials.

For MEMS and IC applications, polysilicon films are commonly deposited using a process known as low-pressure chemical vapor deposition (LPCVD). The typical polysilicon LPCVD reactor is based on a hot wall, resistance-heated furnace. Typical processes are performed at temperatures ranging from 580 °C to 650 °C and pressures from 100 to 400 mtorr. The most commonly used source gas is silane (SiH_4).

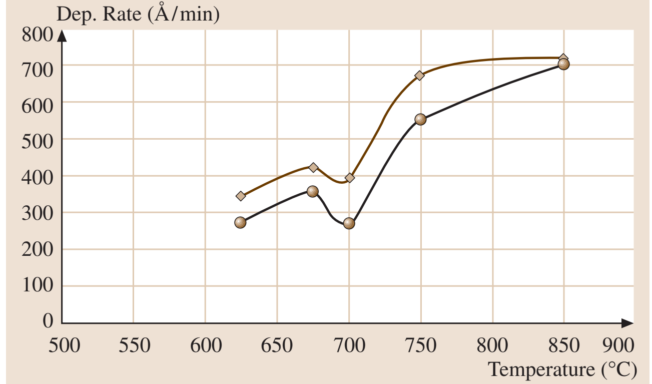

Fig. 7.3 Deposition rate versus substrate temperature for in situ boron-doped (◇) and undoped (●) polysilicon films grown by atmospheric pressure chemical vapor deposition [7.4]

Polysilicon thin films consist of a collection of small single crystal grains whose microstructure and orientation is a function of the deposition conditions [7.5]. For typical LPCVD processes (e.g., 200 mtorr), the amorphous-to-polycrystalline transition temperature is about 570 °C, with amorphous films deposited below the transition temperature. At 600 °C, the grains are small and equiaxed, while at 625 °C, the grains are large and columnar [7.5]. The crystal orientation is predominantly (110) Si for temperatures between 600 °C and 650 °C, while the (100) orientation is dominant for temperatures between 650 °C and 700 °C.

In terms of chemical resistance, polysilicon is very much like single crystal Si. The oxidation rate of undoped polysilicon is typically between that of (100)- and (111)-oriented single crystal Si. For temperatures below 1,000 °C, heavily phosphorus-doped polysilicon oxidizes at a rate significantly higher than undoped polysilicon.

The resistivity of polysilicon can be modified using the doping methods developed for single crystal Si. Diffusion is an effective method for doping polysilicon films, especially for heavy doping of thick films. Phosphorous, which is the most commonly used dopant in polysilicon MEMS, diffuses significantly faster in polysilicon than in single crystal Si, due primarily to enhanced diffusion rates along grain boundaries. The diffusivity in polysilicon thin films (i. e., small equiaxed grains) is about $1 \times 10^{12}\ \mathrm{cm}^2/\mathrm{s}$.

Ion implantation is also used to dope polysilicon films. A high-temperature annealing step is usually required to electrically activate the implanted dopants, as well as to repair implant-related damage in the polysilicon films. In general, the conductivity of implanted polysilicon films is not as high as films doped by diffusion.

In situ doping of polysilicon is performed by simply including a dopant gas, usually diborane (B_2H_6) or phosphine (PH_3), in the CVD process. The addition of dopants during the deposition process not only modifies the conductivity, but also affects the deposition rate of the polysilicon films. As shown in Fig. 7.3, the inclusion of boron generally increases the deposition rate of polysilicon relative to undoped films [7.4], while phosphorus (not shown) reduces the rate. In situ doping can be used to produce conductive films with uniform doping profiles without requiring the high-temperature steps

usually associated with diffusion or ion implantation. Although commonly used to produce doped polysilicon for electrostatic devices, *Cao* et al. [7.6] have used in situ phosphorus-doped polysilicon films in piezoresistive strain gauges, achieving gauge factors as high as 15 for a single strip sensor.

The thermal conductivity of polysilicon is a strong function of its microstructure and, therefore, the conditions used during deposition [7.5]. For fine-grained films, the thermal conductivity is about 25% of the value of single crystal Si. For thick films with large grains, the thermal conductivity ranges between 50% and 85% of the single crystal value.

Like the electrical and thermal properties of polysilicon, the as-deposited residual stress in polysilicon films depends on microstructure. For films deposited under typical conditions (200 mtorr, 625 °C), the as-deposited polysilicon films have compressive residual stresses. The highest compressive stresses are found in amorphous Si films and polysilicon films with a strong, columnar (110) texture. For films with fine-grained microstructures, the stress tends to be tensile. Annealing can be used to reduce the compressive stress in as-deposited polysilicon films. For instance, compressive residual stresses on the order of 500 MPa can be reduced to less than 10 MPa by annealing the as-deposited films at 1,000 °C in a N_2 ambient [7.7, 8]. Recent advances in the area of rapid thermal annealing (RTA) indicate that RTA provides an effective method of stress reduction in polysilicon films. *Zhang* et al. [7.9] reported that a 10 s anneal at 1,100 °C was sufficient to completely relieve the stress in films that originally had a compressive stress of about 340 MPa. RTA is particularly attractive in situations where the process parameters require a low thermal budget.

As an alternative to high-temperature annealing, *Yang* et al. [7.10] have developed an approach that actually utilizes the residual stress characteristics of polysilicon deposited under various conditions to construct polysilicon multilayers that have the desired thickness and stress values. The multilayers are comprised of alternating tensile and compressive polysilicon layers that are deposited in a sequential manner. The tensile layers consist of fine-grained polysilicon grown at a temperature of 570 °C, while the compressive layers are made up of columnar polysilicon deposited at 615 °C. The overall stress in the composite film depends on the number of alternating layers and the thickness of each layer. With the proper set of parameters, a composite polysilicon multilayer can be deposited with near zero residual stress and no stress gradient. The process achieves stress reduction without high-temperature annealing, a considerable advantage for integrated MEMS processes.

Many device designs require thick polysilicon structural layers that are not readily achievable using conventional LPCVD polysilicon, due to process-related limitations. For these designs, epitaxial Si reactors can be used to grow polysilicon films. Unlike conventional LPCVD processes with deposition rates of less than 100 Å/min, epitaxial processes have deposition rates on the order of 1 micron/min [7.11]. The high deposition rates result from the much higher substrate temperatures (> 1,000 °C) and deposition pressures (> 50 torr) used in these processes. The polysilicon films are usually deposited on SiO_2 sacrificial layers to enable surface micromachining. An LPCVD polysilicon seed layer is sometimes used to control nucleation, grain size, and surface roughness. As with conventional polysilicon, the microstructure and residual stress of the epi-poly films, as they are known, is related to deposition conditions. Compressive films generally have a mixture of [110] and [311] grains [7.12, 13], while tensile films have a random mix of [110], [100], [111], and [311] grains [7.12]. The Young's modulus of epi-poly measured from micromachined test structures is comparable to LPCVD polysilicon [7.13]. Mechanical properties test structures [7.11–13], thermal actuators [7.11], electrostatically actuated accelerometers [7.11], and gryoscopes [7.14] have been fabricated from these films.

All of the aforementioned polysilicon deposition processes utilize substrate temperatures in excess of 570 °C either during film deposition, or in post-deposition processing steps. As a low temperature alternative to LPCVD polysilicon, *Abe* et al. [7.15] and *Honer* et al. [7.16] have developed sputtering processes for polysilicon. Early work [7.15] emphasized the ability to deposit very smooth (25 Å) polysilicon films on thermally oxidized wafers at reasonable deposition rates (191 Å/min) and with low residual compressive stresses. The process involved DC magnitron sputtering from a Si target using an Ar sputtering gas, a chamber pressure of 5 mtorr, and a power of 100 W. The authors reported that a post-deposition anneal at 700 °C in N_2 for two hours was needed to crystallize the deposited film and perhaps lower the stress. *Honer* et al. [7.16] sought to develop a polymer-friendly, Si-based surface micromachining process based on polysilicon sputtered onto polyimide and PSG sacrificial layers. To improve the conductivity of the micromachined Si structures, the sputtered Si films were sandwiched between two TiW cladding layers. The device structures on poly-

imide were released using oxygen plasma etching. The processing step with the highest temperature was, in fact, the polyimide cure at 350 °C. To test the robustness of the process, sputter-deposited Si microstructures were fabricated on substrates containing CMOS devices. As expected from thermal budget considerations, the authors reported no measurable degradation of device performance.

7.1.3 Porous Silicon

Porous Si is produced by room temperature electrochemical etching of Si in HF. If configured as an electrode in an HF-based electrochemical circuit, positive charge carriers (holes) at the Si surface facilitate the exchange of F atoms with H atoms, that terminate the Si surface. The exchange continues in the subsurface region, leading to the eventual removal of the fluorinated Si. The quality of the etched surface is related to the density of holes at the surface, which is controlled by the applied current density. For high current densities, the density of holes is high and the etched surface is smooth. For low current densities, the hole density is low and clustered in highly localized regions associated with surface defects. Surface defects become enlarged by etching, which leads to the formation of pores. Pore size and density are related to the type of Si used and the conditions of the electrochemical cell. Both single crystal and polycrystalline Si can be converted to porous Si.

The large surface-to-volume ratios make porous Si attractive for gaseous and liquid applications, including filter membranes and absorbing layers for chemical and mass sensing [7.17]. When single crystal substrates are used, the unetched porous layer remains single crystalline and is suitable for epitaxial Si growth. It has been shown that CVD coatings do not generally penetrate the porous regions, but rather overcoat the pores at the surface of the substrate [7.18]. The formation of localized Si-on-insulator structures is, therefore, possible by simply combining pore formation with epitaxial growth, followed by dry etching to create access holes to the porous region, and thermal oxidation of the underlying porous region. A third application uses porous Si as a sacrificial layer for polysilicon and single crystalline Si surface micromachining. As shown by *Lang* et al. [7.18], the process involves the electrical isolation of the solid structural Si layer by either pn-junction formation through selective doping, or use of electrically insulating thin films, since the formation of pores only occurs on electrically charged surfaces. A weak Si etchant will aggressively attack the porous regions with little damage to the structural Si layers and can be used to release the devices.

7.1.4 Silicon Dioxide

Silicon dioxide (SiO_2) is one of the most widely used materials in the fabrication of MEMS. In polysilicon surface micromachining, SiO_2 is used as a sacrificial material, since it can be easily dissolved using etchants that do not attack polysilicon. SiO_2 is widely used as etch mask for dry etching of thick polysilicon films, since it is chemically resistant to dry etching processes for polysilicon. SiO_2 films are also used as passivation layers on the surfaces of environmentally sensitive devices.

The most common processes used to produce SiO_2 films for polysilicon surface micromachining are thermal oxidation and LPCVD. Thermal oxidation of Si is performed at temperatures of 900 °C to 1,200 °C in the presence of oxygen or steam. Since thermal oxidation is a self-limiting process, the maximum practical film thickness that can be obtained is about 2 μm, which is sufficient for many sacrificial applications. As noted by its name, thermal oxidation of Si can only be performed on Si surfaces.

SiO_2 films can be deposited on a wide variety of substrate materials by LPCVD. In general, LPCVD provides a means for depositing thick (> 2 μm) SiO_2 films at temperatures much lower than thermal oxidation. Known as low-temperature oxides, or LTO for short, these films have a higher etch rate in HF than thermal oxides, which translates to significantly faster release times when LTO films are used as sacrificial layers. Phosphosilicate glass (PSG) can be formed using nearly the same deposition process as LTO by adding a phosphorus-containing gas to the precursor flows. PSG films are useful as sacrificial layers, since they generally have higher etching rates in HF than LTO films.

PSG and LTO films are deposited in hot-wall, low-pressure, fused silica furnaces in systems similar to those described previously for polysilicon. Precursor gases include SiH_4 as a Si source, O_2 as an oxygen source, and, in the case of PSG, PH_3 as a source of phosphorus. LTO and PSG films are typically deposited at temperatures of 425 °C to 450 °C and pressures ranging from 200 mtorr to 400 mtorr. The low deposition temperatures result in LTO and PSG films that are slightly less dense than thermal oxides, due to the incorporation of hydrogen in the films. LTO films can, however, be densified by an annealing step at high temperature (1,000 °C). The low density of LTO and PSG films is partially responsible for the increased etch rate in HF.

Thermal SiO_2 and LTO are electrical insulators used in numerous MEMS applications. The dielectric constants of thermal oxide and LTO are 3.9 and 4.3, respectively. The dielectric strength of thermal SiO_2 is 1.1×10^6 V/cm, and for LTO it is about 80% of that value [7.19]. The stress in thermal SiO_2 is compressive with a magnitude of about 300 MPa [7.19]. For LTO, however, the as-deposited residual stress is tensile, with a magnitude of about 100 MPa to 400 MPa [7.19]. The addition of phosphorous to LTO decreases the tensile residual stress to about 10 MPa for phosphorus concentrations of 8% [7.20]. As with polysilicon, the properties of LTO and PSG are dependent on processing conditions.

Plasma-enhanced chemical vapor deposition (PECVD) is another common method to produce oxides of silicon. Using a plasma to dissociate the gaseous precursors, the deposition temperatures needed to deposit PECVD oxide films is lower than for LPCVD films. For this reason, PECVD oxides are quite commonly used as masking, passivation, and protective layers, especially on devices that have been coated with metals.

Quartz is the crystalline form of SiO_2 and has interesting properties for MEMS. Quartz is optically transparent, piezoelectric, and electrically insulating. Like single crystal Si, quartz substrates are available as high quality, large area wafers that can be bulk micromachined using anisotropic etchants. A short review of the basics of quartz etching by *Danel* et al. [7.21] is recommended for those interested in the subject. Quartz has recently become a popular substrate material for microfluidic devices due to its optical, electronic, and chemical properties.

Another SiO_2-related material that has recently found uses in MEMS is spin-on-glass (SOG). SOG is a polymeric material with a viscosity suitable for spin coating. Two recent publications illustrate the potential for SOG in MEMS fabrication. In the first example, *Yasseen* et al. [7.22] detailed the development of SOG as a thick-film sacrificial molding material for thick polysilicon films. The authors reported a process to deposit, polish, and etch SOG films that were 20 microns thick. The thick SOG films were patterned into molds and filled with 10 micron-thick LPCVD polysilicon films, planarized by selective CMP, and subsequently dissolved in a wet etchant containing HCl, HF, and H_2O to reveal the patterned polysilicon structures. The cured SOG films were completely compatible with the polysilicon deposition process. In the second example, *Liu* et al. [7.23] fabricated high-aspect ratio channel plate microstructures from SOG. Electroplated nickel (Ni) was used as a molding material, with Ni channel plate molds fabricated using a conventional LIGA process. The Ni molds were then filled with SOG, and the sacrificial Ni molds were removed in a reverse electroplating process. In this case, the fabricated SOG structures (over 100 microns tall) were micromachined glass structures fabricated using a molding material more commonly used for structural components.

7.1.5 Silicon Nitride

Silicon nitride (Si_3N_4) is widely used in MEMS for electrical isolation, surface passivation, etch masking, and as a mechanical material. Two deposition methods are commonly used to deposit Si_3N_4 thin films: LPCVD and PECVD. PECVD silicon nitride is generally nonstoichiometric (sometimes denoted as $Si_xN_y:H$) and may contain significant concentrations of hydrogen. Use of PECVD silicon nitride in micromachining applications is somewhat limited because it has a high etch rate in HF (e.g., often higher than that of thermally grown SiO_2). However, PECVD offers the ability to deposit nearly stress-free silicon nitride films, an attractive property for encapsulation and packaging.

Unlike its PECVD counterpart, LPCVD Si_3N_4 is extremely resistant to chemical attack, making it the material of choice for many Si bulk and surface micromachining applications. LPCVD Si_3N_4 is commonly used as an insulating layer because it has a resistivity of 10^{16} $\Omega \times$cm and field breakdown limit of 10^7 V/cm. LPCVD Si_3N_4 films are deposited in horizontal furnaces similar to those used for polysilicon deposition. Typical deposition temperatures and pressures range between 700 °C to 900 °C and 200 mtorr to 500 mtorr, respectively. The standard source gases are dichlorosilane (SiH_2Cl_2) and ammonia (NH_3). To produce stoichiometric Si_3N_4, a NH_3 to SiH_2Cl_2 ratio of 10:1 is commonly used. The microstructure of films deposited under these conditions is amorphous.

The residual stress in stoichiometric Si_3N_4 is large and tensile, with a magnitude of about 1 GPa. Such a large residual stress causes films thicker than a few thousand angstroms to crack. Nonetheless, thin stoichiometric Si_3N_4 films have been used as mechanical support structures and electrical insulating layers in piezoresistive pressure sensors [7.24]. To enable the use of Si_3N_4 films for applications that require micron-thick, durable, and chemically resistant membranes, Si_xN_y films can be deposited by LPCVD. These films, often referred to as Si-rich or low-stress nitride, are intentionally deposited with an excess of Si by simply

decreasing the ratio of NH_3 to SiH_2Cl_2 during deposition. Nearly stress-free films can be deposited using a NH_3 to SiH_2Cl_2 ratio of 1 : 6, a deposition temperature of 850 °C, and a pressure of 500 mtorr [7.25]. The increase in Si content not only leads to a reduction in tensile stress, but also a decrease in the etch rate in HF. Such properties have enabled the development of fabrication techniques that would otherwise not be feasible with stoichiometric Si_3N_4. For example, low stress silicon nitride has been bulk micromachined using silicon as the sacrificial material. In this case, an anisotropic Si etchant (TMAH) was used to dissolve the sacrificial silicon. *French* et al. [7.26] used PSG as a sacrificial layer to surface micromachine low-stress nitride, capitalizing on the HF resistance of the nitride films.

7.2 Germanium-Based Materials

Like Si, Ge has a long history as a semiconductor device material, dating back to the development of the earliest transistors and semiconductor strain gauges. Issues related to the water solubility of germanium oxide, however, stymied the development of Ge for microelectronic devices. Nonetheless, there is a renewed interest in using Ge in micromachined devices due to the relatively low processing temperatures required to deposit the material.

7.2.1 Polycrystalline Ge

Thin polycrystalline Ge (poly-Ge) films can be deposited by LPCVD at temperatures as low as 325 °C on Si, Ge, and SiGe substrates [7.27]. Ge does not nucleate on SiO_2 surfaces, which prohibits the use of thermal oxides and LTO films as sacrificial layers, but enables the use of these films as sacrificial molds. Residual stress in poly-Ge films deposited on Si substrates can be reduced to nearly zero after short anneals at modest temperatures (30 s at 600 °C). Poly-Ge is essentially impervious to KOH, TMAH, and BOE, enabling the fabrication of Ge membranes on Si substrates [7.27]. The mechanical properties of poly-Ge are comparable to polysilicon, having a Young's modulus of 132 GPa and a fracture stress between 1.5 GPa and 3.0 GPa [7.28]. Mixtures of HNO_3, H_2O, and HCl and H_2O, H_2O_2, and HCl, as well as the RCA SC-1 cleaning solution isotropically etch Ge. Since these mixtures do not etch Si, SiO_2, Si_3N_4, and SiN, poly-Ge can be used as a sacrificial substrate layer in polysilicon surface micromachining. Using these techniques, devices such as poly-Ge-based thermistors and Si_3N_4 membrane-based pressure sensors, made using poly-Ge sacrificial layers, have been fabricated [7.27]. *Franke* et al. [7.28] found no performance degradation in Si CMOS devices following the fabrication of surface micromachined poly-Ge structures, thus demonstrating the potential for on-chip integration of Ge electromechanical devices with Si circuitry.

7.2.2 Polycrystalline SiGe

Like poly-Ge, polycrystalline SiGe (poly-SiGe) is a material that can be deposited at temperatures lower than those required for polysilicon. Deposition processes include LPCVD, APCVD, and RTCVD (rapid thermal CVD) using SiH_4 and GeH_4 as precursor gases. Deposition temperatures range from 450 °C for LPCVD [7.29] to 625 °C by rapid thermal CVD (RTCVD) [7.30]. In general, the deposition temperature is related to the concentration of Ge in the films, with higher Ge concentrations resulting in lower deposition temperatures. Like polysilicon, poly-SiGe can be doped with boron and phosphorus to modify its conductivity. In situ boron doping can be performed at temperatures as low as 450 °C [7.29]. *Sedky* et al. [7.30] showed that the deposition temperature of conductive films doped with boron could be further reduced to 400 °C if the Ge content was kept at or above 70%.

Unlike poly-Ge, poly-SiGe can be deposited on a number of sacrificial substrates, including SiO_2 [7.30], PSG [7.28], and poly-Ge [7.28]. For Ge rich films, a thin polysilicon seed layer is sometimes used on SiO_2 surfaces since Ge does not readily nucleate on oxide surfaces. Like many compound materials, variations in film composition can change the physical properties of the material. For instance, etching of poly-SiGe by H_2O_2 becomes significant for Ge concentrations over 70%. *Sedky* et al. [7.31] have shown that the microstructure, film conductivity, residual-stress, and residual stress gradient are related to the concentration of Ge in the material. With respect to residual stress, *Franke* et al. [7.29] produced in situ boron-doped films with residual compressive stresses as low as 10 MPa.

The poly-SiGe, poly-Ge material system is particularly attractive for surface micromachining since H_2O_2 can be used as a release agent. It has been reported that poly-Ge etches at a rate of 0.4 microns/min in H_2O_2, while poly-SiGe with Ge concentrations below 80% have no observable etch rate after 40 hrs [7.32]. The ability to use H_2O_2 as a sacrificial etchant makes the combination of poly-SiGe and poly-Ge extremely attractive for surface micromachining from the processing, safety, and materials compatibility points of view. Due to the conformal nature of LPCVD processing, poly-SiGe structural elements, such as gimbal-based microactuator structures, have been made by high-aspect ratio micromolding [7.32]. Capitalizing on the low deposition temperatures, an integrated MEMS fabrication process with Si ICs has been demonstrated [7.29]. In this process, CMOS structures are first fabricated on Si wafers. Poly-SiGe mechanical structures are then surface micromachined using a poly-Ge sacrificial layer. A significant advantage of this design is that the MEMS structure is positioned directly above the CMOS structure, thus reducing the parasitic capacitance and contact resistance characteristic of interconnects associated with side-by-side integration schemes. Use of H_2O_2 as the sacrificial etchant means that no special protective layers are required to protect the underlying CMOS layer during release. In addition to its utility as a material for integrated MEMS devices, poly-SiGe has been identified as a material well suited for micromachined thermopiles [7.33] due to its lower thermal conductivity relative to Si.

7.3 Metals

It can be argued that of all the material categories associated with MEMS, metals may be among the most enabling, since metallic thin films are used in many different capacities ranging from etch masks used in device fabrication to interconnects and structural elements in microsensors and microactuators. Metallic thin films can be deposited using a wide range of techniques, including evaporation, sputtering, CVD, and electroplating. Since a complete review of the metals used in MEMS is far beyond the scope of this chapter, the examples presented in this section were selected to represent a broad cross section of where metals have found uses in MEMS.

Aluminum (Al) and gold (Au) are among the most widely employed metals in microfabricated electronic and electromechanical devices, as a result of their use as innerconnect and packaging materials. In addition to these critical electrical functions, Al and Au are also desirable as electromechanical materials. One such example is the use of Au micromechanical switches for RF MEMS. For conventional RF applications, chip level switching is currently performed using FET- and PIN diode-based solid state devices fabricated from gallium arsenide (GaAs) substrates. Unfortunately, these devices suffer from insertion losses and poor electrical isolation. In an effort to develop replacements for GaAs-based solid state switches, *Hyman* et al. [7.34] reported the development of an electrostatically actuated, cantilever-based micromechanical switch fabricated on GaAs substrates. The device consisted of a silicon nitride-encased Au cantilever constructed on a sacrificial silicon dioxide layer. The silicon nitride and silicon dioxide layers were deposited by PECVD, and the Au beam was electroplated from a sodium sulfite solution inside a photoresist mold. A thin multilayer of Ti and Au was sputter deposited in the mold prior to electroplating. The trilayer cantilever structure was chosen to minimize the deleterious effects of thermal and process-related stress gradients in order to produce unbent and thermally stable beams. After deposition and pattering, the cantilevers were released in HF. The processing steps proved to be completely compatible with GaAs substrates. The released cantilevers demonstrated switching speeds better than 50 μs at 25 V with contact lifetimes exceeding 10^9 cycles.

In a second example from RF MEMS, *Chang* et al. [7.35] reported the fabrication of an Al-based micromachined switch as an alternative to GaAs FETs and PIN diodes. In contrast to the work by *Hyman* et al. [7.34], this switch utilizes the differences in the residual stresses in Al and Cr thin films to create bent cantilever switches that capitalize on the stress differences in the materials. Each switch is comprised of a series of linked bimorph cantilevers designed in such a way that the resulting structure bends significantly out of the plane of the wafer due to the stress differences in the bimorph. The switch is drawn closed by electrostatic attraction. The bimorph consists of metals that can easily be processed with GaAs wafers, thus making integration with GaAs devices possible. The released switches were

relatively slow, at 10 ms, but an actuation voltage of only 26 V was needed to close the switch.

Thin-film metallic alloys that exhibit the shape-memory effect are of particular interest to the MEMS community for their potential in microactuators. The shape-memory effect relies on the reversible transformation from a ductile martensite phase to a stiff austenite phase in the material with the application of heat. The reversible phase change allows the shape-memory effect to be used as an actuation mechanism, since the material changes shape during the transition. It has been found that high forces and strains can be generated from shape-memory thin films at reasonable power inputs, thus enabling shape-memory actuation to be used in MEMS-based microfluidic devices, such as microvalves and micropumps. Titanium-nickel (TiNi) is among the most popular of the shape-memory alloys, owing to its high actuation work density ($50\,\mathrm{MJ/m^3}$) and large bandwidth (up to 0.1 kHz) [7.36]. TiNi is also attractive because conventional sputtering techniques can be employed to deposit thin films, as detailed in a recent report by *Shih* et al. [7.36]. In this study, TiNi films were deposited by co-sputtering elemental Ti and Ni targets, and a co-sputtering TiNi alloy and elemental Ti targets. It was reported that co-sputtering from TiNi and Ti targets produced better films due to process variations related to the roughening of the Ni target in the case of Ti and Ni co-sputtering. The TiNi/Ti co-sputtering process has been used to produce shape-memory material for a silicon spring-based microvalve [7.37].

Use of thin-film metal alloys in magnetic actuator systems is another example of the versatility of metallic materials in MEMS. Magnetic actuation in microdevices generally requires the magnetic layers to be relatively thick (tens to hundreds of microns) to generate magnetic fields of sufficient strength to generate the desired actuation. To this end, magnetic materials are often deposited by thick film methods, such as electroplating. The thickness of these layers exceeds what can feasibly be patterned by etching, so plating is often performed in microfabricated molds made from materials such as polymethylmethacrylate (PMMA). The PMMA mold thickness can exceed several hundred microns, so X-rays are used as the exposure source during the patterning steps. When necessary, a metallic thin film seed layer is deposited prior to plating. After plating, the mold is dissolved, which frees the metallic component. Known as LIGA (short for Lithography, Galvanoforming and Abformung), this process has been used to produce a wide variety of high-aspect ratio structures from plateable materials, such as nickel-iron (NiFe) magnetic alloys [7.38] and Ni [7.39].

In addition to elemental metals and simple compound alloys, more complex metallic alloys commonly used in commerical macroscopic applications are finding their way into MEMS applications. One such example is an alloy of titanium known as Ti-6Al-4V. Composed of 88% titanium, 6% aluminum and 4% vanadium, this alloy is widely used in commercial aviation due to its weight, strength, and temperature tolerance. *Pornsin-sirirak* et al. [7.40] have explored the use of this alloy in the manufacture of MEMS-based winged structures for micro aerial vehicles. The authors considered this alloy not only because of its weight and strength, but also because of its ductility and its etching rate at room temperature. The designs for the wing prototype were modelled after the wings of bats and various flying insects. For this application, Ti-alloy structures patterned from bulk (250 μm-thick) material by an HF/HNO_3/H_2O etching solution were used, rather than thin films. Parylene-C (detailed in Sect. 7.7.3) was deposited on the patterned alloy to serve as the wing membrane. The miniature micromachined wings were integrated into a test setup, and several prototypes actually demonstrated short duration flight.

7.4 Harsh Environment Semiconductors

Silicon Carbide (SiC) has long been recognized as the leading semiconductor for use in high temperature and high power electronics and is currently receiving attention as a material for harsh environment MEMS.

7.4.1 Silicon Carbide

SiC is a polymorphic material that exists in cubic, hexagonal, and rhombehedral polytypes. The cubic polytype, called 3C-SiC, has an electronic bandgap of 2.3 eV, which is over twice that of Si. Numerous hexagonal and rhombehedral polytypes have been identified, the two most common being 4H-SiC and 6H-SiC. The electronic bandgap of 4H- and 6H-SiC is even higher than 3C-SiC – 2.9 and 3.2 eV, respectively. SiC films can be doped to create n-type and p-type material. The stiffness of SiC is quite large relative to Si, with a Young's modulus ranging from 300 GPa to 450 GPa, depending on the microstruc-

ture. SiC is not etched in any wet Si etchants or by XeF_2, a popular dry Si etchant used for releasing device structures [7.41]. SiC is a material that does not melt, but rather sublimes at temperatures in excess of 1,800 °C. Single crystal 4H- and 6H-SiC wafers are commercially available, but smaller in diameter (3 inches) and much more expensive than Si.

SiC thin films can be grown or deposited using a number of different techniques. For high-quality single crystal films, APCVD and LPCVD processes are most commonly employed. Homoepitaxial growth of 4H- and 6H-SiC yields high quality films suitable for microelectronic applications, but only on substrates of the same polytype. These processes usually employ dual precursors, such as SiH_4 and C_3H_8, and are performed at temperatures ranging from 1,500 °C to 1,700 °C. Epitaxial films with p-type or n-type conductivity can be grown using aluminum and boron for p-type films and nitrogen and phosphorus for n-type films. Nitrogen is so effective at modifying the conductivity of SiC that growth of undoped SiC is extremely challenging, because the concentrations of residual nitrogen in typical deposition systems are sufficient for n-type doping.

APCVD and LPCVD can also be used to deposit 3C-SiC on Si substrates. Heteroepitaxy is possible, despite a 20% lattice mismatch, because 3C-SiC and Si have similar lattice structures. The growth process involves two key steps. The first step, called carbonization, converts the near surface region of the Si substrate to 3C-SiC by simply exposing it to a hydrocarbon/hydrogen mixture at high substrate temperatures ($> 1,200$ °C). The carbonized layer forms a crystalline template on which a 3C-SiC film can be grown by adding a silicon-containing gas to the hydrogen/hydrocarbon mix. The lattice mismatch between Si and 3C-SiC results in the formation of crystalline defects in the 3C-SiC film, with the density being highest in the carbonization layer and decreasing with increasing thickness. The crystal quality of 3C-SiC films is nowhere near that of epitaxially grown 4H- and 6H-SiC films; however, the fact that 3C-SiC can be grown on Si substrates enables the use of Si bulk micromachining techniques to fabricate a host of 3C-SiC-based mechanical devices. These include microfabricated pressure sensors [7.42] and nanoelectromechanical resonant structures [7.43].

Polycrystalline SiC (poly-SiC) has proven to be a very versatile material for SiC MEMS. Unlike single crystal versions of SiC, poly-SiC can be deposited on a variety of substrate types, including such common surface micromachining materials as polysilicon, SiO_2, and Si_3N_4, using a much wider range of processes than epitaxial films. Commonly used deposition techniques include LPCVD [7.41, 44, 45] and APCVD [7.46, 47]. The deposition of poly-SiC requires much lower substrate temperatures than epitaxial films, ranging from roughly 700 °C to 1,200 °C. Amorphous SiC can be deposited at even lower temperatures (25 °C to 400 °C) by PECVD [7.48] and sputtering [7.49]. The microstructure of poly-SiC films is temperature, substrate, and process dependent. For amorphous substrates, such as SiO_2 and Si_3N_4, APCVD poly-SiC films deposited from silane and propane are oriented randomly with equiaxed grains [7.47], whereas for oriented substrates, such as polysilicon, the texture of the poly-SiC film matches that of the substrate [7.46]. By comparison, poly-SiC films deposited by LPCVD from dichlorosilane and acetylene are highly textured (111) films with a columnar microstructure [7.44], while films deposited from disilabutane have a distribution of orientations [7.41]. This variation suggests that device performance can be tailored by selecting the proper substrate and deposition conditions.

Direct bulk micromachining of SiC is very difficult due to its chemical inertness. Although conventional wet chemical techniques are not effective, several electrochemical etch processes have been demonstrated and used in the fabrication of 6H-SiC pressure sensors [7.50]. The etching processes are selective to the conductivity of the material, so dimensional control of the etched structures depends on the ability to form doped layers, which can only be formed by in situ or ion implantation processes, since solid source diffusion is not possible at reasonable processing temperatures. This constraint somewhat limits the geometrical complexity of the patterned structures, as compared with conventional plasma-based etching. To fabricate thick (hundreds of microns), 3-D, high-aspect ratio SiC structures, a molding technique has been developed [7.39]. The molds are fabricated from Si substrates using deep reactive ion etching and then filled with SiC using a combination of thin epitaxial and thick polycrystalline film CVD processes. The thin film process is used to protect the mold from pitting during the more aggressive mold filling SiC growth step. The mold filling process coats all surfaces of the mold with a SiC film as thick as the mold is deep. To release the SiC structure, the substrate is first mechanically polished to expose sections of the Si mold, then the substrate is immersed in a Si etchant to completely dissolve the mold. This process has been used to fabricate solid SiC fuel atomizers [7.39], and a variant has been used to fabricate SiC structures for micropower systems [7.51].

In addition to CVD processes, bulk micromachined SiC structures can be fabricated using sintered SiC powders. *Tanaka* et al. [7.52] describe a process in which SiC components, such as micro gas turbine engine rotors, can be fabricated from SiC powders using a micro-reaction-sintering process. The molds are microfabricated from Si using DRIE and filled with SiC and graphite powders mixed with a phenol resin. The molds are then reaction-sintered using a hot isostatic pressing technique. The SiC components are then released from the Si mold by wet chemical etching. The authors reported that the component shrinkage was less than 3%. The bending strength and Vickers hardness of the micro-reaction-sintered material was roughly 70 to 80% of commercially available reaction-sintered SiC, the difference being attributed to the presence of unreacted Si in the micro-scale components.

In a related process, *Liew* et al. [7.54] detail a technique to create silicon carbon nitride (SiCN) MEMS structures by molding injectable polymer precursors. Unlike the aforementioned processes, this technique uses SU-8 photoresists for the molds. SU-8, detailed later in this chapter, is a versatile photo-definable polymer in which thick films (hundreds of microns) can be patterned using conventional UV photolithographic techniques. After patterning, the molds are filled with the SiCN-containing polymer precursor, lightly polished, and then subjected to a multistep heat-treating process. During the thermal processing steps, the SU-8 mold decomposes, and the SiCN structure is released. The resulting SiCN structures retain many of the same properties of stoichiometric SiC.

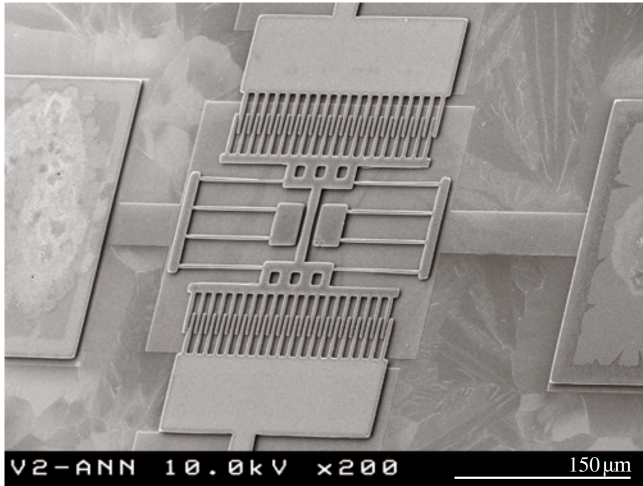

Fig. 7.4 SEM micrograph of a poly-SiC lateral resonant structure fabricated using a multilayer, micromolding-based micromachining process [7.53]

Although SiC cannot be etched using conventional wet etch techniques, thin SiC films can be patterned using conventional dry etching techniques. RIE processes using fluorinated compounds, such as CHF_3 and SF_6 combined with O_2, an inert gas, or H_2. The high oxygen content in these plasmas generally prohibits the use of photoresist as a masking material, therefore, hard masks made of Al, Ni, and ITO are often used. RIE-based SiC surface micromachining processes with polysilicon and SiO_2 sacrificial layers have been developed for single layer devices [7.55,56]. Multilayered structures are very difficult to fabricate by direct RIE because the etch rates of the sacrificial layers are much higher than the SiC structural layers, making critical dimensional control very difficult and RIE-based SiC multilayer processes impractical.

To address the issues related to RIE of multilayer SiC structures, a micromolding process for patterning SiC films on sacrificial layer substrates has been developed [7.57]. In essence, the micromolding technique is the thin film analog to the molding-based, bulk micromachining technique presented earlier. The micromolding process utilizes polysilicon and SiO_2 films as both molds and sacrificial substrate layers, with SiO_2 molds used with polysilicon sacrificial layers and vica versa. These films are deposited and patterned using conventional methods, thus leveraging the well characterized and highly selective processes developed for polysilicon MEMS. Poly-SiC films are simply deposited into the micromolds, and mechanical polishing is used to remove poly-SiC from the top of the molds. Appropriate etchants are then used to dissolve the molds and sacrificial layers. The micromolding method utilizes the differences in chemical properties of the three materials in this system in a way that bypasses the difficulties associated with chemical etching of SiC. This technique has been extended to multilayer processes that have been used to fabricate SiC micromotors [7.57] and the lateral resonant structure shown in Fig. 7.4 [7.53].

Yang et al. [7.43] have recently shown that the chemical inertness of SiC facilitates the fabrication of NEMS devices. In this work, the authors present a fabrication method to realize SiC mechanical resonators with submicron thickness and width dimensions. The resonators were fabricated from ∼ 260 nm-thick 3C-SiC films epitaxially grown on (100) Si wafers. The films were patterned into 150 nm-wide beams ranging in length from 2 to 8 µm. The beams were etched in a $NF_3/O_2/Ar$

plasma using an evaporated Cr etch mask. After patterning, the beams were released by etching isotropically the underlying Si using a NF_3/Ar plasma. The inertness of the SiC film to the Si etchant enables the dry release of the nanomechanical beams. An example of a 3C-SiC nanomechanical beam is shown in Fig. 7.5.

7.4.2 Diamond

Diamond is commonly known as nature's hardest material, making it ideal for high wear environments. Diamond has a very large electronic bandgap (5.5 eV), which makes it attractive for high temperature electronics. Undoped diamond is a high quality insulator with a dielectric constant of 5.5; however it can be relatively easily doped with boron to create p-type conductivity. Diamond has a very high Young's modulus (1,035 GPa), making it suitable for high frequency micromachined resonators, and it is among nature's most chemically inert materials, making it well suited for harsh chemical environments.

Unlike SiC, fabrication of diamond MEMS is currently restricted to polycrystalline and amorphous material, since epitaxial-quality single-crystal diamond wafers are not yet commercially available. Polycrystalline diamond films can be deposited on Si and SiO_2 substrates, but the surfaces often must be seeded by diamond powders, or biased with a negative charge to initiate growth. In general, diamond nucleates much more readily on Si surfaces than on SiO_2 surfaces, an effect that has been used to selectively pattern diamond films into micromachined AFM cantilever probes using SiO_2 molding masks [7.58].

Bulk micromachining of diamond is very difficult given its extreme chemical inertness. Diamond structures have nevertheless been fabricated using bulk micromachined Si molds to pattern the structures [7.59]. The Si molds were fabricated using conventional micromachining techniques and filled with polycrystalline diamond deposited by hot filament chemical vapor deposition (HFCVD). The HFCVD process uses hydrogen as a carrier gas and methane as the carbon source. The process was performed at a substrate temperature of 850 °C to 900 °C and a pressure of 50 mtorr. The Si substrate was seeded prior to deposition using a diamond particle/ethanol solution. After deposition, the top surface of the structure was polished using a hot iron plate. After polishing, the Si mold was removed in a Si etchant, leaving behind the micromachined diamond structure. This process was used to produce high-aspect-ratio capillary channels for microfluidic applications [7.60] and components for diffractive optics, laser-to-fiber alignment, and power device cooling structures [7.61].

Due to the nucleation processes associated with diamond film growth, surface micromachining of polycrystalline diamond thin films requires modifications to conventional micromachining to facilitate film growth on sacrificial substrates. Conventional RIE methods are generally ineffective, so initial work focused on developing selective deposition techniques. One early method used selective seeding to form patterned templates for diamond nucleation. The selective seeding process employed the lithographic patterning of photoresist that contained diamond powders [7.62]. The diamond-loaded photoresist was deposited and patterned onto a Cr-coated Si wafer. During the onset of diamond growth, the patterned photoresist rapidly evaporates, leaving behind the diamond seed particles in the desired locations. A patterned diamond film is then selectively grown on these locations.

A second process utilizes selective deposition directly on sacrificial substrate layers. This process combines conventional diamond seeding with photolithographic patterning and etching to fabricate micromachined diamond structures on SiO_2 sacrificial layers [7.63]. The process can be performed in one of two ways. The first approach begins with the seeding of an oxidized Si wafer. The wafer is coated with photoresist and photolithographically patterned. Unmasked regions of the seeded SiO_2 film are then partially etched, forming a surface unfavorable for diamond growth. The

photoresist is then removed, and a diamond film is deposited on the seeded regions. The second approach also begins with an oxidized Si wafer. The wafer is coated with photoresist, photolithographically patterned, and then seeded with diamond particles. The photoresist is removed, leaving behind a patterned seed layer suitable for selective growth. These techniques have been successfully used to fabricate cantilever beams and bridge structures.

A third method to surface micromachine polycrystalline diamond films follows the conventional approach of film deposition, dry etching, and release. The chemical inertness of diamond renders most conventional plasma chemistries useless; however, oxygen-based ion beam plasmas can be used to etch diamond thin films [7.64]. A simple surface micromachining process begins with the deposition of a polysilicon sacrificial layer on a Si_3N_4-coated Si wafer. The polysilicon layer is seeded using diamond slurry, and a diamond film is deposited by HFCVD. Since photoresist is not resistant to O_2 plasmas, an Al masking film is deposited and patterned. The diamond films are then etched in the O_2 ion beam plasma, and the structures are released by etching the polysilicon with KOH. This process has been used to create lateral resonant structures, but a significant stress gradient in the films rendered the devices nonoperational.

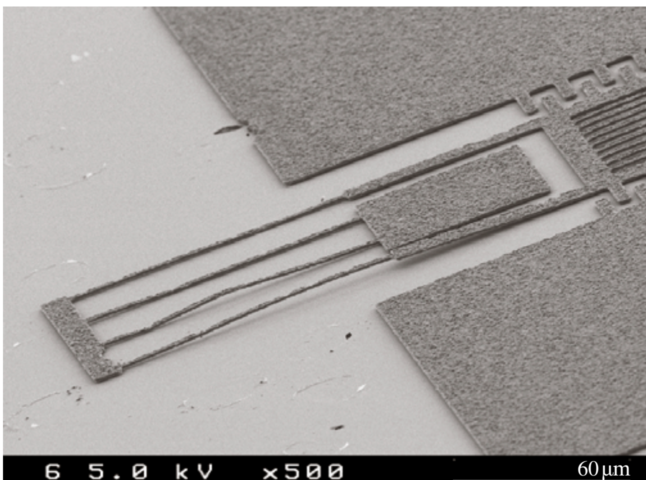

Fig. 7.6 SEM micrograph of the folded beam truss of a diamond lateral resonator. The diamond film was deposited using a seeding-based hot filament CVD process. The micrograph illustrates the challenges currently facing diamond MEMS, namely, roughened surfaces and residual stress gradients

In general, conventional HFCVD requires that the substrate be pretreated with a seeding layer prior to diamond film growth. However, a method called biased enhanced nucleation (BEN) has been developed that enables the growth of diamond on unseeded Si surfaces. *Wang* et al. [7.65] have shown that if Si substrates are masked with patterned SiO_2 films, selective diamond growth will occur primarily on the exposed Si surfaces, and a slight HF etch is sufficient to remove the adventitious diamond from the SiO_2 mask. This group was able to use this method to fabricate diamond micromotor rotors and stators on Si surfaces.

Diamond is a difficult but not impossible material to etch using RIE techniques. It is well-known that diamond will be etched in oxygen plasmas, but these plasmas are not generally well suited for device fabrication, because the etches tend to be isotropic. A recent development, however, suggests that RIE processes for diamond are close at hand. *Wang* et al. [7.65] describe a process to fabricate a vertically actuated, doubly clamped micromechanical diamond beam resonator using RIE. The process outlined here addresses two key issues related to diamond surface micromachining, namely, residual stress gradients in the diamond films and diamond patterning techniques. A microwave plasma CVD reactor was used to grow the diamond films on sacrificial SiO_2 layers pretreated with a nanocrystalline diamond powder, resulting in a uniform nucleation density at the diamond/SiO_2 interface. The diamond films were etched in a CF_4/O_2 plasma using Al as a hard mask. Reasonably straight sidewalls were created, with roughness attributable to the surface roughness of the faceted diamond film. An Au/Cr drive electrode beneath the sacrificial oxide remained covered throughout the diamond patterning steps and, thus, was undamaged during the diamond etching process.

In conjunction with recent advances in RIE and micromachining techniques, work is being performed to develop diamond deposition processes specifically for MEMS applications. Diamond films grown using conventional techniques, especially processes that require pre-growth seeding, tend to have high residual stress gradients and roughened surface morphologies as a result of the highly faceted, large grain polycrystalline films that are produced by these methods (see Fig. 7.6). The rough surface morphology degrades the patterning process, resulting in roughened sidewalls in etched structures and roughened surfaces of films deposited over these layers. Unlike polysilicon and SiC, a post-deposition polishing process is not technically feasible for diamond due to its extreme hardness. For the fabrication of multilayer

diamond devices, methods to reduce the surface roughness of the as-deposited films are highly desirable. Along these lines, *Krauss* et al. [7.66] reported the development of an ultrananocrystalline diamond film that exhibits a much smoother surface morphology than comparable diamond films grown using conventional methods. Unlike conventional CVD diamond films that are grown using a mixture of H_2 and CH_4, the ultrananocrystalline diamond films are grown from mixtures of Ar, H_2, and C_{60} or Ar, H_2, and CH_4. Although the processes are still under development, *Krauss* et al. [7.66] have demonstrated the viability of the ultrananocrystalline diamond films as conformal coatings on Si surfaces, as well as their utility in several micromachining processes.

7.5 GaAs, InP, and Related III–V Materials

Gallium Arsenide (GaAs), Indium Phosphide (InP), and related III-V compounds have favorable piezoelectric and optoelectric properties, high piezoresistive constants, and wide electronic bandgaps relative to Si, making them attractive for various sensor and optoelectronic applications. Like Si, significant research in bulk crystal growth has led to the development of GaAs and InP substrates, which are commercially available as high quality, single crystal wafers. Unlike compound semiconductors, such as SiC, III-V materials can be deposited as ternary and quaternary alloys with lattice constants that closely match the binary compounds from which they are derived (i. e., $Al_xGa_{1-x}As$ and GaAs), thus permitting the fabrication of a wide variety of heterostructures that facilitate device performance.

Crystalline GaAs has a zinc blend crystal structure with an electronic bandgap of 1.4 eV, enabling GaAs electronic devices to function at temperatures as high as 350 °C [7.67]. High quality, single crystal wafers are commercially available, as are well developed metalorganic chemical vapor deposition (MOCVD) and molecular beam epitaxy (MBE) growth processes for epitaxial layers of GaAs and its alloys. GaAs does not outperform Si in terms of mechanical properties, however, its stiffness and fracture toughness are still suitable for micromechanical devices.

Micromachining of GaAs is relatively straightforward, since many of its lattice-matched ternary and quaternary alloys have sufficiently different chemical properties to allow their use as sacrificial layers [7.68]. For example, the most common ternary alloy for GaAs is $Al_xGa_{1-x}As$. For values of x less than or equal to 0.5, etchants containing mixtures of HF and H_2O will etch $Al_xGa_{1-x}As$ without attacking GaAs, while etchants containing NH_4OH and H_2O_2 attack GaAs isotropically, but do not etch $Al_xGa_{1-x}As$. Such selectivity enables the micromachining of GaAs wafers using lattice-matched etch stops and sacrificial layers. Devices fabricated using these methods include comb drive lateral resonant structures [7.68], pressure sensors [7.69, 70], thermopile sensors [7.71], Fabry–Perot detectors [7.72], and cantilever-based sensors and actuators [7.73, 74]. In addition, nanoelectromechanical devices, such as suspended micromechanical resonators [7.75] and tethered membranes [7.76], have been fabricated using these techniques. An example of a nanoelectromechanical beam structure fabricated from GaAs is shown in Fig. 7.7.

In addition to using epitaxial layers as etch stops, ion implantation methods can also be used to produce etch stops in GaAs layers. *Miao* et al. [7.77] describe a process that uses electrochemical etching to selectively remove n-type GaAs layers. The process relies on the creation of a highly resistive near surface GaAs layer on an n-type GaAs substrate by low dose nitrogen implantation in the MeV energy range. A pulsed electrochemical etch method using a H_2PtCl_6, H_3PO_4, H_2SO_4 platinum electrolytic solution at 40 °C with 17 V, 100 ms pulses is sufficient to selectively remove n-type GaAs at about 3 μm/min. Using this method, stress-free, tethered membranes could readily be fabricated from the high resistive GaAs layer. The high implant energies enable the fabrication of membranes several microns in thickness. Moreover, the authors demonstrated that if the GaAs wafer were etched in such a way as to create an undulating surface prior to ion implantation, corrugated membranes could be fabricated. These structures can sustain much higher deflection amplitudes than flat structures.

Micromachining of InP closely resembles the techniques used for GaAs. Many of the properties of InP are similar to GaAs in terms of crystal structure, mechanical stiffness, and hardness. However, the optical properties of InP make it particularly attractive for micro-optomechanical devices to be used in the 1.3 to 1.55 μm wavelength range [7.78]. Like GaAs, single crystal wafers of InP are readily available, and

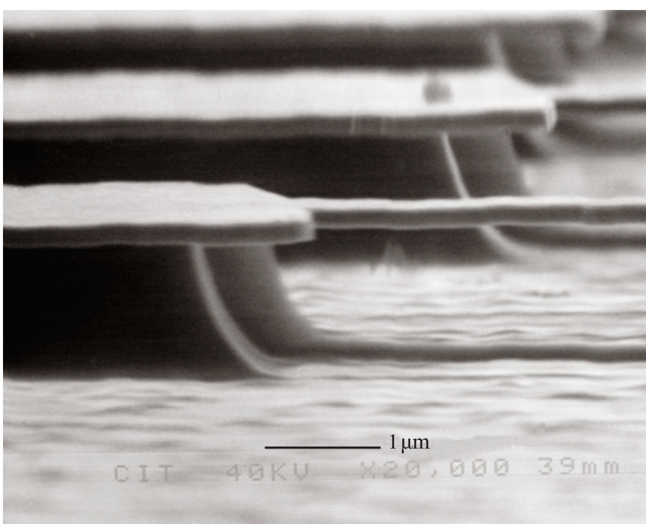

Fig. 7.7 SEM micrograph of a GaAs nanomechanical beam resonator fabricated by epitaxial growth, electron-beam lithography, and selective etching (courtesy of M. Roukes, Caltech)

ternary and quaternary lattice-matched alloys, such as InGaAs, InAlAs, InGaAsP, and InGaAlAs, can be used as either etch stop and/or sacrificial layers, depending on the etch chemistry [7.68]. For instance, InP structural layers deposited on $In_{0.53}Al_{0.47}As$ sacrificial layers can be released using etchants containing $C_6H_8O_7$, H_2O_2, and H_2O. In addition, InP films and substrates can be etched in solutions containing HCl and H_2O using $In_{0.53}Ga_{0.47}As$ films as etch stops. Using InP-based micromachining techniques, multi-air gap filters [7.79], bridge structures [7.78], and torsional membranes [7.72] have been fabricated from InP and its related alloys.

In addition to GaAs and InP, materials such as indium arsenide (InAs) can be micromachined into device structures. Despite a 7% lattice mismatch between InAs and (111) GaAs, high quality epitaxial layers can be grown on GaAs substrates. As described by *Yamaguchi* et al. [7.80], the surface Fermi level of InAs/GaAs structures is pinned in the conduction band, enabling the fabrication of very thin conductive membranes. In fact, the authors have successfully fabricated freestanding InAs structures that range in thickness from 30 to 300 nm. The thin InAs films were grown directly on GaAs substrates by MBE and etched using a solution containing H_2O, H_2O_2, and H_2SO_4. The structures, mainly doubly clamped cantilevers, were released by etching the GaAs substrate using a $H_2O/H_2O_2/NH_4OH$ solution.

7.6 Ferroelectric Materials

Piezoelectric materials play an important role in MEMS technology for sensing and mechanical actuation applications. In a piezoelectric material, mechanical stress produces a polarization, and, conversely, a voltage-induced polarization produces a mechanical stress. Many asymmetric materials, such as quartz, GaAs, and zinc oxide (ZnO), exhibit some piezoelectric behavior. Recent work in MEMS has focussed on the development of ferroelectric compounds, such as lead zirconate titanate, $Pb(Zr_xTi_{1-x})O_3$, or PZT for short, because such compounds have high piezoelectric constants that result in high mechanical transduction. It is relatively straightforward to fabricate a PZT structure on top of a thin freestanding structural layer (i. e., cantilever, diaphragm). Such a capability enables the piezoelectric material to be used in sensor applications or actuator applications for which piezoelectric materials are particularly well suited. Like Si, PZT films can be patterned using dry etch techniques based on chlorine chemistries, such as Cl_2/CCl_4, as well as ion beam milling using inert gases like Ar.

PZT has been successfully deposited in thin film form using co-sputtering, CVD, and sol-gel processing. Sol-gel processing is particularly attractive because the composition and homogeneity of the deposited material over large surface areas can be readily controlled. The sol-gel process outlined by *Lee* et al. [7.81] uses PZT solutions made from liquid precursors containing Pb, Ti, Zr, and O. The solution is deposited by spin coating on a Si wafer that has been coated with a $Pt/Ti/SiO_2$ thin film multilayer. The process is executed to produce a PZT film in layers, with each layer consisting of a spin-coated layer that is dried at 110 °C for 5 min and then heat treated at 600 °C for 20 min. After building up the PZT layer to the desired thickness, the multilayer was heated at 600 °C for up to 6 hrs. Prior to this anneal, a PbO top layer was deposited on

the PZT surface. An Au/Cr electrode was then sputter-deposited on the surface of the piezoelectric stack. This process was used to fabricate a PZT-based force sensor. *Xu* et al. [7.82] describe a similar sol-gel process to produce 12 μm-thick, crack-free PZT films on Pt-coated Si wafers and 5 μm-thick films on insulating ZrO_2 layers to produce micromachined MHz-range, two-dimensional transducer arrays for acoustic imaging.

Thick film printing techniques for PZT have been developed to produce thick films in excess of 100 μm. Such thicknesses are desired for applications that require actuation forces that cannot be achieved with the much thinner sol-gel films. *Beeby* et al. [7.83] describe a thick film printing process whereby a PZT paste is made from a mixture of 95% PZT powder, 5% lead borosilicate powder, and an organic carrier. The paste was then printed through a stainless steel screen using a thick film printer. Printing was performed on an oxidized Si substrate that is capped with a Pt electrode. After printing, the paste was dried and then fired at 850 °C to 950 °C. Printing could be repeated to achieve the desired thickness. The top electrode consisted of an evaporated Al film. The authors found that it was possible to perform plasma-based processing on the printed substrates, but that the porous nature of the printed PZT films made them unsuitable for wet chemical processing.

7.7 Polymer Materials

Polyimides comprise an important class of durable polymers that are well suited for many of the techniques used in conventional MEMS processing. In general, polyimides can be acquired in bulk, or deposited as thin films by spin coating. Polyimides can be patterned using conventional dry etching techniques and processed at relatively high temperatures. These attributes make polyimides an attractive group of polymers for MEMS that require polymer structural and/or substrate layers, such as microfabricated biomedical devices, for which inertness and flexibility are important parameters.

7.7.1 Polyimide

Shearwood et al. [7.84] explored the use of polyimide as a robust mechanical material for microfabricated audio membranes. The authors fabricated 7 μm-thick, 8 mm-diameter membranes on GaAs substrates by bulk micromachining the GaAs substrate using a NH_3/H_2O_2 solution. They realized 100% yield and, despite a low Young's modulus (∼ 3 GPa), observed flat membranes to within 1 nm after fabrication.

Jiang et al. [7.85] capitalized on the strength and flexibility of polyimide to fabricate a flexible sheer-stress sensor array based on Si sensors. The sensor array consisted of a collection of Si islands linked by two polyimide layers. Each Si sensor island was $250 \times 250\,\mu m^2$ in area and 80 μm in thickness. Al was used as an electrical innerconnect layer. The two polyimide layers served as highly flexible hinges, giving the sensor array the ability to be mounted on curved surfaces. The sensor array was successful in profiling the shear-stress distribution along the leading edge of a rounded delta wing.

The chemical and temperature durability of polyimides enables their use as a sacrificial layer for a number of commonly used materials, such as evaporated or sputter-deposited metals. *Memmi* et al. [7.86] developed a fabrication process for capacitive micromechanical ultransonic transducers using polyimide as a sacrificial layer. The authors showed that the polyimide could withstand the conditions used to deposit silicon monoxide by evaporation and silicon nitride by PECVD at 400 °C. Recent work by *Bagolini* et al. [7.87] has shown that polyimides can even be used as sacrificial layers for PECVD SiC.

In the area of microfabricated biomedical devices, polyimide is receiving attention as a substrate material for implantable devices, owing to its potential biocompatiblity and mechanical flexibility. *Stieglitz* [7.88] reported on the fabrication of multichannel microelectrodes on polyimide substrates. Instead of using polyimide sheets as starting substrates, Si carrier wafers coated with a 5 μm-thick polyimide film were used. Pt microelectrodes were then fabricated on these substrates using conventional techniques. Thin polyimide layers were deposited between various metal layers to serve as insulating layers. A capping polyimide layer was then deposited on the top of the substrates, and the entire polyimide/metal structure was peeled off the Si carrier wafers. Backside processing was then performed on the freestanding polyimide structures to create devices that have exposed electrodes on both surfaces. In a later paper, *Stieglitz* et al. [7.89] describe a variation of this process for neural prostheses.

7.7.2 SU-8

SU-8 is a negative-tone, epoxy-like photoresist that is receiving much attention for its versatility in MEMS processing. It is a high-aspect-ratio, UV-sensitive resist designed for applications requiring single-coat resists with thicknesses on the order of 500 microns [7.90]. SU-8 has favorable chemical properties that enable it to be used as a molding material for high-aspect-ratio electroplated structures (as an alternative to LIGA), and as a structural material for microfluidics [7.90]. In terms of mechanical properties, *Lorenz* et al. [7.91] reported that SU-8 has a modulus of elasticity of 4.02 GPa, which compares favorably with a commonly used polyamid (3.4 GPa).

In addition to the aforementioned conventional uses for SU-8, several interesting alternative uses are beginning to appear in the literature. *Conradie* et al. [7.92] have used SU-8 to trim the mass of silicon paddle oscillators as a means to adjust the resonant frequency of the beams. The trimming process involves the patterning of SU-8 posts on Si paddles. The process capitalizes on the relative chemical stability of the SU-8 resin, in conjunction with the relatively large masses that can be patterned using standard UV exposure processes.

SU-8 is also of interest as a bonding layer material for wafer bonding processes using patterned bonding layers. *Pan* et al. [7.93] compared several UV photo-definable polymeric materials and found that SU-8 exhibited the highest bonding strength (20.6 MPa) for layer thicknesses up to 100 μm.

7.7.3 Parylene

Parylene (poly-paraxylylene) is another emerging polymeric MEMS material due in large part to its biocompatibility. It is particularly attractive from the fabrication perspective, because it can be deposited by CVD at room temperature. Moreover, the deposition process is conformal, which enables parylene coatings to be applied to prefabricated structures, such as Si microneedles [7.94], low stress silicon nitride membrane particle filters [7.95], and micromachined polyimide/Au optical scanners [7.96]. In the first two cases, the parylene coating served to strengthen the microfabricated structures, while in the last case, it served to protect the structure from condensing water vapor.

In addition to its function as a protective coating, parylene can actually be micromachined into freestanding components. *Noh* et al. [7.97] demonstrated a method to create bulk micromachined parylene microcolumns for miniature gas chromatographs. The structure is fabricated using a micromolding technique by which Si molds are fabricated by DRIE and coated with parylene to form three sides of the microcolumn. A second wafer is coated with parylene, and the two are bonded together via a fusion bonding process. After bonding, the structure is released from the Si mold by KOH etching. In a second example, *Yao* et al. [7.98] describe a dry release process for parylene surface micromachining. In this process, sputtered Si is used as a sacrificial layer onto which a thick sacrificial photoresist is deposited. Parylene is then deposited on the photoresist and patterned into the desired structural shape. The release procedure is a two step process. First, the photoresist is dissolved in acetone. This results in the parylene structure sticking to the sputtered Si. Next, a dry BrF_3 etch is performed, which dissolves the Si and releases the parylene structures. Parylene beams that were 1 mm long and 4.5 μm thick were successfully fabricated using this technique.

7.8 Future Trends

The rapid expansion of MEMS in recent years is due in large part to the inclusion of new materials that have expanded the functionality of microfabricated devices beyond what is achievable in silicon. This trend will certainly continue as new application areas for micro- and nanofabricated devices are identified. Many of these applications will likely require both new materials and new processes to fabricate the micro- and nanomachined devices for these yet to be identified applications. Currently, conventional micromachining techniques employ a top-down approach that begins with either bulk substrates or thin films. Future MEMS and NEMS will likely incorporate materials that are created using a bottom-up approach. A significant challenge facing device design and fabrication engineers alike will be how to marry top-down and bottom-up approaches to create devices and systems that cannot be made using either process alone.

8. MEMS/NEMS Devices and Applications

Microelectromechanical Systems (MEMS) have played key roles in many important areas, for example transportation, communication, automated manufacturing, environmental monitoring, health care, defense systems, and a wide range of consumer products. MEMS are inherently small, thus offering attractive characteristics such as reduced size, weight, and power dissipation and improved speed and precision compared to their macroscopic counterparts. Integrated circuits (IC) fabrication technology has been the primary enabling technology for MEMS besides a few special etching, bonding and assembly techniques. Microfabrication provides a powerful tool for batch processing and miniaturization of electromechanical devices and systems into a dimensional scale, which is not achievable by conventional machining techniques. As IC fabrication technology continues to scale toward deep sub-micron and nano-meter feature sizes, a variety of nanoelectromechanical systems (NEMS) can be envisioned in the foreseeable future. Nano-scale mechanical devices and systems integrated with nanoelectronics will open a vast number of new exploratory research areas in science and engineering. NEMS will most likely serve as an enabling technology merging engineering with the life sciences in ways that are not currently feasible with the micro-scale tools and technologies. MEMS has been applied to a wide range of fields. Over hundreds of micro-devices have been developed for specific applications. It is thus difficult to provide an overview covering every aspect of the topic. In this chapter, key aspects of MEMS technology and application impacts are illustrated through selecting a few demonstrative device examples, which consist of pressure sensors, inertial sensors, optical and wireless communication devices. Microstructure examples with dimensions on the order of sub-micron are presented with fabrication technologies for future NEMS applications. Although MEMS has experienced significant growth over the past decade, many challenges still remain. In broad terms, these challenges can be grouped into three general categories; (1) fabrication challenges, (2) packaging challenges, and (3) application challenges. Challenges in these areas will, in large measure, determine the commercial success of a particular MEMS device both in technical and economic terms. This chapter presents a brief discussion of some of these challenges as well as possible approaches to address them.

References 250

Microelectromechanical systems, generally referred to as MEMS, has had a history of research and development spanning a few decades. Besides the traditional microfabricated sensors and actuators, the field covers micromechanical components and systems integrated or micro-assembled with electronics on the same substrate or package, achieving high performance functional systems. These devices and systems have played key roles in many important areas, such as transportation, communication, automated manufacturing, environmental monitoring, health care, defense systems, and a wide range of consumer products. MEMS are inherently small, thus offering such attractive characteristics as reduced size, weight, and power dissipation, as well as improved speed and precision compared to their macroscopic counterparts. The development of MEMS requires appropriate fabrication technologies that enable the definition of small geometries, precise dimension

control, design flexibility, interfacing with microelectronics, repeatability, reliability, high yield, and low cost. Integrated circuits (IC) fabrication technology meets all of the above criteria and has been the primary enabling fabrication technology for MEMS, besides a few special etching, bonding and assembly techniques. Microfabrication provides a powerful tool for batch processing and miniaturization of electromechanical devices and systems into a dimensional scale, which is not achievable by conventional machining techniques. Most MEMS devices exhibit a length or width ranging from micrometers to several hundreds of micrometers with a thickness from submicrometer up to tens of micrometers, depending upon the fabrication technique employed. A physical displacement of a sensor or an actuator is typically on the same order of magnitude. Figure 8.1 shows an SEM micrograph of a microelectromechanical motor developed in the late 1980s [8.1]. Polycrystalline silicon (polysilicon) surface micromachining technology was used to fabricate the micromotor, achieving a diameter of 150 μm and a minimum vertical feature size on the order of a micrometer. A probe tip is also shown in the micrograph for a size comparison. This device example, and similar others [8.2], demonstrated what MEMS technology could accomplish in microscale machining at the time and served as a strong technology indicator for continued MEMS development. The field has expanded greatly in recent years along with rapid technology advances. Figure 8.2, for example, shows a photo of micro-gears fabricated in the mid-1990s using a five-level polysilicon surface micromachining technology [8.3]. This device represents one of the most advanced surface micromachining fabrication processes developed to date. One can imagine that a wide range of sophisticated microelectromechanical devices and systems can be realized through applying such technology in the future. As IC fabrication technology continues to scale toward deep submicron and nanometer feature sizes, a variety of nanoelectromechanical systems (NEMS) can be envisioned in the near future. Nanoscale mechanical devices and systems integrated with nanoelectronics will open a vast number of new exploratory research areas in science and engineering. NEMS will most likely serve as an enabling technology, merging engineering with the life sciences in ways that are not currently feasible with microscale tools and technologies.

This chapter will provide a general overview of MEMS and NEMS devices and their applications. MEMS technology has been applied to a wide range of fields. Over hundreds of micro-devices have been developed for specific applications. Therefore, it is difficult to provide an overview that covers every aspect of the topic. It is the authors' intent to illustrate key aspects of MEMS technology, and its impact on specific applications by selecting a few demonstrative device examples. For a wide-ranging discussion of nearly all types of micromachined sensors and actuators, books by *Kovacs* [8.4] and *Senturia* [8.5] are recommended.

8.1 MEMS Devices and Applications

MEMS devices have played key roles in many areas of development. Microfabricated sensors, actuators, and electronics are the most critical components in implementing a complete system for a specific function. Microsensors and actuators can be fabricated by various micromachining processing technologies. In this section, a number of selected MEMS devices are presented to illustrate the basic device operating principles, as well as demonstrate key aspects of microfabrication technology and its application impact.

8.1.1 Pressure Sensor

Pressure sensors are one of the early devices realized by silicon micromachining technologies and have become successful commercial products. The devices have been widely used in various industrial and biomedical applications. The sensors can be based on piezoelectric, piezoresistive, capacitive, and resonant sensing mechanisms. Silicon bulk and surface micromachining techniques have been used for sensor batch fabrication, thus achieving size miniaturization and low cost. Two types of pressure sensors – piezoresistive and capacitive – are described here for illustration purposes.

Piezoresistive Sensor

The piezoresistive effect in silicon has been widely used for implementing pressure sensors. A pressure-induced strain deforms the silicon band structure, thus changing the resistivity of the material. The piezoresistive effect is typically crystal-orientation dependent and is also affected by doping and temperature. A practical piezoresistive pressure sensor can be implemented by fabricating four sensing resistors along the edges of a thin silicon diaphragm, which acts as a mechanical amplifier to increase the stress and strain at the sensor site. The four sensing elements are connected in a bridge configuration with push-pull signals to increase the sensitivity. The measurable pressure range for such a sensor can be from 10^{-3} to 10^{6} torr, depending on the design. An example of a piezoresistive pressure sensor is shown in Fig. 8.3. The device consists of a silicon diaphragm suspended over a reference vacuum cavity to form an absolute pressure sensor. An external pressure applied over the diaphragm introduces a stress on the sensing resistors, resulting in a resistance value change corresponding to the pressure. The fabrication sequence is outlined as follows. The piezoresistors are typically first formed through a boron diffusion process, followed by a high temperature annealing step in order to achieve a resistance value on the order of a few kilo-ohms. The wafer is then passivated with a silicon dioxide layer, and contact windows are opened for metallization. At this point, the wafer is patterned on the backside, followed by a timed silicon wet etch to form the diaphragm, typically having a thickness around a few tens of micrometers. The diaphragm can have a length of several hundreds of micrometers. A second silicon wafer is then bonded to the device wafer in a vacuum to form a reference vacuum cavity, thus completing the fabrication process. The second wafer can also be further etched through to form an inlet port, implementing a gauge pressure sensor [8.6]. The piezoresistive sensors are simple to fabricate and can be readily interfaced with electronic systems. However, the resistors are temperature dependent and consume DC power. Long-term characteristic drift and resistor thermal noise ultimately limit the sensor resolution.

Capacitive Sensor

Capacitive pressure sensors are attractive because they are virtually temperature independent and consume zero DC power. The devices do not exhibit initial turn-on drift and are stable over time. Furthermore, CMOS microelectronic circuits can be readily interfaced with the sensors to provide advanced signal conditioning and processing, thus improving overall system performance. An example of a capacitive pressure sensor is shown in Fig. 8.4. The device consists of an edge-clamped silicon diaphragm suspended over a vacuum cavity. The diaphragm can be square or circular with a typical thickness of a few micrometers and a length or radius of a few hundred micrometers, respectively. The vacuum

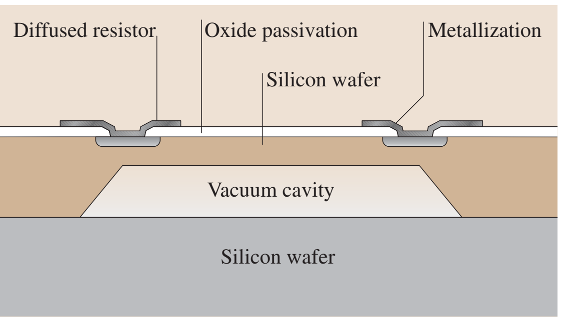

Fig. 8.3 Cross-sectional schematic of a piezoresistive pressure sensor

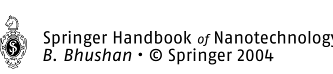

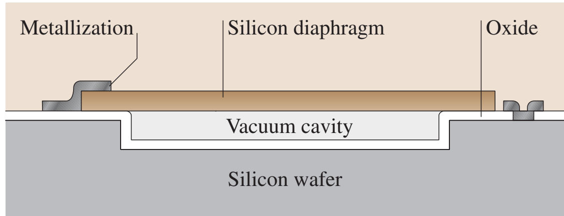

Fig. 8.4 Cross-sectional schematic of a capacitive pressure sensor

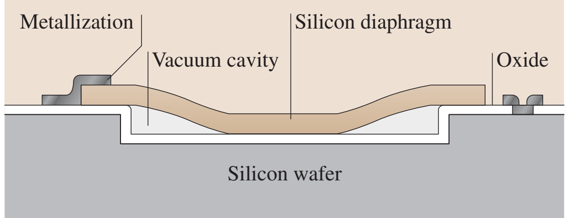

Fig. 8.5 Cross-sectional schematic of a touch-mode capacitive pressure sensor

cavity typically has a depth of a few micrometers. The diaphragm and substrate form a pressure dependent air-gap variable capacitor. An increased external pressure causes the diaphragm to deflect towards the substrate, resulting in an increase in the capacitance value. A simplified fabrication process can be outlined as follows. A silicon wafer is first patterned and etched to form the cavity. The wafer is then oxidized and bonded to a second silicon wafer with a heavily doped boron layer, which defines the diaphragm thickness, at the surface. The bonding process can be performed in a vacuum to realize the vacuum cavity. If the vacuum bonding is not performed at this stage, a low-pressure sealing process can be used to form the vacuum cavity after patterning the sensor diaphragm, provided that sealing channels are available. The silicon substrate above the boron layer is then removed through a wet etching process, followed by patterning to form the sensor diaphragm, which serves as the device top electrode. Contact pads are formed by metallization and patterning. This type of pressure sensor exhibits a nonlinear characteristic and a limited dynamic range. These phenomena, however, can be alleviated by applying an electrostatic-force-balanced feedback architecture. A common practice is to introduce another electrode above the sensing diaphragm through wafer bonding [8.7], forming two capacitors in series, with the diaphragm being the middle electrode. The capacitors are interfaced with electronic circuits, that convert the sensor capacitance value to an output voltage corresponding to the diaphragm position. This voltage is further processed to generate a feedback signal to the top electrode, thereby introducing an electrostatic pull up force to maintain the deflectable diaphragm at its nominal position. This negative feedback loop would substantially minimize the device nonlinearity and also extend the sensor dynamic range.

A capacitive pressure sensor achieving an inherent linear characteristic response and a wide dynamic range can be implemented by employing a touch mode architecture [8.8]. Figure 8.5 shows the cross-sectional view of a touch-mode pressure sensor. The device consists of an edge-clamped silicon diaphragm suspended over a vacuum cavity. The diaphragm deflects under an increasing external pressure and touches the substrate, causing a linear increase in the sensor capacitance value beyond the touch point pressure. Figure 8.6 shows a typical device characteristic curve. The touch point pressure can be designed by engineering the sensor geometric parameters, such as diaphragm size, thickness, cavity depth, etc., for various application requirements. The device can be fabricated using a process flow similar to the flow outlined for the basic capacitive pressure sensor. Figure 8.7 presents a photo of a fabricated touch-mode sensor employing a circular diaphragm with a diameter of 800 μm and a thickness of 5 μm suspended over a 2.5 μm vacuum cavity. The device achieves a touch point pressure of 8 psi and exhibits a linear capacitance range of 33 pF at 10 psi to 40 pF at 32 psi (absolute pressures).

The above processes use bulk silicon materials for machining and are usually referred to as bulk

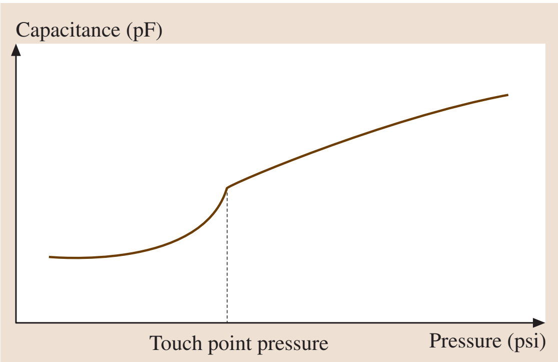

Fig. 8.6 Characteristic response of a touch-mode capacitive pressure

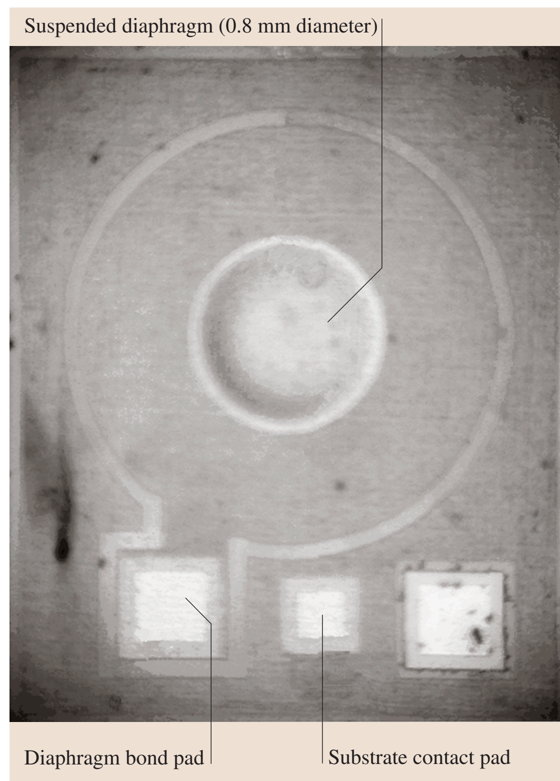

Fig. 8.7 Photo of a touch-mode capacitive pressure sensor [8.12]

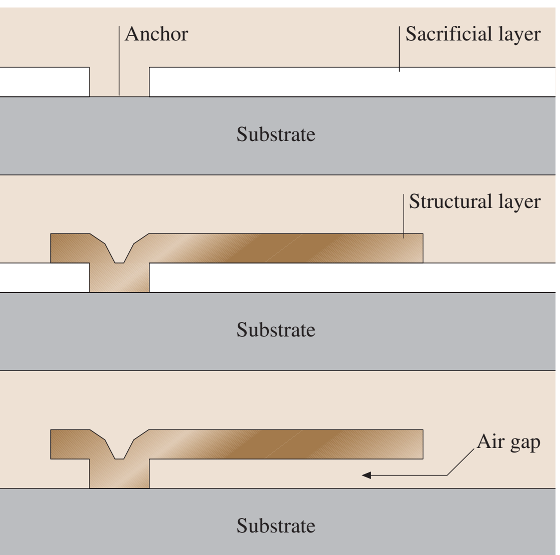

Fig. 8.8 Simplified fabrication sequence of surface micromachining technology

micromachining. The same devices can also be fabricated using so-called surface micromachining. Surface micromachining technology is attractive for integrating MEMS sensors with on-chip electronic circuits. As a result, advanced signal processing capabilities, such as data conversion, offset and noise cancellation, digital calibration, temperature compensation, etc., can be implemented adjacent to microsensors on the same substrate, providing a complete, high performance microsystem solution. The single chip approach also eliminates external wiring, which is critical for minimizing noise pickup and enhancing system performance. Surface micromachining, simply stated, is a method of fabricating MEMS through depositing, patterning, and etching a sequence of thin films with thicknesses on the order of a micrometer. Figure 8.8 illustrates a typical surface micromachining process flow [8.9]. The process starts by depositing a layer of sacrificial material, such as silicon dioxide, over a wafer, followed by anchor formation. A structural layer, typically a polysilicon film, is deposited and patterned. The underlying sacrificial layer is then removed to release the suspended microstructure and complete the fabrication sequence. The processing materials and steps are compatible with the standard integrated circuit process and, thus, can be readily incorporated as an add-on module to an IC process [8.9–11]. A similar surface micromachining technology has been developed to produce monolithic pressure sensor systems [8.12]. Figure 8.9 shows an SEM micrograph of an array of MEMS capacitive pressure sensors fabricated with BiCMOS electronics on the same substrate. Each sensor consists of a 0.8 μm-thick circular polysilicon membrane with a diameter on the order of 20 μm suspended over a 0.3 μm-deep vacuum cavity. The devices operate using the same principle as the sensor shown in Fig. 8.4. A close view of the sensor cross section is shown in Fig. 8.10, which shows the suspended membrane and underneath air gap. These sensors have demonstrated operations in pressure ranges up to 400 bar with an accuracy of 1.5%.

8.1.2 Inertial Sensor

Micromachined inertial sensors consist of accelerometers and gyroscopes. These devices are one of the important types of silicon-based MEMS sensors that have been successfully commercialized. MEMS ac-

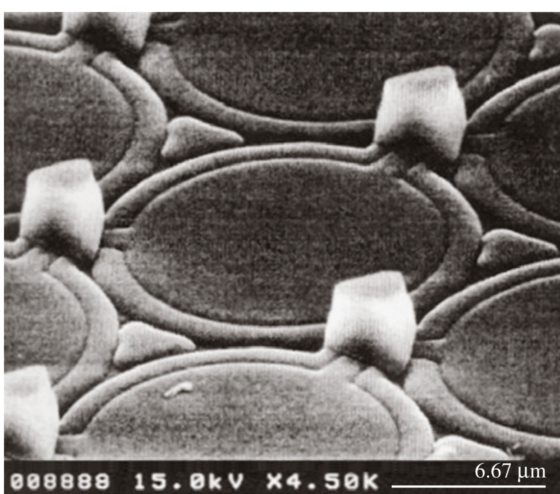

Fig. 8.9 SEM micrograph of polysilicon surface-micromachined capacitive pressure sensors [8.12]

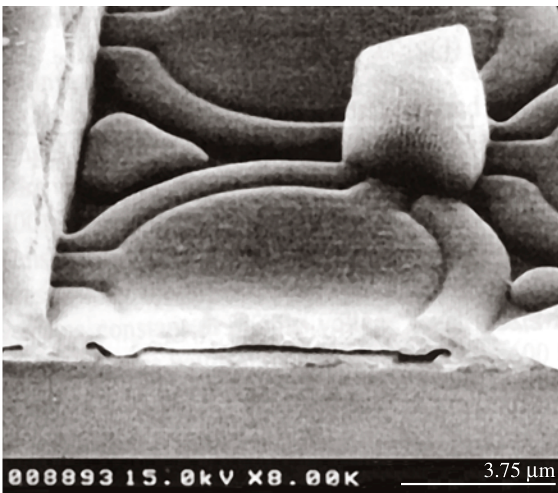

Fig. 8.10 SEM micrograph of a close-up view of a polysilicon surface-micromachined capacitive pressure sensor [8.12]

celerometers alone have the second largest sales volume after pressure sensors. Gyroscopes are expected to reach a comparable sales volume in the foreseeable future. Accelerometers have been used in a wide range of applications, including automotive application for safety systems, active suspension and stability control, biomedical application for activity monitoring, and numerous consumer products, such as head-mount displays, camcorders, three-dimensional mouse, etc. High sensitivity accelerometers are crucial for implementing self-contained navigation and guidance systems. A gyroscope is another type of inertial sensor that measures rate or angle of rotation. The devices can be used along with accelerometers to provide heading information in an inertial navigation system. Gyroscopes are also useful in such applications as automotive ride stabilization and rollover detection, camcorder stabilization, virtual reality, etc. Inertial sensors fabricated by micromachining technology can achieve reduced size, weight, and cost, all which are critical for consumer applications. More importantly, these sensors can be integrated with microelectronic circuits to achieve a functional microsystem with high performance.

Accelerometer

An accelerometer generally consists of a proof mass suspended by compliant mechanical suspensions anchored to a fixed frame. An external acceleration displaces the support frame relative to the proof mass. The displacement can result in an internal stress change in the suspension, which can be detected by piezoresistive sensors as a measure of the external acceleration. The displacement can also be detected as a capacitance change in capacitive accelerometers. Capacitive sensors are attractive for various applications because they exhibit high sensitivity and low temperature dependence, turn-on drift, power dissipation, and noise. The sensors can also be readily integrated with CMOS electronics to perform advanced signal processing for high system performance. Capacitive accelerometers may be divided into two categories: vertical and lateral sensors. Figure 8.11 shows sensor structures for the two versions. In a vertical device, the proof mass is suspended above the substrate electrode by a small gap typically on the order of a micrometer, forming a parallel-plate sense capacitance. The proof mass moves in the direction perpendicular to the substrate (z-axis) upon a vertical input acceleration, thus changing the gap and the capacitance value. The lateral accelerometer consists of a number of movable fingers attached to the proof mass, forming a sense capacitance with an array of fixed parallel fingers. The sensor proof mass moves in a plane parallel to the substrate when subjected to a lateral input acceleration, thus changing the overlap area of these fingers and, hence, the capacitance value. Figure 8.12 shows an SEM top view of a surface micromachined polysilicon z-axis accelerometer [8.13]. The device consists of a $400\,\mu m \times 400\,\mu m$ proof mass with a thickness of $2\,\mu m$ suspended above the substrate electrode by four folded beam suspensions with an air gap around $2\,\mu m$, thus achieving a sense capacitance of approximately 500 fF.

The visible holes are used to ensure complete removal of the sacrificial oxide underneath the proof mass at the end of the fabrication process. The sensor can be interfaced with a microelectronic charge amplifier, converting the capacitance value to an output voltage for further signal processing and analysis. Force feedback architecture can be applied to stabilize the proof mass position. The combs around the periphery of the proof mass can exert an electrostatic levitation force on the proof mass to achieve the position control, thus improving the system frequency response and linearity performance [8.13].

Surface micromachined accelerometers typically suffer from severe mechanical thermal vibration, commonly referred to as Brownian motion [8.14], due to the small proof mass, resulting in a high mechanical noise floor that ultimately limits the sensor resolution. Vacuum packaging can be employed to minimize this adverse effect, but with a penalty of increasing system complexity and cost. Accelerometers using large proof masses fabricated by bulk micromachining, or a combination of surface and bulk micromachining techniques are attractive for circumventing this problem. Figure 8.13 shows an SEM micrograph of an all-silicon z-axis accelerometer fabricated through a single silicon wafer by using a combined surface and bulk micromachining process to obtain a large proof mass with dimensions of approximately $2\,\mathrm{mm} \times 1\,\mathrm{mm} \times 450\,\mu\mathrm{m}$ [8.15]. The large mass suppresses the Brownian motion effect, achieving a high performance with a resolution on the order of several μg.

A surface micromachined lateral accelerometer developed by Analog Devices Inc. is shown in Fig. 8.14. The sensor consists of a center proof mass supported by folded beam suspensions with arrays of attached movable fingers, forming a sense capacitance with the fixed parallel fingers. The device is fabricated using a 6 μm-thick polysilicon structural layer with a small air gap on the order of a micrometer to increase the sensor capacitance value, thus improving the device resolution. Figure 8.15 shows a close-up view of the finger structure for a typical lateral accelerometer. Each movable finger forms differential capacitances with two adjacent fixed fingers. This sensing capacitance configuration is attractive for interfacing with differential electronic detection circuits to suppress common-mode noise and other undesirable signal coupling. Monolithic accelerometers with a three-axis sensing capability integrated with on-chip electronic detection circuits have been realized using surfacing micromachining and CMOS microelectronics fabrication technologies [8.16]. Figure 8.16 shows

a photo of one of these microsystem chips, which has an area of 4 mm × 4 mm. One vertical accelerometer and two lateral accelerometers are placed at the chip center with corresponding detection electronics along the periphery. A z-axis reference device, which is not movable, is used with the vertical sensor for electronic interfacing. The prototype system achieves a sensing resolution on the order of 1 mG with a 100 Hz bandwidth along each axis. The level of performance is adequate for automobile safety activation systems, vehicle stability, active suspension control, and various consumer products.

Gyroscope

Most micromachined gyroscopes employ vibrating mechanical elements to sense rotations. The sensors rely on the energy transfer between two vibration modes of a structure caused by Coriolis acceleration. Figure 8.17 presents a schematic of a z-axis vibratory rate gyroscope. The device consists of an oscillating mass electrostatically driven into resonance along the drive-mode axis using comb fingers. An angular rotation along the vertical axis (z-axis) introduces a Coriolis acceleration, which results in a structure deflection along the sense-mode axis, shown in the figure. The deflection changes the differential sense capacitance value, which can be detected as a measure of input angular rotation. A z-axis vibratory rate gyroscope operating on this principle is fabricated using surface micromachining technology and integrated

together with electronic detection circuits, as illustrated in Fig. 8.18 [8.17]. The micromachined sensor is fabricated using polysilicon structural material with a thickness around 2 µm and occupies an area of 1 mm × 1 mm. The sensor achieves a resolution of approximately $1°/\mathrm{s}/\sqrt{\mathrm{Hz}}$ under a vacuum pressure around 50 mtorr.

A dual-axis gyroscope based on a rotational disk at its resonance can be used to sense angular rotation along two lateral axes (x-axis and y-axis). Figure 8.19 shows a device schematic demonstrating the operating principle. A rotor disk supported by four mechanical suspensions can be driven into angular resonance along the z-axis. An input angular rotation along the x-axis will generate a Coriolis acceleration, causing the disk to rotate along the y-axis and vice versa. This Coriolis acceleration-induced rotation will change the sensor capacitance values between the disk and the different sensing electrodes underneath. The capacitance change can be detected and processed by electronic interface circuits. Angular rotations along the two lateral axes can be measured simultaneously using this device architecture. Figure 8.20 shows a photo of a dual-axis gyroscope fabricated using a 2 µm-thick polysilicon surface micromachining technology [8.18]. As shown in the figure, curved electrostatic drive combs are positioned along the circumference of the rotor dick to drive it into resonance along the vertical axis. The gyroscope exhibits a low random walk of $1°/\sqrt{\mathrm{h}}$ under a vacuum pressure around 60 mtorr. With accelerometers and gyroscopes, each capable of three-axis sensing, a micromachine-based inertial measurement system providing a six-degree-of-freedom sensing capability can be realized. Figure 8.21 presents a photo of such a system containing a dual-axis gyroscope, a z-axis gyroscope, and a three-axis accelerometer chip integrated with microelectronic circuitry. Due to the precision in device layout and fabrication, the system can measure angular rotation and acceleration without the need to align individual sensors.

8.1.3 Optical MEMS

Surface micromachining has served as a key enabling technology to realize microeletromechanical optical devices for various applications ranging from sophisticated visual information displays and fiber-optic telecommunication to bar-code reading. Most of the existing optical systems are implemented using conventional optical components, which suffer from bulky size, high cost, large power consumption, and poor efficiency and reliability issues. MEMS technology is promising for producing miniaturized, reliable, inexpensive

optical components to revolutionize conventional optical systems [8.19]. In this section of the chapter, a few selected MEMS optical devices will be presented to illustrate their impact on the fields of visual display, precision optical platform, and data switching for optical communication.

Visual Display

An early MEMS device successfully used for various display applications is the Texas Instruments Digital Micromirror Device (DMD). The DMD technology can achieve higher performance in terms of resolution, brightness, contrast ratio, and convergence than the conventional cathode ray tube and is critical for digital high definition television applications. A DMD consists of a large array of small mirrors with a typical area of $16\,\mu\text{m} \times 16\,\mu\text{m}$, as illustrated in Fig. 8.22. A probe tip is shown in the figure for a size comparison. Figure 8.23 shows an SEM micrograph of a close-up view of a DMD pixel array [8.20]. Each mirror is capable of rotating by ± 10 degrees, corresponding to either the "on" or "off" position, due to an electrostatic actuation force. Light reflected from any on-mirrors passes through a projection lens and creates images on a large screen. Light from the remaining off-mirrors is reflected away from the projection lens to an absorber. The amount of time during each video frame that a mirror remains in the on-state determines shades of gray, from black for zero on-time to white for a hundred percent on-time. Color can be added by a color wheel or a three-DMD chip setup. The three-DMD chips are used for projecting red, green, and blue colors. Each DMD pixel consists of a mirror connected by a mirror support post to an underlying yoke. The yoke, in turn, is connected by torsion hinges to the support posts, as shown in Fig. 8.24 [8.21]. The support post and hinges are hidden under the mirror to avoid light diffraction and, thus, improve contrast ratio and optical efficiency. There are two gaps on the order of a micrometer, one between the mirror, the underlying hinges and the address electrodes, and a second between the coplanar address electrodes, the hinges and an underlying metal layer from the CMOS static random access memory (SRAM) structure. The yoke is tilted over the second gap by an electrostatic actuation force, thereby rotating the mirror plate. The SRAM determines which angle the mirror needs to be tilted by applying proper actuation voltages to the mirror and address electrodes. The DMD is fabricated using an aluminum-based surface micromachining technology. Three layers of aluminum thin film are deposited and patterned to form the mirror and its suspension system. Polymer material is used as the sacrificial layer and is removed by a plasma etch at the end of the process to freely release the micromirror structure. The micromachining process is compatible with standard CMOS fabrication, allowing the DMD to be monolithically integrated with a mature CMOS address circuit technology, thus achieving high yield and low cost. Figure 8.25 shows an SEM micrograph of a fabricated DMD pixel revealing its cross section after an ion milling. A close-up view of the yoke and hinge support under the mirror is shown in Fig. 8.26.

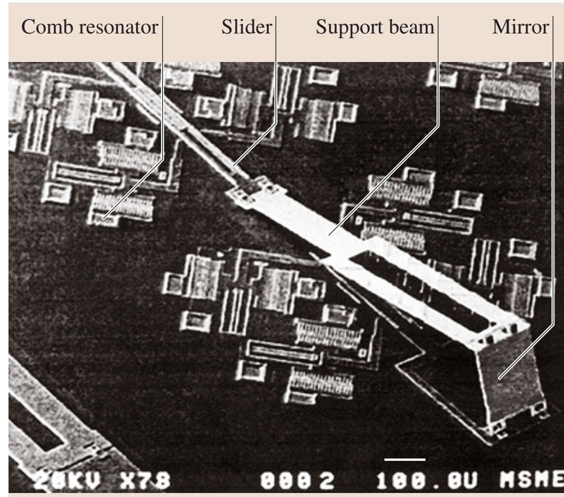
Precision Optical Platform

The growing optical communication and measurement industry requires low cost, high performance optoelectronic modules, such as laser-to-fiber couplers, scanners, interferometers, etc. A precision alignment and the ability to actuate optical components, such as mirrors, gratings, and lenses, with sufficient accuracy are critical for high performance optical applications. Conventional hybrid optical integration approaches, such as the silicon optical bench, suffers from a limited alignment tolerance of $\pm 1\ \mu m$ and also lacks component actuation capability [8.22, 23]. As a result, only simple optical systems can be constructed with no more than a few components, thus severely limiting the performance. Micromachining, however, provides a critical enabling technology, allowing movable optical components to be fabricated on a silicon substrate. High-precision component movement can be achieved through electrostatic actuation. By combining micromachined movable optical components with lasers, lenses, and fibers on the same substrate, an on-chip, complex, self-aligning optical system can be realized. Figure 8.27a shows an SEM micrograph of a surface micromachined, electrostatically actuated microreflector for laser-to-fiber coupling and external cavity laser applications [8.24]. The device consists of a polysilicon mirror plate hinged to a support beam. The mirror and the support, in turn, are hinged to a vibromotor-actuator slider. The micro-hinge technology [8.25] allows the joints to rotate out of the substrate plane to achieve large aspect ratios. Common-mode actuation of the sliders results in a translational motion, while differential slider motion produces an out-of-plane mirror rotation. These motions permit the microreflector to redirect an optical beam in a desirable location. Each of the two slides is actuated with an integrated microvibromotor, shown in Fig. 8.27b. The vibromotor consists of four electrostatic comb resonators with attached impact arms driving a slider through oblique



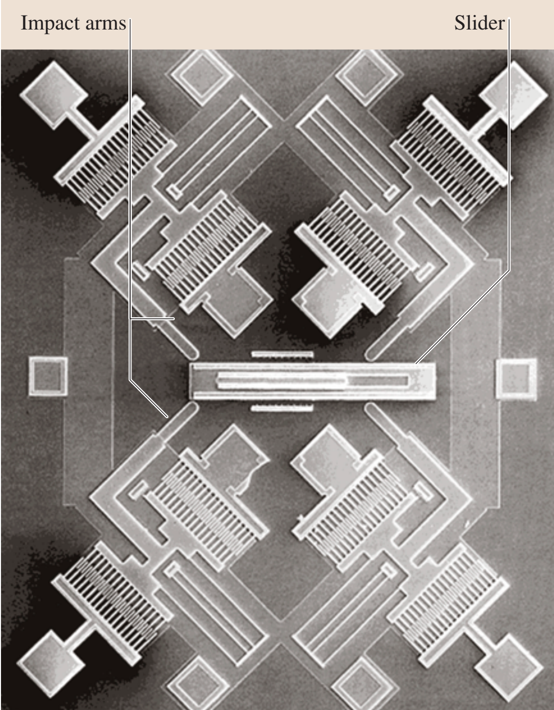


Fig. 8.27 (a) SEM micrograph of a surface-micromachined, electrostatically actuated microreflector; **(b)** SEM micrograph of a surface-micromachined vibromotor [8.24]

impact. The two opposing impacters are used for each travel direction to balance the forces. The resonator is a capacitively driven mass anchored to the substrate through a folded beam flexure. The flexure compliance determines the resonant frequency and travel range of the resonator. When the comb structures are driven at their resonant frequency (around 8 KHz), the slider exhibits a maximum velocity of over 1 mm/s. Characterization of the vibromotor also shows that a slider step resolution of less than 0.3 μm can be achieved [8.26], making it attractive for precision alignment of various optical components. The prototype microreflector can obtain an angular travel range over 90 degrees and a translational travel range of 60 μm. By using this device, beam steering, fiber coupling, and optical scanning have been demonstrated.

Optical Data Switching

High-speed communication infrastructures are highly desirable for transferring and processing real-time voice and video information. Optical fiber communication technology has been identified as the critical backbone to support such systems. A high performance optical data switching network, which routes various optical signals from sources to destinations, is one of the key building blocks for system implementation. At present, optical signal switching is performed by using hybrid optical-electronic-optical (O-E-O) switches. These devices first convert incoming light from input fibers to electrical signals and then route the electrical signals to the proper output ports after signal analyses. At the output ports, the electrical signals are converted back to streams of photons or optical signals for further transmission over the fibers. The O-E-O switches are expensive to build, integrate, and maintain. Furthermore, they consume a substantial amount of power and introduce additional latency. It is, therefore, highly desirable to develop an all-optical switching network in which optical signals can be routed without intermediate conversion into electrical form, thus minimizing power dissipation and system delay. While a number of approaches are being considered for building all-optical switches, MEMS technology is attractive because it can provide arrays of tiny movable mirrors that can redirect incoming beams from input fibers to corresponding output fibers. As described in the previous sections, these micromirrors can be batch fabricated using silicon micromachining technologies, achieving an integrated solution with the potential for low cost. A significant reduction in power dissipation is also expected.

Figure 8.28 shows an architecture of a two-dimensional micromirror array forming a switching matrix with rows of input fibers and columns of output fibers (or vice versa). An optical beam from an input fiber can be directed to an output fiber by activating the cor-

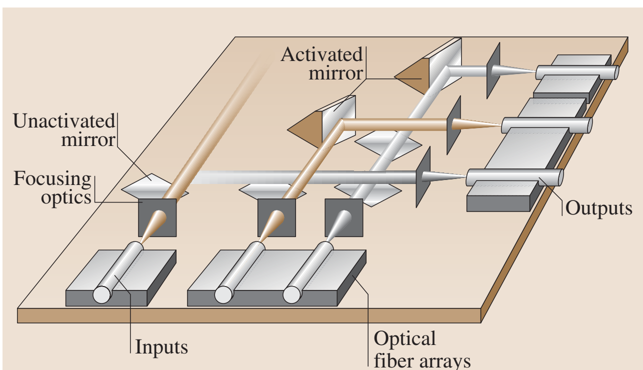

Fig. 8.28 Schematic of a two-dimensional micromirror-based fiber optic switching matrix

responding reflecting micromirror. Switches with eight inputs and eight outputs can be readily implemented using this technique, which can be further extended to a 64×64 matrix. The micromirrors are moved between two fixed stops by digital control, eliminating the need for precision motion control. Figure 8.29 presents an SEM micrograph of a simple 2×2 MEMS fiber optic switching network prototype for an illustration purpose [8.27]. The network includes a mirror chip passively integrated with a silicon submount, which contains optical fibers and ball lenses. The mirror chip consists of four surface-micromachined vertical torsion mirrors. The four mirrors are arranged so that in the "reflection" mode, the input beams are reflected by two 45-degree vertical torsion mirrors and coupled with the output fibers located on the same side of the chip. In the "transmission" mode, the vertical torsion mirrors are rotated out of the optical paths, allowing the input beams to be coupled with the opposing output fibers. Figure 8.30 shows an SEM micrograph of a polysilicon vertical torsion mirror. The device consists of a mirror plate attached to a vertical supporting frame by torsion beams and a vertical back electrode plate. The mirror plate is approximately 200 µm wide, 160 µm long, and 1.5 µm thick. The mirror surface is coated with a thin layer of gold to improve the optical reflectivity. The back plate is used to electrostatically actuate the mirror plate, so that the mirror can be rotated out of the optical path in the "transmission" mode. Surface micromachining with micro-hinge technology is used to realize the overall structure. The back electrode plate is integrated with a scratch drive actuator array [8.28] for self-assembly. The self-assembly approach is critical when multiple vertical torsion mirrors are used to implement more advanced functions.

A more sophisticated optical switching network with a large scaling potential can be implemented by using a three-dimensional (3-D) switching architecture, as shown in Fig. 8.31. The network consists of arrays of two-axis mirrors to steer optical beams from input fibers to output fibers. A precision analog closed-loop mirror position control is required to accurately direct a beam along two angles, so that one input fiber can be optically

connected to any output fiber. The optical length depends little on which sets of fibers are connected, thus achieving a more uniform switching characteristic, which is critical for implementing large scale networks. Two-axis mirrors are the crucial components for implementing the 3-D architecture. Figure 8.32 shows an SEM micrograph of a surface micromachined two-axis beam-steering mirror positioned by using self-assembly technique [8.29]. The self-assembly is accomplished during the final release step of the mirror processing sequence. Mechanical energy is stored in a special high-stress layer during the deposition, which is put on top of the four assembly arms. Immediately after the assembly arms are released, the tensile stress in this layer causes the arms to bend upward, pushing the mirror frame and lifting it above the silicon substrate. All mirrors used in the switching network can be fabricated simultaneously without any human intervention or external power supply.

8.1.4 RF MEMS

The increasing demand for wireless communication applications, such as cellular and cordless telephony, wireless data networks, two-way paging, global positioning systems, etc., feeds a growing interest in building miniaturized wireless transceivers with multi-standard capabilities. Such transceivers will greatly enhance the convenience and accessibility of various wireless services independent of geographic location. Miniaturizing current single-standard transceivers through a high level of integration is a critical step toward building transceivers that are compatible with multiple standards. Highly integrated transceivers will also result in reduced package complexity, power consumption, and cost. At present, most radio transceivers rely on a large number of discrete frequency-selection components, such as radio frequency (RF) and intermediate frequency (IF) band-pass filters, RF voltage-controlled oscillators (VCOs), quartz crystal oscillators, solid-state switches, etc., to perform the necessary analog signal processing. Figure 8.33 shows a schematic of a super-heterodyne radio architecture, in which discrete components are shaded. These off-chip devices occupy the majority of the system area, thus severely hindering transceiver miniaturization. MEMS technology, however, offers a potential solution to integrate these discrete components onto silicon substrates with microelectronics, achieving a size reduction of a few orders of magnitude. It is, therefore, expected to become a technology that will ultimately enable the miniaturization of radio transceivers for future wireless communications.

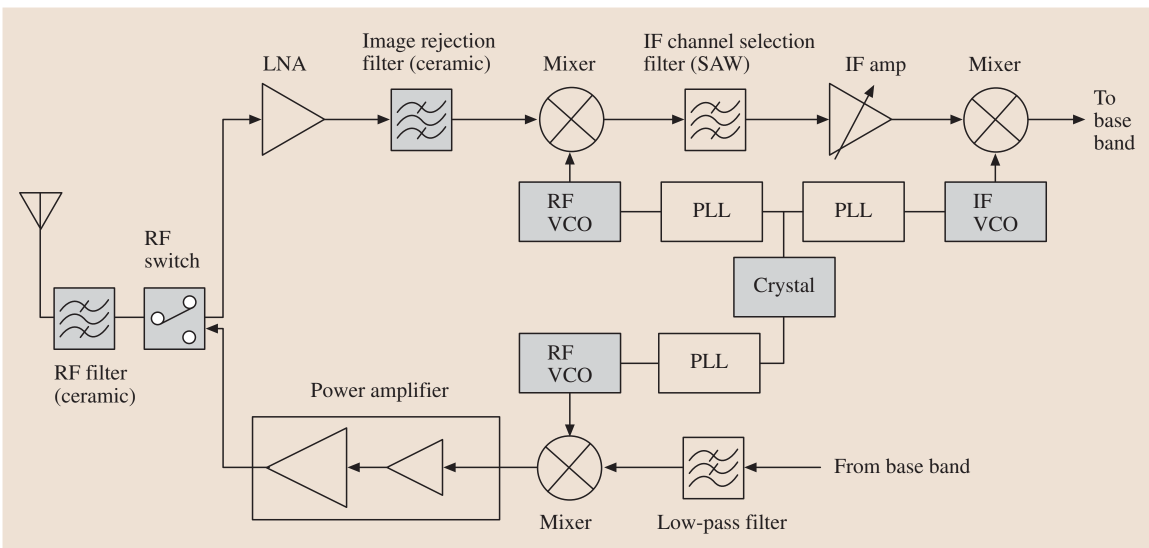

Fig. 8.33 Schematic of a super-heterodyne radio architecture

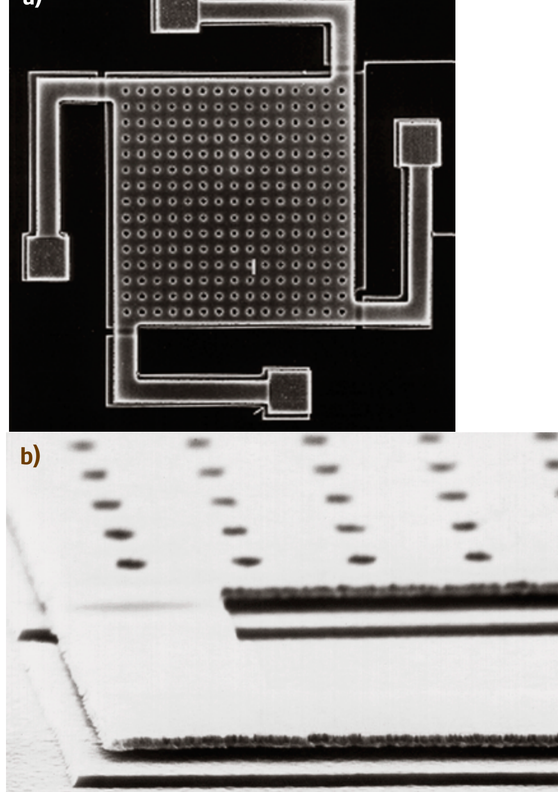
MEMS Variable Capacitors

Integrated high performance variable capacitors are critical for low noise VCOs, antenna tuning, tunable matching networks, etc. Capacitors with high quality factors (Q), large tuning range, and linear characteristics are crucial for achieving system performance requirements. On-chip silicon PN junction and MOS-based variable capacitors suffer from low quality factors (below 10 at 1 GHz), limited tuning range, and poor linearity, and are, therefore, inadequate for building high performance transceivers. MEMS technology has demonstrated monolithic variable capacitors, achieving stringent performance requirements. These devices typically rely on an electrostatic actuation method to vary the air gap between a set of parallel plates [8.30–33], or vary the capacitance area between a set of conductors [8.34], or mechanically displace a dielectric layer in an air-gap capacitor [8.35]. Improved tuning ranges have been achieved with various device configurations. Figure 8.34 shows SEM micrographs of an aluminum micromachined variable capacitor fabricated on a silicon substrate [8.30]. The device consists of a 200 μm × 200 μm aluminum plate with a thickness of



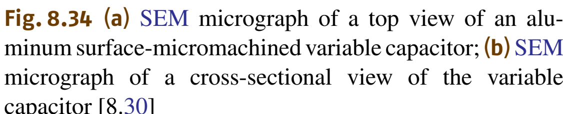


Fig. 8.34 (a) SEM micrograph of a top view of an aluminum surface-micromachined variable capacitor; **(b)** SEM micrograph of a cross-sectional view of the variable capacitor [8.30]

1 μm suspended above the bottom electrode by an air gap of 1.5 μm. Aluminum is selected as the structural material due to its low resistivity, which is critical for achieving a high quality factor at high frequencies. A DC voltage applied across the top and bottom electrodes introduces an electrostatic pull-down force, which pulls the top plate towards the bottom electrode, thus changing the device capacitance value. The capacitors are fabricated using aluminum-based surface micromachining technology. Sputtered aluminum is used for building the capacitor top and bottom electrodes. Photoresist serves as the sacrificial layer, which is then removed through an oxygen-based plasma dry etch to release the microstructure. The processing technology requires a low thermal budget, allowing the variable capacitors to be fabricated on top of wafers with completed electronic circuits without degrading the performance of active devices. Figure 8.35 presents an SEM micrograph of four MEMS tunable capacitors connected in parallel. This device achieves a nominal capacitance value of 2 pF and a tuning range of 15% with 3 V. A quality factor of 62 has been demonstrated at 1 GHz, which matches or exceeds that of discrete varactor diodes and is at least an order of magnitude larger than that of a typical junction capacitor implemented in a standard IC process.

MEMS tunable capacitors, based on the varying capacitance area between a set of conductors, have been demonstrated. Figure 8.36 shows an SEM micrograph of such a device [8.34]. The capacitor is composed of arrays of interdigitated electrodes, which can be electrostatically actuated to vary the electrode overlap area. A close-up view of the electrodes is shown in Fig. 8.37. The capacitor is fabricated using a silicon-on-insulator (SOI) substrate with a top silicon layer thickness of about 20 μm to obtain a high-aspect ratio for the electrodes, which is critical for achieving a large capacitance density and reduced tuning voltage. The silicon layer is etched to form the device structure, followed by the removal of the oxide underneath to release the capacitor. A thin aluminum layer is then sputtered over the capacitor to reduce the series resistive loss. The device exhibits a quality factor of 34 at 500 MHz and can be tuned between 2.48 pF and 5.19 pF with an actuation voltage under 5 V, corresponding to a tuning range of 100%. Figure 8.38 shows the variation of electrode overlap under different tuning voltages.

Tunable capacitors relying on a movable dielectric layer have been fabricated using MEMS technology. Figure 8.39 presents an SEM micrograph of a copper-based micromachined tunable capacitor [8.35]. The device consists of an array of copper top electrodes suspended above a bottom copper plate with an air gap of approximately 1 μm. A thin nitride layer is deposited, patterned, and suspended between the two copper layers by lateral mechanical spring suspensions after sacrificial release. A DC voltage applied across the copper layers introduces a lateral electrostatic pull-in force on the nitride, resulting in a movement that changes the overlapping area between each copper electrode and the bottom plate and, hence, the device capacitance. The

tunable capacitor achieves a quality factor of over 200 at 1 GHz with 1 pF capacitance, due to the highly conductive copper layers, and a tuning range around 8% with 10 V.

Micromachined Inductors

Integrated inductors with high quality factors are as critical as the tunable capacitors for high performance RF system implementation. They are the key components

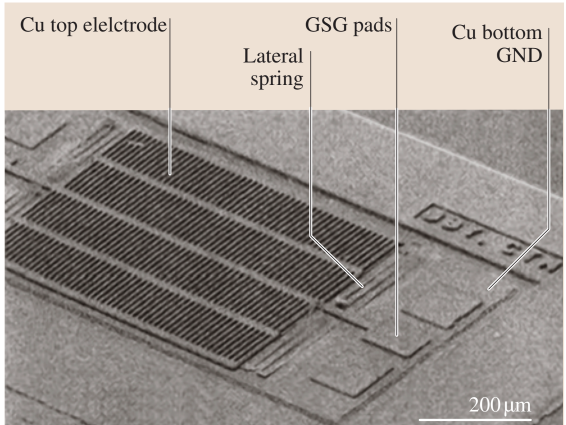

Fig. 8.39 SEM micrograph of a copper surface-micromachined tunable capacitor with a movable dielectric layer [8.35]

for building low noise oscillators, low loss matching networks, etc. Conventional on-chip spiral inductors suffer from limited quality factors of around 5 at 1 GHz, an order of magnitude lower than the required values from discrete counterparts. The poor performance is mainly due to substrate loss and metal resistive loss at high frequencies. Micromachining technology provides an attractive solution to minimizing these loss contributions, hence, enhancing the device quality factors. Figure 8.40 shows an SEM micrograph of a 3-D coil inductor fabricated on a silicon substrate [8.36]. The device consists of four-turn 5 µm-thick copper traces electroplated around an insulating Alumina core with a 650 µm × 500 µm cross section. Compared to spiral inductors, this geometry minimizes the coil area, which is in close proximity to the substrate, and, hence, the eddy-current loss, resulting in a maximized Q-factor and device self-resonant frequency. Copper is selected as the interconnect metal because of its low sheet resistance, critical for achieving a high Q-factor. The inductor achieves a 14 nH inductance value with a quality factor of 16 at 1 GHz. A single-turn 3-D device exhibits a Q-factor of 30 at 1 GHz, which matches the performance of discrete counterparts. The high-Q 3-D inductor and MEMS tunable capacitors, shown in Fig. 8.35, have been employed to implement a RF CMOS VCO achieving a low phase noise performance suitable for typical wireless communication applications, such as GMS cellular telephony [8.37].

Other 3-D inductor structures, such as the levitated spiral inductors, have been demonstrated using micromachining fabrication technology. Figure 8.41 shows an SEM micrograph of a levitated copper inductor,

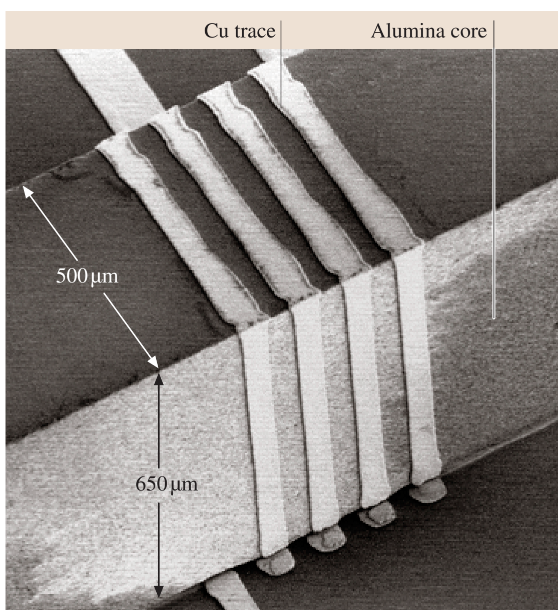

Fig. 8.40 SEM micrograph of a 3-D coil inductor fabricated on a silicon substrate [8.36]

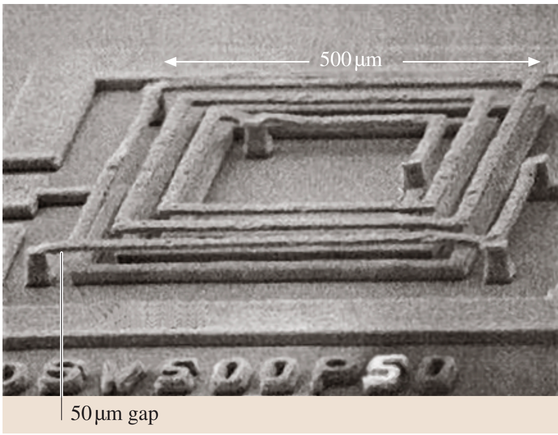

Fig. 8.41 SEM micrograph of a levitated spiral inductor fabricated on a glass substrate [8.38]

which is suspended above the substrate by supporting posts [8.38]. The levitated geometry can minimize the substrate loss, thus achieving an improved quality factor. The inductor shown in the figure achieves a 14 nH inductance value with a Q-factor of 38 at 1.8 GHz using a glass substrate.

A self-assembled out-of-plane coil has been fabricated using micromachining technology. The inductor winding traces are made of refractory metals with controlled built-in stress such that the traces can curl out of the substrate surface upon release and interlock into each other to form coil windings. Figure 8.42 shows an SEM micrograph of a self-assembled out-of-plane coil inductor [8.39]. A close-up view of an interlocking trace is shown in Fig. 8.43. Copper is plated on the interlocked traces to form highly conductive windings at the end of the processing sequence. The inductor shown in Fig. 8.42 achieves a quality factor around 40 at 1 GHz.

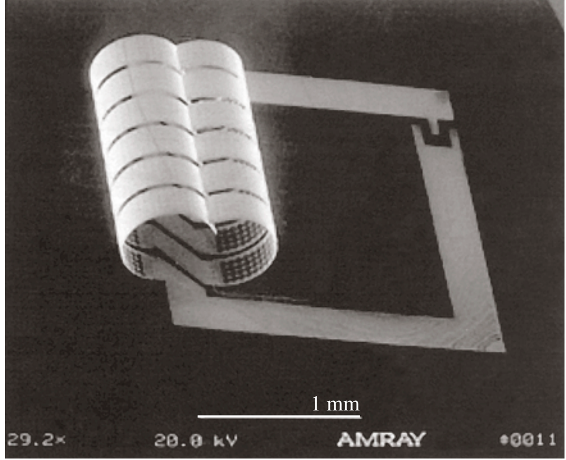

Fig. 8.42 SEM micrograph of a self-assembled out-of-plane coil inductor [8.39]

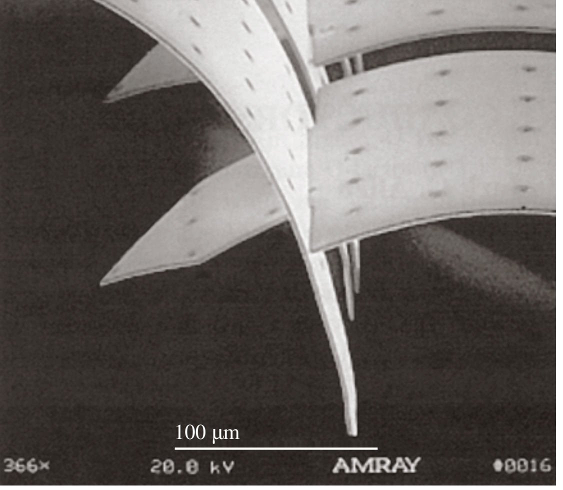

Fig. 8.43 SEM micrograph of an interlocking trace from a self-assembled out-of-plane oil inductor [8.39]

MEMS Switches

The microelectromechanical switch is another potentially attractive miniaturized component enabled by micromachining technologies. These switches offer superior electrical performance in terms of insertion loss, isolation, linearity, etc. and are intended to replace off-chip solid state counterparts, which provide switching between the receiver and transmitter signal paths. They are also critical for building phase shifters, tunable antennas, and filters. The MEMS switches can be broken into two categories: capacitive and metal-to-metal contact types. Figure 8.44 presents a cross-sectional schematic of a RF MEMS capacitive switch. The device consists of a conductive membrane, typically made of aluminum or gold alloy, suspended above a coplanar electrode by an air gap of a few micrometers. For RF or microwave applications, actual metal-to-metal contact is not necessary; rather, a step change in the plate-to-plate capacitance realizes the switching function. A thin silicon nitride layer with a thickness on the order of 1,000 Å is typically deposited above the bottom electrode. When the switch is in the on-state, the membrane is high, resulting in a small plate-to-plate capacitance and, hence, a minimum high-frequency signal coupling (high isolation) between the two electrodes. In the off-state (with a large enough applied DC voltage), the switch provides a large capacitance due to the thin dielectric layer, thus causing a strong signal coupling (low insertion loss). The capacitive switch consumes near zero power, which is attractive for low power portable applications. Switching cycles numbering in the millions for this type of device have been demonstrated. Figure 8.45 shows a top view photo of a fabricated MEMS capacitive switch [8.40]. Surface micromachining technology, using metal for the electrodes and polymer as the sacrificial layer, is used to fabricate the device. The switch can be actuated with a DC voltage on the order of 50 V and exhibits a low insertion loss of approximately −0.28 dB at 35 GHz and a high isolation of −35 dB at the same frequency.

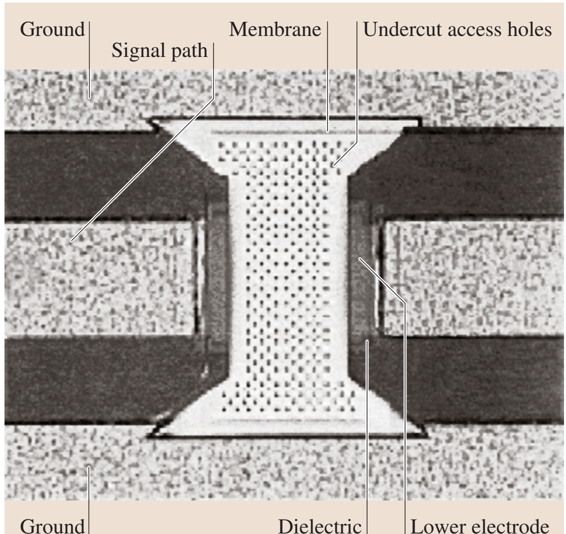

Fig. 8.45 Top view photo of a fabricated RF MEMS capacitive switch [8.40]

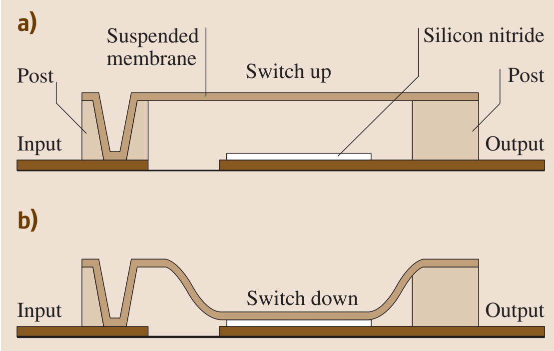

Fig. 8.44 Cross-sectional schematics of an RF MEMS capacitive switch

Metal-to-metal contact switches are important for interfacing large bandwidth signals, including DC. This type of device typically consists of a cantilever beam, or clamped-clamped bridge with a metallic contact pad positioned at the beam tip or underneath the bridge center. Through an electrostatic actuation, a contact can be formed between the suspended contact pad and an underlying electrode on the substrate [8.41–43]. Figure 8.46 shows a cross-sectional schematic of a metal-to-metal contact switch [8.43]. The top view of the fabricated device is presented in Fig. 8.47. The switch exhibits an actuation voltage of 30 V, a response time of 20 μs, and the mechanical strength to withstand 10^9 actuations. An isolation greater than 50 dB below 2 GHz and insertion loss less than 0.2 dB from DC through 40 GHz have been demonstrated.

MEMS Resonators

Microelectromechanical resonators based on polysilicon comb-drive structures, suspended beams, and center-pivoted disk configurations have been demonstrated for performing analog signal processing [8.44–48]. These micro-resonators can be excited into mechanical reso-

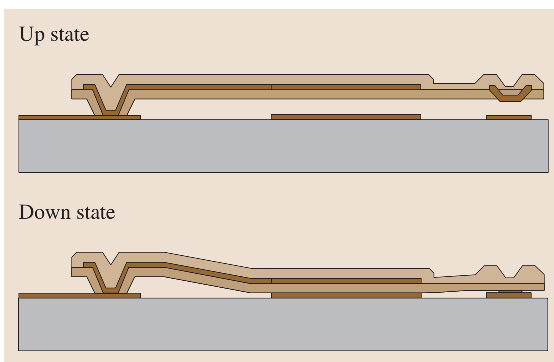

Fig. 8.46 Cross-sectional schematic of a metal-to-metal contact switch [8.43]

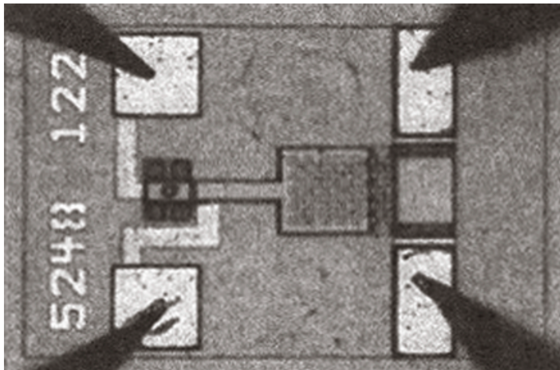

Fig. 8.47 Top view photo of a fabricated metal-to-metal contact switch [8.43]

nance through an electrostatic drive. The mechanical motion causes a change of device capacitance, resulting in an output electrical current when a proper DC bias voltage is used. The output current exhibits the same frequency as the mechanical resonance, thus achieving an electrical filtering function through the electro mechanical coupling. Micromachined polysilicon flexural-mode mechanical resonators have demonstrated a quality factor greater than 80,000 in a 50 µtorr vacuum [8.49]. This level of performance is comparable to a typical quartz crystal and is, therefore, attractive for implementing monolithic low noise and low drift reference signal sources. Figure 8.48 shows an SEM micrograph of a surface micromachined comb-drive resonator integrated with CMOS sustaining electronics on the same substrate to form a monolithic high-Q MEMS resonator-based oscillator [8.44]. The oscillator achieves an operating frequency of 16.5 KHz with a clean spectral purity.

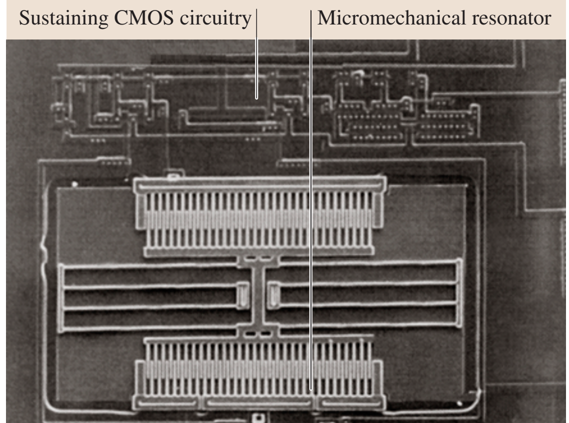

Fig. 8.48 SEM micrograph of a surface micromachined comb drive resonator integrated with CMOS sustaining electronics [8.44]

A chip area of approximately 420 µm × 230 µm is consumed for fabricating the overall system, representing a size reduction by orders of magnitude compared to conventional quartz crystal oscillators.

Micromachined high-Q resonators can be coupled to implement low-loss frequency selection filters. Figure 8.49 shows an SEM micrograph of a surface micromachined polysilicon two-resonator, spring-coupled bandpass micromechanical filter [8.46]. The filter consists of two silicon micromechanical clamped-clamped beam resonators, coupled mechanically by a soft spring, all suspended 0.1 µm above the substrate. Polysilicon strip lines underlie the central regions of each resonator and serve as capacitive transducer electrodes positioned

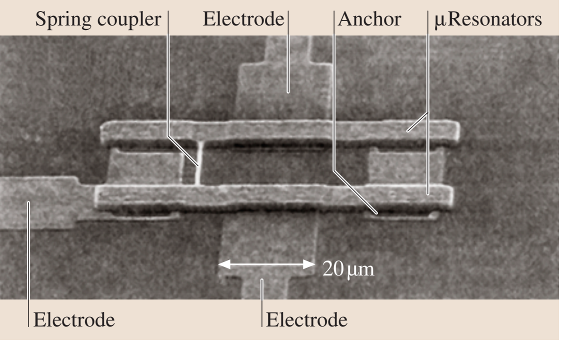

Fig. 8.49 SEM micrograph of a polysilicon surface micromachined two-resonator spring-coupled bandpass micromechanical filter [8.46]

to induce resonator vibration in a direction perpendicular to the substrate. Under normal operation, the device is excited capacitively by a signal voltage applied to the input electrode. The output is taken at the other end of the structure, also by capacitive transduction. The filter achieves a center frequency of 7.81 MHz, a bandwidth of 0.23%, and an insertion loss less than 2 dB. The achieved performance is attractive for implementing filters in the low MHz range.

To obtain a higher mechanical resonant frequency with low losses, a surface micromachined contour-mode disk resonator has been proposed, as shown in Fig. 8.50 [8.48]. The resonator consists of a polysilicon disk suspended 5,000 Å above the substrate with a single anchor at its center. Plated metal input electrodes surround the perimeter of the disk with a narrow separation of around 1,000 Å, which defines the capacitive, electromechanical transducer of the device. To operate the device, a DC bias voltage is applied to the structure with an AC input signal applied to the electrodes, resulting in a time varying electrostatic force acting radially on the disk. When the input signal matches the device resonant frequency, the resulting electrostatic force is amplified by the Q factor of the resonator, resulting in the expansion and contraction of the disk along its radius. This motion, in turn, produces a time varying output current at the same frequency, thus achieving the desirable filtering. The prototype resonator demonstrates an operating frequency of 156 MHz with a Q factor of 9,400 in vacuum. The increased resonant frequency is comparable to the first intermediate frequency used in a typical wireless transceiver design and is thus suitable for implementing IF bandpass filters. A higher operating frequency is needed in order to potentially replace the RF frequency selection filters with microelectromechanical resonators.

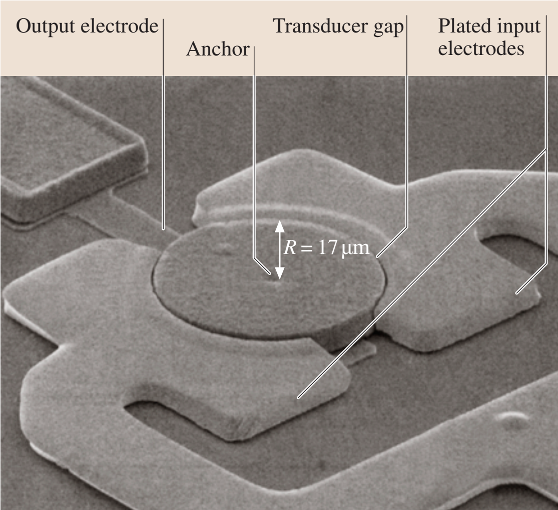

Fig. 8.50 SEM micrograph of a polysilicon surface-micromachined contour-mode disk resonator [8.48]

8.2 NEMS Devices and Applications

Unlike their microscale counterparts, nanoelectromechanical systems (NEMS) are made of electromechanical devices that have critical structural dimensions on the submicron scale. These devices are attractive for applications where structures of very small mass provide essential functionality, such as force sensors, chemical sensors, biological sensors, and ultrahigh frequency resonators, to name a few. NEMS fabrication processes can be categorized according to the two approaches used to create the structures. Top-down approaches utilize submicron lithographic techniques to fabricate device structures from bulk material, either thin films or thick substrates. Bottom-up approaches involve the fabrication of nanoscale devices in much the same way that nature constructs objects, by sequential assembly using atomic and molecular building blocks. While many contend that bottom-up approaches will eventually dominate the fabrication of NEMS, most of the functional NEMS devices are currently created utilizing top-down techniques that combine existing process technologies, such as submicron electron-beam lithography, conventional film growth, and chemical etching. Top-down approaches make integration with microscale packaging relatively straightforward since the only significant difference between the nanoscale and microscale processing steps is the method used to pattern the various features.

In large measure, NEMS has followed a developmental path similar to that of MEMS in that both have leveraged existing processing techniques. For instance, the electron-beam lithographic techniques used in top-down NEMS fabrication are the same techniques that

have become standard in the fabrication of submicron ICs. Furthermore, the materials used in many of the first generation, top-down NEMS devices (Si, GaAs, Si_3N_4, SiC) were first used in ICs and then in MEMS. Like the first MEMS devices, the first generation NEMS structures consist of freestanding nanomechanical beams, paddle oscillators, and tethered plates made using simple bulk and single layer surface "nano" machining processes. As an introduction to this new and exciting class of devices, the following section reviews the development of some of these first generation NEMS devices.

Like Si MEMS, Si NEMS capitalizes on well developed processing techniques for Si and the availability of high quality substrates. *Cleland* et al. [8.50] reported a relatively simple process to fabricate nanomechanical clamped-clamped beams directly from single crystal (100) Si substrates. As illustrated in Fig. 8.51, the process begins with the thermal oxidation of a Si substrate (Fig. 8.51a). Large Ni contact pads were then fabricated using optical lithography and lift-off. A polymethyl methacrylate (PMMA) lift-off mold was then deposited and patterned, using electron-beam lithography, into the shape of nanomechanical beams (Fig. 8.51b). Ni was then deposited and patterned by lifting off the PMMA (Fig. 8.51c). Next, the underlying oxide film was patterned by RIE using the Ni film as an etch mask. After oxide etching, nanomechanical beams were patterned by etching the Si substrate using RIE, as shown in Fig. 8.51d. Following Si RIE, the Ni etch mask was removed, and the sidewalls of the Si nanomechanical beams were lightly oxidized in order to protect them during the release step (Fig. 8.51e). After performing an anisotropic SiO_2 etch to clear any oxide from the field areas, the Si beams were released using an isotropic Si RIE step, as shown in Fig. 8.51f. After release, the protective SiO_2 film was removed by wet etching in HF (Fig. 8.51g). Using this process, the authors reported the successful fabrication of nanomechanical Si beams with micron-scale lengths ($\sim 8\,\mu m$) and submicron widths (330 nm) and heights (800 nm).

The advent of silicon-on-insulator (SOI) substrates with high quality, submicron-thick silicon top layers enables the fabrication of nanomechanical Si beams with fewer processing steps than the aforementioned technique, since the buried oxide layer makes these device structures relatively easy to pattern and release. Additionally, the buried SiO_2 layer electrically isolates the beams from the substrate. *Carr* et al. [8.51] detail a process that uses SOI substrates to fabricate submicron clamped-clamped mechanical beams and

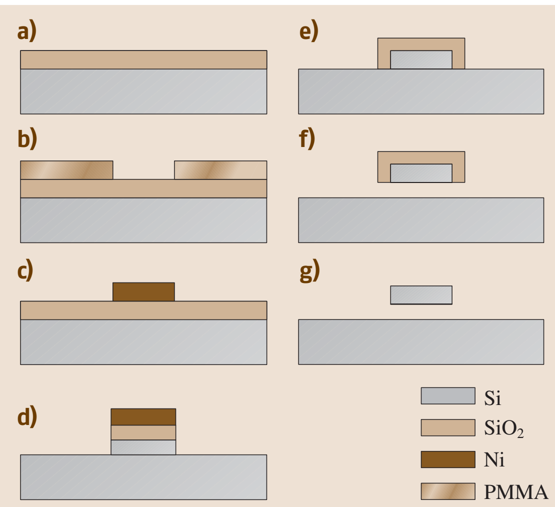

Fig. 8.51a–g Cross-sectional schematics of a process to fabricate nanomechanical beams directly from a silicon substrate: **(a)** after thermal oxidation; **(b)** after PMMA coating and electron beam lithography; **(c)** after Ni deposition and lift-off; **(d)** after anisotropic SiO_2 and Si etching; **(e)** after Ni etching, thermal oxidation, and anisotropic SiO_2 etching; **(f)** after release by isotropic Si etching; **(g)** after oxide removal

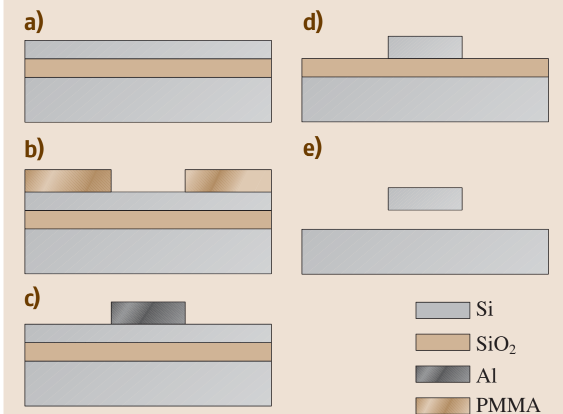

Fig. 8.52a–e Cross-sectional schematics of a process to fabricate nanomechanical structures using silicon-on-insulator substrates: **(a)** starting SOI substrate; **(b)** after coating with PMMA and electron beam lithography; **(c)** after Al deposition and lift-off; **(d)** after anisotropic Si etching; **(e)** after release by SiO_2 etching

suspended plates with submicron tethers. The process, presented in Fig. 8.52, begins with the deposition of PMMA on an SOI substrate. The SOI substrate has a top Si layer that is either 50 nm or 200 nm in thickness. The PMMA is patterned into a metal lift-off mask by electron beam lithography (Fig. 8.52b). An aluminum film is then deposited and patterned by lift-off into a Si etch mask, as shown in Fig. 8.52c. The nanomechanical beams are then patterned by Si RIE and released by etching the underlying SiO_2 in a buffered hydrofluoric acid solution, as shown in Fig. 8.52d and Fig. 8.52e, respectively. Using this process, nanomechanical beams that were 7 to 16 μm in length, 120 to 200 nm in width, and 50 or 200 nm in thickness were successfully fabricated.

Fabrication of NEMS structures is not limited to Si. In fact, III-V compounds, such as gallium arsenide (GaAs), make particularly good NEMS materials from a fabrication perspective because thin epitaxial GaAs films can be grown on lattice-matched materials that can be used as sacrificial release layers. A collection of clamped-clamped nanomechanical GaAs beams fabricated on lattice-matched sacrificial layers having micron-scale lengths and submicron widths and thicknesses is shown in Fig. 8.53. *Tighe* et al. [8.52] reported on the fabrication of GaAs plates suspended with nanomechanical tethers. The structures were made from single crystal GaAs films that were epitaxially grown on aluminum arsenide (AlAs) sacrificial layers. Ni etch masks were fabricated using electron beam lithography and lift-off, as described previously. The GaAs films were patterned into beams using a chemically assisted ion beam etching process and released using a highly selective AlAs etchant. In a second example, *Tang* et al. [8.53] capitalized on the ability to grow high quality GaAs layers on ternary compounds, such as $Al_xGa_{1-x}As$, to fabricate complex GaAs-based structures, such as submicron clamped-clamped beams from GaAs/AlGaAs quantum well heterostructures. As with the process described by *Tighe* et al. [8.52], this process exploits a lattice matched sacrificial layer, in this case $Al_{0.8}Ga_{0.2}As$, which can be selectively etched to release the heterostructure layers.

Several unique approaches have been developed to actuate and sense the motion of NEMS devices. Electrostatic actuation can be used to actuate beams [8.54], tethered meshes [8.55], and paddle oscillators [8.56]. *Sekaric* et al. [8.57] have recently shown that low power lasers can be used to drive paddle oscillators into self-oscillation by induced thermal effects on the structures.

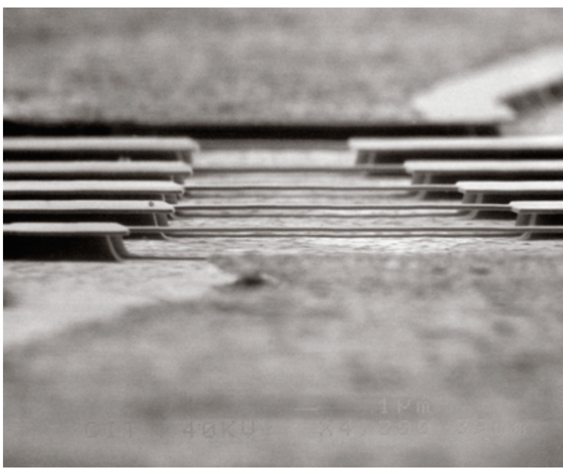

Fig. 8.53 SEM micrograph of a set of nanomechanical GaAs clamped-clamped beam resonators (courtesy of M. Roukes, Caltech)

In these examples, an optical detection scheme based on the modulation of incident laser light by a vibrating beam is used to detect the motion of the beams. *Cleland* et al. [8.50] describe a magnetomotive transduction technique that capitalizes on a time-varying Lorentz force created by an alternating current in the presence of a strong magnetic field. In this case, the nanomechanical beam is positioned in the magnetic field so that an AC current passing through the beam is transverse to the field lines. The resulting Lorentz force causes the beam to oscillate, which creates an electromotive force along the beam that can be detected as a voltage. Thus, in this method, the excitation and detection are performed electrically. In all of the above-mentioned cases, the measurements were performed in vacuum, presumably to minimize the effects of squeeze-film damping, as well as mass loading due to adsorbates from the environment.

For the most part, NEMS technology is still in the initial stage of development. Technological challenges related to fabrication and packaging will require innovative solutions before such devices make a significant commercial impact. Nevertheless, NEMS devices have already been used for precision measurements [8.58], enabling researchers to probe the properties of matter [8.59, 60] on a nanoscopic level. Whether or not NEMS makes an impact in the commercial sector, they will undoubtedly prove to be useful platforms for a host of experiments and scientific discoveries in fields ranging from physics to biology.

8.3 Current Challenges and Future Trends

Although the field of MEMS has experienced significant growth over the past decade, many challenges still remain. In broad terms, these challenges can be grouped into three general categories: (1) fabrication, (2) packaging, and (3) application. Challenges in these areas will, in large measure, determine the commercial success of a particular MEMS device, both in technical and economic terms. The following presents a brief discussion of some of these challenges, as well as possible approaches to address them.

In terms of fabrication, MEMS is currently dominated by planar processing techniques, which find their roots in silicon IC fabrication. The planar approach and the strong dependence on silicon worked well in the early years, since many of the processing tools and methodologies that are commonplace in IC fabrication could be directly utilized in the fabrication of MEMS devices. This approach lends itself to the integration of MEMS with silicon ICs. Therefore, it is still popular for various applications. However, modular process integration of micromachining with standard IC fabrication is not straightforward and represents a great challenge in terms of processing material compatibility, thermal budget requirements, etc. Furthermore, planar processing places significant geometric restrictions on device designs, especially for complex mechanical components requiring high-aspect ratio three-dimensional geometries, which are certain to increase as the application areas for MEMS continue to grow. Along the same lines, new applications will likely demand materials other than silicon that may not be compatible with the conventional microfabrication approach, posing a significant challenge if integration with silicon microelectronics is required. Micro-assembly technique can become an attractive solution to alleviate these issues. Multifunctional microsystems can be implemented by assembling various MEMS devices and electronic building blocks fabricated through disparate processing technologies. Microsystem on a common substrate will likely become the ultimate solution. Development of sophisticated modeling programs for device design and performance will become increasingly important as fabrication processes and device designs become more complex. In terms of NEMS, the most significant challenge is likely the integration of nano- and microfabrication techniques into a unified process, since NEMS devices are likely to consist of both nanoscale and microscale structures. Integration will be particularly challenging for nanoscale devices fabricated using a bottom-up approach, since no analog is found in microfabrication. Nevertheless, hybrid systems consisting of nanoscale and microscale components will become increasingly common as the field continues to expand.

Fabrication issues notwithstanding, packaging is and will continue to be a significant challenge to the implementation of MEMS. MEMS is unlike IC packaging, which benefits from a high degree of standardization. MEMS devices inherently require interaction with the environment, and since each application has in some way a unique environment, standardization of packaging becomes extremely difficult. This lack of standardization tends to drive up the costs associated with packaging, making MEMS less competitive with alternative approaches. In addition, packaging tends to negate the effects of miniaturization based upon microfabrication, especially for MEMS devices requiring protection from certain environmental conditions. Moreover, packaging can cause performance degradation of MEMS devices, especially in situations where the environment exerts mechanical stresses on the package, which, in turn, results in a long-term device performance drift. To address many of these issues, wafer-level packaging schemes that are customized to the device of interest will likely become more common. In essence, packaging of MEMS will move away from the conventional IC methods, which utilize independently manufactured packages, toward custom packages, which are created specifically for the device as part of the batch fabrication process.

Without question, the advancement of MEMS will open many new potential application areas to the technology. In most cases, MEMS will be one of several alternatives available for implementation. For cost-sensitive applications, the trade off between technical capabilities and cost will challenge those who desire to commercialize the technology. The biggest challenge to the field will be to identify application areas that are well suited for MEMS/NEMS technology and have no serious challengers. As MEMS technology moves away from the component level and towards microsystems solutions, it is likely that such application areas will come to the fore.

9. Microfluidics and Their Applications to Lab-on-a-Chip

Various microfluidic components and their characteristics, along with the demonstration of two recent achievements of lab-on-a-chip systems have been reviewed and discussed. Many microfluidic devices and components have been developed during the past few decades, as introduced earlier for various applications. The design and development of microfluidic devices still depend on the specific purposes of the devices (actuation or sensing) due to a wide variety of application areas, which encourages researchers to develop novel, purpose-specific microfluidic devices and systems. Microfluidics is the real multidisciplinary research field that requires basic knowledge in fluidics, micromachining, electromagnetics, materials, and chemistry for better applications.

Among the various application areas of microfluidics, one of the most important application areas is the lab-on-a-chip system. Lab-on-a-chip is becoming a revolutionary tool for many different applications in chemical and biological analyses due to its fascinating advantages (fast and low cost) over conventional chemical or biological laboratories. Furthermore, the simplicity of lab-on-a-chip systems will enable self-testing capability for patients or health consumers overcoming space limitation.

Microfluidics covers the science of fluidic behaviors on the micro/nanoscales and the engineering of design, simulation, and fabrication of the fluidic devices for the transport, delivery, and handling of fluids on the order of microliters or smaller volumes. It is the backbone of the BioMEMS (Biological or Biomedical Microelectromechanical Systems) and lab-on-a-chip concept, as most biological analyses involve fluid transport and reaction. Biological or chemical reactions on the micro/nanoscale are usually rapid since small amounts of samples and reagents are used, which offers a quick and low cost analysis.

A fluidic volume of 1 nanoliter (1 nl) can be understood as the volume in a cube surrounded by 100 μm in each direction. It is much smaller than the size of a grain of table salt! Microfluidic devices and systems handle sample fluids in this range for various applications, including inkjet printing, blood analysis, biochemical detection, chemical synthesis, drug screening/delivery, protein analysis, DNA sequencing, and so on.

Microfluidic systems consist of microfluidic platforms or devices for fluidic sampling, control, monitoring, transport, mixing, reaction, incubation, and analysis. To construct microfluidic systems, or lab-on-a-chips, microfluidic devices must be functionally integrated on a microfluidic platform using proper micro/nano fabrication techniques. In this chapter, the basics of microfluidicdevices and their applications to

lab-on-a-chip are briefly reviewed and summarized. Basic materials and fabrication techniques for microfluidic devices will be introducedfirst and various active and passive microfluidic components will be described. Then, their applications to lab-on-a-chip, or biochemical analysis, will be discussed.

9.1 Materials for Microfluidic Devices and Micro/Nano Fabrication Techniques

Various materials are being used for the fabrication of microfluidic devices and systems. Silicon is one of the most popular materials in micro/nano fabrication because its micromachining has been well established over decades. In general, the advantages to using silicon as a substrate or structural material include good mechanical properties, excellent chemical resistance, well characterized processing techniques, and the capability for integration of control/sensing circuitry as a semiconductor. Other materials such as glass, quartz, ceramics, metals, and polymers are also being used for substrates and structures in micro/nano fabrication, depending on the application. Among these materials, polymers or plastics have recently become one of the more promising materials for lab-on-a-chip applications, due to their excellent material properties for biochemical fluids and their low cost manufacturability. Main issues in the fabrication techniques of microfluidic devices and systems usually lie in forming microfluidic channels, key micro/nano structures of lab-on-a-chip. In this section, the basic micro/nano fabrication techniques for silicon, glass, and polymers are described.

9.1.1 Silicon

Microfluidic channels on silicon substrates are usually formed either by wet (chemical) etching or by dry (plasma) etching. Crystalline silicon has a preferential etch direction, depending on which crystalline plane is exposed to an etchant. Etch rate is slowest in ⟨111⟩ crystalline direction – approximately 100:1 etch rate anisotropy compared with ⟨100⟩:⟨111⟩ or ⟨110⟩:⟨111⟩. Potassium hydroxide (KOH), tetra-methyl ammonium hydroxide (TMAH), and ethylene diamine pyrocatechol (EDP) are commonly used silicon anisotropic etchants. In most cases, silicon dioxide (SiO_2) or silicon nitride (Si_3N_4) is used as a masking material during the etching process. Anisotropic etchants and basic etching mechanisms are summarized by *Ristic* et al. [9.1]. There is also an isotropic wet etching process available using a mixture of fluoric acid (HF), nitric acid (HNO_3), and acetic acid (CH_3COOH), so-called "HNA". HNA etches in all directions with almost the same etch rate regardless of crystalline directions. Figure 9.1 illustrates wet anisotropic and isotropic etching profiles.

Reactive ion etching (RIE) is also one of the most commonly used dry etching processes to generate microfluidic channels or deep trench structures on silicon substrate. In this dry etching technique, radio frequency (RF) energy is used to excite ions in a gas to an energetic state. The energized ions supply the necessary energy to generate physical and chemical reactions on the exposed area of the substrate, which starts the etching process. RIE can generate strong anisotropic, as well as isotropic profiles, depending on the gases used, the condition of plasma, and the applied power. Further information on reactive ion etching process, including deep reactive ion etching (DRIE), on silicon substrate can be found in the literature [9.2–5].

Many microfluidic devices were realized using silicon as a substrate material, including microvalves and micropumps, which are covered in the next section.

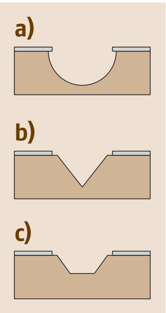

Fig. 9.1a–c Wet etching of silicon substrate for anisotropic and isotropic etching: **(a)** isotropic etching profile, **(b)** anisotropic etching profile (long term), and **(c)** anisotropic etching profile (short term)

9.1.2 Glass

Glass substrate has been widely used for the fabrication of microfluidic systems and lab-on-a-chip due to its ex-

cellent optical transparency and ease of electro-osmotic flow (EOF). Chemical wet etching and thermal fusion bonding are the common fabrication techniques for glass substrate. Chemical wet etching and the bonding technique have also been widely reported [9.6, 7]. Most commonly used etchants are hydrofluoric acid (HF), buffered hydrofluoric acid, and a mixture of hydrofluoric acid, nitric acid, and deionized water (HF, HNO_3, H_2O). Gold with an adhesion layer of chrome is most often used as etch mask for wet etching of glass substrate. Since glass has no crystalline structure, only isotropic etch profiles are obtained as forming a hemispherical-shaped channel. Often the problem is that stresses within the surface layers of the glass cause preferential etching, and scratches created by polishing or handling errors cause spikes etched in the channels. Pre-etching is one method to release stress, which causes defects in channels after etching. Another way to improve the channel etching process is to anneal the glass wafers before etching. Annealing can be done nearly at glass transition temperature for at least a couple of hours. Figure 9.2 shows two examples of poorly etched channels without the pre-etching and annealing steps compared with an etched channel without defects. Other fabrication techniques for glass substrate include photoimageable glass, as *Dietrich* et al. [9.8] reported. Anisotropy is introduced in glass by making the glass photosensitive using lithium/aluminium/silicates composition.

One of the most successful examples of using glass as a substrate material in lab-on-a-chip applications is the capillary electrophoresis (CE) chip, fabricated using the glass etching and fusion bonding technique, since the most advantageous property of glass is an excellent optical transparency that is required for the most lab-on-a-chip using optical detection including capillary electrophoresis microchips [9.6, 7, 9].

9.1.3 Polymer

Among several substrates available for lab-on-a-chip, polymers, or plastics, have recently become one of the most popular and promising substrates due to their low cost, ease-of-fabrication, and favorable biochemical reliability and compatibility. Plastic substrates, such as polyimide, PMMA, PDMS, polyethylene or polycarbonate, offer a wide range of physical and chemical material parameters for the applications of lab-on-a-chip, generally at low cost using replication approaches. Polymers and plastics are promising materials in microfluidic and lab-on-a-chip applications because they can be used for mass production using casting, hot embossing, and injection molding techniques. This mass production capability allows the successful commercialization of lab-on-a-chip technology, including disposable lab-on-a-chip. While several fabrication methods have recently been developed, three fabrication techniques – casting, hot embossing, and injection molding – are major techniques of great interest. Figure 9.3 shows schematic illustrations of these polymer microfabrication techniques.

For polymer or plastic micro/nano fabrication, a mold master is essential for replication. Mold masters are fabricated using photolithography, silicon/glass bulk etching, and metal electroplating, depending on the application. Figure 9.4 summarizes mold masters from different fabrication techniques.

Photolithography, including UV-LIGA [9.10, 11] and LIGA [9.12], is used to fabricate mold masters for casting or soft lithography replication, while silicon-based and electroplated mold masters are used for hot embossing replication. For injection molding, electroplated metallic mold masters are preferable.

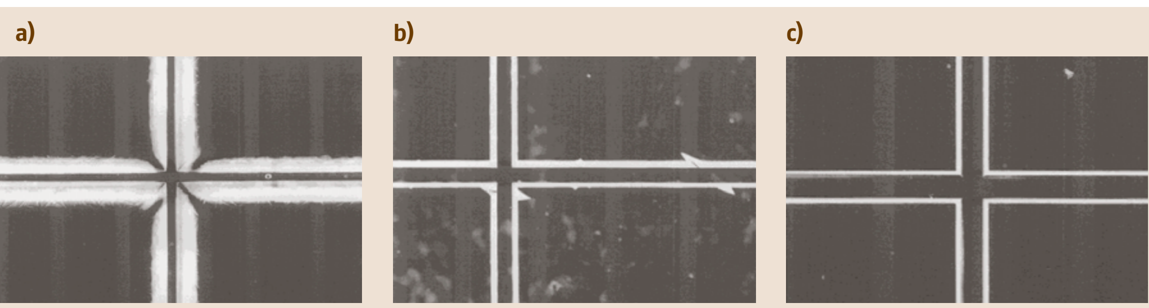

Fig. 9.2a–c Isotropically etched microfluidic channels on glass substrate: **(a)** poorly etched channel with large under etching, **(b)** poorly etched channel with spikes, and **(c)** well etched channel without any defects

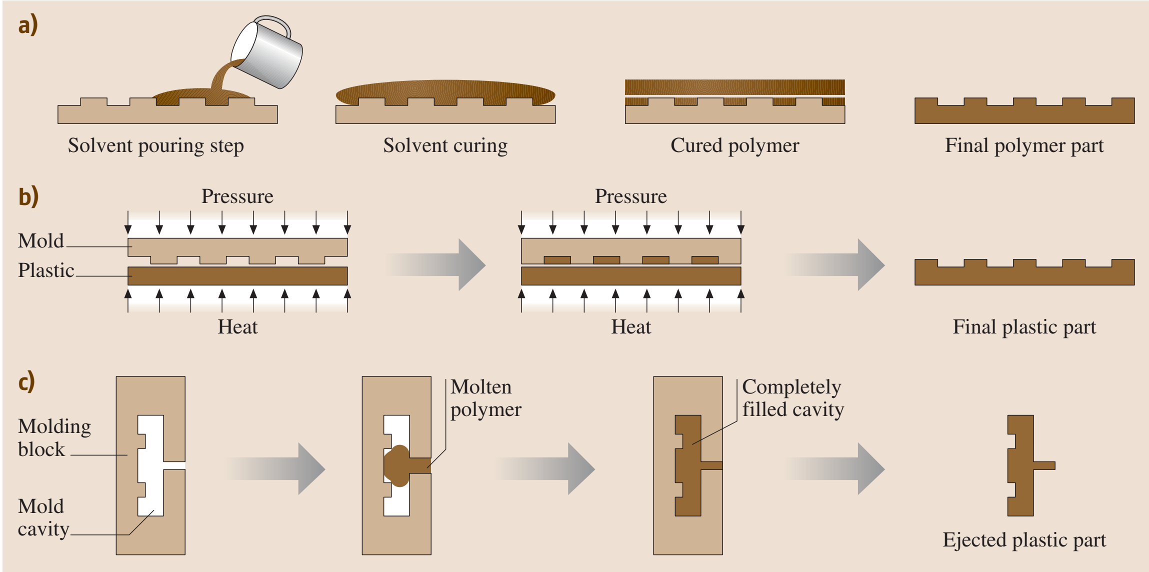

Fig. 9.3a–c Concept of polymer micro/nano fabrication techniques: **(a)** casting, **(b)** hot embossing, and **(c)** injection molding

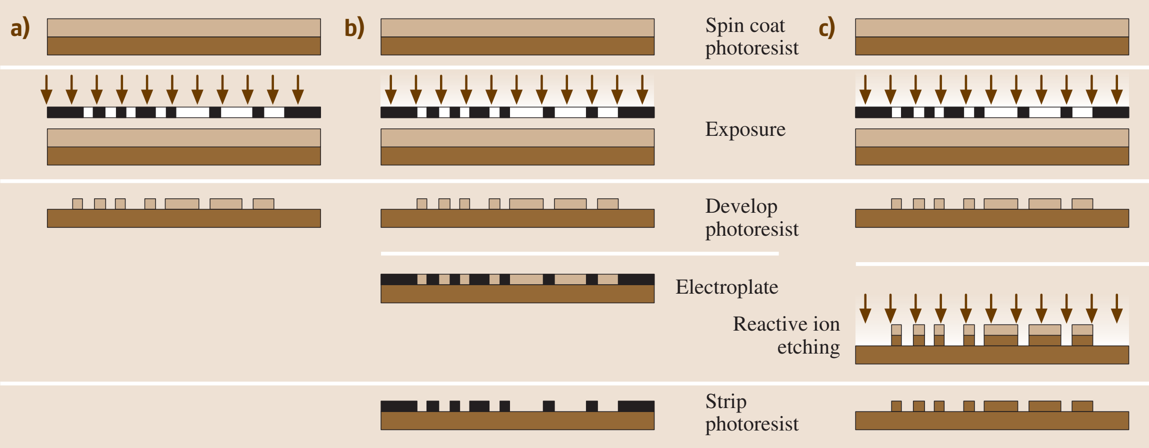

Fig. 9.4a–c Mold masters in polymer/plastic fabrication: **(a)** photolithography-based mold master, **(b)** silicon-based mold master, and **(c)** mold master by electroplating

Casting or soft lithography [9.13, 14] usually offers flexible access to microfluidic structures using mostly poly(dimethylsiloxane) (PDMS) as a casting material. A mixture of the elastomer precursor and curing agent is poured over a master mold structure. After curing, the replicated elastomer is released from the mold master, having transferred a reverse structure of the mold master. Patterns of a few nm can be achieved using this technique.

While casting can be carried out in room temperature, hot embossing requires a slightly higher temperature – up to glass transition temperature of the plastic substrate to be replicated. The hot embossing technique has been developed by several research groups [9.15–17]. A mold master is placed in the chamber

Table 9.1 Overview of the different polymer micro/nano fabrication techniques

Fabrication type	Casting	Hot embossing	Injection molding
Investment	Low	Moderate	High
Manufacturability	Low	Moderate	High
Cycle time	8–10 hrs	1 hr	1 min
Polymer choices	Low	Moderate	Moderate
Mold replication	Good	Good	Good
Reusability of mold	No (photolithography-based molds)	Yes	Yes

of a hot embossing system with the plastic substrate, then heated plates press both the plastic substrate and the mold master, as illustrated in Fig. 9.3b. After a certain amount of time (typically 5–20 minutes, depending on the plastic substrate), the plates are cooled down to release the replicated plastic substrate. Hot embossing offers mass production of polymer microstructures, as its cycle time is less than an hour.

Injection molding is a technique to fabricate polymer microstructures at low cost and high volumes [9.18]. A micromachined mold master is placed in the molding block of the injection molding machine, as illustrated in Fig. 9.3c. The plastic in granular form is melted and then injected into the cavity of a closed mold block, where the mold master is located. The molten plastic continues to flow into and fill the mold cavity until the plastic cools down to a highly viscous melt, and a cooled plastic part is ejected. In order to ensure good flow properties during the injection molding process, thermoplastics with low or medium viscosity are desirable. So the filling of the mold cavity, and, subsequently, the microstructures depend on the viscosity of the plastic melt, injection speed, molding block temperature, and nozzle temperature of the injection unit. This technique allows very rapid replication and high volume mass production. Typical cycle time is several seconds for most applications. However, due to high shear force on the mold master inside of the mold cavity during injection molding, metallic mold masters are highly recommended. Polymethylmethacrylate (PMMA), polyethylene (PE), polystyrene (PS), polycarbonate (PC), and cyclic olefin copolymers (COC) are common polymer/plastic materials for both hot embossing and injection mold replication.

All of these polymer/plastic replication techniques are summarized in Table 9.1. Since each technique differs from the others, fabrication techniques and materials have to be selected according to the application.

9.2 Active Microfluidic Devices

Microfluidics devices are essential for the development of lab-on-a-chip or μTAS (Micro-Total Analysis Systems). A number of different microfluidic devices have been developed with basic structures analogous to the macroscale fluidic devices. Such devices include microfluidic valves, microfluidic pumps, microfluidic mixers, etc. The devices listed above have been developed both as active and passive devices. While passive microfluidic devices are generally easy to fabricate, they do not offer the same functional diversity that the active microfluidic devices provide. For example, passive microvalves based on surface tension effect [9.19] can operate a few times to hold the liquid, which is acceptable for a disposable format. Once the air-liquid interface passes over the valve mechanism, the operation characteristics of the valve will differ, due to the change of surface energy over the channel. Similarly, passive check valves [9.20–22] are dependent on the pressure of the fluid for operation. Since the active microvalves can be triggered on/off depending on an external signal regardless of the fluid system status, there have been considerable research efforts to develop active mi-

crofluidic devices. However, the active devices usually require its expense as desired functional and fabrication complexity.

This section reviews some of the active microfluidic devices, such as microvalves, micropumps, and active microfluidic mixers. Passive counterparts of these microfluidic devices will be discussed in the next section.

9.2.1 Microvalves

Active microvalves have been an area of intense research over the past decade, and a number of novel design and actuation schemes have been developed. This makes the categorization of active microvalves a confusing enterprise. Classification schemes for active microvalves include:

1. Fluidics handled – liquid/gas/liquid and gas
2. Materials used for the structure – silicon/polysilicon/glass/polymer
3. Actuation mechanisms – electrostatic/pneumatic/thermopneumatic, etc.
4. Physical actuating microstructures – membrane type, flap type, ball valve, etc.

All of the classification schemes listed above are valid, but the most commonly used method [9.23, 24] is the classification based on the actuation mechanisms.

In this section, the various microvalves are discussed in terms of their actuation mechanisms and their relevance to the valve mechanism, as well as fluid handled and special design criteria.

Pneumatically/Thermopneumatically Actuated Microvalves

Pneumatic actuation uses an external air line (or pneumatic source) to actuate a flexible diaphragm. Pneumatic actuation offers such attractive features as high force, high displacement, and rapid response time. Figure 9.5 illustrates a schematic concept of pneumatically actuated microvalves. *Schomburg* et al. [9.25] demonstrated pneumatically actuated microvalves.

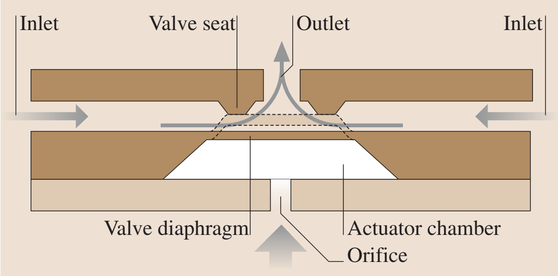

Fig. 9.5 Schematic concept of pneumatically actuated microvalve

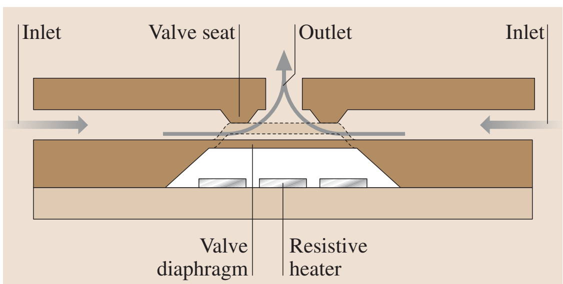

Fig. 9.6 Schematic concept of thermopneumatically actuated microvalve

Pneumatically actuated microvalves have also been demonstrated using polymeric substrate. *Hosokawa* et al. [9.26] demonstrated a pneumatically actuated three-way microvalve system using a PDMS platform. The microfluidic lines and the pneumatic lines are fabricated on separate layers.

Thermopneumatic actuation is typically performed by heating a fluid (usually gas) in a confined cavity, as illustrated in Fig. 9.6. The increase in temperature leads to a rise in pressure of the gas, and this pressure is used for deflecting a membrane for valve operation. Thermopneumatic actuation is an inherently slow technique but offers very high forces when compared to other techniques [9.23]. Thermopneumatically actuated microvalves have been realized by many researchers using various substrates and diaphragm materials [9.27–29].

Electrostatically Actuated Microvalves

Electrostatic actuation has been widely explored for a number of applications, including pressure sensors, comb drives, active mirror arrays, etc. Electrostatically actuated devices typically have a fairly simple structure and are easy to fabricate. A number of fabrication issues, such as stiction and release problems of membranes and valve flaps, need to be addressed for realizing practical electrostatic microvalves. *Sato* et al. [9.30] have developed a novel membrane design in which the deflection "propagates" through the membrane, rather than deforming it entirely. Figure 9.7 shows a schematic sketch of the actuation mechanism and valve design. The use of this "S-shaped" design allows them to have relatively large gaps across the two surfaces, as the electrostatic force must only be concentrated at the edges of the S-shape where the membrane is deflected. *Robertson* et al.

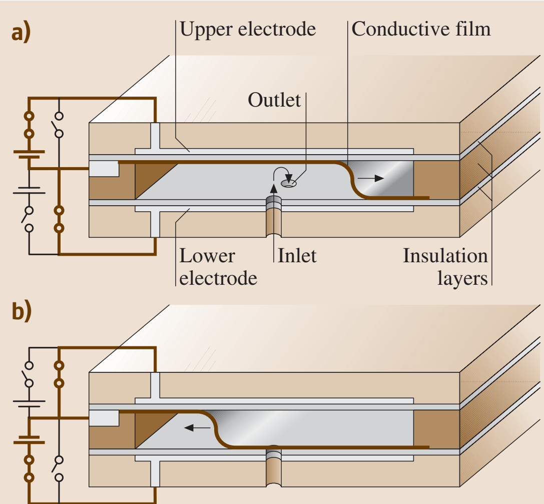

Fig. 9.7a,b Electrostatically actuated microvalve with S-Shaped film element: propagation of bend in the film as **(a)** open and **(b)** closed (adapted from [9.30]). Reproduced by permission of IOP Publishing Limited

[9.31] have developed an array of electrostatically actuated valves using a flap design (rather than a membrane) for sealing fluid flow. The demonstrated system is suitable for very low pressure gas control systems such as the ones needed in a clean room environment.

Wijngaart et al. [9.33] have developed a high-stroke, high pressure electrostatic actuator for valve applications. This reference provides a good overview of the theoretical design parameters used to design and analyze an electrostatically actuated microvalve.

Piezoelectrically Actuated Microvalve

Piezoelectric actuation schemes offer a significant advantage in terms of operating speed; they are typically the fastest actuation scheme at the expense of a reduced actuator stroke. Also, piezoelectric materials are more challenging to incorporate into fully integrated MEMS devices. *Watanabe* et al. [9.34] and *Stehr* et al. [9.35] demonstrated piezoelectric actuators for valve applications. A film of piezoelectric material is deposited on the movable membrane, and upon application of an electric potential, a small deformation occurs in the piezo film that is transmitted to the valve membrane.

Electromagnetically Actuated Microvalves

Electromagnetic actuators are typically capable of delivering high force and range of motion. A significant advantage of electromagnetic microvalves is that they are relatively insensitive to external interference. However, electromagnetic actuators involve a fairly complex fabrication process. Usually, a soft electromagnetic material like Ni-Fe (nickel-iron permalloy) is used as a membrane layer, and an external electromagnet is used to actuate this layer. *Sadler* et al. [9.32] have developed a microvalve using the electromagnetic actuation scheme shown in Fig. 9.8.

They have demonstrated a fully integrated magnetic actuator with magnetic interconnection vias to guide the magnetic flux. The valve seat design, also shown in Fig. 9.8, allows for very intimate contact between the Ni-Fe valve membrane and the valve seat, hence, achieving an ultralow leak rate when the valve is closed.

Jackson et al. [9.36] demonstrate an electromagnetic microvalve using "magnetic" PDMS as the membrane material. For this application, the PDMS pre-polymer is loaded with soft magnetic particles and then cured to form the valve membrane. The PDMS membrane

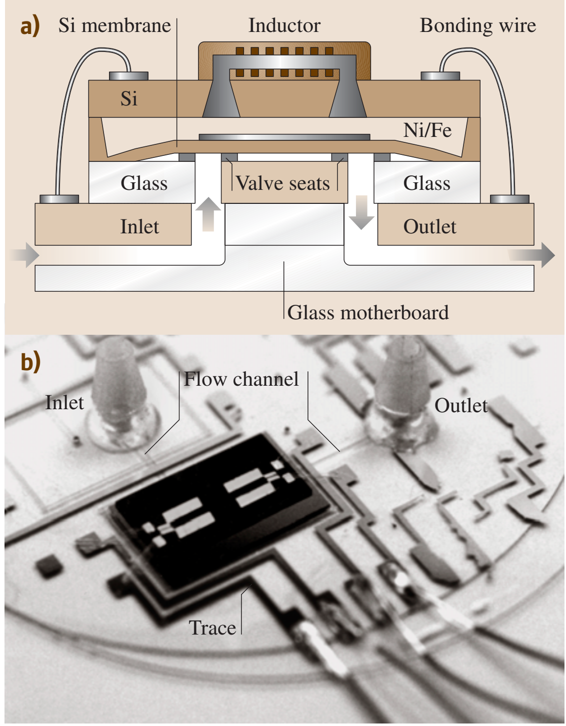

Fig. 9.8a,b Electromagnetically actuated microvalves: **(a)** schematic illustration and **(b)** photograph of the electromagnetically actuated microvalve as a part of lab-on-a-chip (after [9.32])

is then assembled over the valve body, and miniature electromagnets are used to actuate the membrane.

Other Microvalve Actuation Schemes

Microvalves have most commonly been implemented with one of the actuation schemes listed above. However, these are not the only actuation schemes that are used for microvalves. Some others include the use of SMA (shape memory alloys) [9.37], electrochemical actuation [9.38], etc. SMA actuation schemes offer the advantage of generating very large forces when the SMA material is heated to its original state. *Neagu* et al. [9.38] present an electrochemically actuated microvalve. In their device, an electrolysis reaction is used to generate oxygen in a confined chamber. This chamber is sealed by a deformable membrane that deflects due to increased pressure. The reported microvalve has relatively fast actuation time and can generate very high pressures. *Yoshida* et al. [9.39] present a novel approach to the microvalve design: a micro-electro-rheological valve (ER valve). An electro-rheological fluid is loaded into the microchannel, and, depending on the strength of an applied electric field, the viscosity of the ER fluid changes considerably. A higher viscosity is achieved when an electric field is applied perpendicular to the flow direction. This increased viscosity leads to a drop in the flow rate, allowing the ER fluid to act as a valve. Of course, this technique is limited to fluids that can exhibit such properties; nevertheless, it provides a novel idea to generate on-chip microvalves.

The ideal characteristics for a microvalve are listed by Kovacs [9.24]. However, of all the microvalves listed above, none can satisfy all the criteria. Thus, microvalve design, fabrication, and utility are highly application-specific and most microvalves try to generate the performance characteristics that are most useful for the intended application.

9.2.2 Micropumps

One of the most challenging tasks in developing a fully integrated microfluidic system has been the development of efficient and reliable micropumps. In macroscale, a number of pumping techniques exist such as peristaltic pumps, vacuum-driven pumps, venturi-effect pumps, etc. However, in microscale, most mechanical pumps rely on pressurizing the working fluid and forcing it to flow through the system. Practical vacuum pumps are not available in microscale. There are also some effects such as electro-osmotic pumping, that are only possible on the microscale. Consequently, electrokinetic driving mechanisms have also been widely studied for microfluidic pumping applications.

In the previous section, various microvalves that are used for microfluidic control were discussed. They were presented based on the actuation schemes that they employ. A similar classification can also be adopted for micropumps. However, rather than using the same classification scheme, the micropumps are categorized based on the type of microvalve mechanism used as part of the pumping mechanism. Broadly, the mechanical micropumps can be classified as check-valve controlled microvalves or diffuser pumps. Either mechanism can use various actuation schemes such as electrostatic, electromagnetic, piezoelectric, etc. Micropumps driven by direct electrical control form separate category and are discussed following the mechanical micropumps.

Micropumps Using Check Valve Design

Figure 9.9 shows a typical mechanical micropump with check valves. This pump consists of an inlet and an outlet check valve with a pumping chamber in between. A membrane is deflected upwards, and a low pressure zone is created in the pumping chamber. This forces the inlet check valve open, and fluid is sucked into the pumping chamber. As the membrane returns to its original state and continues to travel downwards, a positive pressure builds up, which seals the inlet valve while simultaneously opening the outlet valve. The fluid is then ejected and the pump is ready for another cycle.

A number of other techniques have been used to realize mechanical micropumps with check valves and a pumping chamber. *Jeon* et al. [9.40] present a micropump that uses PDMS flap valves to control the pumping mechanism, *Koch* et al. [9.41], *Cao* et al. [9.42], *Park* et al. [9.43], and *Koch* et al. [9.44] present piezoelectrically driven micropumps. *Xu* et al. [9.45] and *Makino*

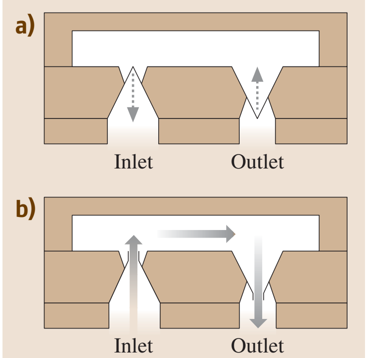

Fig. 9.9a,b Operation of micropump using check valve design: **(a)** check valves are closed and **(b)** check valves are open

et al. [9.46] present SMA driven micropumps. *Chou* et al. [9.47] present a novel rotary pump using a soft lithography approach. As explained in the active valve section, valves can be created on a PDMS layer using separate liquid and air layers. When a pressure is applied to the air lines, the membranes deflect to seal the fluidic path. *Chou* et al. [9.47] have implemented a series of such valves in a loop. When they are deflected in a set sequence, the liquid within the ring is pumped by peristaltic motion.

An interesting approach toward the development of a bidirectional micropump has been used by *Zengerle* et al. [9.48]. Their design has two flap valves at the inlet and outlet of the micropump, which work in the forward mode at low actuation frequencies and in the reverse direction at higher frequencies. *Zengerle* et al. [9.48] attribute the change in pumping direction to the phase shift between the response of the valves and the pressure difference that drives the fluid. *Carrozza* et al. [9.49] use a different approach to generate the check valves. Rather than using the conventional membrane or flap type valves, they use ball valves by employing a stereolithographic approach. The developed pump is actuated using a piezoelectric actuation scheme.

Diffuser Micropumps

The use of nozzle-diffuser sections, or pumps with fixed valves, or pumps with dynamic valves has been extensively researched. The basic principle of these pumps is based on the idea that the geometrical structure used as an inlet valve has a preferential flow direction toward the pumping chamber, and the outlet valve structure has a preferential flow direction away from the pumping chamber. An illustrative example of this concept is shown in Fig. 9.10. As can be readily seen, these pumps are designed to work with liquids only. When the pump is in suction mode, the flow in the inlet diffuser structure is primarily directed toward the pump, and a slight backflow occurs from the outlet diffuser (acting as a nozzle) section. When the pump is in pressure mode, the outlet diffuser section allows most of the flow out of the pump, whereas the inlet diffuser section allows a slight backflow. The net effect is that liquid pumping occurs from left to right.

Diffuser micropumps are simple and valveless structures that improve pumping reliability [9.50], but they cannot eliminate backflow problems.

These micropumps can also be described as flow rectifiers, analogous to diodes in electrical systems. *Forster* et al. [9.51] have used the Tesla valve geometry, instead of the diffuser section, and the reference

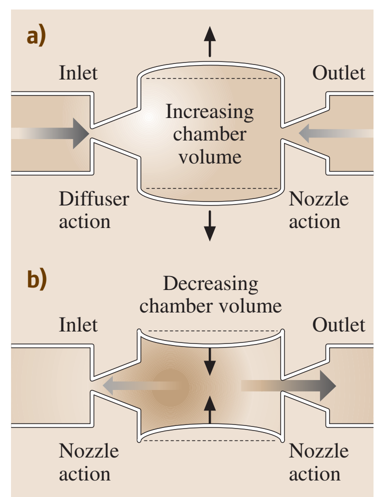

Fig. 9.10a,b Operating principle of a diffuser micropump: **(a)** suction mode and **(b)** pumping mode

presents a detailed discussion of the design parameters and operational characteristics of their fixed-valve micropumps.

Electric/Magnetic Field Driven Micropumps

An electric field can be used to directly pump liquids in microchannels using such techniques as electro-omosis (EO), electrohydrodynamic (EHD) pumping, magnetohydrodynamic (MHD) pumping, etc. These pumping techniques rely on creating an attractive force for some of the ions in the liquid, and the remaining liquid is dragged along to form a bulk flow.

When a liquid is introduced into a microchannel, a double-layer charge exists at the interface of the liquid and the microchannel wall. The magnitude of this charge is governed by the zeta potential of the channel-liquid pair. Figure 9.11 shows a schematic view of the electro-osmotic transport phenomenon.

As shown in Fig. 9.11, the channel wall is negatively charged, which attracts the positive ions in solution. When a strong electric field is applied along the length of the microchannel, the ions at the interface experience an attractive force toward the cathode. As the positive ions move toward the cathode, they exert a drag force on the bulk fluid, and net fluid transport occurs from the anode to the cathode. It is interesting to note that the flow profile of the liquid plug is significantly different from the pressure-driven flow. Unlike the parabolic flow profile of pressure-driven flow, electro-osmotic transport leads to an almost vertical flow profile. The electro-osmotic transport phenomenon is only effective across very narrow channels.

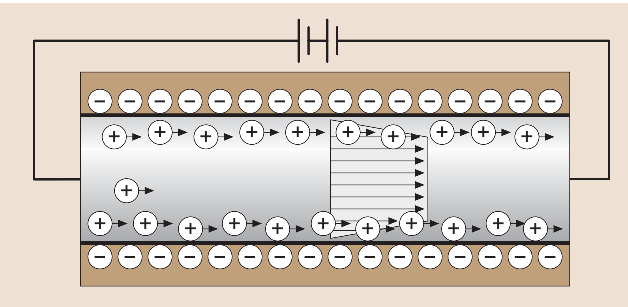

Fig. 9.11 Schematic sketch explaining the principle of electro-osmotic fluid transport

EHD can be broadly broken down into two subcategories: injection type and induction type. In injection type EHD, a strong electric field ($\sim 100\,\mathrm{kV/cm}$) is applied across a dielectric liquid. This induces charge formation in the liquid, and these induced (or injected) charges are then acted upon by the electrical field for pumping. Induction type EHD relies on generating a gradient/discontinuity in the conductivity and/or permitivity of the liquid. *Fuhr* et al. [9.52] explain various techniques that can be used to generate gradients for non-injection type EHD pumping.

MHD pumps rely on creating a Lorentz force on the liquid particles in the presence of an externally applied electric field. MHD has been demonstrated using both DC [9.53] and AC [9.54] excitations. MHD, EHD, and electro-osmotic transport share one feature in common that makes them very appealing for microfluidic systems; namely, none requires microvalves to regulate the flow. This makes these pumping techniques very reliable, as there is no concern of wear and tear of the microvalves, or any other moving parts of the micropump. However, it has been difficult to implement these actuation schemes on a complete microscale, owing to the high voltages/electromagnets, etc. required for these actuation schemes.

9.3 Smart Passive Microfluidic Devices

Passive microfluidics is a powerful technique for the rapidly evolving discipline of BioMEMS. It is a fluid control topology in which the physical configuration of the microfabricated system primarily determines the functional characteristics of the device/system. Typically, passive microfluidic devices do not require an external power source, and the control exerted by the devices is based, in part, on energy drawn from the working fluid, or based purely on surface effects, such as surface tension, selective hydrophobic/hydrophilic control, etc. Most passive microfluidic devices exploit various physical properties such as shape, contact angle, and flow characteristics to achieve the desired function. Passive microfluidic systems are usually easier to implement and allow for a simple microfluidic system with little or no control circuitry. A further list of advantages and disadvantages of passive microfluidic systems (or devices) is considered toward the end of this section.

Passive microfluidic devices can be categorized based on:

- Function – microvalves, micromixers, filters, reactors, etc.
- Fluidic medium – gas or liquid
- Application – biological, chemical, or other
- Substrate material – silicon, glass, polysilicon, polymer, or others

In this section, we will study various passive microfluidic devices that are categorized based on their function. Passive microfluidic devices include, but are not limited to, microvalves, micromixers, filters, dispensers, etc. [9.24].

9.3.1 Passive Microvalves

Passive microvalves have been a subject of great interest ever since the inception of the lab-on-a-chip concept. Microvalves are a key component of any microfluidic system and are essential for fluidic sequencing operations. Since most chemical and biochemical reactions require about five to six reaction steps, passive microvalves with limited functionality are ideally suited for such simple tasks. Passive microvalves can be broadly categorized as follows:

- Silicon/polysilicon or polymer-based check valves
- Passive valves based on surface tension effects
- Hydrogel-based biomimetic valves

Passive Check Valves

Shoji et al. [9.23] provide an excellent review of check-type passive microvalves. Some of the valves, shown in Fig. 9.12, illustrate the various techniques that can be used to fabricate check valves.

Figure 9.12a shows a microvalve fabricated using silicon bulk etching techniques. A through hole (pyramidal cavity) is etched through a silicon wafer that is sandwiched between two glass wafers. The normally closed valve is held in position by the spring effect of the silicon membrane. Upon applying pressure at the lower fluidic port, the membrane deflects upwards, allowing fluid flow through the check valve. The same working principle is employed by the microvalve shown in Fig. 9.12b. However, instead of using a membrane supported on all sides, a cantilever structure is used for the flap. This reduces the burst pressure, i.e., the minimum pressure required to open the microvalve. Figure 9.12c shows that the membrane structure can also be realized using a polysilicon layer deposited on a bulk-etched silicon wafer. Poly-silicon processes typically allow tighter control over dimensions and, consequently, offer more repeatable operating characteristics. Figure 9.12d shows the simplest type of check valve where the V-groove etched in a bulk silicon substrate acts as a check valve. However, the low contact area between the flaps of the microvalve leads to nontrivial leakage rates in the forward direction. Figures 9.12e and f show check valve designs that are realized using polymer/metal films, in addition to the traditional glass/silicon platform. This technique offers a significant advantage in terms of biocompatibility characteristic and controllable operating characteristics. The surface properties of polymers can be easily tailored using a wide variety of techniques such as plasma treatment and surface adsorption [9.55]. Thus, in applications for which the biocompatibility requirements are very stringent, it is preferable to have polymers as the fluid contacting material. Furthermore, polymer properties such as stiffness, can also be controlled in some cases based on the composition and/or processing conditions. Thus, it may be possible to fabricate microvalves with different burst pressures by using different processing conditions for the same polymer.

In addition to the passive check valves reviewed by *Shoji* et al. [9.23], other designs include check valves using composite titanium/polyimide membranes [9.20,21], polymeric membranes such as Mylar or KAPTON [9.56], or PDMS [9.40], and metallic membranes such as [9.22].

Terray et al. [9.57] present an interesting approach to fabricating ultra-small passive valve structures. They have demonstrated a technique to polymerize colloidal particles into linear structures using an optical trap to form microscale particulate valves.

Passive Valves Based on Surface Tension Effects

The passive valves listed in the previous section use the forced motion of the membrane or flap to control the flow of fluids. These valves are prone to such problems as clogging and mechanical wear and tear. Passive valves based on surface tension effects, on the other

hand, have no moving parts and control the fluid motion based on their physical structure and the surface property of the substrate. Figure 9.13 shows a schematic sketch of a passive microvalve on a hydrophobic substrate [9.19].

The Hagen–Poiseuille equation for laminar flow governs the pressure drops in microfluidic systems with laminar flow. For a rectangular channel with a high width to height ratio, the pressure drop is governed by the equation

$$\Delta P = \frac{12L\mu.Q}{wh^3}\,, \tag{9.1}$$

where L is the length of the microchannel, μ is the dynamic viscosity of the fluid, Q is the flow rate, and w and h are the width and height of the microchannel, respectively. Varying L or Q can control the pressure drop for a given set of w and h.

An abrupt change in the width of the channel causes a pressure drop at the point of restriction. For a hydrophobic channel material, an abrupt decrease in channel width causes a positive pressure drop:

$$\Delta P_2 = 2\sigma_l \cos(\theta_c)\left[\left(\frac{1}{w_1}+\frac{1}{h_1}\right)-\left(\frac{1}{w_2}+\frac{1}{h_2}\right)\right]\,, \tag{9.2}$$

where σ_l is the surface tension of the liquid, θ_c is the contact angle, and w_1, h_1 and w_2, h_2 are the width and height of the two sections before and during the restriction, respectively. Setting h as constant through the system, ΔP_2 can be varied by adjusting the ratio of w_1 and w_2. *Ahn* et al. [9.19] have proposed and implemented a novel structurally programmable microfluidic system (sPROMs) based on the passive microfluidic approach. In short, the sPROMs system consists of a network of microchannels with passive valves of the type shown in the passive valve section. If the pressure drop of the passive valves is set to be significantly higher than the pressure drop of the microchannel network, then the position of the liquid in the microchannel network can be controlled accurately. By applying sequentially higher pressure pulses, the liquid is forced to move from one passive valve to another. Thus, the movement of the fluid within the microfluidic channels is "programmed" using the physical structure of the microfluidic system, and this forms the basic idea behind sPROMs.

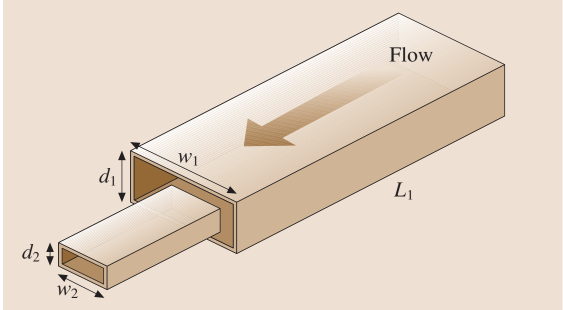

Fig. 9.13 Structure of a passive microvalve based on surface tension effects (adapted from [9.19])

The abrupt transition from a wide channel to a narrow channel can also be affected along the height of the microchannel. Furthermore, the passive valve geometry shown in Fig. 9.13 is not exclusive. *Puntambekar* et al. [9.58] have demonstrated different geometries of passive valves, as shown in Fig. 9.14a. As shown in Fig. 9.14b,

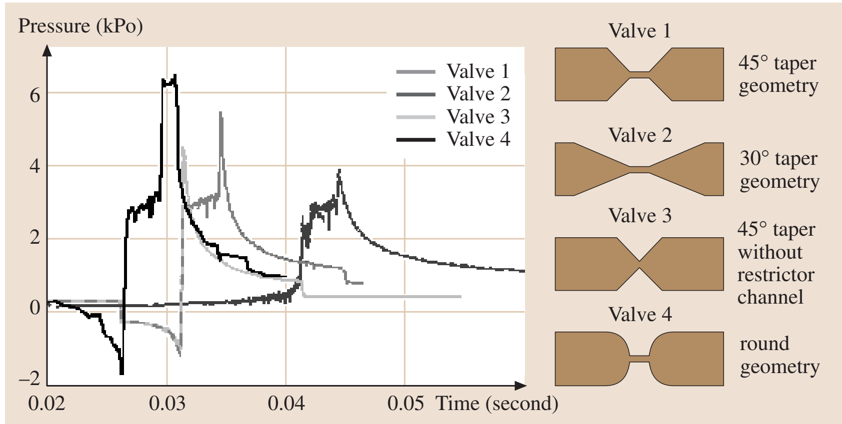

Fig. 9.14 Analysis of different geometries of passive valves. After [9.58], reproduced by permission of The Royal Society of Chemistry

the various geometries of the passive valves in Fig. 9.14a can act as effective passive valves without having an abrupt transition. This is important in order to avoid the dead volume that is commonly encountered across an abrupt step junction.

The use of surface tension to control the operation of passive valves is not limited to hydrophobic substrates. *Madou* et al. [9.59] demonstrate a capillarity-driven stop valve on a hydrophilic substrate. On a hydrophilic substrate, the fluid can easily "wick through" in the narrow region. However, at the abrupt transition to a larger channel section, the surface tension effects will not allow the fluid to leave the narrow channel. Thus, in this case, the fluid is held at the transition from the narrow capillary to the wide outlet channel.

Another mechanism to implement passive valves is the use of hydrophobic patches on a normally hydrophilic channel. *Handique* et al. [9.60] demonstrate the use of this technique to implement passive valves for a DNA analysis system. The fluid is sucked into the microfluidic channels via capillary suction force. The hydrophobic patch exerts a negative capillary pressure that stops the further flow of fluid. The use of hydrophobic patches as passive valves is reported by *Andersson* et al. [9.61].

Other Passive Microvalves

A novel approach to realizing passive valves that are responsive to their surrounding environment is demonstrated by *Low* et al. [9.62] and *Yu* et al. [9.63]. *Yu* et al. [9.63] have developed customized polymer "cocktails" that are polymerized in situ around prefabricated posts. The specialized polymer is selectively responsive to stimuli such as pH, temperature, electric fields, light, carbohydrates, and antigens.

Another interesting approach in developing passive valves has been adopted by *Foster* et al. [9.51]. They have developed the so-called no moving part (NMP) valves, which are based on a physical configuration that allows a higher flow rate along a direction compared to the reverse direction.

9.3.2 Passive Micromixers

The successful implementation of microfluidic systems for many lab-on-a-chip systems is partly owing to the significant reduction in volumes handled by such systems. This reduction in volume is made possible by the use of microfabricated features and channel dimensions ranging from a few µm to several hundred µm. Despite the advantage offered by the micron-sized channels, one of the significant challenges has been the implementation of effective microfluidic mixers on the microscale. Mixing on a macroscale is a turbulent flow regime process. However, on the microscale, because of the low Reynolds numbers as a result of the small channel dimensions, most flow streams are laminar in nature, which does not allow for efficient mixing. On the other hand, diffusion is an important factor in mixing because of the short diffusion lengths.

There have been numerous attempts to realize micromixers using both active and passive techniques. Active micromixers rely on creating localized turbulence to enhance the mixing process, whereas passive micromixers usually enhance the diffusion process. The diffusion process can be modeled by the following equation:

$$\tau = \frac{d^2}{D}\,, \tag{9.3}$$

where τ is the mixing time, d is the distance, and D is the diffusion coefficient. Equation (9.3) illustrates the diffusion-dominated mixing at the microscale. Because of the small diffusion lengths (d), the mixing times can be made very short. The simplest category of micromixers is illustrated in Fig. 9.15. In these mixers, creating a convoluted path increases the path length that the two fluids share, leading to higher diffusion and more complete mixing. However, these mixers only exhibit good mixing performance at low flow rates, in the range of a few µl/min.

Mitchell et al. [9.64] have demonstrated three-dimensional micromixers that can achieve better

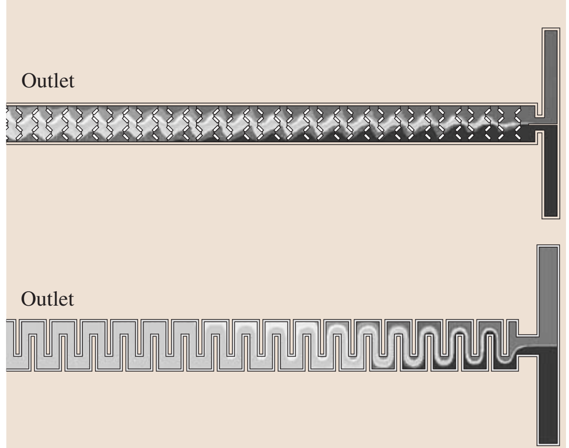

Fig. 9.15 Diffusion-enhanced mixers based on long, convoluted flow path

performance by alternately laminating the two fluid streams to be mixed. *Beebe* et al. [9.65] have created a chaotic mixer that has the convoluted channel along three dimensions. This micromixer works on the principle of forced advection resulting from repeated turns in three dimensions. Furthermore, at each turn, eddies are generated because of the difference in flow velocities along the inner and outer radii, which enhances the mixing.

Stroock et al. [9.68] demonstrate a passive micromixer that uses chaotic mixing by superimposing a transverse flow component on the axial flow. Ridges are fabricated at the bottom of microchannels. The flow resistance is lower along the ridges (peak/valley) and higher in the axial direction. This generates a helical flow pattern that is superimposed on the laminar flow. The demonstrated mixer shows good mixing performance over a wide range of flow velocities.

Hong et al. [9.66] have demonstrated a passive micromixer based on the Koanda effect. Their design uses the effects of diffusion mixing at low flow velocities; at high flow velocities, a convective component is added perpendicular to the flow direction, allowing for rapid mixing. This mixer shows excellent mixing performances across a wide range of flow rates because of the dual mixing effects. Figure 9.16 shows a schematic sketch of the mixer structure.

The mixer works on the principle of superimposing a parabolic flow profile in a direction perpendicular to the flow direction. The parabolic profile creates a Taylor dispersion pattern across the cross section of the flow path. The dispersion is directly proportional to the flow velocity, and higher flow rates generate more dispersion mixing.

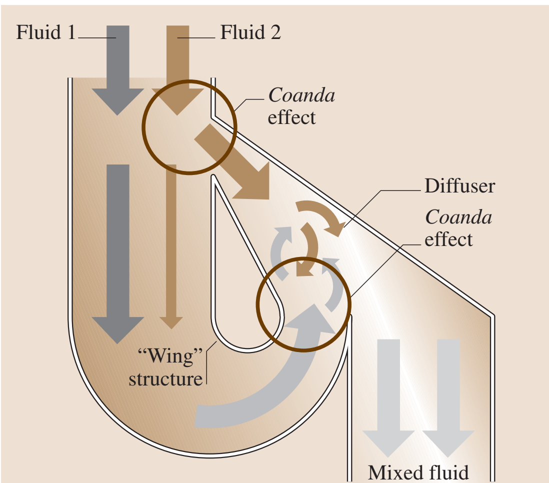

Fig. 9.16 Mixing unit design for the Coanda effect mixer. The actual mixer has mixing unit pairs in series (after [9.66])

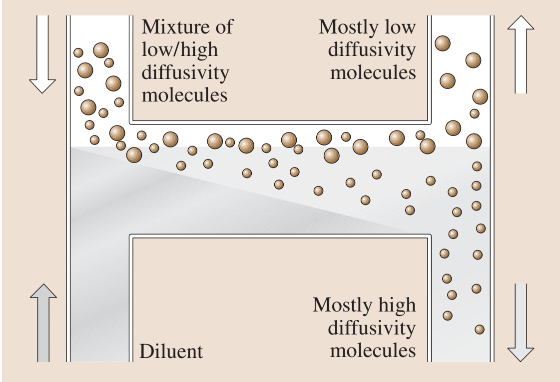

Fig. 9.17 Conceptual illustration of the H-Sensor. Adapted from [9.67]

Brody et al. [9.67] have used the laminar flow characteristics in a microchannel to develop a diffusion-based extractor. When two fluid streams, where fluid 1 is loaded with particles of different diffusivity and fluid 2 is a diluent, are forced to flow together in a microchannel, they form two laminar streams with little mixing. If the length that the two streams are in contact is carefully adjusted, only particles with high diffusivity (usually small molecules) can diffuse across into the diluent stream, as shown in Fig. 9.17. The same idea can be extended to a T-filter. *Weigl* et al. [9.69] have demonstrated a rapid diffusion immunoassay using the T-filter.

9.3.3 Passive Microdispensers

The principle of the structurally programmable microfluidic systems (sPROMs) was introduced earlier in the passive valve section. One of the key components of the sPROMs system is the microdispenser, which is designed to accurately and repeatedly dispense fluidic volumes in the micro- to nanoliter range. This would allow the dispensing of a controlled amount of the analyte into the system that could be used for further biochemical analysis. Figure 9.18 shows a schematic sketch of the microdispenser design [9.58].

The microdispenser works on the principle of graduated volume measurement. The fluid fills up the exact fixed volume of the reservoir, and the second passive valve at the other end of the microdispenser stops further

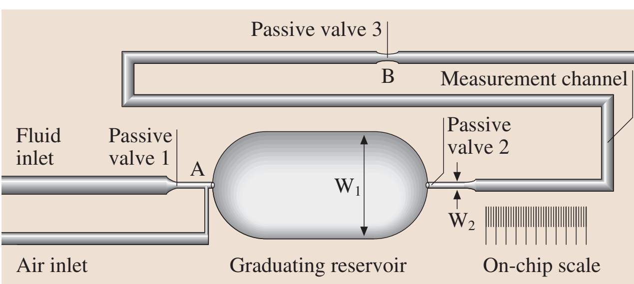

Fig. 9.18 Schematic sketch of the microdispenser. Adapted from [9.58], reproduced by permission of The Royal Society of Chemistry

motion. When the reservoir is filled with fluid, the fluidic actuation is stopped, and, simultaneously, pneumatic actuation from the air line causes a split in the fluid column at point A (Fig. 9.18). Thus, the accuracy of the reservoir decides the accuracy of the dispensed volume. Since the device is manufactured using UV-LIGA lithography techniques, highly accurate and reproducible volumes can be defined. The precisely measured volume of fluid is expelled to the right from the reservoir. The expelled fluid then starts to fill up the measuring channel. When the fluid reaches point B (Fig. 9.18), the third microvalve holds the fluid column.

Figure 9.19 shows an actual operation sequence of the microdispenser. Figure 9.19f shows that the dispensed volume is held by passive valve 3, and at this stage, the length (and hence volume) can be calculated using the on-chip scale. In experiments only, the region in the immediate vicinity of the scale was viewed using a stereomicroscope for measuring the length of the fluid column. The microdispenser demonstrated above is reported to have dispensing variation of less than 1% between multiple dispensing cycles.

9.3.4 Microfluidic Multiplexer Integrated with Passive Microdispenser

Ahn et al. [9.19] have demonstrated the sPROMs technology to be an innovative method of controlling liquid

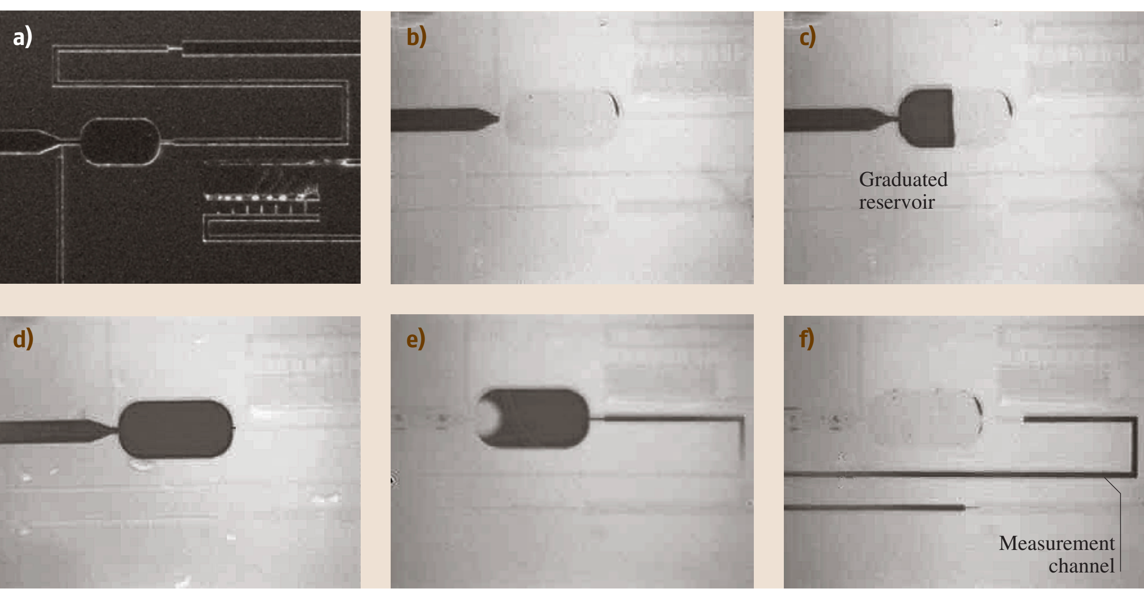

Fig. 9.19a–f Microphotographs of microdispenser sequence: **(a)** fabricated device; **(b)** fluid at reservoir inlet; **(c)** reservoir filling; **(d)** reservoir filled; **(e)** split in liquid column due to pneumatic actuation; and **(f)** fluid ejected to measurement channel and locked in by passive valve. After [9.58], reproduced by permission of The Royal Society of Chemistry

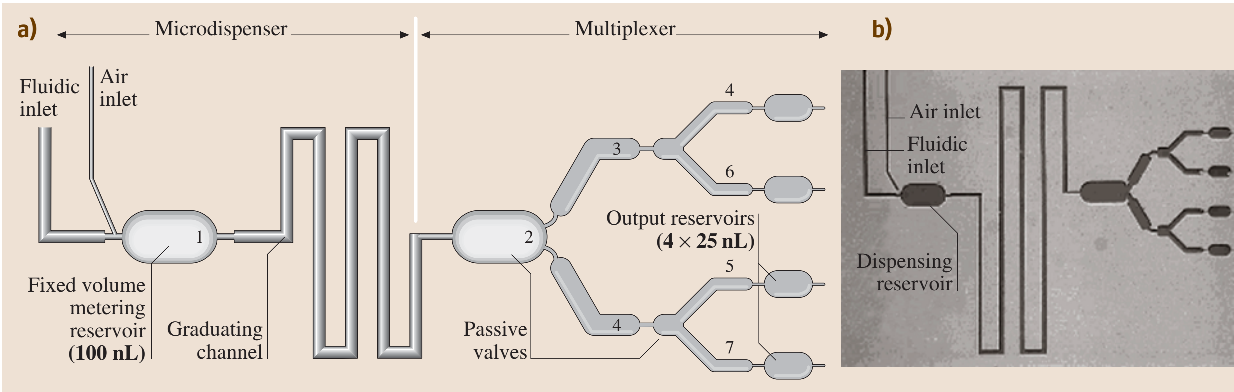

Fig. 9.20a,b Microfluidic multiplexer with integrated dispenser: **(a)** schematic sketch and **(b)** fabricated device filled with dye (after [9.58])

movement in a programmed fashion in a microfluidic network. By integrating this technique with the microdispensers, a more functionally useful microfluidic system can be realized. Figure 9.20a shows a schematic illustration of the microfluidic multiplexer with the integrated dispenser, and Fig. 9.20b shows an actual device fabricated using rapid prototyping techniques [9.70].

The operation of the microdispenser has been explained earlier in this section. Briefly, the fluid is loaded in the fixed-volume metering reservoir via a syringe pump. The fluid is locked in the reservoir by the passive valve at the outlet of the reservoir. When a higher pressure is applied via the air inlet line, the liquid column is split and the fluid is dispensed into the graduating channel.

The microfluidic multiplexer is designed to have a programmed delivery sequence, as shown in Fig. 9.20a, where the numbers on each branch of the multiplexer indicates the filling sequence. This sequential filling is achieved by using different ratios of passive valves along the multiplexer section. For instance, at the first branching point, the passive valve at the upper branch offers less resistance than the passive valve at the beginning of the lower branch. Thus, the dispensed fluid will first fill the top branch. After filling the top branch, the liquid encounters another passive valve at the end of the top branch. The pressure needed to push beyond this valve is higher than the pressure needed to push liquid into the lower branch of the first split. The liquid will then fill the lower branch. This sequence of nonsymmetrical passive valves continues along all the branches of the multiplexer, as shown in Fig. 9.21.

The ability to sequentially divide and deliver liquid volumes was demonstrated for the first time using a passive microfluidic system. This approach has the potential to deliver very simple microfluidic control systems that are capable of a number of sequential microfluidic manipulation steps required in a biochemical analysis system.

Fig. 9.21a–d Microphotographs showing operation of sequential multiplexer: **(a)** first level division; **(b)** second level division; **(c)** continued multiplexing; and **(d)** end of sequential multiplexing sequence (after [9.58])

9.3.5 Passive Micropumps

A passive system is defined inherently as one that does not require an external energy source. Thus, the term passive micropump might seem misnomer upon initial inspection. However, there have been some efforts dedicated to realizing a passive micropump that essentially does not draw energy from an external source, but stores the required actuation energy in some form and converts it to mechanical energy on demand.

Passive Micropump Based on Osmotic Pressure

Nagakura et al. [9.71] have demonstrated a mesoscale osmotic actuator that converts chemical energy to mechanical displacement. Osmosis is a well-known phenomenon by which liquid is transported across a semipermeable membrane to achieve a uniform concentration distribution across the membrane. If the membrane is flexible, such as the one used by *Nagakura* et al. [9.71], then the transfer of liquid would cause the membrane to deform and act as an actuator. The inherent drawback of using osmosis as an actuation mechanism is that it is a very slow process: Typical response times (on a macroscale) are on the order of several hours. However, osmotic transport scales favorably to the microscale, and it is expected that these devices will have response times on the order of several minutes, rather than hours. Based on this idea, *Nagakura* et al. [9.71] are developing a miniature insulin pump. *Su* et al. [9.72] have demonstrated a microscale osmotic actuator that is capable of developing pressures as high as 35 MPa. This is still a relatively unexplored realm in BioMEMS actuation, and it has good potential for applications such as sustained drug delivery.

Passive Pumping Based on Surface Tension

Glenn et al. have demonstrated pumping action using the difference between the surface tension pressure at the inlet and outlet of a microfluidic channel. In the simplest case, a small drop of a fluid is placed at one end of a straight microchannel, and a much larger drop of fluid is placed at the opposite end of the microchannel. The pressure within the small drop is significantly higher than the pressure within the large drop, due the difference in the surface tension effects across the two drops. Consequently, the liquid will flow from the small drop and add to the larger drop. The flow rate can be varied by changing various parameters such as the volume of the pumping drop, the surface free energy of the liquid, or the resistance of the microchannel, etc. This pumping scheme is very easy to realize and can be used for a wide variety of fluids.

Evaporation-Based Continuous Micropump

Effenhauser et al. [9.73] have demonstrated a continuous flow micropump based on a controlled evaporation approach. Their concept is based on the controlled evaporation of a liquid through a membrane into a gas reservoir. The reservoir contains a suitable adsorption agent that draws out the liquid vapors and maintains a low vapor pressure conducive to further evaporation. If the liquid being pumped is replenished from a reservoir, capillary forces will ensure that the fluid is continuously pumped through the microchannels as it evaporates on the other end into the adsorption reservoir. Though the pump suffers from inherent disadvantages such as strong temperature dependence and operation only in suction mode, it offers a very simple technique for fluidic transport.

9.3.6 Advantages and Disadvantages of the Passive Microfluidic Approach

This chapter has covered a number of different passive microfluidic devices and systems. Passive microfluidic devices have only recently been a subject of considerable research effort. One of the reasons for this interest is the long list of advantages that passive microfluidic devices offer. However, since most microfluidic devices are very application-specific (and even more so for passive microfluidic devices), the advantages are not to be considered universally applicable for all the devices/systems. Some of the advantages that are commonly found are:

- avoid the need for an "active" control system;
- usually very easy to fabricate;
- the passive microfluidic systems with no moving parts are inherently more reliable because of the lack of mechanical wear and tear;
- offer very repeatable performance once the underlying phenomena are well understood and characterized;
- highly suited for BioMEMS applications – can easily handle a limited number of microfluidic manipulation sequences;
- well suited for low cost, mass production approach;

- low cost offers the possibility of having disposable microfluidic systems for specific applications, such as working with blood;
- can offer other interesting possibilities, such as biomimetic response.

However, like all MEMS devices, passive microfluidic devices or systems are not the solution to the microfluidic handling problem. Usually they are very application-specific – they cannot be reconfigured for another application easily. Other disadvantages are listed below:

- suited for well understood, niche applications for which the fluidic sequencing steps are well decided,
- strongly dependent on variances in the fabrication process,
- usually not very suitable for a wide range of fluidic mediums.

9.4 Lab-on-a-Chip for Biochemical Analysis

Recent development in MEMS (microelectromechanical systems) has brought a new and revolutionary tool in biological or chemical applications: "lab-on-a-chip". New terminology, such as micro total analysis systems and lab-on-a-chip, was introduced in the last decade, and several prototype systems have been reported.

The idea of lab-on-a-chip is basically to reduce biological or chemical laboratories to a microscale system, hand-held size or smaller. Lab-on-a-chip systems can be made out of silicon, glass, and polymeric materials, and the typical microfluidic channel dimensions are in the range of several tens to hundreds of μm. Liquid samples or reagents can be transported through the microchannels from reservoirs to reactors using electrokinetic, magnetic, or hydrodynamic pumping methods. Fluidic motions or biochemical reactions can also be monitored using various sensors, which are often used for biochemical detection of products.

There are many advantages to using lab-on-a-chip over conventional chemical or biological laboratories. One of the important advantages lies in its low cost. Many reagents and chemicals used in biological and chemical reactions are expensive, so the prospect of using very small amounts (in micro- to nanoliter range) of reagents and chemicals for an application is very appealing. Another advantage is that lab-on-a-chip requires very small amounts of reagents/chemicals (which enables rapid mixing and reaction) because biochemical reaction is mainly involved in the diffusion of two chemical or biological reagents, and microscale fluidics reduces diffusion time as it increases reaction probabilities. In practical terms, reaction products can be produced in a matter of seconds/minutes, whereas laboratory scale can take hours, or even days. In addition, lab-on-a-chip systems minimize harmful by-products since their volume is so small. Complex reactions of many reagents could happen on lab-on-a-chip that have ultimate potential in DNA analysis, biochemical warfare agent detection, biological cell/molecule sorting, blood analysis, drug screening/development, combinatorial chemistry, and protein analysis. In this section, two recent developments of microfluidic systems for lab-on-a-chip applications will be introduced: (a) magnetic micro/nano bead-based biochemical detection system and (b) disposable smart lab-on-a-chip for blood analysis.

9.4.1 Magnetic Micro/Nano Bead-Based Biochemical Detection System

In the past few years, a large number of microfluidic prototype devices and systems have been developed, specifically for biochemical warfare detection systems and portable diagnostic applications. The BioMEMS team at the University of Cincinnati has been working on the development of a remotely accessible generic microfluidic system for biochemical detection and biomedical analysis, based on the concepts of surface-mountable microfluidic motherboards, sandwich immunoassays, and electrochemical detection techniques [9.74, 75]. The limited goal of this work is to develop a generic MEMS-based microfluidic system and to apply the fluidic system to detect bio-molecules, such as specific proteins and/or antigens, in liquid samples. Figure 9.22 illustrates the schematic diagram of a generic microfluidic system for biochemical detection using a magnetic bead approach for both sampling and manipulating the target bio-molecules [9.76, 77].

The analytical concept is based on sandwich immunoassay and electrochemical detection [9.78], as illustrated in Fig. 9.23. Magnetic beads are used as both substrates of antibodies and carriers of target antigens.

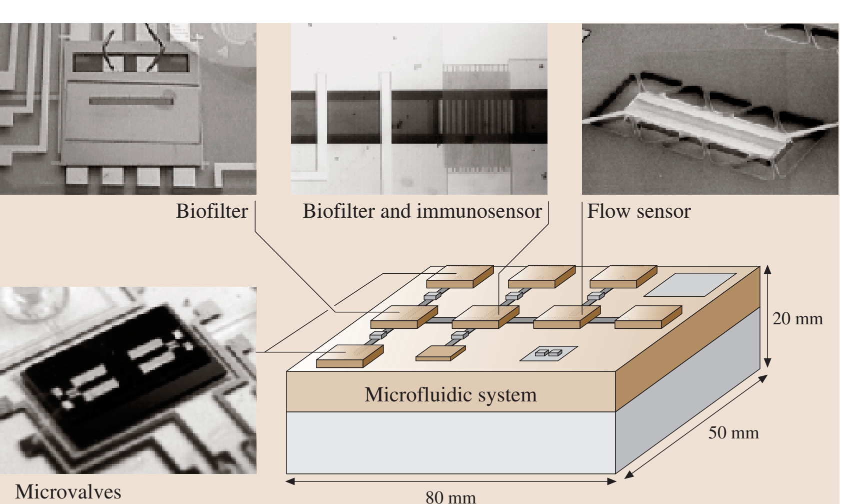

Fig. 9.22 Schematic diagram of a generic microfluidic system for biochemical detection (after [9.75])

A simple concept of magnetic bead-based bio-sampling with electromagnet for the case of sandwich immunoassay is shown in Fig. 9.24.

Antibody-coated beads are introduced on the electromagnet and separated by applying magnetic fields. While holding the antibody-coated beads, antigens are injected into the channel. Only target antigens are immobilized and, thus, separated on the magnetic bead surface due to antibody/antigen reaction. Other antigens get washed out with the flow. Next, enzyme-labeled secondary antibodies are introduced and incubated, along with the immobilized antigens. The chamber is then rinsed to remove all unbound secondary antibodies. Substrate solution, which will react with enzyme, is injected into the channel, and the electrochemical detection is performed. Finally, the magnetic beads are released to the waste chamber, and the bio-separator is ready for another immunoassay. Alkaline phosphatase (AP) and p-aminophenyl phosphate (PAPP) were chosen as enzyme and electrochemical substrate, respectively. Alkaline phosphatase makes PAPP turn into its electrochemical product, p-aminophenol (PAP). By applying potential, PAP gives electrons and turns into 4-quinoneimine (4QI), which is the oxidant form of PAP.

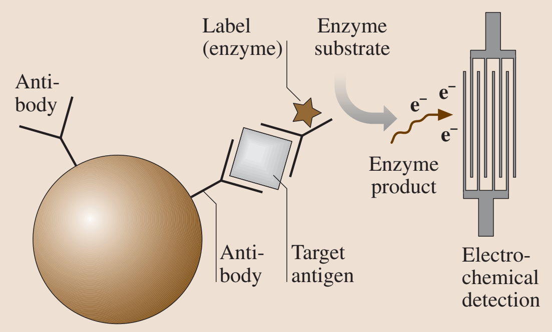

Fig. 9.23 Analytical concept based on sandwich immunoassay and electrochemical detection. After [9.77], reproduced by permission of The Royal Society of Chemistry

For the successful immunoassay, the biofilter [9.76] and the immunosensor were fabricated separately and integrated together. The integrated biofilter and immunosensor were surface-mounted using a fluoropolymer bonding technique [9.79] on a microfluidic motherboard, which contains microchannels fabricated by glass etching and glass-to-glass direct bonding technique. Each inlet and outlet were connected to sample reservoirs through custom-designed microvalves. Figure 9.25 shows the integrated microfluidic biochemical detection system for magnetic bead-based immunoassay.

After a fluidic sequencing test, full immunoassays were performed in the integrated microfluidic system to prove magnetic bead-based biochemical detection and sampling function. Magnetic beads (Dynabeads® M-280, Dynal Biotech Inc.) coated with biotinylated sheep anti-mouse immunoglobulin G (IgG) were injected into the reaction chamber and separated on the surface of the biofilter by applying magnetic fields. While holding the magnetic beads, antigen (mouse IgG) was injected into the chamber and incubated. Then

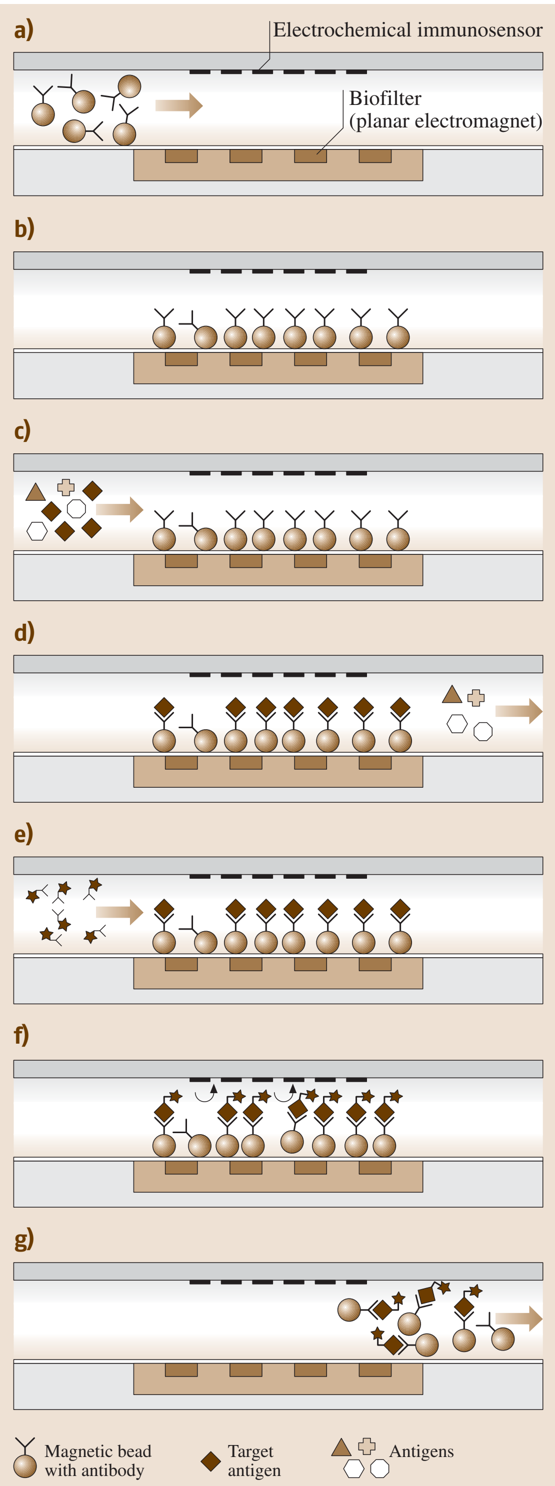

Fig. 9.24a–g Conceptual illustration of bio-sampling and immuno-assay procedure: **(a)** injection of magnetic beads; **(b)** separation and holding of beads; **(c)** flowing samples; **(d)** immobilization of target antigen; **(e)** flowing labeled antibody; **(f)** electrochemical detection; and **(g)** washing out magnetic beads and ready for another immunoassay (after [9.77], reproduced by permission of The Royal Society of Chemistry)

secondary antibody with label (rat anti-mouse IgG conjugated alkaline phosphatase) and electrochemical substrate (PAPP) to alkaline phosphatase was sequentially injected and incubated to ensure production of PAP. Electrochemical detection using an amperometric time-based detection method was performed during incubation. After detection, magnetic beads with all the reagents were washed away, and the system was ready for another immunoassay. This sequence was repeated for every new immunoassay. The flow rate was set to 20 μl/min in every step. After calibration of the electrochemical immunosensor, full immunoassays were performed following the sequence stated above for different antigen concentrations: 50, 75, 100, 250, and 500 ng/ml. Concentration of primary antibody-coated magnetic beads and conjugated secondary antibody was 1.02×10^7 beads/ml and 0.7 μg/ml, respectively. Immunoassay results for different antigen concentrations are shown in Fig. 9.26.

Immunoreactant consumed during one immunoassay was 10 μl (20 μl/min × 30 s), and total assay time was less than 20 min, including all incubation and detection steps.

The integrated microfluidic biochemical detection system has been successfully developed and fully tested for fast and low volume immunoassays using magnetic beads, which are used as both immobilization surfaces and bio-molecule carriers. Magnetic bead-based immunoassay, as a typical example of biochemical detection and analysis, has been performed on the integrated microfluidic biochemical analysis system that includes a surface-mounted biofilter and immunosensor on a glass microfluidic motherboard. Protein sampling capability has been demonstrated by capturing target antigens.

The methodology and system can also be applied to generic bio-molecule detection and analysis systems by replacing the antibody/antigen with appropriate bio receptors/reagents, such as DNA fragments or oligonucleotides, for the application to DNA analysis and/or high throughput protein analysis.

9.4.2 Disposable Smart Lab-on-a-Chip for Blood Analysis

One of several substrates available for bio-fluidic chips, plastics have recently become one of the most popular and promising substrates due to their low cost, ease of fabrication, and favorable biochemical reliability and compatibility. Plastic substrates, such as polyimide, PMMA, PDMS, polyethylene, or polycarbonate, offer a wide range of physical and chemical material parameters for the applications of bio-fluidic chips, generally at low cost using replication approaches. The disposable smart plastic biochip is composed of integrated modules of plastic fluidic chips for fluid regulation, chemical and biological sensors, and electronic controllers. As a demonstration vehicle, the biochip has the specific goal of detecting and identifying three metabolic parameters such as PO_2 (partial pressure of oxygen), lactate, and glucose from a blood sample. The schematic concept of the cartridge-type disposable lab-on-a-chip for blood analysis is illustrated in Fig. 9.27. The disposable lab-on-a-chip cartridge has been fabricated using plastic micro-injection molding and plastic-to-plastic direct bonding techniques. The biochip cartridge consists of a fixed volume microdispenser based on the sPROMs (structurally programmable microfluidic system) technique [9.70], an air-bursting, on-chip pressure source [9.80], and electrochemical biosensors [9.81].

A passive microfluidic dispenser measures exact amounts of sample to be analyzed, and then the air-bursting on-chip power source is detonated to push the graduated sample fluid from the dispenser reservoir. Upon air bursting, the graduated sample fluid travels through the microfluidic channel into sensing reservoirs, under which the biosensor array is located, as shown in Fig. 9.28.

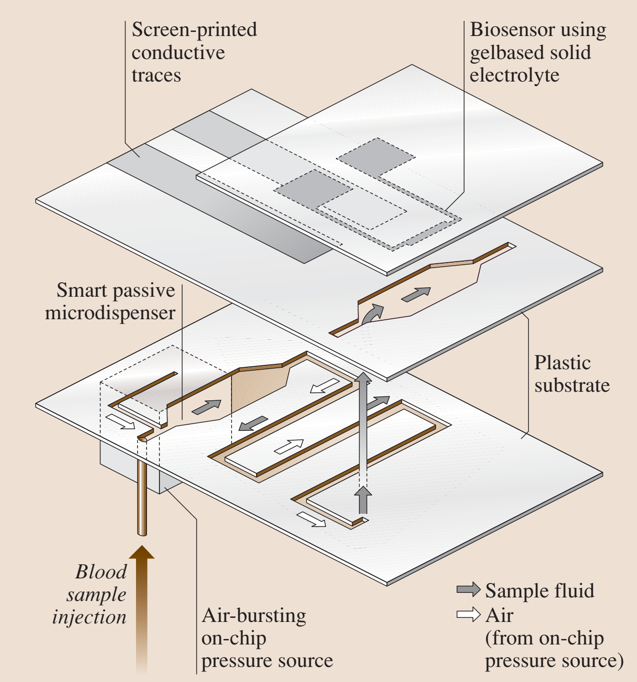

Fig. 9.27 Schematic illustration of smart and disposable plastic lab-on-a-chip by *Ahn* et al. [9.82]

An array of disposable biosensors consisting of an oxygen sensor and a glucose sensor has been fabricated using screen-printing technology [9.81]. Measurements from the developed biosensor array can be done based on tiny amounts of sample (as low as 100 nl). The glucose sensor is designed by adding two additional layers above the oxygen sensor (Fig. 9.29), which are glucose semipermeable membrane and glucose oxidase (GOD) layers.

The principle of the oxygen sensor is based on amperometric detection that when the oxygen diffusion profile from the sample to electrode surface is saturated, which means a constant oxygen gradient distribution profile is generated, the current is proportional only to the oxygen concentration in the solution. A silicone layer is spin-coated and utilized as an oxygen semipermeable membrane because of its high permeability and low signal-to-noise ratio. Water molecules pass through the silicone membrane and reconstitute the gel-based electrolyte so the Cl^- ions can move close to the anode to coalesce with Ag^+. The number of electrons in this reaction is counted by the measuring system.

For the glucose sensor, the additional layers – glucose semipermeable membrane (polyurethane) and the immobilized GOD (in a polyacrylamide gel) – allow direct conversion of the oxygen sensor to a glucose sensor. The glucose molecules will pass through the semipermeable layer and be oxidized immediately. The oxygen sensor will measure hydrogen peroxide, which is a byproduct of glucose oxidation. The level of hydrogen peroxide is proportional to the glucose level in sample. The fabricated disposable plastic lab-on-a-chip cartridge was inserted into a hand-held type biochip analyzer for analysis of human blood sample, as shown in Fig. 9.30. The prototype biochip analyzer consists of biosensor detection circuitry, timing/sequence circuitry for the air-bursting, on-chip power source, and a display unit. The battery-operated biochip analyzer initiated the sensing sequence and displayed readings in one minute. Measured glucose and PO_2 levels in human blood sample are also shown in Fig. 9.31.

The development of the disposable smart microfluidic-based biochips is of immediate relevance to several patient-monitoring systems, specifically for point-of-care health monitors. Since the developed biochip is a low cost, plastic-based system, we envision a disposable application for monitoring clinically significant parameters such as PO_2, glucose, lactate, hematocrit, and pH. These health indicators provide an early warning system for the detection of patient status and can also serve as markers for disease and toxicity monitoring.

10. Therapeutic Nanodevices

Therapeutic nanotechnology offers minimally invasive therapies with high densities of function concentrated in small volumes, features that may reduce patient morbidity and mortality. Unlike other areas of nanotechnology, novel physical properties associated with nanoscale dimensionality are not the raison d'etre of therapeutic nanotechnology, whereas the aggregation of multiple biochemical (or comparably precise) functions into controlled nanoarchitectures is. Multifunctionality is a hallmark of emerging nanotherapeutic devices, and multifunctionality can allow nanotherapeutic devices to perform multi-step work processes, with each functional component contributing to one or more nanodevice subroutine such that, in aggregate, subroutines sum to a cogent work process. Canonical nanotherapeutic subroutines include tethering (targeting) to sites of disease, dispensing measured doses of drug (or bioactive compound), detection of residual disease after therapy and communication with an external clinician/operator. Emerging nanotherapeutics thus blur the boundaries between medical devices and traditional pharmaceuticals. Assembly of therapeutic nanodevices generally exploits either (bio)material self assembly properties or chemoselective bioconjugation techniques, or both. Given the complexity, composition, and the necessity for their tight chemical and structural definition inherent in the nature of nanotherapeutics, their cost of goods (COGs) might exceed that of (already expensive) biologics. Early therapeutic nanodevices will likely be applied to disease states which exhibit significant unmet patient need (cancer and cardiovascular disease), while application to other disease states well-served by conventional therapy may await perfection of nanotherapeutic design and assembly protocols.

10.1 Definitions and Scope of Discussion

Nanotechnology is a field in rapid flux and development, as cursory examination of this volume shows, and definition of its meets and bounds, as well as identification of sub-disciplines embraced by it, can be elusive. The word means many things to many people, and aspects of multiple disciplines, from physics to information technology to biotechnology, legitimately fall into the intersection of the Venn diagram of disciplines that defines nanotechnology. The breadth of the field allows almost any interested party to contribute to it, but the same ambiguity can render the field diffuse and amorphous. If nanotechnology embraces everything, what then is it? The ambiguity fuels cognitive dissonance that can result in frustrating interactions between investigators and funders, authors and editors, and entrepreneurs and investors. Some consideration of the scope of the field therefore is useful.

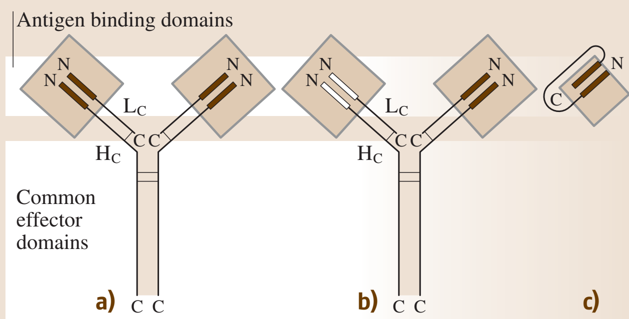

Fig. 10.1a–c Antibodies resemble purpose-built devices with distinct functional domains [10.1]. Native antibodies are composed of four polypeptide chains: two heavy chains (H_C) and two light chains (L_C), joined by interchain disulfide linkages (lines between H_C and L_C moieties). Amino and carboxy termini of individual polypeptide chains are indicated (by N and C). Antigen binding domains are responsible for specific antigen recognition, vary from antibody to antibody, and are indicated by the thicker lines. Common effector functions (F_C receptor binding, complement fixation, etc.) are delimited to domains of the antibodies that are constant from molecule to molecule. **(a)** A native IgG antibody is monospecific but bivalent in its antigen binding capacity. **(b)** An engineered, bispecific, bivalent antibody capable of recognizing two distinct antigens. **(c)** An engineered antibody fragment (single chain Fv or SCFv) that is monospecific and monovalent can recognize only one antigenic determinant and is engineered to lack common effector functions. This construct is translated as a single, continuous polypeptide chain (hence the name SCFv) because a peptide linker (indicated by the connecting line in the figure) is incorporated to connect the carboxy end of the H_C fragment and the amino end of the L_C fragment

To frame the discussion, we will define nanotechnology as the discipline that aims to satisfy desired objectives using materials and devices whose valuable properties are based on a specific nanometer-scale element of their structures. The field is unabashedly application-oriented, so its raison d'être is fulfillment of tasks of interest: technical information is important primarily to the extent that it bears on device design, function, or application.

The meaning of "therapeutic" is largely self-explanatory and refers here to intervention in *human* disease processes (although many of the approaches discussed are equally applicable to veterinary medicine). Our discussion will be confined primarily to therapeutics used in vivo, because such applications clearly benefit from the low invasiveness that ultra-small, but multipotent, nanotherapeutics potentially offer. It is debatable whether imaging, diagnostic, or sensing devices can be considered therapeutic in this context, though, as we will see, sensing/diagnostic functionalities are often inextricable elements of therapeutic nanodevices, and it is difficult to consider so-called smart nanotherapeutics without discussion of their sensing capabilities.

Our definition of nanotechnology projects several corollaries. First, it embraces macroscale structures whose useful properties derive from their nanoscale aspects. Second, the modifier "specific" (as in, "specific nanometer-scale elements") is intended to exclude materials whose utility derives solely from properties inherent in being finely divided (high surface-to-volume ratios, for instance), or other bulk chemical and physical properties. We made the exclusion based on our assessment that therapeutic nanodevices are more intriguing than nanomaterials per se (see below), though we will engage these attributes where they are germane to specific devices or therapeutic applications. Third, our definition implies that limited nanotechnology has been available since the 1970s in the form of biotechnology. Based on their nanoscale structures, individual biological macromolecules (such as proteins) often exhibit the coordinated, modular multifunctionality that is characteristic of purpose-built devices (Fig. 10.1). An analogous, but perhaps less persuasive, argument can be made that organic chemistry is an early form of nanotechnology. Compared to organic small molecules, protein functional capabilities and properties are generally more complex and extremely dependent on their

conformation in three-dimensional space at nanometer scale. The nanotechnology sobriquet, therefore, may be more appropriate to biotechnology than organic chemistry.

Biological macromolecules rely on the deployment of specific chemical functionalities to specific relative distributions in space with nanometer (and greater) resolution for their function, so the inclusion of molecular engineering aspects of biotechnology practice under the nanotechnology rubric is legitimate, despite the discomfort it may cause traditionally trained engineers. As we will see, intervention in human disease often requires inclusion of biomolecules in therapeutic devices: frequently, no functional synthetic analogue of active proteins and nucleic acids is available.

As described above, this chapter focuses primarily on nanoscale therapeutic devices as opposed to therapeutic nanomaterials. Devices are integrated functional structures and not mixtures of materials. Devices exhibit desirable emergent properties inherent in their design: the properties emerge as the result of the spatial and/or temporal organization, and coordination and regulation of action of individual components. The organization of components in devices allows them to perform multistep, cogent work processes that can't be mimicked by simple admixtures of individual components. In fact, if device functions can be mimicked well by simple mixtures of components, the labor involved in configuring and constructing a nanoscale device is not warranted. Our device definition thus excludes nanomaterials used as drug formulation excipients (pharmacologically inert materials included in formulations that improve pharmacophore uptake, biodistribution, pharmacokinetic, handling, storage, or other properties), but embraces those same materials as integral components of drug delivery or other clinical devices.

10.1.1 Design Issues

The biotechnology industry historically has focused on production of individual soluble protein and nucleic acid molecules for pharmaceutical use, with only limited attention paid to functional supramolecular structures [10.2–7]. This bias toward free molecules flies in the face of the obvious importance of integrated supramolecular structures in biology and, to the casual observer, may seem an odd gap in attention and emphasis on the part of practicing biotechnologists. The bias toward single molecule, protein therapeutics, however, follows from the fact that biotechnology is an industrial activity, governed by market considerations. Of the myriad potential therapeutics that might be realized from biotechnology, single protein therapeutics are among the easiest to realize from both technical and regulatory perspectives and so warrant extensive industrial attention. This is changing, however, and more complex entities (actual supramolecular therapeutic devices) have and will appear with increasing frequency in the twenty-first century.

New top-down and bottom-up materials derived from micro/nanotechnology provide the opportunity to complement the traditional limits of biotechnology by providing scaffolds that can support higher level organization of multiple biomolecules to perform work activities they could not perform as free, soluble molecules. Such supramolecular structures have been called nanobiotechnological devices [10.8], nanobiological devices [10.2–7], or semi-synthetic nanodevices and figure prominently in therapeutic nanotechnology.

Incorporation of / Interaction with Biomolecules

In general, design of nanodevices is similar to design of other engineered structures, providing that the special properties of the materials (relating to their nanoscale aspects such as quantum, electrical, mechanical, biological properties, etc.), as well as their impact in therapy, are considered. Therapeutics can interact with patients on multiple levels, ranging from organismal to molecular, but it is reasonable to expect that most nanotherapeutics will interface with patients at the nanoscale at least to some extent [10.2–5, 9–14]. Typically, this means interaction between therapeutics and biological macromolecules, supramolecular structures and organelles, which, in turn, often dictates the incorporation of biological macromolecules (and other biostructures) into nanodevices [10.2, 5, 13–15]. Incorporating biological structures into (nanobiological) devices presents special challenges that do not occur in other aspects of engineering practice.

Unlike fully synthetic devices, semi-biological nanodevices must incorporate pre-fabricated biological components (or derivatives thereof), and therefore the intact nanodevices are seldom made entirely de novo. As a corollary, knowledge of properties of biological device components is often incomplete (as they were not made by human design), and therefore the range of activities inherent in any nanobiological device design may be much less obvious and less well-defined than it is for fully synthetic devices. Further complicating the issue, the activities of biological molecules are often multifaceted (many genes and proteins exhibit

pleiotropic activities), and the full range of functionality of individual biological molecules in interactions with other biological systems (as in nanotherapeutics) is often not known. This makes design and prototyping of biological nanodevices an empirically intensive, iterative process [10.3–5, 14].

Biological macromolecules have properties, particularly those relating to their stability, that can limit their use in device contexts. In general, proteins, nucleic acids, lipids, and other biomolecules are more labile to physical insult than are synthetic materials. With the possible exceptions of topical agents or oral delivery and endosomal uptake of nanotherapeutics (both involving exposure to low pH), patients can tolerate conditions encountered by nanobiological therapeutics in vivo, and device lability in the face of *physical* insult is generally a major consideration only in ex vivo settings (relating to storage, sterilization, ex vivo cell culture, etc.). Living organisms remodel themselves constantly in response to stress, development, pathology, and external stimuli. For instance, epithelial tissues and blood components are constantly eliminated and regenerated, and bone and vasculature are continuously remodeled. The metabolic facilities responsible (circulating and tissue-bound proteases and other enzymes, various clearance organs, the immune system, etc.) can potentially process biological components of nanobiological therapeutic devices as well as endogenous materials, leading to partial or complete degradation of nanotherapeutic structure, function, or both. Furthermore, the host immune and wound responses protect the host against pathogenic organism incursions by mechanisms that involve sequestering and degrading the pathogens. Nanobiological therapeutics are subject to the actions of these host defense systems and to normal remodeling processes. As we will discuss, various strategies to stabilize biomolecules and structures in heterologous in vivo environments are applicable to nanobiological therapeutics [10.3, 16–20]. Conversely, instability of active biocomponents can offer a valuable and simple way to delimit the activity of nanotherapeutics containing biomolecules.

Nanotherapeutic Design Paradigms

Several early attempts to codify the canonical properties of ideal nanobiological devices, and therapeutic nanodevices in particular, have been made [10.5, 13, 15, 21] and are summarized in Table 10.1. In general, nanobiological devices contain biological components that retain their function in new (device) contexts. In other words, one must abstract enough of a functional biological unit from its native context to allow it to perform the function for which it was selected. If one wishes, for example, to appropriate the specific antigen recognition property of an antibody for a device function (say, in targeting, discussed later), it is not necessary to incorporate the entire 150,000 atomic mass unit (AMU) antibody, the bulk of which is devoted to functions other than antigen recognition (see Fig. 10.1 [10.1]), but it *is* critical to incorporate the approximately 20,000 AMU of the antibody essential for specific antibody–antigen

Table 10.1 Some ideal characteristics of nanodevices. (**A**) Characteristics of all nanobiological devices [10.2, 5, 13–15]. (**B**) Desirable characteristics of therapeutic platforms [10.2, 5, 13–15]

A
Biological molecules must retain function.
Device function is the result of the summed activities of device components.
The relative organization of device components drives device function.
Device functions can be unprecedented in the biological world.
B
Therapeutics should be minimally invasive.
Therapeutics should have the capacity to target sites of disease.
Therapeutics should be able to sense disease states in order to:
– report conditions at the disease site to clinicians.
– administer metered therapeutic interventions.
Therapeutic functions should be segregated into standardized modules.
Modules should be interchangeable to tune therapeutic function.

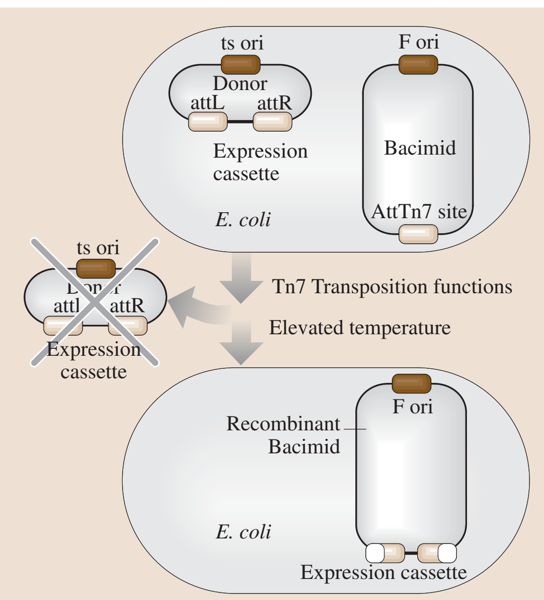

Fig. 10.2 The bacmid molecular cloning system is a molecular device designed to allow efficient production of recombinant insect viruses (baculovirus) in *Escherichia coli* [10.22–24]. Baculovirus is replicated in *E. coli* by the F plasmid origin of replication (F ori), and as such, is called a bacmid. The bacmid also includes an engineered transposable DNA element 7 (Tn7) attachment site isolated from the chromosome of an enteric bacteria (AttTn7). AttTn7 can receive Tn7 elements transposed from other cellular locations. A donor plasmid (donor) is replicated by a temperature-sensitive plasmid pSC101 origin of replication (ts ori). The donor also incorporates an expression cassette containing both the gene of interest for ultimate expression in insect cells and a selectable genetic marker operable in *E. coli*. The expression cassette is flanked by DNA sequences (attL and attR) that are recognized by the Tn7 transposition machinery. Tn7 transposition machinery resides elsewhere in the same *E. coli* cell. When donor plasmid is introduced into *E. coli* containing bacmid, Tn7 transposition machinery causes the physical relocation of expression cassettes from donor plasmid to bacmid. Unreacted donor plasmid is conveniently removed by elevating the incubation temperature, causing the ts pSC101 replicon to cease to function, in turn, causing the donor to be lost. If selection for the genetic markers within the expression cassette is applied at this point, the only *E. coli* that survive are those containing recombinant bacmid (i. e., those that have received the gene for insect cell expression by transposition from the donor). Recombinant bacmid are conveniently isolated from *E. coli* and introduced into insect cell culture, where expression of the gene of interest occurs

binding. Device function is the result of the summed and various activities of biological and synthetic device components, as well, though functional biological components generally exist in the context of higher order systems that support the organisms of which they are a part by the control the nanobiological device designer can exert on the relative organization of biological device components allows biomolecules abstracted from their native context and incorporated in nanobiotechnological devices to contribute to functions entirely different from those they performed in their organismal contexts. All of these features are illustrated in the bacmid, or Bac-to-Bac, system, a commercially available molecular cloning device ([10.22–24] and Fig. 10.2). This system configures prokaryotic genetic elements from multiple sources into a device for producing recombinant eukaryotic viruses, a function that is unprecedented in nature. The system is feasible because of the modularity of the genetic elements involved and because of the strict control of the relative arrangement of genetic elements allowed by recombinant DNA technology. Analogous devices based on bacterial and eukaryotic regulatory elements to pre-program the micro- and nanoscale architectural properties and physiological behavior of living things are now being realized [10.25, 26].

Bacmid provides an example of a nontherapeutic nanobiological device and illustrates some specific design approaches for building functional devices with biocomponents. Hypothetical properties of nanoscale devices specifically for therapeutic purposes have been codified (Table 10.1) and bear examination [10.13, 15].

In nanotherapeutic applications, devices should be noninvasive and target therapeutic payloads to sites of disease to maximize therapeutic benefit while minimizing undesired side effects. This of course implies the existence of therapeutic effector functions in these nanodevices, to give devices the ability to remediate a physiologically undesirable condition. Beyond that, several attributes relate to sensing of biomolecules, cells, or physical conditions (sensing disease itself, identification of residual disease, and, potentially, targeting capacity, responding to intrinsic or externally supplied triggers for payload release). Other properties relate to communication between device subunits (for instance, between sensor and effector domains of the device)

Fig. 10.3 A hypothetical, modular nanotherapeutic patterned after the dendrimer-based cluster agent for oncology of Baker [10.15]. As described in the text, each dendrimer subunit is grown from an initiator core (C), and the tunable surface groups of the dendrimers are represented by Z. Each dendrimer subunit has a specific, dedicated function in the device: the central dendrimer encapsulates small molecule therapeutics (E), whereas other functional components are segregated to other dendrimer components. These include biochemical targeting/tethering functions (Ta), therapeutic triggering functions to allow activation of prodrug portions of the device by an external operator (Tr), metal or other constituents for imaging (I), and sensing functions (S) to mediate intrinsically controlled activation/release of therapeutic. This design constitutes a therapeutic platform [10.13, 15] because of its modular design. The depicted device is only one possible configuration of an almost infinite number of analogous therapeutics that can be tuned to fit particular therapeutic needs by interchanging functional modules

or between the device and an external operator (external triggering and data documentation capability). With appropriate design, device functions can be modular [10.13, 15]. As discussed below, this approach allows construction of nanotherapeutic platforms (such as the dendrimer-based therapeutic of Fig. 10.3, dendrimer synthesis and assembly are discussed later), as opposed to single one-off devices that are capable of only one therapeutic task.

The vision of nanoscale therapeutic platforms arose from collaboration between the National Cancer Institute (NCI) and the National Aeronautics and Space Agency (NASA). NASA is concerned with minimal mass therapeutics: therapeutics, along with almost

everything else used by astronauts, must be launched from Earth. NCI is interested in early detection of disease to improve prognosis. Since this requires screening a population predominantly of healthy patients, the screening mode must be minimally invasive. The considerations of both agencies might be met with ultra-small (micro- or nanoscale) multipotent therapeutic devices. Furthermore, the proposed therapeutic platforms should not only remediate undesired physiological conditions but also have the capacity to recognize them and report them. Extensive capability for molecular recognition and communication with external clinicians/operators is integral to the requirements of NASA and NCI. These capacities would allow drugs or other therapeutic interventions to be provided in a controlled fashion, to maximize benefit and minimize side effects, and is the essence of "smart" therapeutics (see the discussion of targeting and triggering below).

Though substantial progress has been made in device design and realization, no fully realized multipotent nanoscale therapeutic platform has yet been commercialized, but the therapeutic platform paradigm, in which devices are modular, with functional tasks segregated into individual modules, has potential to be extremely powerful. Classes of broadly similar devices could be tailored to specific disease states by interchanging modules (targeting modules, drugs dispensers, etc.) as appropriate to the disease state or therapeutic course. Thus, the hypothetical device represents a possible therapeutic platform composed of functional modules that could be for use in particular indications or in specific individuals.

10.1.2 Utility and Scope of Therapeutic Nanodevices

Therapeutic nanotechnology will be useful, of course, when the underlying biology of the disease states involved is amenable to intervention at the nanoscale. As we will discuss, while several disease states and physiological conditions (cancer, vaccination, cardiovascular disease, etc.) are particularly accessible to nanoscale interventions, some nanotechnological approaches may be applicable more broadly. Much as was the case with the introduction of recombinant protein therapeutics over the last 20 years, nanotherapeutics may present regulatory and pharmacoeconomic challenges related to their novelty and their cost of goods (COGs).

10.2 Synthetic Approaches: "top-down" versus "bottom-up" Approaches for Nanotherapeutic Device Components

Synthesis of nanomaterials is commonly thought of in terms of "top-down" or "bottom-up" processes. Top-down approaches begin with larger starting materials and, in a more or less controlled fashion (depending on the technique), remove material until the desired structure is achieved. Most microfabrication techniques for inorganic materials (lithography and milling techniques, etc.) fit this description. In contrast, bottom-up approaches begin with smaller subunits that are assembled, again with varying levels of control, depending on technique, into the final product. Key examples of materials made by bottom-up approaches include some inorganic structures. This includes "handmade" structures created by using direct atomic or molecular placement by force microscopy (discussed below), structures built using various deposition or growth methods, as well as all polymerization methods of synthesis. Thus, almost all biologic macromolecules and most biogenic structures, including mineralized biomaterials, are made by bottom-up methods. To make the distinction between top-down and bottom-up approaches more concrete, we will consider an example of each.

10.2.1 Production of Nanoporous Membranes by Microfabrication Methods: A top-down Approach

Lithography can be summarized by three basic steps: 1) Pattern Design (generation of masks), 2) Pattern Definition (exposure), and 3) Pattern Transfer (etching/liftoff). Optical lithography uses masks to form patterns on resist/substrate surfaces to produce features. The technique's power lies in its reproducibility and its capacity to manufacture via highly parallel processes. The key limitation of photolithography lies in the fact that resolution of features is diffraction-limited by the wavelength of light used. To address this limitation, short-wave radiation (i. e., X-rays with wavelengths of

about 1nm wavelength) can be generated by synchrotron or other sources (from X-ray tubes, discharge plasma, or laser plasma), controlled, and focused for use in X-ray lithographic techniques [10.27]. The process is identical conceptually to optical lithography but requires special masks and resists amenable to the high-frequency radiation used. Combinations of filters and mirrors can produce resolutions in feature size of less than 100 nm, with fabrication throughputs congruent with those of other optical lithography processes. Limited access to synchrotron sources in turn limits the wide application of the method, however. The relatively long wavelengths used in conventional photolithography are generally unsuitable for formation of nanoscale features unless some clever technical expedient, like the use of a sacrificial layer (described below for generating nanoporous membranes) is employed.

As we will discuss in consideration of applications of nanotherapeutic devices, there are numerous potential applications for tunable nanopore membranes [10.16–18]. For certain applications, such as immunoisolation (see below), the distribution of pore sizes must be tight and nearly perfect. Until the late 1990s, this was an unattainable objective.

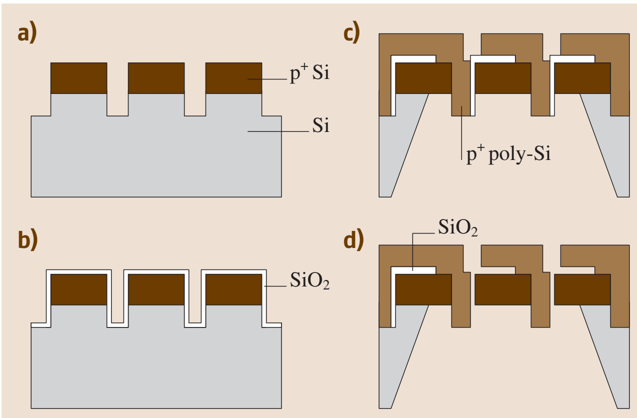

Fig. 10.4a–d Nanoporous silicon membranes are fabricated by a top-down approach [10.16–18]. **(a)** Pore exit holes are plasma-etched through p+ silicon (*dark brown*) and boronated silicon (*grey*). **(b)** Controlled depth silicon oxide (*white*) layer is grown on the structure. **(c)** A thick polysilicon layer (*light brown*) is deposited over the oxide, and pore exits are established by back-side plasma etch. **(d)** Pores are opened by removal of the sacrificial layer with hydrofluoric acid. The membranes themselves are macroscale objects that fit under the nanotechnology rubric because they derive their useful properties from controlled nanoscale architecture

The key technical innovation facilitating the microfabrication of highly defined nanoporous membranes was an approach featuring a sacrificial oxide layer sandwiched between two structural layers that ultimately is etched away to define the pore pathway and diameter [10.16–18]. The sacrificial layer (SiO_2) is sandwiched between a silicon wafer and a polysilicon layer: pore channel diameter is determined by the SiO_2 thickness. In the process (Fig. 10.4), the top of a silicon wafer is doped with boron to increase its mechanical robustness, and p+ silicon is overlaid. Pore exit holes are plasma etched through the p+ and doped material. In the pore dimension-determining step, SiO_2 is grown on the wafer by dry thermal oxidation, a process allowing control of oxide layer thickness to within 1 nm. This oxide constitutes the critical sacrificial layer. A thick polysilicon layer (again, boron-doped for mechanical strength) is then deposited over the oxide. Pore entry holes are etched by plasma etch, offset from the exit pores. Ultimately, the offset will require the diffusion pathway of the finished structure to pass through a "bottleneck" whose diameter is determined by the thickness of the sacrificial layer. The backside of the wafer is anisotropically etched to expose the doped layer of the wafer (now the bottom of the membrane structure). Pores are opened by removal of exposed sacrificial layer using concentrated hydrofluoric acid.

10.2.2 Synthesis of Poly(amido) Amine (PAMAM) Dendrimers: A bottom-up Approach

PAMAM dendrimers are remarkably defined synthetic molecules made using polymer chemistry (Fig. 10.5). Their unique structural attribute is their fractal geometry, and their unique physical property is their high monodispersity. Clever use of orthogonal conjugation strategies in their synthesis drives their monodispersity [10.28–30].

Orthogonal conjugation involves the mutually exclusive reactivity of the chemical specificities present in the reaction: when the orthogonal reactants are present in a vessel, and the reaction is carried at appropriate stoichiometry, only a monodisperse single product is formed. PAMAM dendrimers are among the most monodisperse synthetic materials available and, within limits, their sizes, surface chemistries, and shapes can be controlled at the synthetic level. To a greater or lesser extent, these desirable material properties of dendrimers are caused by an orthogonal synthetic strategy.

Fig. 10.5 PAMAM dendrimers are grown bottom-up using sequential orthogonal synthetic steps [10.28–30]. Dendrimers are grown from amine cores, in this case ammonia, by sequential addition of methyl acrylate, followed by an independent reaction addition reaction involving ethylene diamine. Together, these two half-steps constitute a full generation of dendrimer growth. PAMAM dendrimers are classified by their generation of growth as being G_0, G_1, G_2, etc., as indicated in the figure

PAMAM dendrimers are usually built from an initiator core (an amine) in sequential shells, called generations (i. e., G_0, G_1, G_2, etc.). Each generation comprises two synthetic half-steps, each of which is self-limiting in that the reagents performing each addition step are reactive only with the distinct chemical functionalities added to the growing dendrimer in the *previous* addition reaction. Reagent is added until the chemical functionalities from the previous step are fully consumed (Fig. 10.5). In the first synthetic half-step, methyl acrylate is added to the amine precusor, adding a carboxy-terminated functionality to all amine branch points. Polymer intermediates terminating in such carboxy functionalities are called "half-generation." In the second half-step, the generation is completed. Ethylene diamine is added, resulting in a branched amine-terminated adduct for each carboxylate group of the half-generation precursor. In general, before proceeding to downstream synthetic operations, products of individual reactions are purified so that only functionalities incorporated into growing dendrimer are available for subsequent reactions. Under ideal conditions, only a single chemical structure can result from each generation of growth, and with adequate purification between addition reactions; in the absence of limitations on the completeness of each reaction (such as steric limitations which become manifest in dendrimers of generation 6 and above), dendrimers of each generation are perfectly identical to each other.

10.2.3 The Limits of top-down and bottom-up Distinctions with Respect to Nanomaterials and Nanodevices

Some materials can be produced by alternate means, some of which are bottom-up, some of which are top-down approaches. For instance, carbon nanotubes can be synthesized in an arguably top-down approach from graphite sheets in an arc oven or can be grown bottom-up, by a metal-catalyzed polymerization method [10.31]. Additionally, not all finished materials can be classified as either top-down or bottom-up: synthetic protocols can contain both steps. For instance, while proteins are synthesized from lower molecular weight amino acid precursors by chemically or biologically mediated polymerization (bottom-up), they are often made as precursor molecules that are processed to a final product by chemical or enzymatic cleavage (top-down, see [10.32] for an overview). While the question of whether any given material is made top-down or bottom-up can be ambiguous, the synthetic provenance of multicompo-

nent nanodevices can be even more so. In analogy to biogenic materials, synthetic polymers are bottom-up materials per se, but fabrication of raw polymeric materials into final device architectures often involves top-down steps [10.33]. As we will see, therapeutic nanodevices frequently contain both synthetic and biologic components, and strict top-down and bottom-up categorization of these devices is often not applicable.

10.3 Technological and Biological Opportunities

This section considers selected enablers for therapeutic nanodevices. Some are purely technological: nanomaterial self-assembly properties, bioconjugation methods, engineered polymers for conditional release of therapeutics, external triggering strategies, and so forth. Others relate to disease-state tissue or cell-specific biology that can be exploited by nanotherapeutics, such as the emerging vascular address system and intrinsic triggering approaches. In association with those applications, we will consider additional biological opportunities for nanoscale approaches specific to particular disease states.

10.3.1 Assembly Approaches

Assembly of components into devices is amenable to multiple approaches. In the case of devices comprising a single molecule or processed from a single crystal (some microfabricated structures, single polymers, or grafted polymeric structures) assembly may not be an issue. Integration of multiple, separately microfabricated components may sometimes be necessary (as in the immunoisolation capsule discussed below) and may sometimes drive the need for assembly, even for silicon devices. Furthermore, many therapeutic nanodevices contain multiple, chemically diverse components that must be assembled precisely to support their harmonious contribution to device function.

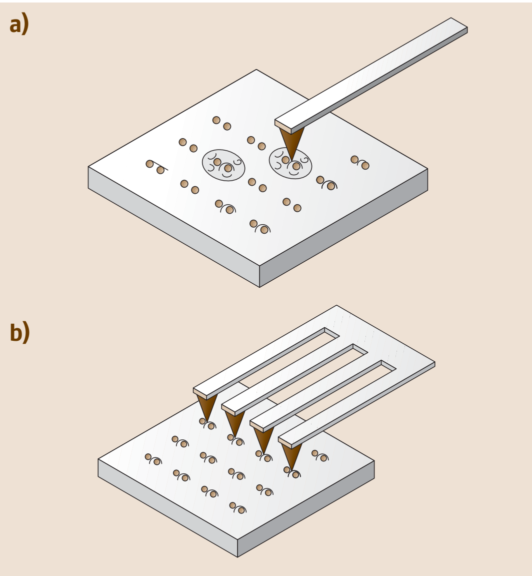
"One off" Nanostructures and Low Throughput Construction Methods

Direct-write technologies can obtain high (nanometer scale) resolution. For instance, electron-beam (e-beam) lithography is a technique requiring no mask, and that can yield resolutions on the order of tens of nanometers, depending on the resist materials used [10.34]. Resolution in e-beam lithography ultimately is limited by electron scattering in the resist and electron optics, and like most direct-write approaches, e-beam lithography is limited in its throughput. Parallel approaches involving simultaneous writing with up to 1,000 shaped e-beams are under development [10.34] and may mitigate limitations in manufacturing rate.

Force microscopy approaches utilize an ultrafine cantilever tip (typically with point diameters of 50 nm or less, Fig. 10.6) in contact with, or tapping, a surface or a stage. The technique can be used to image molecules, to analyze molecular biochemical properties (like ligand-receptor affinity [10.35]), or to manipulate materials at nanoscale. In the latter mode, force microscopy has been used to manipulate atoms to build individual nanostructures since the mid-1980s. This has led to construction of structures that are precise to atomic levels of resolution (Fig. 10.6), though the manufacturing throughput of "manual" placement of atoms by force microscopy is limited.

Dip-pen nanolithography (DPN) is a force microscopy methodology that can achieve high resolution features (features of 100 nm or less) in a single step. In DPN, the AFM tip is coated with molecules to be deployed on a surface, and the molecules are transferred from the AFM tip to the surface as the coated tip contacts it. DPN also can be used to functionalize surfaces with two or more constituents and is well suited for deployment of functional biomolecules on synthetic surfaces with nanoscale precision [10.36, 37]. DPN suffers the limitations of synthetic throughput typical of AFM construction strategies.

Much as multibeam strategies might improve throughput in e-beam lithography [10.34], multiple tandem probes may increase assembly throughput for construction methods that depend on force microscopy significantly, but probably not sufficiently to allow manufacture of bulk quantities of nanostructures, as will likely be needed for consumer nanotherapeutic devices. As standard of care evolves increasingly toward tailored courses of therapy [10.38] and individual therapeutics become increasingly multicapable and powerful, however, relatively low throughput synthesis/assembly methods may become more desirable. For the moment, though, ideal manufacturing approaches for nanotherapeutic devices resemble either industrial polymer chemistry, occurring in bulk, in convenient buffer



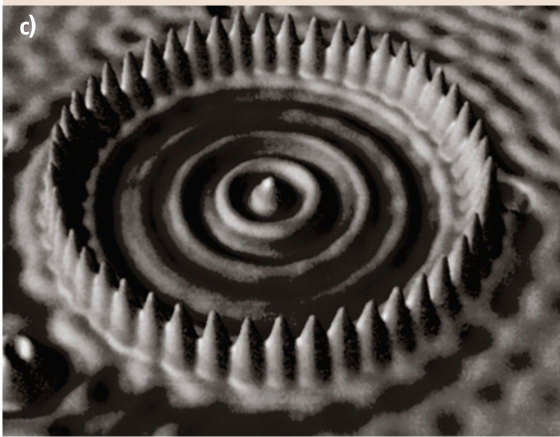


Fig. 10.6 **(a)** A schematic depiction of an atomic force microscope cantilever and tip interacting with materials on a surface. Tips typically have points of 50 nm or less in diameter [10.31, 39]. **(b)** Schematic of multiplexed AFM tips performing multiple operations in parallel [10.31, 39]. **(c)** AFM image of a quantum corral, a structure built using AFM manipulation of individual atoms (from the IBM Image Gallery)

systems, or in massively parallel industrial microfabrication approaches. In any case, therapy for a single patient may involve billions of billions of individual nanotherapeutic units, so each individual nanotherapeutic structure must require only minimal input from a human synthesis/manufacturing technician.

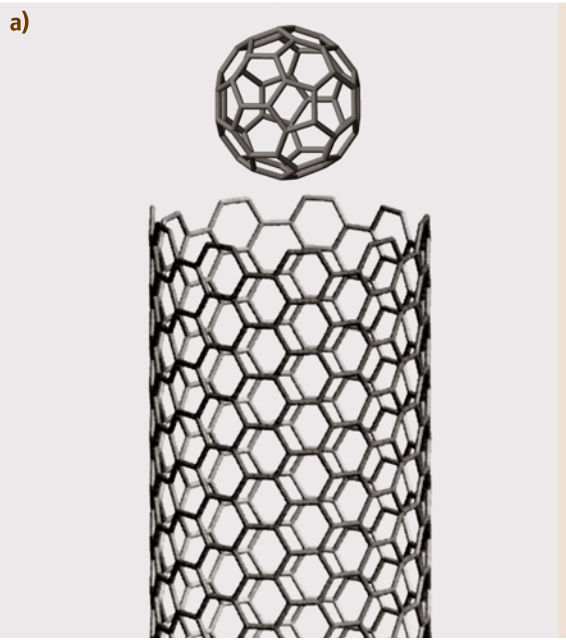
Self-Assembly of Nanostructures

Self-assembly has been long recognized as a potentially critical labor-saving approach to construction of nanostructures [10.40], and many organic and inorganic materials have self-assembly properties that can be exploited to build structures with controlled configurations. Self-assembly processes are driven by thermodynamic forces and generally result in structures that are not covalently linked. Intra/intermolecular forces driving assembly can be electrostatic or hydrophobic interactions, hydrogen bonds, and van der Waals interactions between and within subunits of the self-assembling structures and the assembly environment. Thus, final configurations are limited by the ability to "tune" the properties of the subunits and control the assembly environment to generate particular structures.

Self-Assembly of Carbon Nanostructures

Carbon nanotubes (Fig. 10.7) spontaneously assemble into higher order [10.31] structures (nanoropes) as the result of hydrophobic interactions between individual tubes. Multi-wall carbon nanotubes (MWCNT) are well-known structures that can be viewed as self-assembled, nested structures of nanotubes with tube diameters decreasing serially from the outermost to innermost tubes. The striking resemblance that MWCNT have to macroscale bearings has been noted and exploited [10.41]. MWCNT linear bearings can be actuated by application of mechanical force to the inner nanotubes of the MWCNT assembly. Actuation causes the assembly to undergo a reversible telescoping motion. Interestingly, these linear MWCNT bearings exhibit essentially no wear as the result of friction between bearing components.

C_{60} fullerenes and single wall carbon nanotubes (SWCNT) also spontaneously assemble (Fig. 10.7) into higher order nanostructures called "peapods" [10.42] in which fullerene molecules are encapsulated in nanotubes. The fullerenes of peapods modulate the local electronic properties of the SWCNT in which they are encapsulated and may allow tuning of carbon nanotube electrical properties. The potentially fine-level control of nanotube properties may prove useful in nanotube-containing electrical devices, particularly in cases wherein nanotubes are serving as molecular wires. In this capacity, carbon nanotubes have been incorporated into FETs (field effect transistors, discussed below under sensing architectures [10.43]), and other molecular electronic structures. Ultimately, these architectures may result in powerful, ultra-small computers to provide the intelligence of "smart," indwelling nanotherapeutic



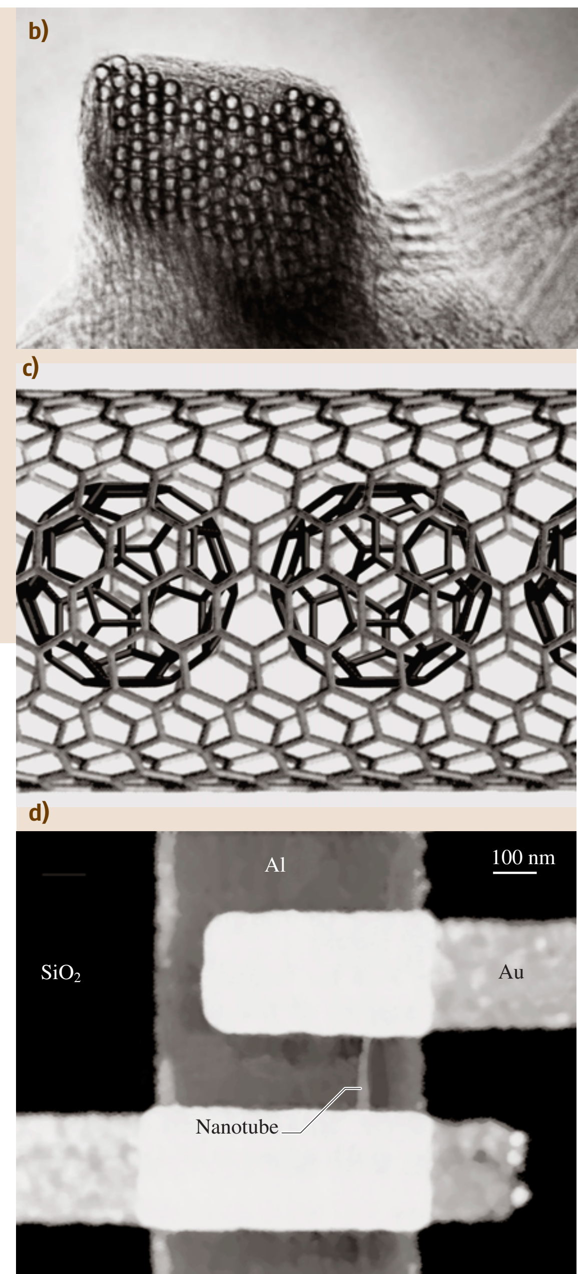


Fig. 10.7a–d **(a)** Shown to scale are two highly defined carbon nanostructures: a C_{60} fullerene and (10, 10) single wall carbon nanotube (SWCNT). **(b)** A self-assembled nanorope composed of carbon nanotubes that assemble by virtue of hydrophobic interactions [10.31,39]. **(c)** Schematic depiction of another self-assembled carbon nanostructure (a peapod) consisting of the fullerenes and SWCNT of 7a, and wherein the fullerenes are encapsulated in the SWCNT [10.42]. Fullerene encapsulation in the peapods modulates local electronic properties of the SWCNT. **(d)** A nanotube field effect transistor (FET) consisting of gold source and drain electrodes on an aluminum stage with a carbon nanotube serving as the FET channel [10.43]

devices. In general, though, fullerenes, nanotubes carbon nanoropes, nanotube bearings, and peapods have yet to find extensive biological application, in part because of their extreme hydrophobicity, presumably poor biocompatibility, and high chemical stability [10.31, 39]. But controlled derivatization of nanotubes may be possible through a number of approaches [10.31, 39] including controlled introduction of bond strain to render individual carbons of the tubes selectively chemically reactive (so-called mechanosynthesis). Carbon nanotubes and fullerenes, however, owe many of their remarkable properties (chemical stability, mechanical robustness, some electrical properties) to the fact that all the valences of the constituent carbon atoms (except those at the ends of nanotubes that are "open") are satisfied. Thus, to derivatize carbon nanostructures is to degrade them, a fact one must consider when the design purposes that drove incorporation of carbon structures into a therapeutic depends on the chemical perfection of the material.

Self-Assembly of Materials Made by Traditional Polymer Chemistry

In the realms of drug delivery and biomedical micro and nanodevices, the most familiar self-assembled structures are micelles [10.44–46]. These structures are formed from the association of block co-polymer subunits (Fig. 10.8), each individual subunit containing hydrophobic and hydrophilic domains. Micelles spontaneously form when the concentration of their subunits exceeds the critical micelle concentration (cmc) in a solvent in which one of the polymeric domains is immiscible (Fig. 10.8). The cmc is determined by the immiscible polymeric domain and can be adjusted by control of the chemistry and length of the immiscible domain, as well as by control of solvent conditions. Micelles formed at low concentrations from low-cmc polymers are stable at high dilution. Micelles formed from polymer monomers with high cmcs can dissociate upon dilution, a phenomenon that might be exploited to control release of therapeutic cargos. If desired, micelles can be stabilized by covalent cross-linking to generate shell-stabilized structures [10.44–47].

The size dispersity and other properties of micelles can be manipulated by control of solvent conditions, incorporation of excipients (to modulate polymer packing properties), temperature, and agitation. From the standpoint of size, reasonably monodisperse preparations (polydispersity of 1–5%) of nanoscale micellar structures can be prepared [10.44–47]. The immense versatility of industrial polymer chemistry allows micellar structures to be tuned chemically to suit the task at hand. They can be modified for targeting or to support higher order assembly properties. They can be made to imbibe therapeutic or other molecules for delivery and caused to dissociate or disgorge themselves of payloads at desired times or bodily sites under the influence of local physical/chemical conditions. The tunability of these and other properties at the level of monomeric polymer subunits as well as the level of assembled higher order structures make micelles potentially powerful nanoscale drug delivery and imaging vehicles.

Fractal materials, such as dendritic polymers, whose synthesis and structure were discussed previously, exhibit packing properties that can be exploited to assemble higher order aggregate structures called "tecto(dendrimers)" [10.48]. In fact, these self-assembly properties are being exploited in oncological nanotherapeutics as Fig. 10.3 shows [10.15, 49]. In principle, these self-assembling therapeutic complexes need not be pre-formed prior to administration. Individual functional modules of the therapeutic assembly might be administered sequentially, potentially to tailor therapies more precisely to individual patient responses.

Stoichiometric Control and Self-Assembly

As the preceding examples demonstrate, self-assembly approaches sometimes do not feature precise control of subunit identity and stoichiometry in the assembled complexes. This can be a limitation when the stoichiometry and relative arrangement of differentiable individual subunits is critical to device function. Stoichiometry is less an issue when the self-assembling components are identical and functionally fungible, as in the synthetic, peptidyl anti-infective illustrated in Fig. 10.9 [10.50,51].

In the anti-infective architecture, individual peptide components are flat, circular molecules. The planar character of the toroidal subunits is a consequence of the alternating chirality of alternating D-L amino acids (aas) in the primary sequence of the peptide rings. Alternating D and L aas is not possible in proteins made by ribosomal synthesis [10.32]. Ribosomes recognize and incorporate into nascent polypeptides only L amino acids, and so, as the result of aa chirality and bond strain, peptides made by ribosomes cannot be made flat, closed toroids like those of the peptidyl anti-infectives. Much as in α-helical domains of ribosomally synthesized proteins, however, the aa R-groups (which are of varying hydrophobic or hydrophilic chemical specificities [10.32]) are arranged in the plane of the closed D, L rings extending out from the center of the rings. Hydrogen bonds between individual rings govern self-assembly of the toroids into rod-like stacks, while the R-groups dominate interactions between multiple stacks of toroids and other macromolecules and structures (see below).

The planar toroidal subunits can be administered as monomers and self-assemble into multi-toroid rods at the desired site of action (in biological membranes). But the peptide toroids R-groups are chemically tuned so that the rod structures into which they spontaneously assemble intercalate preferentially in specific lipid bilayers (i. e., in pathogen vs. host membranes). Moreover, the assembled rods may undergo an additional level of self-assembly into multi-rod structures, spanning pathogen membranes [10.50, 51]. Whether as single rod or multiple rod assemblies, membrane intercalation by stacked toroids reduces the integrity of pathogen membranes selectively, and therefore particular toroid species exhibit selective toxicity to specific pathogens.

Hydrophobic and hydrophilic polymer blocks, copolymers containing the blocks, micelles generated from the block copolymers, and (hydrophobic) drugs for encapsulation in the micelles are indicated. **(b)** Micelle self-assembly and charging with drug occuring simultaneously when the drug-polymer formulation is transitioned from organic to aqueous solvent by dialysis. **(c)** Pre-formed micelles can be passively imbibed with drugs in organic solvent. Organic solvent is then removed by evaporation, resulting in compression of the (now) drug-bearing hydrophobic core of the micelle. **(d)** An illustration of concentration-driven micelle formation. At and above the critical micelle concentration (cmc), block copolymer monomers assemble into micelles, rather than exist as free block copolymer molecules. The *arrow* indicates the cmc for this system

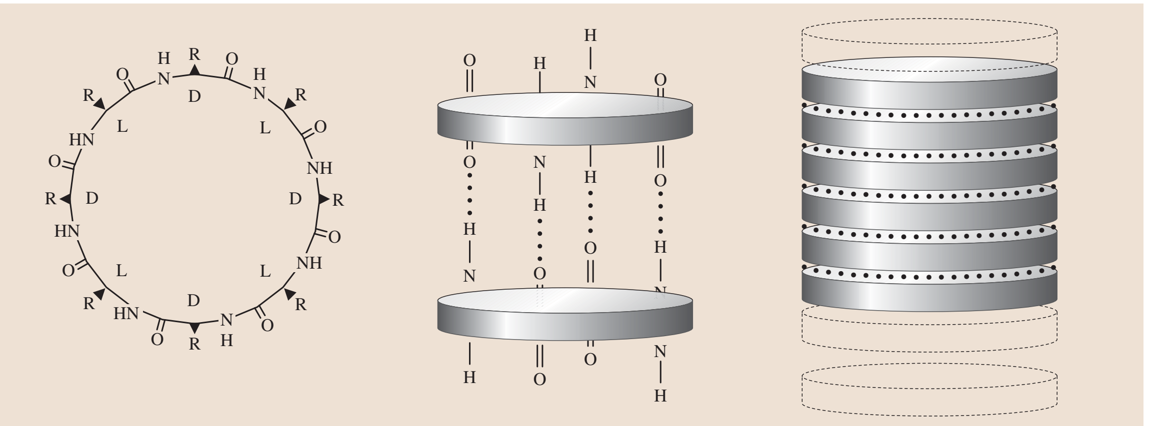

Fig. 10.9 A self-assembling peptide antibiotic nanostructure [10.50, 51]. Peptide linkages and the α-carbons and their pendant R groups are indicated. The synthetic peptide rings are planar as the result of the alternating chirality (D or L) of their amino acid (aa) constituents. R groups of aas radiate out from the center of the toroid structure. Individual toroids self-assemble (stack) as the result of hydrogen bonding interaction between amine and carboxy groups of the peptide backbones of adjacent toroids. The surface chemistry of multi-toroid stacks is tuned at the level of the aa sequence and, therefore, R group content of the synthetic peptide rings. The chemical properties of the stacked toroid surfaces allow them to intercalate into the membranes of pathogenic organisms with lethal consequences. The specific membrane preferences for intercalation of the compound are tuned by control of R group content of torroids

These toroidal, synthetic antibiotics, and other nanoscale antimicrobials represent critically needed, novel antibacterial agents. Resistance to traditional, microbially derived antibiotics often is tied to detoxifying functions associated with secondary metabolite synthesis; these detoxifying functions are essential for the viability of many antibiotic producing organisms (for instance, see [10.52]). The genes encoding such detoxifying functions are rapidly disseminated to other microorganisms, accounting for the rapid evolution of drug resistant organisms that has bedeviled antimicrobial chemotherapy for the last 25 years. Synthetic nanoscale antibiotics, like the peptide toroids [10.50, 51] and the N8N antimicrobial nanoemulsion [10.53], act by mechanisms entirely distinct from those of traditional secondary metabolite antibiotics, and no native detoxifying gene exists. Therefore, novel nanoscale antimicrobials may not be subject to the unfortunately rapid rise in resistant organisms associated with most secondary metabolite antibiotics, though this remains to be seen. As bacterial infection continues to re-emerge as a major cause of morbidity and mortality in the developed world, consequence of increasing antibiotic-resistant pathogens, novel nanoscale antibiotics will become more important.

Biomolecules in Therapeutic Nanodevices: Self-Assembly and Orthogonal Conjugation

Biological macromolecules undergo self-assembly at multiple levels, and like all instances of such construction, biological self-assembly processes are driven by thermodynamic forces. Some biomolecules undergo intramolecular self-assembly (as in protein folding from linear peptide sequences, Fig. 10.10). Higher order structures are, in turn, built by self-assembly of smaller self-assembled subunits (for instance, structures assembled by hybridization of multiple oligonucleotides, enzyme complexes, fluid mosaic membranes, ribosomes, organelles, cells, tissues, etc.).

Proteins are nonrandom copolymers of 20 chemically distinct amino acid (aa) subunits [10.32]. The precise order of aas (i. e., via interactions between aa side chains) drives the linear polypeptide chains to form specific secondary structures (the α helices and β sheet structures seen in Fig. 10.10). The secondary structures have their own preferences for association, which, in turn, leads to the formation of the tertiary and quartenary structures that constitute the folded protein structures. In its entirety, this process produces consistent structures that derive their biological functions from strict control of the deployment of chemical

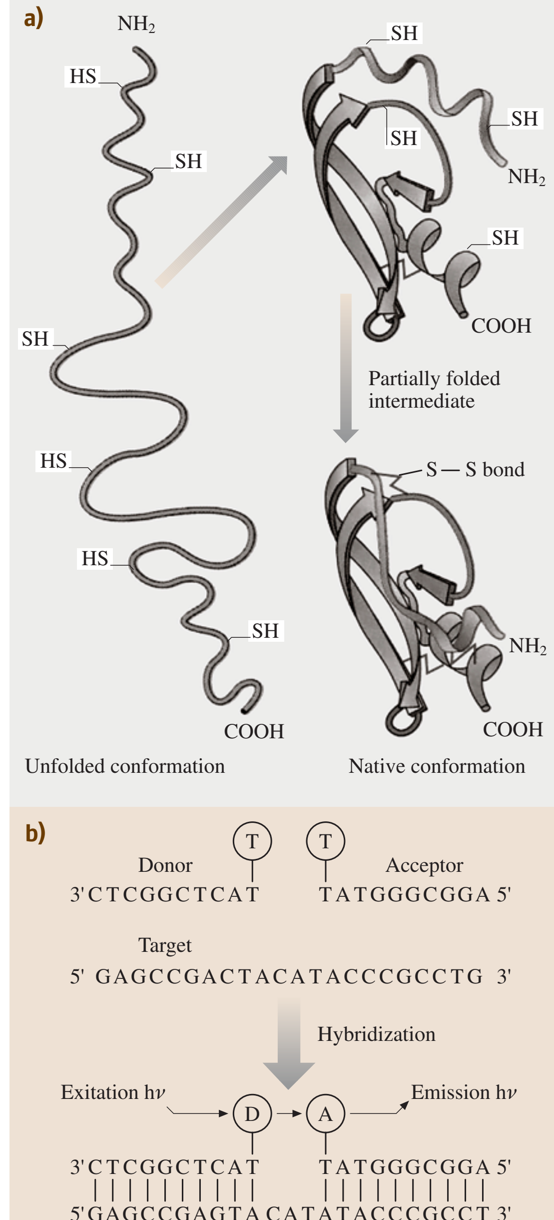

Fig. 10.10a,b Self-assembly and biological macromolecules **(a)** Linear peptide chains (with amino and carboxy ends, as well as sulfhydral groups of cysteine residues indicated) undergoe a multistep folding process that involves the formation of secondary structures (α-helices, indicated by heavy helical regions, and β-sheet regions, indicated by the heavy anti-parallel arrows) that themselves associate into a tertiary structure. Final conformation is stabilized by the formation of intrachain disulfide linkages involving cysteine thiol groups. **(b)** A fluorescence transfer device that depends on self-assembly of biomolecules. The device is composed of donor (D) and acceptor (A) molecules brought into close proximity (within a few angstroms) by the base pair hybridization of complementary oligonucleotides. When the structure is assembled, acceptor and donor are energetically coupled, and fluorescence transfer can occur [10.54–57]

specificities (the aa side chains) in three-dimensional space.

Biomolecules can be used to drive assembly of nanostructures, either as free molecules or conjugated to heterologous nanomaterials. For instance, three-dimensional nanostructures can be made by DNA hybridization [10.54–57]. Such DNA nanostructures can exhibit tightly controlled topographies but limited integrity in terms of geometry [10.57], due to the flexibility of DNA strands. Oligonucleotides, antibodies and other specific biological affinity reagents can also be used to assemble nanostructures (Fig. 10.10, see also targeting and triggering discussions below). Often the domains of biomolecules responsible for assembly and recognition are small, continuous, and discrete enough that they can be abstracted from their native context as modules and appended to other nanomaterials of interest to direct formation of controlled nanoscale architectures (for instance, see the SCFv antibody fragement of Fig. 10.1).

Several orthogonal bioconjugate approaches have arisen from the field of protein semisynthesis [10.20, 58, 59]. These protein synthetic chemistries allow site-specific conjugation of polypeptides to heterologous materials in bulk, as the result of conjugation between exclusively, mutually reactive electrophile-nucleophile pairs (analogous to dendrimer synthesis discussed above, see Table 10.2). They have been applied to the synthesis of multiple therapeutic nanodevices [10.2–5, 7, 14, 58, 59].

As described above, proteins are profoundly dependent on their three-dimensional shapes: chemical derivatization at critical aa sites can profoundly impact protein bioactivity. Because conjugation can be directed to pre-selected sites via orthogonal approaches, and since the sites of conjugation in the protein can be chosen because the proteins involved tolerate adducts at those positions, proteins coupled to nanomaterials by such orthogonal methodologies often retain their

Table 10.2 Orthogonal conjugation chemistries originally derived for protein semi-synthesis but applicable to conjugation of proteins to nanomaterials [10.20, 58, 59] (R′ = H: Aldehyde, R = alkyl: Ketone)

	Electrophile		Nucleophile		Product
1.	O ‖ R R'	+	H_2N-O-R"	⟶	O-R" O ‖ R R'

biological activity. In contrast, protein bioactivity in conjugates generally is lost or profoundly impaired when proteins are coupled to nanomaterials using promiscuous chemistries. For instance, proteins such as cytokines (and other protein hormones) elicit their effects by interacting with a receptor, and a large fraction of their surface (20% or more) is involved in receptor binding, directly or indirectly. Promis-

cuous chemistries (1-ethyl-3-(3-diamethylaminopropyl) carbodiimide or EDC, conjugation, see [10.60]) used to conjugate cytokines to nanoparticles tend to inactivate hIL-3 and other cytokines whereas the same protein/particle bioconjugates retain bioactivity if judiciously chosen orthogonal conjugation strategies are used (Lee & Parthasarathy, unpublished). Proteins for which only a small portion of their surfaces contribute to the interesting portions of their bioactivities (from the standpoint of the nanodevice designer), such as some enzymes or intact antibodies (Fig. 10.1) may be somewhat less sensitive to promiscuity of the bioconjugate strategy used [10.20, 58, 59], but the benefits of orthogonal conjugation strategies can also apply to these protein bioconjugates [10.20, 58, 59]. The potential utility of orthogonal conjugation for incorporation of active biological structures into semi-synthetic nanodevices is becoming more fully recognized and cannot be overestimated [10.58, 59].

10.3.2 Targeting: Delimiting Nanotherapeutic Action in Three-Dimensional Space

Delivery of therapeutics to sites of action is a key strategy to enhance clinical benefit, particularly for drugs useful within only narrow windows of concentration because of their toxicity (i. e., drugs with narrow therapeutic windows). Diverse targeting approaches are available, ranging from methods exploiting differential extravasation limits of vasculature of different tissues (see the discussion of oncology below), sizes, and surface chemistry preferences for cellular uptake (see discussion of vaccines below); preferential partition of molecules and particles into specific tissues by virtue of their charges, sizes, surface chemistry, or extent of opsonization (see below); or the affinity of biological molecules decorating the nanodevice for counter-receptors on the cells or tissues of interest.

The Reticuloendothelial System and Clearance of Foreign Materials

Physical properties such as surface chemistry and particle size can drive targeting of nanomaterials (and presumably nanodevices containing them) to some tissues. For instance, the pharmacokinetic (P_k) and biodistribution (B_d) properties [10.32] of many drugs and nanomaterials are driven by their clearance in urine, which is in turn governed by the filtration preferences of the kidney. Most molecules making transit into urine have masses of less than 25 to 50 kilodaltons (kDa; 25–50 kDa particles corresponding *loosely* to effective diameters of about 5 nm or less) and are preferably positively charged; these parameters are routinely modulated to control clearance rates of administered drugs. Clearance of low molecular weight (nano)materials in urine can be suppressed by tuning their molecular weights and effective diameters, typically accomplished by chemical conjugation, to polymers such as poly(ethylene glycol) [10.19]. Polymer conjugation (pegylation) has been applied to many different materials and may provide some degree of charge shielding. Pegylation also increases effective molecular weights of small materials above the kidney exclusion limit, diverting them from rapid clearance in urine.

Coating foreign particles with serum proteins (opsonization [10.61]) is the first step in the clearance of foreign materials. Opsonized particles are recognized and taken up by tissue dendritic cells (DCs) and specific clearance organs. These tissues (thymus, liver, and spleen, constituting the organs of the reticuloendothelial system or RES) extract materials from circulation by both passive diffusion and active processes (receptor-mediated endocytosis). Charge-driven, receptor-mediated uptake of synthetic nanomaterials occurs in the RES and can result in partition of positively charged nanoparticles into the RES. For instance, PAMAM dendritic polymers exhibit high positive charge densities related to the large number of primary amines on their surfaces [10.28–30]. In experimental animals, biodistribution of unmodified PAMAM dendrimers is limited nearly exclusively to RES organs [10.62]. This unfavorable biodistribution can be modulated by "capping" the dendrimers (i. e., derivatizing the dendrimer to another chemical specificity, such as carboxy or hydroxyl functionalities [10.15, 62]).

Despite legitimate applications of targeting to the kidney and the RES (for instance in glomerular disease [10.63]), intrinsic targeting to clearance sites is of interest primarily as a technical problem that impedes therapeutic delivery to other sites. In such cases, numerous targeting strategies are available, some of which depend on synthetic nanomaterial properties (for instance, see discussion of the enhanced permeability and retention or EPR effect in the context of oncology, below) to minimize uptake of nanotherapeutic devices by clearance systems and maximize delivery to desired sites. Targeting via biological affinity reagents decorating the surfaces of therapeutic nanodevices may be the most direct approach.

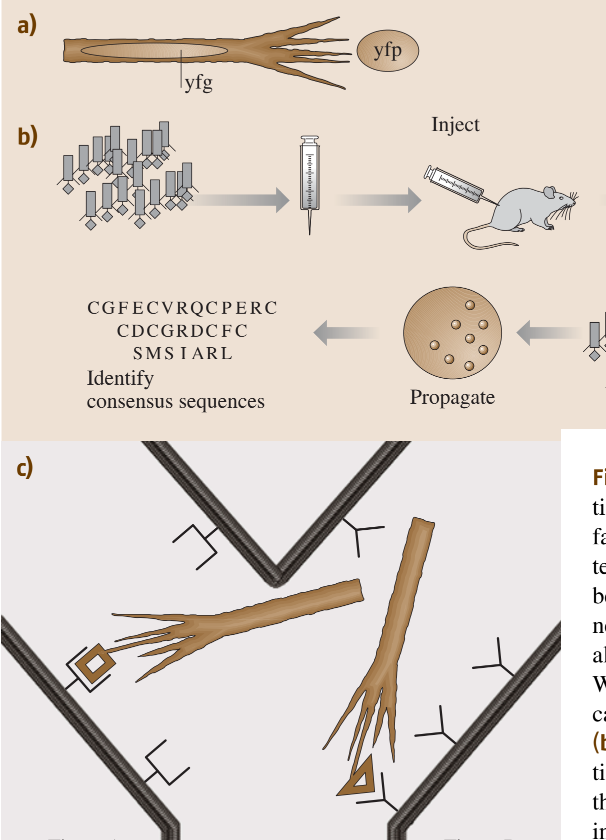

Fig. 10.11 **(a)** A schematic of a filamentous phage particle encapsulating DNA encoding a gene of interest (your favorite gene, or yfg) and presenting the corresponding protein (your favorite protein or yfp) on its surface. The linkage between yfp and yfg provided by the phage allows simultaneous affinity isolation and recovery of proteins of interest along with replicable genetic elements encoding them. When variant protein libraries are built by this method, they can be sorted for their ability to bind receptors by affinity. **(b)** A library of filamentous phage presenting random peptides is shown schematically. The library is injected into the vasculature of an animal (in this case, a mouse), where individual phage bind specific receptors present in the vasculature of different tissues. The animals are sacrificed, and organs of interest are harvested. Phage particles bound to receptors of vasculature of the organ at hand can be eluted by any of several methods (low pH elution is schematically shown here). *E. coli* is infected with the eluted phage particles and clonally propagated, allowing identification of the peptides encoded by the eluted phage, which mediated binding to the vascular receptors. Ultimately, this allows the identification of consensus peptide sequences that recognize specific receptors on the vasculature of the organ or tissue involved. These receptors constitute the molecular addresses for these organs, and the peptides isolated from phage eluted from them are biological affinity reagents that can be used to direct nanotherapeutic devices to vasculature of particular organs. **(c)** Specific recognition of vascular beds of two distinct tissues (A and B) via recognition of organ-specific vascular addresses (the Y and box-shaped receptors shown on vascular endothelium) by specific peptides (the *triangle* and the *square*) presented on the phage surface is depicted [10.64–66]

Nanotherapeutic Targeting Exploiting Biological Affinity Properties

Tissue-specific delivery by biological affinity requires the presence of tissue-specific surface features, most commonly proteins or glycoproteins (tissue-specific antigens). Historically the search for tissue-specific antigens for drug targeting, whether associated with tumors or other cells, organs or tissues, has been arduous and not entirely gratifying. The primary problems are specificity (few antigens are uniquely present in any single tissue), availability (some tissues may not have their own unique antigenic signature or marker), and therapeutic extravasation or directed migration in tissue spaces (markers in tissue may not be accessible from vasculature). An exciting recent development in biochemical targeting is the discovery of a vascular address system [10.64–66].

The vascular address system has been characterized by administering a peptide phage display to library animals, resecting individual organs, and extracting phage from the vasculature of the isolated organs (Fig. 10.11 [10.64–66]; see [10.67] for a discussion of display technology). Amazingly, phage isolated from different organs exhibited distinct consensus presented peptide sequences, indicating that the vasculature of individual organs presented unique cognate receptors, each bound by a different short (ten amino acids or fewer) consensus peptide sequence that had been affinity selected from the phage display library. Furthermore, the affinity-selected peptides have the capacity to tether nano- to microscale particles to the site of their cognate receptors (as illustrated by the binding phage particles presenting the peptides to specific vascular locations). Site-specific drug delivery using the vascular address system has already been demonstrated [10.68,69]: it has further been used to target an apoptotic (cytocidal) agent to the prostate and to direct destruction of the organ in an animal model [10.68].

Mapping of the vascular address system is currently underway [10.64] and holds the promise of specific delivery of therapeutic agents to vasculature of specific organs. It remains to be seen whether each organ has a single molecular marker constituting its address that is amenable to binding a single peptide sequence; organs may instead have unique constellations of antigenic markers. If so, specific targeting may be possible using multiple peptides, each peptide binding its cognate receptor on target organ vasculature very weakly. Peptides used in such a multivalent targeting strategy would be chosen to reflect the unique constellation of address markers present in the target tissue. Affinities of cognates for linear peptides are often very low [10.67], though their aggregate affinity may be substantially higher than that of any peptide-vascular address cognate alone. Under ideal conditions, the affinity of such a multipeptide, multicognate complex should be the equivalent of the products of the affinities of each constituent peptide for its individual constituent cognate. Such multivalent interaction avidities can be extremely high (and the corresponding effective affinity constants are also high) but seldom fully realize their theoretical maximums (Lee & Parthasarathy, unpublished; see [10.32] for a review of receptor biochemistry).

It should be noted that most of the vascular addresses identified to date deliver materials to the organ vasculature: extravasation and access of organ tissue spaces by nanotherapeutics remains a separate issue.

10.3.3 Triggering: Delimiting Nanotherapeutic Action in Space and Time

Controlled triggering of therapeutic action is the other side of the targeting coin. If the site and time of nanotherapeutic delivery cannot be adequately controlled, the site of therapeutic action can be delimited by spatially- or temporally-specific triggering. The triggering event might drive release of active therapeutic from a reservoir, or chemical or physical processing of drug materials from an inert to an active form (inert administrations that are converted to active form at a specific time or place drugs which are activated by a chemical reaction occurring their sites of action are called prodrugs, Fig. 10.12). Three major triggering strategies are widely used: external stimuli, intrinsic triggering, and secondary signaling (multicomponent systems). Triggering strategies require nanotherapeutic delivery devices to be sensitive to a controlled triggering event, or a spatially/temporally intrinsic triggering event mediated by the host. Obviously, the triggering event itself must be tolerable to the patient.

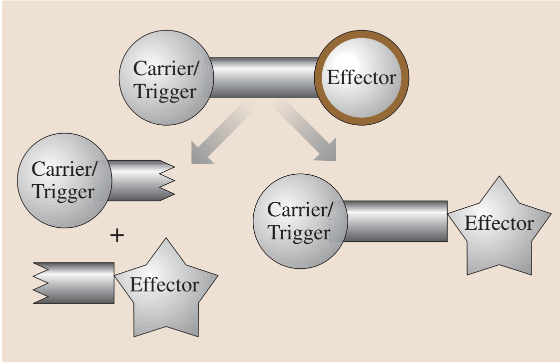

Fig. 10.12 One possible configuration of a prodrug, in which carrier/trigger and effector functions are separate functional domains of the therapeutic. The key feature of prodrugs is that they are therapeutically inert (as indicated by the colorless effector domain) until an activation event occurs (mediated here through the carrier/trigger domain, with effector activation indicated by its change to a star shape). Activation events can involve cleavage of inhibitory carrier/trigger domains from effectors. Other activation strategies involve a chemical change or shift in conformation of the effector, mediated through the carrier/trigger domain and in response to an environmental condition

Nanotherapeutic Triggering Using External Stimuli

External stimuli are provided by an external nanodevice operator/clinician, usually in the form of a site-specific energy input, typically light, ultrasound, or magnetic or electrical fields. Organic polymeric structures are very amenable to interaction with these energy sources. For instance, micellar structures can be reversibly dissociated with ultrasound, in which case they disgorge their contents or expose their internal spaces to the environment during ultrasound pulses (20 to 90 kilohertz range). The process has been used to control release of cytotoxin (doxorubicin) from micelles (Fig. 10.13), and short ultrasound transients might be used for pulsatile or intermittent exposure of patients to therapeutics [10.70].

Light is another popular external triggering modality. Bioactive materials can be covalently associated to a nanoscale-delivery vehicle by photo-labile linkages [10.15, 71, 72], or micelles can be constructed so that their permeability is altered as the result of exposure to light [10.72]. In the latter case, light input can cause photopolymerization resulting in micelle compaction that drives release of therapeutic cargo or photo-oxidation, which causes loss of micellar integrity to release encapsulated materials. The ability of light to penetrate dense tissues is a clear limitation to this approach. This concern can be accommodated by polymer systems responsive to wavelengths that penetrate tissue efficiently (usually in the red-infrared region of the spectrum), or by use of systems such as fiber optics to deliver light to deep tissues [10.15, 71, 72].

Externally applied magnetic fields can also be used to control nanotherapeutic activity. For instance, eddy currents induced by alternating magnetic fields can heat nanometallic particles and their immediate vicinity, an approach that has been successfully applied to control the bioactivity of individual biological macromolecules [10.73]. Colloidal gold particles are covalently conjugated to biomolecules (nucleic acid, or NA, duplexes or proteins), and alternating magnetic

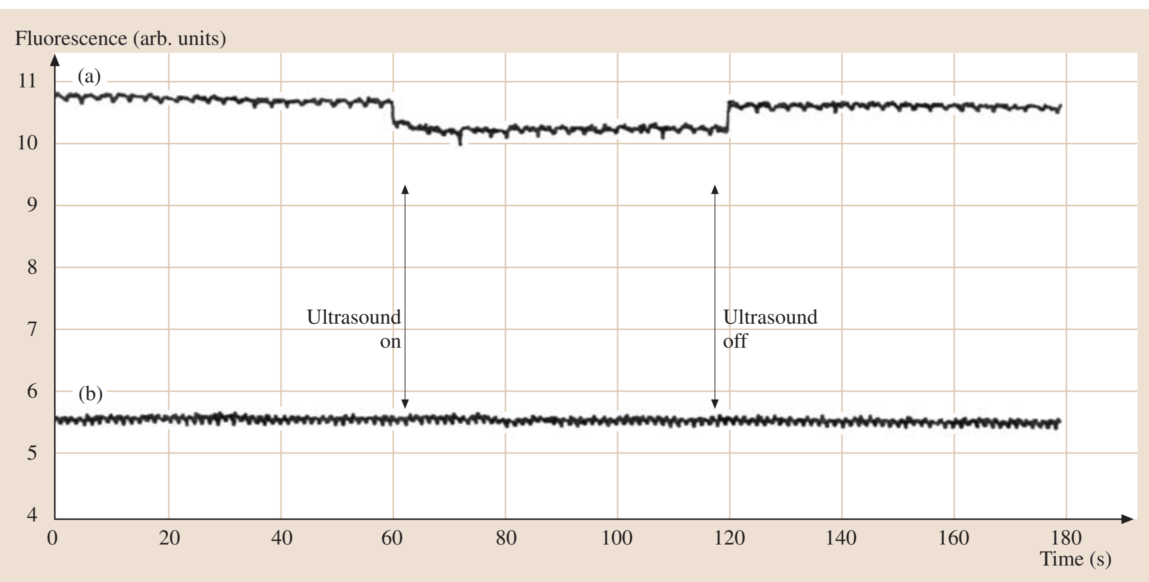

Fig. 10.13 Externally applied stimuli can trigger drug release: hydrophobic drug molecules are reversibly deployed from micelles in response to acoustic stimuli [10.70]. Intact pluoronic micelles maintain the hydrophobic cytotoxin doxorubicin in a hydrophobic environment (the core of the micelle, as in Fig. 10.4). Doxorubicin fluorescence is quenched in aqueous environments, and hence changes in integrity of pluoronic micelles carrying doxorubicin can be monitored by doxorubicin fluorescence. Here, an ultrasound pulse is applied to suspensions of such micelles or to doxorubicin in solution. Application of ultrasound triggers exposure of micelle-encapsulated doxorubicin to the aqueous solvent (i. e., drug release), as demonstrated by the reduction in fluorescence. After cessation of the acoustic pulse, doxorubicin is repackaged into the micelles, as evidenced by the increase in fluorescence after the ultrasound administration (*Line* a). Ultrasound has no impact on fluorescence of doxorubicin in solution, as expected (*Line* b)

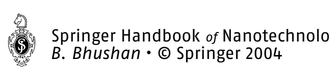

fields are used to induce heating sufficient to cause dissociation of hybridized NA structures or denaturation of protein three-dimensional structures. Within certain parameters, the process is reversible and so allows the construction of semi-biological assembly or release switches. The modality has clear application to temporally specific triggered release, but the current inability to direct magnetic fields to pre-selected tissue locations may limit its use for spatially specific triggering.

Nanotherapeutic Triggering by Intrinsic Physiological Conditions

Intrinsic triggering is a prodrug strategy that depends on the conditions at the desired site of action to trigger the activity of the nanotherapeutic. Much as the three-dimensional conformation of, and therefore the activity of, proteins can be controlled in external triggering strategies [10.73], proteins can be engineered to make their conformations sensitive to intrinsic conditions at their desired sites of activity (see [10.3] for a discussion of protein engineering for use in nanobiotechnological devices). For instance, noncovalent complexes of a diphtheria toxin (DT) protein variant and a bispecific antibody (Fig. 10.1) have been engineered for specific toxicity to cells that can take up the complexes [10.75]. The bi-specific antibody recognizes both a cell-specific surface receptor as well as the DT in an inactive (non-toxic) configuration. Antibody binding to the receptor results in receptor-mediated endocytosis of the complex in target cells. As a result of the lower pH of the endosomal compartment (reaching pH 4–5 in endosomes, as opposed to the constant pH 7–8 in circulation) into which the bound complex is taken up, the DT variant protein undergoes a three-dimensional conformational shift to its toxic form. This conformation of DT is not recognized by the bispecific antibody, so the toxin dissociates from the complex and kills the cell. Hypoxia-triggered prodrugs have also been developed that are activated either by chemical reduction or by enzymatic activities induced in hypoxic tissues. Extreme hypoxia [10.76] is a unique feature of neoplastic tissue, so these strategies have clear application in oncology. Clinical manipulation of the extent of tumor oxygenation is possible [10.77] and may also be possible in other tissues. If so, redox state-dependent triggering approaches may have applications beyond cancer (Fig. 10.14a).

Enzyme-activated delivery (EAD [10.74], Fig. 10.14) is another prodrug-like triggering strategy in which the properties of a nanoscale drug-delivery vehicle are altered at the site of action by an enzymatic activity endogenous to that site. Most typically, this involves a liposomal or micellar nanostructure from which designed pendent groups can be cleaved by metabolic enzymes (alkaline phosphatase, phospholipases, proteases, glycosidic enzymes, etc.) that are highly expressed at the site of therapy. Nanostructures are designed so that enzymatic cleavage of the pendent group causes a conformational or electrostatic change in the polymeric components of the delivery device, rendering the micellar structure fusogenic, leaky, or causing partial or complete dissociation of the structure [10.12] (Fig. 10.14c). This has the result of delivering or releasing therapeutic payloads at pre-selected sites.

Target cell

Fig. 10.14 Intrinsic conditions at desired sites of therapeutic action can trigger release of active drug molecules. Enzyme activated delivery (EAD) is an intrinsic triggering strategy that depends on chemical cleavage of the carrier/trigger to induce changes in the properties of the delivery vehicle to allow delivery of drug [10.74]. Here a surface functionality is cleaved from a micellar drug delivery vehicle, rendering the micelle fusogenic and allowing it to fuse with the cell membrane. As a result, the therapeutic payload of the micelle is delivered to the cytosol of target cells. Tuning of micellar surface functionalities and their linkages to the block copolymers constituting micelles theoretically can be used as target delivery to a variety of intracellular compartments

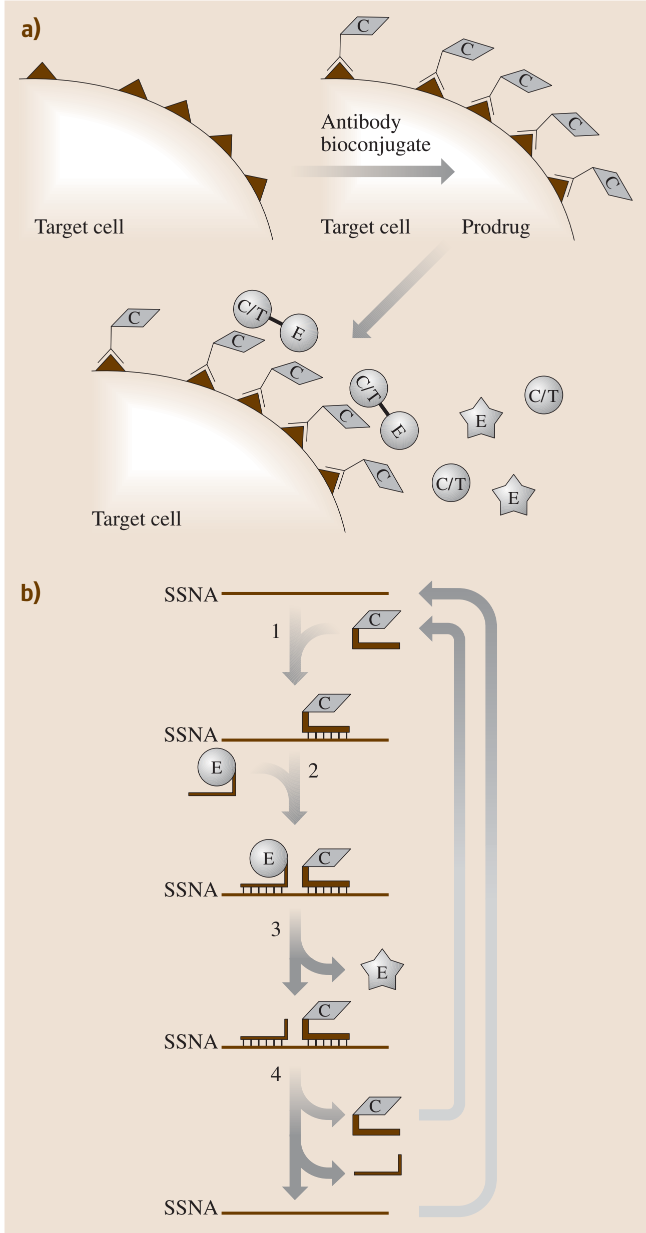

Fig. 10.15a,b Secondary biochemical signals can trigger release of active therapeutics. **(a)** Antibody directed enzyme-prodrug therapy (ADEPT) exploits enxyme-monoclonal antibody (mAB) bioconjugates to activate prodrugs [10.78]. Here, a mAB (like the native IgG of Fig. 10.1) is covalently liked to a catalyst (C in rhombus, usually an enzyme). The binding specificity of the monoclonal antibody causes the bioconjugate to bind to a desired target site (possibly by recognition of a vascular address, as shown in Fig. 10.11). The catalyst (enzyme) specificity of the bioconjugate is capable of triggering activation of a prodrug, much as in Fig. 10.12. The corresponding prodrug is then administered (represented as in Fig. 10.12). The enzyme localized at the desired target site of therapeutic action then activates the prodrug (represented here by cleavage of carrier/trigger moiety and change in shape of the effector to a star, as in Fig. 10.12). **(b)** Another secondary signaling triggering strategy [10.55]. Here, single stranded nucleic acid (SSNA) drives assembly of an activating complex for a prodrug. A catalyst (indicated again by C) is conjugated to an oligonucleotide that hybridizes to a single stranded nucleic acid (SSNA). A prodrug, containing an effector domain (E) and a second oligonucleotide, in this case homologous to a region of the same SSNA, and proximal to the site of hybridization of the first oligonucleotide, is also administered. Catalyst specificity is tuned to correspond to linkage between the prodrug effector and oligonucleotide. The catalyst in the assembled structure is sufficiently close to the prodrug to cleave the linkage between effector and oligonucleotide, releasing active drug (star). Potentially, prodrug and catalyst oligonucleotides might dissociate from the SSNA and the cycle could be repeated. Note the similarity to Fig. 10.10

Nanotherapeutic Triggering Using Secondary Signaling

Secondary signaling or multicomponent delivery systems are more complex delivery strategies (Fig. 10.15). These systems can feature site-specific and systemic delivery of one or more components. One class of such systems is the so-called ADEPTS devices (antibody directed enzyme-prodrug therapy, Fig. 10.15 [10.78]). ADEPTS systems feature affinity-based targeting of an enzymatic prodrug activator to a desired site, followed by systemic administration of a prodrug. ADEPTS is used primarily for oncology, and so the prodrug involved is generally one that can be activated to cytotoxicity. Since prodrug dosing is systemic, prodrug toxicity must be de minimus in the inactive form, and the activating catalyst must not be present at locations where cytotoxicity would be deleterious. To address this issue, the nanotherapeutic designer can chose to engineer an activation mechanism that has no physiological analogue in the host. In addition, tuned, high lability of the active drug can potentially delimit the site and extent of cytotoxic effect mediated by ADEPTS systems.

Other secondary signaling systems rely on DNA hybridization to assemble therapeutic components into catalytically active complexes at their sites of action [10.55]: in this system, the individual components lack therapeutic activity until they are brought within a few nanometers of each other by hybridization to a target single-stranded nucleic acid molecule (SSNA in Fig. 10.15, potentially a RNA species expressed in a tissue or cell type of interest). At this point, the catalytic moiety and the prodrug moieties are sufficiently close in space to allow catalytic cleavage of the active component from the prodrug. As depicted, this strategy makes no provision for delivery of drug and catalyst bioconjugates to the site of interest, nor for their transit across biological membranes. The system is similar to the DNA hybridization-driven fluorescence transfer system of Fig. 10.10.

Alternatively, secondary signaling systems can exploit competitive displacement of therapeutics from a carrier structure [10.79]. In this case, a non-covalent complex of engineered antibody and plasminogen activator (PA) is tethered to blood and fibrin clots by antibody affinity for fibrin. PA is released from the bound complex (to dissociate the clot) using bolus systemic administration of a nontoxic binding competitor for PA to the antibody complex. The strategy establishes a high local concentration of PA at clot sites, efficiently dissolving clots and potentially minimizing systemic side effects.

Layering Strategies for Fine Control of Nanotherapeutic Action

It should be clear that many of these approaches may be broadly applicable to trigger events other than drug release or to drive assembly or disassembly of therapeutic nanostructures in situ. It should also be clear that these approaches are often complementary, and that multiple approaches can be used in single nanotherapeutic devices (Fig. 10.3, Table 10.1 [10.11–13, 15, 71, 78, 80]). Layering targeting and triggering approaches tends to make devices more complex, but it also allows clinician/operators to intervene at multiple points in therapy, potentially leading to finer control of the therapeutic process and better clinical outcomes.

10.3.4 Sensing Modalities

The need for "smart" therapy is a key theme of therapeutic nanotechnology and pharmacology as a whole. Drugs with narrow therapeutic windows should be delivered only to their desired site of action and be pharmacologically active only when that activity is needed. These strategies can limit undesired secondary effects of therapy, some of which can be debilitating or life threatening, as discussed elsewhere in this chapter. One possible approach to this issue is the incorporation of sensing capability (specifically, the capacity to recognize appropriate contexts for therapeutic activity) into nanotherapeutic devices. Sensing capability may allow self-regulation of a therapeutic device, reporting to an external clinician/device operator (though this begins to touch on imaging applications, see below), or both. In the context of our discussion of therapeutic nano- and microscale devices, we will consider primarily electrical and electrochemical sensor systems, particularly microfabricated (Field Effect Transistor or FET, and cantilever) and conducting polymer sensors.

Sensor Systems

Sensing is predominantly a higher-order device functionality, depending on multiple device components, though one could argue that some targeting/triggering strategies, particularly targeting by bioaffinity and intrinsic triggering strategies, must, a priori, incorporate at least limited sensing capability. But biosensors, as they are typically considered, are multifunctional, multicomponent devices [10.81]. Usually a biosensor system is composed of signal transducer, sensor interface, biological detection (bioaffinity) agent, and an associated assay methodology, with each system component governed by its inherent operational considerations.

The transducer component determines the physical size and portability of the biosensor system. Signal transducers are moieties that are sensitive to a physical-chemical change in their environment and that undergo some detectable change in chemistry, structure, or state as the result of analyte (the thing to be sensed) recognition. Analytes for nanotherapeutic application could be biomolecules, like proteins, small molecules (organic or inorganic), ions (salts or hydrogen ions), or physical conditions (such as redox state, temperature). Interfaces are the sensor components that interact directly with the analyte. For sensor use in nanotherapeutic devices, immobilized or otherwise captured biological molecules (proteins, nucleic acids) often constitute the sensor interface. Whatever the chemical nature of the interface, it determines the selectivity, sensitivity, and stability of the sensing system and also is a dominant determinant of sensor operational limits. Assay methodology determines the need (or lack thereof) for analyte tracers, the number of analytical reagents, and the complexity and rapidity of the sensing process. Nanotherapeutics

are of interest at least in part because they can be minimally invasive, low complexity, yet robust and accurate; convenient assay methods are therefore highly desirable.

Cantilever Biosensors

Micromechanical cantilevers (discussed above in conjunction with force microscopy, Fig. 10.6) transduce sensed events by mechanical means [10.82]. Both changes in the resonant frequency and deflection of cantilevers resulting from analyte binding or dissociation can be conveniently and sensitively detected. These changes in cantilever state can be conveniently detected by optical, capacitive, interferometry, or piezoresistive/piezoelectric methods, among others. Microfabricated cantilever dimensions range from micron to sub-micron range, with potential for further dimensional optimization (by carbon nanotubes appended to them, for instance [10.82]). They are operationally versatile and can be used in air, vacuum, or liquid, although they suffer some degradation in performance in liquid media. Like most micromachined structures, they can be batch fabricated and conveniently multiplexed.

Cantilevers used in atomic force microscopy (AFM, see also discussion of one-off nanostructures above) approaches can be used to study individual biomolecular interactions [10.35, 81]. In this approach, cantilever tips are derivatized with biomolecules (effectively, one member of a receptor/counter-receptor pair), and the tip-bound biomolecule is allowed to bind its counter-receptor (itself bound on a surface). Under non-equilibrium conditions, (i. e., conditions that result in thermodynamically irreversible changes in analyte molecular structures), the force required to disrupt single molecular interactions can be measured and related to classical biochemical parameters of receptor binding. The method has been applied to interactions between hormones and their receptors, sugars and lectins, as well as hybridizing DNA strands.

Cantilever systems sensitively detect changes in mass at their surfaces: changes as small as a mass density of $0.67\,\mathrm{ng/cm^{-3}}$ are theoretically detectable. This can allow detection of binding of extremely small objects to the cantilever and has been applied to detection and enumeration of prokaryotic and eukaryotic cells, as well as small numbers of macromolecules [10.82]. The incorporation of biological receptors or affinity reagents on the cantilever surface can drive specific binding events for particular sensing tasks. Microcantilevers are also highly sensitive to temperature, detecting changes as low as 10^{-5} K; they can also detect small changes in pH.

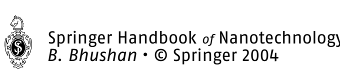
Field Effect Transistor Biosensors

Field effect transistor (FET) architectures are another sensing architecture that can be conveniently produced by micro-nanofabrication. FETs consist of a current source, a current drain, a conductive path (sensing channel) between them, and a sensing gate to which a bias can be applied. Analyte binding to the sensing channel induces a charge transfer resulting in a dipole between the surface and the underlying depletion region of the semiconductor: current that passes between the source and drain of a semiconductor FET is quite sensitive to the charge state and potential of the surface in the connecting channel region. Moving a standard silicon FET from depletion to strong inversion (i. e., shifting the surface potential by $> \sim 0.5\,\mathrm{eV}$) requires less than $\sim 10^{-7}\,\mathrm{C/cm^2}$ or $\sim 6\times10^{12}\,\mathrm{charges/cm^2}$, corresponding to transfer of $6.25\times10^{11}\,\mathrm{e/cm^2}$. With FETs of 2,000 square micrometers, detection of biological analytes in sub-nanomolar concentrations is easily feasible. Specificity for binding of macromolecular analytes of interest can be provided by deployment of biological affinity reagents in the FET sensing channel. Submicron FETs are routinely manufactured; use of carbon nanotubes in FETS will offer still greater miniaturization [10.43, 83].

Carbon nanotubes also have excellent mechanical properties and chemical stability in addition to potentially tunable electrical properties, making them highly desirable electrode/nanoelectrical materials for any number of nanoelectrical applications [10.84]. Biomolecules can be bound to carbon nanotubes, particularly in FET and nanoelectrode applications. Most biomolecules bound to carbon nanotubes are not covalently bound (as discussed above) and do not exhibit direct electrical communication with the nanotube, though redox enzymes bound to nanotubes and other conductive nanomaterials may [10.84, 85]. Flavin adenine dinucleotide (FAD) and flavoenyzme glucose oxidase (Gox) both display quasi-reversible one electron transfer when absorbed onto unannealed carbon nanotubes in glassy carbon electrodes. Gox so immobilized retains its substrate-specific (glucose) oxidative activity, leading to applications in sensing circulating glucose for diabetes and, perhaps, to a strategy of harvesting electrical power from metabolic energy.

Conducting Polymers and Sensor Biocompatibility

Biocompatibility of most metallic structures (as might be used in the bioelectrical sensors described) is limited at best; metal structures rapidly foul with serum pro-



teins (i. e., become opsonized), undergo electrochemical degradation, or have other problematic properties. Polymer chemistry, however, has the capacity to tune composition to enhance biocompatibility properties and is commonly used to make synthetic surfaces more biologically tolerable. Electrically conductive polymers are potentially attractive in this context.

Polymeric materials are available with intrinsic conductivities comparable to that of metals (up to $1.5\times10^{7}\,(\Omega\,\mathrm{m})^{-1}$, which, by weight, is about twice that of copper [10.86]). Significant conductivity has been documented for a dozen or so polymers, including polyacetylene, polyparaphenylene, polypyrrole, and polyaniline, doped with various impurities. Careful control of doping can tune electrical conductivity properties over several orders of magnitude [10.87].

Conductive polymeric materials may be extremely well suited to biosensing applications. The polymeric materials themselves are often compatible with proteins and other biomolecules in solution. Furthermore, polymers are amenable to very simple assembly of sensor transducer-interface components by deposition of the polymer and trapped protein (sensor interface) directly on a metallic micro- or nanoelectrode surface [10.87,88]. Combined with a facile nanoelectrode array microfabrication method [10.89], simultaneous conducting polymer-interface protein deposition may offer an extremely simple way to fabricate multiplexed sensor arrays.

These electrochemical and electrophysical sensing modalities are of little use in and of themselves: they must communicate with either other device components (such as drug-dispensing effector components) or with external observers or operators. Sensor coupling in autonomously operating devices produced by microfabrication can be done directly, and the coupling linkages incorporated into the fabrication protocol. Coupling with biological device components can also be direct, as when conductive materials are conjugated to biomolecules, and can directly modulate their activity [10.73].

Sensor-device coupling can also be indirect, through electrochemically produced mediator molecules [10.85]. Sensors might be independent of nanotherapeutics and report conditions at the site of therapeutic action to an external operator, who would use any one of the external triggering strategies discussed above to engage therapy when and where appropriate. Communication/sensor interrogation might be accomplished most crudely by direct electrical wiring of sensors to an external observation station. Alternatively, if the event to be detected is transduced optically, as in colorimetric smart polymers that change optical properties in the presence of analyte [10.90], sensors might be interrogated by fiber optics. These modalities are most applicable to sensor arrays delivered to the site of interest by a catheter. The use of a catheter may be justified in some therapeutic applications, but it is an invasive procedure and is not optimal.

We have already seen multiple examples of prodrugs that are activated by cleavage of an inhibitory domain from the complex. One noninvasive approach to communication with external operators could exploit this phenomenon by detecting the cleaved fragment in bodily fluids. If the cleaved moiety cleared through urine, the extent of drug activation could be monitored noninvasively via urinalysis. There is no a priori need to connect the cleavage event to drug activation. For instance, an operator might administer a catalyst that cleaves a detectable material from a nanotherapeutic. If this secondary signaling moeity was independently targeted to the desired site of therapy, presence of the detectable cleaved product would provide information regarding the bodily location of the therapeutic nanodevice. The cleaved product would not be detectable unless the therapeutic and secondary signaling moiety co-localized at a single site. Other sophisticated communication involves ultrasound or electro-magnetic radiation to carry information. Application of these sorts of modalities currently occurs in in vivo imaging approaches.

10.3.5 Imaging Using Nanotherapeutic Contrast Agents

Imaging is a minimally invasive procedure that allows visualization of organs and tissues following the administration of a detectable moiety (contrast agent). The contrast agent is then exposed to some condition that interacts with the contrast agent so as to produce an emission or response detectable to an external monitoring device. Nano-sized particles (5–100 nm in diameter) have found application as contrast-enhancing agents for medical imaging modalities such as magnetic resonance imaging (MRI, our primary topic, reviewed in [10.91, 92]). MRI currently provides cross-sectional and volumetric images with high spatial resolution (< 1 mm) and is potentially applicable to many clinical purposes, though enhanced imaging capabilities are desirable. For instance, blood flow measurements of healthy and diseased arteries can be quantified better by the aid of improved contrast agents that highlight blood flow at the vessel

wall. Similarly, some tissues (certain tumors) do not exhibit strong contrast within the MRI field and cannot be readily identified or characterized at present. It is of great interest, therefore, to develop nanoscale particles that provide enhanced contrast for many applications.

Magnetic Resonance Imaging (MRI): the Basics

Objects to be imaged are exposed to a strong magnetic field and a well-defined radio frequency pulse. The external magnetic field (B_0) serves to loosely align protons either with (lower energy level) or against (high energy level) the field, the difference between the two energy levels being proportional to B_0. Once the protons are separated into these two populations, a short multi-wavelength burst (or pulse) of radio frequency energy is applied. Any particular proton will absorb only the frequency that matches its particular energy (the Larmor frequency). This *resonance* absorption is followed by the excitation of protons from the low to high energy level and of equivalent protons moving from high to low energy levels. After the radio frequency pulse, protons rapidly return to their original equilibrium energy levels. This process is called relaxation and involves the release of absorbed energy. Once equilibrium is again established, another pulse can be applied.

Data is collected by positioning a receiver perpendicular to the transmitter: relaxation energy release induces a detectable, quantifiable signal (i. e., in amplitude, phase, and frequency) at the receiver coil. Since multiple protons in multiple chemical environments are involved, the signal at the receiver includes many frequencies. The received signal consists of multiple, superimposed signals (called the free induction decay or FID) signal, resulting from the relaxation of multiple, chemically distinct protons. FID is converted from the time domain to frequency domain (by Fourier transformation), within which individual proton types can be identified. Iterations of this procedure in two or three dimensions can create a high-resolution image of anatomical cross section or volume.

Intrinsic factors affecting image quality include the proton density of the tissues, local blood flow, and two relaxation time constants [10.93]: longitudinal relaxation time (T_1) and transverse relaxation time (T_2). Control of T_1 and T_2 relaxation effects are most critical for high-resolution MR images. T_1 relaxation measures energy transfer from an excited proton to its environment. In tissues, protons of fats and cholesterol molecules (relatively movement-constrained macromolecules) relax efficiently after a pulse and exhibit a short T_1 time. Water in solutions (a small molecule tumbling relatively freely in solution) has a much longer T_1 time. T_2 relaxation measures the duration of coherency between resonating protons after a pulse, prior to their return to equilibrium. Tightly packed, solid tissues with closely interacting hydrogen nuclei relax more quickly than loosely structured liquids, so tissues such as skeletal muscle have a short T_2s, while cerebrospinal fluid has a very long T_2. Intrinsic factors are manipulated through extrinsic factors, such as the external magnetic field strength, the specific pulse sequence, etc., allowing the collection of meaningful MR images.

Nanoparticle Contrast Agents

Signal intensity in tissue is influenced linearly by proton density, while changes in T_1 or T_2 result in exponential changes in signal intensity. T_1 and T_2, therefore, are manipulated to enhance imaging by administration of exogenous contrast-enhancing agents. MRI contrast agents are divided into paramagnetic, ferromagnetic, or superparamagnetic materials. Metal ion toxicity is an unfortunate consequence of physiologic administration of contrast agents but can be mitigated somewhat by complexation of the metals with organic molecules.

Paramagnetic metals used for enhanced MRI contrast (gadolinium, Gd, iron, Fe, chromium, Cr, and manganese, Mn) have permanent magnetic fields, though the magnetic moments of individual domains are unaligned [10.94]. Upon exposure to an external magnetic field, individual domain moments become aligned, generating a strong local field (up to 10^4 gauss [10.95]). Paramagnetic metal ions interact with water molecules, causing an enhanced relaxation of the water molecules via tumbling of the water-metal complex, dramatically decreasing the T_1 value for the water molecules and enhancing the proton signal [10.94]. Contrast enhancement by paramagnetics is thus due to the indirect effect the contrast agent has on water and its magnetic resonance properties.

Ferromagnetic and superparamagnetic materials both contain iron (Fe) clusters, which generate magnetic moments 10 to 1,000 times greater than do individual iron ions. Clusters greater than 30 nm in diameter are ferromagnetic, whereas smaller particles are superparamagnetic [10.93]. Ferromagnetic materials maintain their magnetic moment after the external field is removed, but superparamagnetic materials lose their magnetic field after the field is removed, as

do paramagnetics. Both ferromagnetic and superparamagnetic substances minimize the proton signal by shortening T_2 [10.96], resulting in negative contrast (i. e., darkening of the image [10.97]).

Nanobiotechnological Contrast Agent Design

First generation contrast agents often contained a single metal ion/complex, whereas emerging agents incorporate nanoscale metal clusters, crystals, or aggregates, sometimes encapsulated within a synthetic or biopolymer matrix or shell [10.98–100]. These metal cluster agents improve contrast effects and, hence, output MR images profoundly. Furthermore, surface chemical groups (from the matrix or shell) can be derivatized to improve biocompatibility or allow targeting to a tissue or site of interest.

Typically particles are prepared from colloidal suspension where metallic cores are thoroughly mixed with the matrix material before being aggregated out of solution with a non-solvent. Dextran (a polymer of 1,6-β-D-glucose) is a typical matrix material used in commercial imaging reagents: Combidex is coated with 10,000 molecular weight dextran [10.99, 101, 102], Feridex has an incomplete, variable dextran coating [10.102], and Resovist is coated with carboxydextran [10.97]. Other polymeric materials are also used (oxidized starch [10.98, 100]), and matrix-less particles are also produced [10.103].

Nanoparticle contrast agents must be purified under tightly controlled conditions (generally by centrifugation or high pressure liquid chromatography [10.104]) and accurately characterized (for size dispersity by light scattering, chromatography, photon correlation, or electron microscopy [10.100, 104]) to assure the reproducibility of imaging agent production lots. Elemental analysis, X-ray powder diffraction, and Mössbauer spectroscopy have also been used to characterize metallic cores [10.103, 105]. Tight definition of the finished particles ensures accurate correlation between structural properties of imaged materials and prior in vitro and in vivo studies, allowing collection and interpretation of meaningful images. Metallic cores generally range from 4 to 20 nm in diameter [10.106], while coated particles can be up to 100 nm or more in diameter [10.105]. Compared to larger cores, however, nanoparticles less than 20 nm in diameter exhibit considerably longer blood half-life and improved T_1 and T_2 relaxivity effects [10.107].

As previously discussed, clearance of nanoparticles via the RES is a critical problem usually approached by surface modifications to mitigate nonspecific adsorption of proteins to the biomaterial surface (i. e., the opsonization of synthetic materials). Neutral, hydrophilic surfaces tend to adsorb less serum protein than hydrophobic or charged surfaces. Bisphosphonate and phosphorylcholine-derived thin film coatings have been applied to nanoparticles to stabilize iron oxide particles against pH, opsonization, and aggregation [10.108]. Such thin films do not fully eliminate protein adsorption, and dense layers or thick brushes of polysaccharides or hydrophilic polymers may more effectively avoid opsonization [10.109].

Other, as yet incompletely understood, biological factors influence the use of nanoparticles in vivo. For instance, a direct correlation between the circulating half-life of nanoparticles (i. e., their $T_{1/2}$s) and age of animals used has been reported [10.106]. The observed increase in $T_{1/2}$ may be correlated to age-related changes in phagocytic activity [10.106]. Local environments also influence particle stability: iron oxide particles are degraded at a pH of 4.5 or less [10.100], a condition sometimes attained in some intracellular vesicles.

First generation contrast agents were primarily blood-pool agents that moved freely through the entire vasculature. Targeting contrast-enhancing nanoparticles to sites of interest can reduce heavy metal toxicity associated with the commonly used agents by diminishing the dose required to obtain an acceptable image. Contrast agent targeting can also provide enhanced diagnostic information. For instance, nanoparticles that bind to molecular fibrin at a clot site on a vessel wall have been developed [10.110], potentially allowing differentiation between vulnerable and stable atherosclerotic plaques. Similarly prognostically valuable data regarding disruptions of the blood–brain barrier (BBB) have been visualized with MRI as the result of delivery of contrast-enhancing nanoparticles to the affected site [10.102].

10.4 Applications for Nanotherapeutic Devices

As discussed above, nanotherapeutic devices are novel, emerging therapeutics with properties not fully understood or predictable. Nanotherapeutics, therefore, must be justifiable on at least two levels. As we have seen, the nature of the therapeutic task and the state of current nanoscale-materials technology make the incorporation of biological macromolecules unavoidable for many nanotherapeutics. Proteins, for example, typically are substantially more expensive than small molecule therapeutics, and precise nanostructures containing proteins will be more costly still. Nanotherapeutics must justify their high COGs. Secondly, as new therapeutic modalities, nanotherapeutics may carry significantly larger risks than those associated with more conventional therapies. Expensive, novel moieties, such as nanobiotechnological therapeutic devices, are therefore most likely to be accepted for treatment of conditions that not only are accessible to intervention at the nanoscale but also for which existing therapeutic modalities have acknowledged shortcomings in patient morbidity or mortality. We have selected two disease states sufficiently grave and sufficiently unserved to warrant nanotherapy: cancer and cardiovascular disease. Modulation of immune responses and vaccination is our third application area.

10.4.1 Nanotherapeutic Devices in Oncology

The economic burden imposed by cancer is immense, measuring in the billions of dollars annually in the United States alone. Existing therapies such as surgical resection, radiotherapy, and chemotherapy have profoundly limited efficacy and frequently provide unfavorable outcomes as the result of catastrophic therapeutic side effects. Additionally, the biology, chemistry, and physics of cancer, in general, and solid tumors in particular, provide therapeutic avenues accessible only by nanoscale therapeutics. Oncology is thus an ideal arena for emerging nanotechnological therapies.

Tumor Architecture and Properties

Tumors as tissues are relatively chaotic structures exhibiting vast structural heterogeneity as a function of both time and space [10.9, 77, 111, 112]. In healthy tissues, vasculature resembles a regular mesh in which the mean distance of tissue spaces to the nearest vessel is tightly controlled and highly uniform. On the other hand, the vasculature of tumors resembles a percolation network containing regions experiencing vastly different levels of perfusion. Tumors of 1 mm^3 or larger typically contain measurably hypoxic domains, with pO2 values as much as two- to threefold lower than in normal tissue. High levels of hypoxia are characteristic of enhanced metastatic potential and tumor progression. Also due to insufficiency of perfusion, tumors frequently contain necrotic domains.

The average torturosity of vascular flow paths in tumors is also much greater than in healthy tissue, and transient thrombotic events lead to enhanced resistance to flow and ongoing vascular remodeling. Aside from its plasticity, tumor vasculature itself is highly irregular, may be incompletely lined with endothelial cells, and often exhibits significantly higher extravasation limits (the highest molecular weight of materials that can leave the vasculature and diffuse into the interstitial spaces) than normal vasculature. Tumor tissue is also poorly drained by lymphatics, so extravasated materials tend to remain in situ in tumors and are not cleared efficiently.

These biological phenomena all differentiate tumor tissue from normal tissue and can be exploited in therapy. For instance, the special vascular integrity and lymphatic drainage properties of tumors constitute the Enhanced Permeability and Retention effect (EPR) [10.11, 12, 80, 113]. EPR presents an obvious opportunity for intervention with nanoscale therapeutics (Fig. 10.3). Extravasation limits for normal tissues are variable, but structures larger than a few nanometers in diameter do not leave circulation efficiently in most tissues, whereas tumor vasculature frequently allows egress of materials in the tens to hundreds of nanometer range. Further, nanomaterials, once extravasated, are not cleared by lymphatic drainage. EPR provides tumor targeting that does not depend on biological affinity reagents: tumor tissue provides preferential depot sites for extravasated drug delivery devices. Targeting to a desired site of action is highly desirable for cytotoxic therapeutics, and EPR provides the basis for a growing class of polymer therapeutics [10.11, 12, 80, 113]. That said, EPR and targeting by biological affinity are not necessarily mutually exclusive. A number of antigens more or less specifically related to tumors are known (tumor associated antigens or TAAs), and as discussed above tumor-/organ-specific vascular addresses might be exploited for delivery of therapeutics [10.65, 66]. For instance, various biological reagents that recognize TAAs (i. e., antibody to carcinoembryonic antigen, transferrin) have been conjugated to nanoscale contrast agents to enhance contrast agent localization to tumoral sites [10.104].

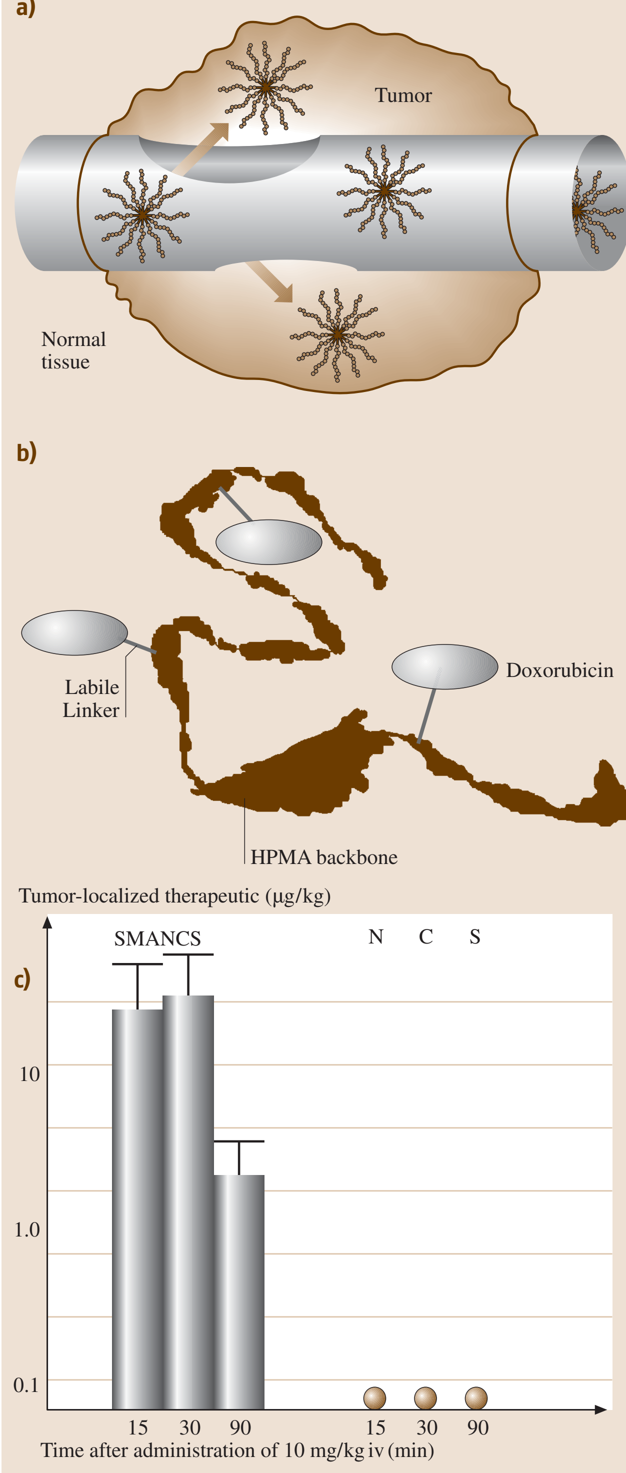


Fig. 10.16a–c Therapeutic nanodevices can be specifically delivered to tumors by virtue of their size [10.11, 12, 80, 113]. **(a)** An illustration of the relatively low integrity of tumor vasculature. Therapeutic nanodevices (in this case, micelles carrying cytotoxins) cannot leave (i. e., extravasate from) the vasculature of normal tissue, but the vasculature of tumors is sufficiently leaky to allow specific delivery to tumoral interstitial spaces. This is the basis of size-dependent targeting to tumors by the enhanced permeability and retention, or EPR effect. **(b)** A polymer nanotherapeutic (PK1, [10.80]) that exploits EPR effect to deliver a cytotoxin (doxorubicin) to tumors. The overall mass of the complex is tuned by control of the mass of the N-2-(hydroxypropyl) methacrylimide backbone, so as to be above extravasation limits for normal tissues but below both tumor extravasation limits and the size limit for excretion through the kidney. A final feature of the device that favors delimiting doxorubicin cytotoxicity to tumoral sites is the fact that the device is a prodrug. The cytotoxicity of doxorubicin is severely curtailed when the doxorubicin is covalently linked to the polymer therapeutic, though it manifests its full toxicity when it is released from the complex by cleavage of the labile (peptidic) linker. The labile linker contains a cleavage site recognized by a protease known to be over-expressed in the target tumor type. Thus, the device produces a depot of inactive doxorubicin in tumors that is activated preferentially to full toxicity by conditions prevalent in the tumor. **(c)** EPR can drive localization of appropriately sized therapeutics to tumoral sites [10.113]. The polymer therapeutic SMANCS accumulates rapidly in murine tumors, whereas the NCS, the parent therapeutic (not engineered for EPR delivery), does not

Tumor (EPR) Properties and Nanotherapeutics

PK1 (Fig. 10.16) is an early example of a growing and increasingly sophisticated class of polymer therapeutics [10.11, 12, 80, 113]. It is a nanoscale molecular therapeutic device wherein the therapeutic moiety (doxorubicin) is covalently linked to the polymeric backbone. As we will see, each component of the polymer therapeutic fulfills a discrete function, so the device rubric is warranted [10.6].

PK1 consists of a polymeric backbone (HPMA, hydroxyl polymethacrylamide) which, as discussed below, targets desired sites by virtue of its specific nanoscale size (by EPR effect) and a cytotoxin (doxorubicin), covalently linked together by a peptide. PK1 exhibits multiple design features that allow it to preferentially deliver doxorubicin to tumors. The size of the complex

is tuned to be too large to extravasate in healthy tissue but still small enough for renal clearance. Effectively, tumors and the excretory system compete for PK1. This aspect of the relationship between therapeutic size and systemic tolerability is illustrated in Fig. 10.16. The therapeutic device has to be sufficiently large to have limited access to healthy tissues but must have relatively unimpaired access to tumors and the excretory system via the kidneys.

A second engineered feature of PK1 relates to tumor-specific release of cytotoxin. Doxorubicin is toxic as a free molecule but is nontoxic as a part of a polymer complex. In PK1, doxorubicin is linked covalently to the polymeric backbone by a peptide chosen specifically because it is the substrate for a highly expressed protease in the target tumor. Thus PK1 deposits cytotoxin to tumors in an inactive form that is processed to an active form preferentially by tumoral metabolic activity. In all, the design features of PK1 act to minimize systemic exposure to cytotoxin and augment tumoral exposure, thereby enhancing therapeutic benefit and diminishing undesired side effects.

Therapeutics need not be covalently linked complexes to be delivered by EPR. In some cases, bioactives can be engineered to interact with blood constituents non-covalently so as to bring the apparent size of the complex into a range that allows preferential tumor deposition. This is the mechanism of delivery for the oldest EPR-exploiting therapeutic in clinical use, SMANCS (S-Methacryl-neocarzinostatin) [10.113]. Neocarzinostatin (NCS) is a small (12 kDa, a few nm in diameter), cytotoxic protein that elicits its toxicity by generating intracellular superoxide radicals enzymatically, which in turn damage DNA. Unmodified NCS is cleared rapidly and exhibits dose-limiting bone-marrow toxicity. Both problems are mitigated by the site-specific conjugation of two small (about 2 kDa and less than 1 nm in length) styrene-comaleic acid polymer chains, resulting in SMANCS. The $T_{1/2}$ of SMANCS is about ten-fold higher than that of NCS, though SMANCS itself is too small to accumulate preferentially in tumors by EPR. This is mitigated by the fact that SMANCS (but not NCS) is efficiently bound by serum albumin. The resulting non-covalent complex is sufficiently large not to extravasate into normal tissue, though it still partitions efficiently into many tumors. The EPR-driven partitioning of the non-covalent SMANCS-albumin complexes into tumors suggests that other non-covalent complexes (such as the multi-dendrimer device of Fig. 10.3, were it pre-assembled prior to administration) might also target to tumors via EPR.

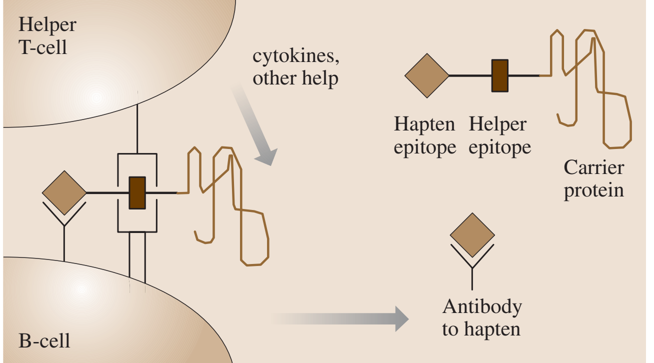

Fig. 10.17 Antibody responses [10.1] are efficiently triggered by antigens that contain both B-cell epitopes (diamond) and helper T-cell epitopes (rectangle). The B-cell epitope binds a receptor on the B-cell surface (the Y shape shown interacting with the B-cell epitope) that is essentially a membrane-bound form of the antibody species that the particular B-cell can produce. The peptidic T-helper epitope engages another receptor complex on the B-cell surface (class II MHC, the two part receptor schematically depicted as interacting with the T-helper epitope, see text). When presented in the context of the class II MHC complex of the B-cell, the T-helper epitope can be recognized by a cognate T-cell receptor on the helper T-cell surface (shown as a receptor on the T-cell surface interacting with the T-helper epitope/class II MHC complex). In response to recognition of its appropriately presented, cognate T-helper antigen, the helper T-cell provides multiple stimulatory signals that cause the B-cell to proliferate, secrete antibody, and differentiate. This is a classical hapten-carrier configuration of an immunogen [10.1], in which a synthetic B-cell epitope is the hapten (in our cases, a PAMAM dendrimer or SWCNT epitope), and the protein covalently linked to the hapten is the carrier, providing the T-helper epitope. Note that the antibody produced recognizes *only* the B-cell epitope and *not* the T-helper epitope. The T-helper epitope also need not be present for antibody recognition of carrier epitopes, nor is its presence necessary to maintain the ongoing antibody response once antibody production is triggered. Note that whether the T-helper epitope remains covalently linked to the B-cell epitope during antigen presentation (here, the intact carrier protein is shown linked to the B-cell epitope) is debatable. Proximity of the B-cell epitope/receptor complex and T-helper epitope/class II MHC complex on the B-cell surface may be sufficient to trigger a robust antibody response

Delivery of antitumor agents using EPR can be highly efficacious. As shown in Fig. 10.17, conjugation of therapeutics to produce controlled-size delivery complexes can enhance tumoral accumulation by multiple orders of magnitude relative to free therapeutics [10.11, 12, 80, 113]. In effect, EPR targeting broadens the thera-

peutic window (the range of concentration between the lowest effective and highest tolerable dose), allowing more intensive therapy. Increased therapeutic intensity allowed by EPR strategies also produces significantly enhanced clinical outcomes [10.11, 12, 80, 113]. The benefits of EPR strategies seem to be general in that a broad range of materials can be targeted to tumors and almost any particulate material falling within the appropriate size range will partition into tumor tissue via EPR. This includes not only linear and dendritic polymers but also higher-order, self-assembled structures such as micelles or shell cross-linked structures and inorganic materials such as ferromagnetic particles. In addition to EPR tumor targeting, each of these structures has intrinsic properties that might be exploited in therapeutic nanodevices (see the discussion of imaging above). Targeted contrast agents may be particularly important for early tumor detection.

10.4.2 Cardiovascular Applications of Nanotherapeutics

The cardiovascular system is one of the most dynamic and vital systems of the body. In principle, every cell in the body is accessible to the bloodstream via the vasculature. If controlled navigation of, and extravasation from, the vasculature can be accomplished, therefore, the potential of nanotherapeutic devices is virtually unlimited. But as mentioned throughout this chapter, opsonization and immune clearance, as well as targeting and triggering of therapeutics, remain key issues to address in order to facilitate wide application of nanotherapeutic devices to cardiovascular disease. In this section we provide a brief overview of categories and examples of nanotherapeutic devices used in blood-contacting applications.

Cardiovascular Tissue Engineering

A usable, immunologically compatible artery for coronary bypass is not always available, so synthetic or semi-synthetic artery substitutes are highly valuable. Tissue engineering approaches might mitigate the lack of acceptable homologous artery, as long as an acceptable artery substitute can be produced. Current tissue engineering approaches involve synthesis of three-dimensional, porous scaffolds that allow adhesion, growth, and proliferation of seeded cells to generate a functional vessel. Cellular organization and growth in synthetic scaffolds are often chaotic and random, and sufficient blood supply is seldom achieved within the scaffold. These conditions often result in death of the seeded cells and compromise the integrity of the vascular prosthesis.

Microfabrication techniques have allowed miniaturization of the tissue engineering scaffolds. These techniques allow the molecular-level control of cellular adhesion and propagation by control of surface topography, surface chemistry, and arrangement of morphogenic and proliferative signaling ligands and cytokines. Microfabrication schemes are being developed for the elucidation of parameters necessary for cellular attachment and orientation on well-defined silicon- and polymer-based surfaces. One particularly powerful application of controlled cellular growth is for the development of artificial capillaries to remediate vascular disease [10.114] (Moldovan, unpublished). Micro-machined silicon or polymer channels of the dimensions of capillaries have shown promise as effective conduits to direct endothelial cells to form tubes through which a fluid (blood) could eventually flow.

MEMS technology and nanoscale control of molecular events and interactions has also been applied to the development of cardiovascular sensors. For instance, blood cell counters have successfully detected red and white blood cells and show promise for quick, reliable blood cell analysis [10.115]. Additionally, force transducers have been developed to measure the contractile force of a single cardiac myocyte [10.116]. Basic research into cellular function and response to stimuli such as these will eventually support more efficacious and robust cardiovascular tissue engineering approaches.

Nanoparticulate Carriers for Therapy and Imaging

Two major cardiovascular applications of nanoparticles are targeted contrast agents for imaging (MRI, CT, X-ray, etc.) and targeted drug delivery vehicles to address vascular lesions (atherosclerotic plaques) and other vascular disease states. In either application, nanoparticle surfaces must be appropriately modified to avoid RES clearance and to drive interaction with the desired effector cells. Decades of research in the area of molecular and cell biology have provided researchers with many tools to make the appropriate protein component selection for nanotherapeutic contrast agents. For instance, knowing that the procoagulant protein tissue factor is expressed only at the surface of injured endothelial cells provides a means to differentiate healthy from diseased vasculature. It also provides a method to target disease sites. Similar sorts of information regarding disease and normal vasculature at specific tissue sites can be crit-

ically important for targeting specialized vascular beds, such as that which occurs at the BBB. Several groups have begun efforts to develop nanoparticles that selectively pass across the BBB to deliver chemotherapeutic or other drugs to the brain [10.117, 118], and this may improve outcomes from stroke.

With regard to MRI approaches, particles used for targeted contrast enhancement in specific tissues or vascular beds may be quite powerful for detection of unstable atherosclerotic plaques and quantitative analysis of blood flow. For instance, nonspecific accumulation of nanoparticles within human atherosclerotic plaques has been reported [10.119, 120] and may ultimately provide a way to distinguish vulnerable and stable plaques. Such data might be used to direct therapy, with the intent, as always, to improve therapeutic outcome. Furthermore, nanotherapeutic devices have been designed to include both contrast and drug delivery functions (Fig. 10.3). Single-platform, multifunctional particles for cardiovascular therapy represent a cutting edge in the cardiovascular field. These delivery vehicles are being designed and improved continual for longer circulation time, more efficient targeting [10.66, 121], degradability, and biocompatibility [10.122].

10.4.3 Nanotherapeutics and Specific Host Immune Responses

Immune responses directed to immunogens (molecules or structures capable of eliciting specific immune responses, also called antigens) are a pervasive aspect of the responses of vertebrates to exposure to foreign macromolecules, proteins, particles, and organisms (for overviews, see [10.1, 123, 124]). Undesired antibody responses, in particular, are the single most important hurdle for clinical use of recombinant proteins. On the other hand, undesired cellular immune responses are key mediators of frequently devastating disorders for patients, whether the responses are directed to self (as in autoimmune disease) or to foreign antigens (as in transplant rejection). As we shall see, host immune responses to nanotherapeutic devices are a critical determinant of their efficacy. Any strategy (including the biotechnological strategies) that allows controlled manipulation of immune responses either to augment desirable responses, as in vaccines, or to mitigate deleterious responses holds substantial potential benefit.

Basic Immunology

Specific immune responses are directed to individual macromolecules or assemblages of them and can be categorized into cellular responses, mediated by cytotoxic T-lymphocytes (CTLs), and humeral responses, mediated by soluble proteins (found in blood serum and other biological fluids) secreted by B-cells (antibodies). Regardless of the effector (CTLs or antibodies), specific responses are directed to individual molecular features of antigens called epitopes. The three types of epitopes are: cytotoxic T-cell (CTL) epitopes, helper T-cell epitopes, and B-cell epitopes. The first two types are peptides that must be presented on cell surfaces in the context of the class I (in the case of CTL epitopes for CTL responses) or class II (in the case of T-helper epitomes, involved in both antibody and CTL responses) major histocompatibility complex (MHC) molecules. B-cell epitopes are a chemically and structurally heterogeneous group of epitopes and include synthetic molecules as well as peptides. In addition to CTL and B-cell epitopes, which are recognized by immune effectors, T-helper epitopes are recognized by regulatory components of the immune system (helper T-cells). Vibrant CTL and antibody responses require immunogens containing T-helper epitopes along with either B-cell or CTL epitopes.

While epitope-presenting MHC class I and class II complexes must be present on cell surfaces to trigger immune responses, the machinery for antigen processing and loading of MHC class I or class II proteins for antigen presentation reside in distinct membrane-bound compartments in the cell [10.1]. For instance, processing for class I presentation (to trigger CTL responses) occurs through the cytosol, but charging of MHC class I complexes is accomplished in the endoplasmic reticulum. On the other hand, processing for class II presentation (to augment antibody and CTL responses), as well as the loading of class II, occur in endosomal compartments. Although these are membrane bounded compartments in the cytosol, topographically the interiors of endosomal compartments are part of the extracellular environment and are not inside the cell at all.

In the case of both class I and class II, the antigen presenting complexes are moved to the cell surface after charging. The moving of molecules between different cellular locations (called trafficking) is tightly regulated by and driven by specific cellular proteins, systems, and structures. Proper trafficking is essential to assure that all cellular components assume their correct position in the cellular organization, which in this case, is to assure antigens are directed to the compartments that will (most often) produce most protective immune responses. These complex antigen processing and presentation systems can be perturbed and exploited to offer novel opportunities in vaccine design.

Nanotherapeutic Vaccines: Eliciting Desired Host Immune Responses

Both therapeutic and prophylactic vaccines are naturals for nanobiological approaches. Therapeutics that modulate immune responses (antibody, CTL responses, or both), vaccines typically produce desired immunity to disease or pathogens. Ideally they are chemically well defined, safe, and induce long term (preferably, multiyear) protective immune responses [10.125]. Recent developments in immunobiology have opened opportunities for nanobiological vaccine design [10.126, 127].

Particulate Vaccines

The immune system, through dendritic cells (DCs), other antigen presenting cells (APCs), and immune effectors, performs ongoing surveillance for non-self antigens using the MHC antigen presentation system described above [10.1]. It has long been known that APCs sample serum for antigens that they process and present using the MHC class II pathway for antibody production [10.1]. Research of the last few years has shown that DCs, macrophages, and other APCs also take up particulate materials and process and present the constituent peptide epitopes via the MHC class I pathway to trigger specific CTL responses. Previous dogma held that only endogenous antigens (such as those produced in virally infected cells) could be presented through the class I MHC pathway. Both soluble and particulate antigens can be presented via the class I pathway, but particulate antigens are orders of magnitude more potent than the same immunogens formulated in soluble form [10.125–128].

APCs are not particularly fastidious regarding chemical composition of the particles they take up: latex beads [10.126, 128] as well as iron beads [10.126] have been used. Self-assembled nanoparticles made of lipidated epitope peptides also deliver orders of magnitude of better immunization than do soluble formulations of the same peptides [10.129]. The specific size for optimal CTL responses is not fully defined but clearly is in the nanometer to micrometer size range [10.125, 126, 128, 129]. One could imagine a systematic exploration of optimum size and compositional preferences for uptake by APCs using such chemically and morphologically tunable polymeric nanomaterials as dendrimers and tectodendrimers.

Nanobiological Design of Nanotherapeutic Vaccines

As mentioned earlier, antigen trafficking determines which specific MHC complex (class I or class II) epitopes are presented on and, therefore, which immune effectors are produced in the subsequent response. The process, while tightly regulated, is amenable to intervention using nanotherapeutic vaccines. Nanobiological design strategies (discussed above) can take advantage of the numerous proteins and peptides now known to mediate the trafficking of carried materials to specific sites. In the device context, these trafficking moieties might assure delivery of antigens to the appropriate cellular compartments to trigger desired class I- or class II-mediated responses.

Vaccine polypeptides, for instance, might be fused or formulated with pathogen polypeptides that will deliver them across epithelium from outside the host for use in mucosal vaccination [10.130]. Still other peptides are known to carry injected materials across the cell envelope into the cytosol [10.131]. Alternatively, vaccine entities taken up by receptor-mediated endocytosis (into endosomal vesicles, the traditional site of uptake for antigens destined for MHC class II presentation) could be shuttled into the cytosol (and hence to the class I MHC pathway) by the incorporation of peptide domains of bacterial toxins that mediate endosomal escape to cytoplasm [10.132]. Potentially, nanobiological therapeutic design strategies [10.5, 13, 15] can combine knowledge of polymer chemistry, nanomaterials, chemistry, cell, molecular, and immunobiology to generate highly effective nanotherapeutic vaccines.

Nanotechnology and Modulation of Immune Responses

On the other hand, protein immunogenicity represents a critical limitation to the therapeutic use of recombinant proteins, particularly when specific antibody responses to the therapeutics are engendered [10.32]. The consequences of antibody responses to proteins are variable, ranging from no effect to decidedly negative consequences to the host. Antibodies can neutralize therapeutic bioactivity, rendering drug entities inactive in repeated rounds of therapy, distort drug P_k and B_d properties, and, in the worst case, trigger autoimmune responses with cross-reactive host antigens (host antigens that share some identity with the immunizing epitopes).

Antibody Responses to Nanotherapeutic Devices

Antibody responses to protein components are a major challenge for nanobiological therapeutic devices in vivo. We, and others [10.6, 14, 21, 133–136], have demonstrated that protein components of bioconjugates to diverse nanomaterials can not only retain their intrinsic immunogenicity but, worse, can render the

otherwise non-immunogenic synthetic nanomaterials to which they are linked capable of inducing antibody responses [10.6, 7, 14, 21, 126, 133–135]. The mechanism of immunogenicity seems to be haptenization, a well-known phenomenon in immunology. Haptenization occurs when antigens containing only B-cell epitopes are covalently linked to proteins containing T-helper epitopes, thereby creating hybrid antigens that are fully immunogenic with respect to antibody responses. The process is illustrated in Fig. 10.17.

As a result of the chemically repetitive structure of many synthetic nanomaterials, the antibodies directed to them have interesting properties. Most notably, antibodies generated to nanostructures are often cross-reactive to other chemically similar nanostructures. For example, antibodies raised using haptenized fullerenes also recognize carbon nanotubes [10.133], and antibodies raised to haptenized generation 0 (G_0) PAMAM dendrimers also recognize higher generation PAMAM dendrimers (G_1, G_2, G_3, etc. [10.14, 21, 133–136]. Presumably, cross-reactivity results from the presence of common B-cell epitopes in the immunogen used and in structurally similar cross-reactive antigens. Thus, patients immunized with any therapeutic containing one haptenized nanostructure could potentially raise antibodies that would recognize any nanotherapeutic containing a material structurally similar to the haptenized nanomaterial.

This is a potentially serious problem, in light of the documented ability of antibody responses to interfere with therapy by neutralizing drug or distorting P_k and B_d properties. As discussed before, molecular weights of serum antibodies are around 150,000 AMU with an effective diameter in excess of 10 nm [10.1, 123, 124]. Many of the desirable properties of nanotherapeutics derive from their precisely controlled sizes, and size-dependent properties like EPR targeting could be jeopardized if the therapeutic to be delivered were non-covalently complexed with antibodies directed to its synthetic components. Due to long-term persistence of memory immune responses, exposure to haptenized nanotherapeutics could endanger patient responsiveness to structurally similar materials for the duration of their lives. Obviously, immunogenicity is a critical challenge to the nanobiological therapeutic paradigm that has yet to be satisfactorily addressed.

Polymer Conjugation to Mitigate Immune Responses

There are multiple approaches to mitigating immunogenicity, some of which are applicable to nanobiotechnological therapeutic devices. Polymer conjugation, particularly conjugation of proteins to poly (ethylene glycol) (PEG, a flexible, biologically well-tolerated hydrophilic polymer) has been used to control immunogenicity of a broad class of proteins and synthetic molecules since the mid-1970s [10.19, 137]. Typically, pegylation involves covalent linkage (often by promiscuous conjugation chemistry) of variable numbers (usually two to six polymer molecules) of size-polydisperse (usually 3,000 to 10,000 AMU) linear or branched PEG chains to the potential immunogen. This approach results in polydisperse bioconjugates, which flies in the face of the molecular level-structural precision often considered essential for nanotechnology. Still, pegylation may be useful in some limited nanobiological applications.

The mechanism of molecule-specific immunosuppression remains obscure, despite almost 30 years of research. The flexibility of the PEG strands allows them to wrap around the molecules they are conjugated to, perhaps delimiting access of immune effectors and immune processing machinery to the potential immunogens. Pegylated molecules exhibit dramatically enhanced apparent diameters and vastly enhanced solubility in aqueous buffer. Both of these phenomena result in substantially diminished clearance of pegylated molecules by the RES and may account for the retention of in vivo bioactivity despite the apparent steric hindrance that may result from wrapping PEG moieties around their protein bioconjugate partners. Pegylation-related, bioconjugate-specific immunosuppressive phenomena cannot be fully accounted for by sterics, though. Immunological experiments in syngeneic mice show that the protein-specific immunosuppression associated with pegylated proteins is transmissible from one animal to another by surgically harvested splenocytes. This finding is more consistent with a mechanism of suppression involving immunologically induced tolerance of foreign antigens as opposed to one caused by simple steric considerations [10.137].

Synthetic Nanoporous Membranes for Immunoisolation

A second approach to avoiding immune responses to nanodevices or biocomponents is immunoisolation by encapsulation [10.16, 17]. In this strategy, potentially immunogenic structures (nanodevices, cells, macromolecules) are sequestered from high molecular weight, large host immune effectors, and immunosurveillance, while small molecules, such as glucose and small proteins, diffuse freely (Fig. 10.18). While conceptually simple, immunoisolation is technically challenging in that the number of pores must be high to maximize

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

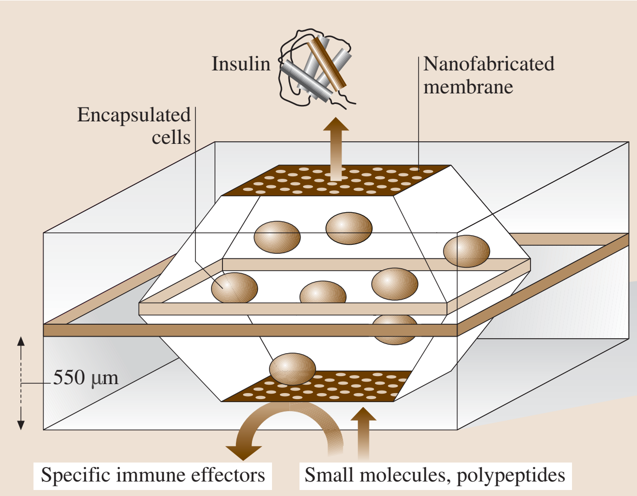

Fig. 10.18 Biological components can be protected from unfavorable environments by encapsulation [10.16–18]. Shown is an immunoisolation capsule containing heterologous (immunogenic) cells producing insulin (a four helical bundle protein, see text). The cells are protected from immune responses by membranes with 10 nm pores that allow free diffusion of small molecules (oxygen, nutrients) into the capsule and small proteins (insulin, shown here not to scale) out of it. However, immune effectors with diameters greater than pore size (immune cells like CTLs and APCs, antibodies, other effectors) don't access the capsule interior, protecting the xenograft from immune rejection. The structure integrates both micro- and nanoscale components (including the nanoporous membranes of Fig. 10.4) into a macroscale construct

flux, and the pores must be highly uniform in dimension.

Because of the exquisite sensitivity of the immune system, immunoisolation must be nearly perfect if it is to work at all. Particularly in the case of immunoisolation of cells for xenografts, if only a tiny fraction (as few as 1%) of the pores of an immunoisolation capsule are large enough to admit immune effectors (for instance, antibodies and complement components, exclusion of which requires pores of 50 nm or less), or the viability of the graft will be compromised [10.16, 17, 138]. Thus, the strategy requires fabrication of membranes with pores that have very tightly controlled dispersities in terms of their maximum diameters. Until recently, immunoisolation for xenografts has failed for lack of such membranes.

The technological innovations that made the synthesis of these high-quality nanoporous membranes were described above and in Fig. 10.4. The nanoporous membranes can be used to form immunoisolation capsules when either two such membranes are joined so that they bind an enclosed space or that a nanoporous membrane is used to enclose a compartment of some sort in a therapeutic structure. The enclosed spaces can be charges with functional nanodevices or, for that matter, living cells. Such immunoisolation capsules charged with heterologous pancreatic islet cells have demonstrated immense promise for regulating normoglycemia in diabetic animal models [10.16–18].

Biogenic, Nanoporous, Immunoisolation Membranes

The novel microfabrication strategy has made it possible to make these highly defined membranes in an industrial process, and they are applicable to numerous biomedical applications beyond immunoisolation [10.16, 17]. Still the fabrication process is rigorous, and an alternative biogenic method to derive selectively porous silicon capsules has been proposed [10.139, 140]. Diatoms are encapsulated in biogenic amorphous silicon shells (called frustules), which the living cells secrete. Frustules must necessarily be porous to allow the cells to take on nutrients and excrete wastes, and the porosity, pore dimensions, and other micro- and nanoscale morphological frustule features are tightly controlled at genetic and physiological levels. Using techniques well known to microbiologists (manipulation of culture conditions), geneticists (mutagenesis), and cell biologists (optically driven cell sorting in flow systems), it is theoretically possible to select and propagate diatoms whose frustule morphology, size, and pore characteristics fall within pre-selected limits [10.139, 140]. Frustules can be isolated intact from diatom cultures, so biogenic production of silicon membranes with porosity characteristics similar to the microfabricated membranes discussed above may be feasible. Though they have yet to be realized, immunoisolation capsules made from genetically/physiologically tuned frustules have been proposed [10.140]: one wonders what other biomineralized structures eventually might also be put to nanobiotechnological use.

10.5 Concluding Remarks: Barriers to Practice and Prospects

The effort to produce nanoscale therapeutic devices is clearly highly interdisciplinary. As we have seen, it touches on numerous established disciplines, encompassing elements of physiology, biotechnology, bioconjugate chemistry, electrical engineering, and materials science, to name just a few of the fields involved. Obviously, this broad sweep of knowledge is difficult for any one investigator to master fully. The breadth of the effort constitutes just one of the major barriers to entry in the field. Other challenges include the raw complexity of biology, the fashion in which biologists hold and distribute information, and cultural differences between engineers and biological scientists.

10.5.1 Complexity in Biology

Biology is characterized by particularity: nuances of biological systems are often unique to the system at hand and highly idiosyncratic. This follows from the fact that biological systems are not purpose-built, as are designed devices (although they can give that appearance, as seen in Fig. 10.1), but rather arose as the consequence of evolutionary processes. Evolution is a highly chaotic business, with the outcome of any given evolutionary process highly sensitive to initial conditions (populations of organisms subjected to selection, other organisms in the environment, biology of all organisms involved, resource availability, other environmental factors, etc.). Moreover, many of the variables affecting natural selection processes are nonstatic and change, as a function of time or space or both, *while* selection is exerted against a population of organisms. Conditions leading to one evolutionary adaptation or another are therefore seldom duplicated exactly, so that individual adaptive features are idiosyncratic, with elements relating not only to their biological functions but also to their evolutionary history. Individual systems and adaptive features thereof can be almost baroquely complex because the structures themselves arose under unique conditions, under unique selective pressures, and from unique initial biological systems. The extent of the complexity of biological systems is apparent even in individual macromolecular constituents of biological systems and can be made clear by comparison of synthetic nanostructures to biological nanostructures with similar dimensional aspects.

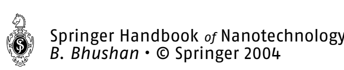
SWCNT (single wall carbon nanotubes) have a minimal diameter of about 1.3 nm, and many proteins likewise have diameters of few nms. SWCNTs are regular and homogeneous polymeric structures composed entirely of carbon atoms (Fig. 10.6). Proteins, on the other hand, are not polymers of one repeating subunit, but rather are nonrandom copolymers of 20 chemically distinct amino acids (aas). The order of the aas drives specific folding events that produce three-dimensional structures that, in turn, present specific aas and their side chains at specific positions in space (Fig. 10.10). This control of aa position in space drives protein activity: small changes in aa sequence can perturb structure and function profoundly. Therefore, though they fall within the same broad size regime, proteins are structurally and functionally much more complex than SWCNTs. The extent of biological complexity can be glimpsed when one considers that individual living things are ordered aggregates of multiple macromolecules and supramolecular structures (potentially, billions and billions of them), belonging to distinct chemical classes (lipids, proteins, nucleic acids, etc.), with each individual macromolecule being at least as complex in structure and function as the protein of Fig. 10.10. The nearly irreducible complexity of biological systems is a central fact of practice in the biological sciences and drives the way biologists gather and disseminate information. It is the key informant of the culture of biologists.

10.5.2 Dissemination of Biological Information

Biologists typically consider themselves primarily as scientists, as opposed to being engineers or technology developers. The product biologists generate, then, is information rather than devices or structures. Their interest in technological application of the knowledge they produce is typically secondary to their desire to develop the information itself. Additionally, as we have just seen, biology is a ferociously complex discipline.

As a practical matter, biological data itself is often much more rich (and often more ambiguous) than data from harder scientific endeavors. The data can be so very rich that biologists must make choices as to what data is relevant to a given phenomena and, therefore, what data they will publish. With absolutely no intent to conceal or mislead, biologists are often driven to publish only a small fraction of the data they gather.

Since they see themselves primarily as scientists, biologists tend to publish data they believe to be of broad scientific significance. Typically, the chosen in-



B. Bhushan • © Springer 2004

formation does not include data that might be critical to technology development, frequently making the biological literature an inadequate resource for engineers. The omitted information thus becomes lore. That is to say, the infomation is critical for the practice or development of a given technology but usually is not accessible to persons outside the field (as many nanotherapeutic device producers may be). This can be illustrated by recent experiences around phage display-mediated affinity maturation of four helical bundle proteins [10.141–143].

Four helical bundle proteins are loosely related small proteins consisting of four α helices arranged in a specific configuration (see the dynamite stick representation of insulin that occurs in Fig. 10.18). They include insulin, growth hormone, most cytokines, and various other molecules involved in cell to cell signaling. They have a wide range of therapeutically valuable properties that might be made even more desirable if their potencies could be enhanced. There is thus significant interest in variant four-helical bundle proteins with improved bioactivities.

Phage display [10.67] is a method that can be used to sort protein variant libraries for variants with enhanced affinity for a target receptor. This is usually accomplished by iterative rounds of affinity selection on the receptor followed by propagation of selected phage. As rounds of selection and propagation proceed, the mean affinity of the selected variants for the receptor increases (so-called affinity maturation). A phage display method is depicted in Fig. 10.11.

Affinity maturation by phage display can be used to identify variant proteins from libraries that have enhanced biological activities, providing that affinity for receptor is limiting in the overall activity of the parent protein [10.134]. Phage display affinity maturation has been successfully used to select some enhanced activity variants of four helical bundle proteins [10.144, 145] but is *not* applicable to engineering increased activity for *all* four helical bundle proteins [10.134]. The reason for the inapplicability of display methods to engineer high-activity human growth hormone (hGH) variants became apparent in a recent publication from Genentech [10.142].

In the case of hGH, the affinity of the parent molecule for receptor is in excess of that required to drive maximal biological responses [10.142]. This fact was inferred after a multiyear effort (beginning in the late 1980s and culminating in 1999) to derive more active hGH proteins, involving literally thousands of hGH variants. Many of the variants did indeed exhibit enhanced affinity for the hGH binding protein (receptor), but none exhibited significantly enhanced biological activity. Each data point (i. e., the biological activity of each individual variant) essentially constituted a failure of a technology to provide a desired result and was therefore seen, not unreasonably, as negative (and therefore uninteresting) data by the investigators. Consequently, the information was not broadly disseminated until a significant conclusion could be presented (i. e., that biological responses to hGH are not limited by ligand-receptor affinity). Thus, between the late 1980s and the 1999 publication, this information was known primarily and unambiguously only to the investigators involved, even though it would have been critical to any technologist planning to affinity mature hGH by phage display for enhanced activity [10.134].

10.5.3 Cultural Differences Between Technologists and Biologists

Biology is the realm of particularity, whereas more physical sciences are realms within which general rules can be derived and broadly applied. The vast complexity of biology usually drives biologists to be highly specialized, perhaps making a career from the study of particular macromolecules (specific enzymes, growth factors, genetic elements, etc.) or biological systems. Biologists are, therefore, neither trained nor encouraged by funding agencies to see themselves as fungible, and frequently they are very reluctant to step away from their primary research focuses into new areas. Doing so is a major undertaking, and a substantial risk, for most biologists.

Engineers, on the other hand, often see themselves as operating from first principles and are more (if not entirely) willing to step into new areas. After all, crossing disciplines is feasible for engineers working in the physical sciences, whereas it is much more difficult, not only for reasons of training but also because of the biological realities discussed above, for biologists. Also by reason of their training and experience, engineers often vastly underestimate the complexity of biological systems and sometimes exhibit what biologists perceive as naïveté in their approach to biological systems. Unfortunately, or fortunately, depending on your perspective, therapeutic nanodevices require both biological and engineering expertise. An often bruising debate as to how best to prepare students for practice in this extremely challenging field is currently playing out in biomedical engineering and other related academic departments across the country.

The traditional approach for training biomedical engineers has been to train conventional engineers with a smattering of biological knowledge. This "primarily engineers" model of biomedical engineering has been reasonably successful in multiple endeavors (orthopedics, imaging technologies, etc.), but it seems unlikely in the extreme that it will suffice for robust practice in nanotherapeutic devices. As this chapter shows, the role of biology is pivotal to success in the field, and sophisticated nanotherapeutics are virtually impossible to design without deep knowledge of the biology involved. A reasonable argument can be made that successful engineering of therapeutic nanostructures will demand intense focus on biology and a smattering of engineering knowledge (a "primarily biologists" approach, as opposed to the historically prevalent "primarily engineers" training model). This view is often strongly and passionately resisted in colleges of engineering, which are the usual homes of biomedical engineering and related efforts. The outcome of the debate is not finalized, but it is critically important: it will determine whether or not a ready cadre of researchers is prepared for a career in the area. If not, the field will progress much as it has, very slowly bringing the benefits of the research to patients. It seems apparent to us, and it also seems that experience to date shows, that a substantial biological component of training for the discipline is simply unavoidable if we are committed to realizing the vast potential of nanotechnology in human therapy.

11. Scanning Probe Microscopy – Principle of Operation, Instrumentation, and Probes

Since the introduction of the STM in 1981 and AFM in 1985, many variations of probe based microscopies, referred to as SPMs, have been developed. While the pure imaging capabilities of SPM techniques is dominated by the application of these methods at their early development stages, the physics of probe–sample interactions and the quantitative analyses of tribological, electronic, magnetic, biological, and chemical surfaces have now become of increasing interest. Nanoscale science and technology are strongly driven by SPMs which allow investigation and manipulation of surfaces down to the atomic scale. With growing understanding of the underlying interaction mechanisms, SPMs have found applications in many fields outside basic research fields. In addition, various derivatives of all these methods have been developed for special applications, some of them targeted far beyond microscopy.

This chapter presents an overview of STM and AFM and various probes (tips) used in these instruments, followed by details on AFM instrumentation and analyses.

11.1 **Scanning Tunneling Microscope** 327
11.1.1 Binnig et al.'s Design.................. 327
11.1.2 Commercial STMs......................... 328
11.1.3 STM Probe Construction 330

11.2 **Atomic Force Microscope** 331
11.2.1 Binnig et al.'s Design.................. 333
11.2.2 Commercial AFM.......................... 333
11.2.3 AFM Probe Construction 338
11.2.4 Friction Measurement Methods...... 342
11.2.5 Normal Force and Friction Force Calibrations of Cantilever Beams..................... 346

The Scanning Tunneling Microscope (STM) developed by *Dr. Gerd Binnig* and his colleagues in 1981 at the IBM Zurich Research Laboratory, Rueschlikon, Switzerland, is the first instrument capable of directly obtaining three-dimensional (3-D) images of solid surfaces with atomic resolution [11.1]. *Binnig* and *Rohrer* received a Nobel Prize in Physics in 1986 for their discovery. STMs can only be used to study surfaces which are electrically conductive to some degree. Based on their design of the STM, in 1985, *Binnig* et al. developed an Atomic Force Microscope (AFM) to measure ultrasmall forces (less than 1 μN) present between the AFM tip surface and the sample surface [11.2] (also see [11.3]). AFMs can be used for measurement of all engineering surfaces which may be either electrically conductive or insulating. The AFM has become a popular surface profiler for topographic and normal force measurements on the micro to nanoscale [11.4]. AFMs modified in order to measure both normal and lateral forces, are called Lateral Force Microscopes (LFMs) or Friction Force Microscopes (FFMs) [11.5–11]. FFMs have been further modified to measure lateral forces in two orthogonal directions [11.12–16]. A number of researchers have continued to improve the AFM/FFM designs and used them to measure adhesion and friction of solid and liquid surfaces on micro- and nanoscales [11.4, 17–30]. AFMs have been used for scratching, wear, and measurement of elastic/plastic mechanical properties (such as indentation hardness and the modulus of elasticity) [11.4,10,11,21,23,26–29,31–36]. AFMs have been used for manipulation of individual atoms of Xenon [11.37], molecules [11.38], silicon surfaces [11.39], and polymer surfaces [11.40]. STMs have been used for formation of nanofeatures by localized heating or by inducing chemical reactions under the STM tip [11.41–43] and nanomachining [11.44]. AFMs

Table 11.1 Comparison of Various Conventional Microscopes with SPMs

	Optical	SEM/TEM	Confocal	SPM
Magnification	10^3	10^7	10^4	10^9
Instrument Price (U.S. $)	$10 k	$250 k	$30 k	$100 k
Technology Age	200 yrs	40 yrs	20 yrs	20 yrs
Applications	Ubiquitous	Science and technology	New and unfolding	Cutting edge
Market 1993	$800 M	$400 M	$80 M	$100 M
Growth Rate	10%	10%	30%	70%

have been used for nanofabrication [11.4, 10, 45–47] and nanomachining [11.48].

STMs and AFMs are used at extreme magnifications ranging from 10^3 to 10^9 in x, y and z directions for imaging macro to atomic dimensions with high resolution information and for spectroscopy. These instruments can be used in any environment such as ambient air [11.2, 49], various gases [11.17], liquid [11.50–52], vacuum [11.1, 53], at low temperatures (lower than about 100 K) [11.54–58] and high temperatures [11.59, 60]. Imaging in liquid allows the study of live biological samples and it also eliminates water capillary forces present in ambient air present at the tip–sample interface. Low temperature (liquid helium temperatures) imaging is useful for the study of biological and organic materials and the study of low-temperature phenomena such as superconductivity or charge-density waves. Low-temperature operation is also advantageous for high-sensitivity force mapping due to the reduction in thermal vibration. They also have been used to image liquids such as liquid crystals and lubricant molecules on graphite surfaces [11.61–64]. While the pure imaging capabilities of SPM techniques dominated the application of these methods at their early development stages, the physics and chemistry of probe–sample interactions and the quantitative analyses of tribological, electronic, magnetic, biological, and chemical surfaces have now become of increasing interest. Nanoscale science and technology are strongly driven by SPMs which allow investigation and manipulation of surfaces down to the atomic scale. With growing understanding of the underlying interaction mechanisms, SPMs have found applications in many fields outside basic research fields. In addition, various derivatives of all these methods have been developed for special applications, some of them targeting far beyond microscopy.

Families of instruments based on STMs and AFMs, called Scanning Probe Microscopes (SPMs), have been developed for various applications of scientific and industrial interest. These include – STM, AFM, FFM (or LFM), scanning electrostatic force microscopy (SEFM) [11.65, 66], scanning force acoustic microscopy (SFAM) (or atomic force acoustic microscopy (AFAM)) [11.21, 22, 36, 67–69], scanning magnetic microscopy (SMM) (or magnetic force microscopy (MFM)) [11.70–73], scanning near field optical microscopy (SNOM) [11.74–77], scanning thermal microscopy (SThM) [11.78–80], scanning electrochemical microscopy (SEcM) [11.81], scanning Kelvin Probe microscopy (SKPM) [11.82–86], scanning chemical potential microscopy (SCPM) [11.79], scanning ion conductance microscopy (SICM) [11.87, 88], and scanning capacitance microscopy (SCM) [11.82, 89–91]. Families of instruments which measure forces (e.g., AFM, FFM, SEFM, SFAM, and SMM) are also referred to as scanning force microscopy (SFM). Although these instruments offer atomic resolution and are ideal for basic research, they are used for cutting edge industrial applications which do not require atomic resolution. Commercial production of SPMs started with the STM in 1987 and the AFM in 1989 by Digital Instruments Inc. For comparisons of SPMs with other microscopes, see Table 11.1 (Veeco Instruments, Inc.). Numbers of these instruments are equally divided between the U.S., Japan and Europe, with the following industry/university and Government labs. splits: 50/50, 70/30, and 30/70, respectively. It is clear that research and industrial applications of SPMs are rapidly expanding.

11.1 Scanning Tunneling Microscope

The principle of electron tunneling was proposed by *Giaever* [11.92]. He envisioned that if a potential difference is applied to two metals separated by a thin insulating film, a current will flow because of the ability of electrons to penetrate a potential barrier. To be able to measure a tunneling current, the two metals must be spaced no more than 10 nm apart. *Binnig* et al. [11.1] introduced vacuum tunneling combined with lateral scanning. The vacuum provides the ideal barrier for tunneling. The lateral scanning allows one to image surfaces with exquisite resolution, lateral-less than 1 nm and vertical-less than 0.1 nm, sufficient to define the position of single atoms. The very high vertical resolution of the STM is obtained because the tunnel current varies exponentially with the distance between the two electrodes, that is, the metal tip and the scanned surface. Typically, tunneling current decreases by a factor of 2 as the separation is increased by 0.2 nm. Very high lateral resolution depends upon sharp tips. *Binnig* et al. overcame two key obstacles for damping external vibrations and for moving the tunneling probe in close proximity to the sample. Their instrument is called the scanning tunneling microscope (STM). Today's STMs can be used in the ambient environment for atomic-scale image of surfaces. Excellent reviews on this subject are presented by *Hansma* and *Tersoff* [11.93], *Sarid* and *Elings* [11.94], *Durig* et al. [11.95]; *Frommer* [11.96], *Güntherodt* and *Wiesendanger* [11.97], *Wiesendanger* and *Güntherodt* [11.98], *Bonnell* [11.99], *Marti* and *Amrein* [11.100], *Stroscio* and *Kaiser* [11.101], and *Güntherodt* et al. [11.102].

The principle of the STM is straightforward. A sharp metal tip (one electrode of the tunnel junction) is brought close enough (0.3–1 nm) to the surface to be investigated (the second electrode) that, at a convenient operating voltage (10 mV–1 V), the tunneling current varies from 0.2 to 10 nA which is measurable. The tip is scanned over a surface at a distance of 0.3–1 nm, while the tunneling current between it and the surface is measured. The STM can be operated in either the constant current mode or the constant height mode, Fig. 11.1. The left-hand column of Fig. 11.1 shows the basic constant current mode of operation. A feedback network changes the height of the tip z to keep the current constant. The displacement of the tip given by the voltage applied to the piezoelectric drives then yields a topographic map of the surface. Alternatively, in the constant height mode, a metal tip can be scanned across a surface at nearly constant height and constant voltage while the current is monitored, as shown in the right-hand column of Fig. 11.1. In this case,

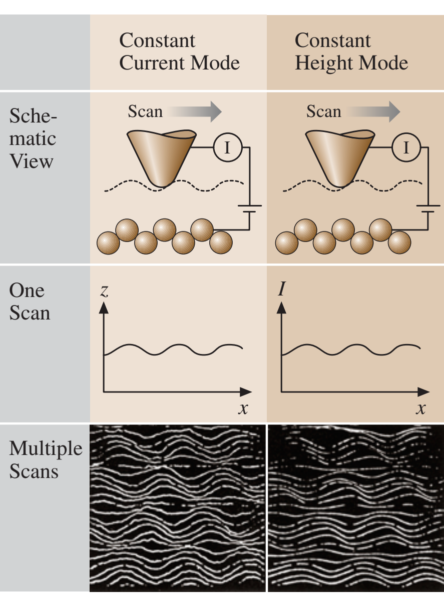

Fig. 11.1 STM can be operated in either the constant-current or the constant-height mode. The images are of graphite in air [11.93]

the feedback network responds only rapidly enough to keep the average current constant. A current mode is generally used for atomic-scale images. This mode is not practical for rough surfaces. A three-dimensional picture $[z(x, y)]$ of a surface consists of multiple scans $[z(x)]$ displayed laterally from each other in the y direction. It should be noted that if different atomic species are present in a sample, the different atomic species within a sample may produce different tunneling currents for a given bias voltage. Thus the height data may not be a direct representation of the topography of the surface of the sample.

11.1.1 Binnig et al.'s Design

Figure 11.2 shows a schematic of one of Binnig and Rohrer's designs for operation in ultrahigh vacuum [11.1, 103]. The metal tip was fixed to rectangular piezodrives P_x, P_y, and P_z made out of commercial piezoceramic material for scanning. The sample is mounted via either superconducting magnetic levitation or a two-stage spring system to achieve a stability of the gap width of about 0.02 nm. The tunnel current J_T is a sensitive function of the gap width d that is $J_T \propto V_T \exp(-A\phi^{1/2}d)$, where V_T is the bias voltage, ϕ is the average barrier height (work function) and the constant $A = 1.025\,\text{eV}^{-1/2}\text{Å}^{-1}$. With a work function of a few eV, J_T changes by an order of magnitude for

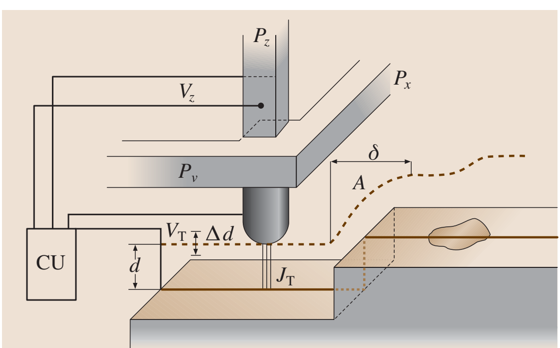

Fig. 11.2 Principle of operation of the STM made by *Binnig* and *Rohrer* [11.103]

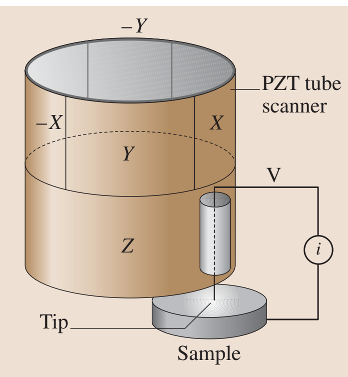

Fig. 11.3 Principle of operation of a commercial STM, a sharp tip attached to a piezoelectric tube scanner is scanned on a sample

every angstrom change of d. If the current is kept constant to within, for example, 2%, then the gap d remains constant to within 1 pm. For operation in the constant current mode, the control unit CU applies a voltage V_z to the piezo P_z such that J_T remains constant when scanning the tip with P_y and P_x over the surface. At constant work function ϕ, $V_z(V_x, V_y)$ yields the roughness of the surface $z(x, y)$ directly, as illustrated at a surface step at A. Smearing the step, δ (lateral resolution) is on the order of $(R)^{1/2}$, where R is the radius of the curvature of the tip. Thus, a lateral resolution of about 2 nm requires tip radii on the order of 10 nm. A 1-mm-diameter solid rod ground at one end at roughly 90° yields overall tip radii of only a few hundred nm, but with closest protrusion of rather sharp microtips on the relatively dull end yields a lateral resolution of about 2 nm. In-situ sharpening of the tips by gently touching the surface brings the resolution down to the 1-nm range; by applying high fields (on the order of 10^8 V/cm) during, for example, half an hour, resolutions considerably below 1 nm could be reached. Most experiments were done with tungsten wires either ground or etched to a radius typically in the range of 0.1–10 µm. In some cases, in-situ processing of the tips was done for further reduction of tip radii.

11.1.2 Commercial STMs

There are a number of commercial STMs available on the market. Digital Instruments, Inc. located in Santa Barbara, CA introduced the first commercial STM, the Nanoscope I, in 1987. In a recent Nanoscope IV STM for operation in ambient air, the sample is held in position while a piezoelectric crystal in the form of a cylindrical tube (referred to as PZT tube scanner) scans the sharp metallic probe over the surface in a raster pattern while sensing and outputting the tunneling current to the control station (Fig. 11.3). The digital signal processor (DSP) calculates the desired separation of the tip from the sample by sensing the tunneling current flowing between the sample and the tip. The bias voltage applied between the sample and the tip encourages the tunneling current to flow. The DSP completes the digital feedback loop by outputting the desired voltage to the piezoelectric tube. The STM operates in both the "constant height" and "constant current" modes depending on a parameter selection in the control panel. In the constant current mode, the feedback gains are set high, the tunneling tip closely tracks the sample surface, and the variation in the tip height required to maintain constant tunneling current is measured by the change in the voltage applied to the piezo tube. In the constant height mode, the feedback gains are set low, the tip remains at a nearly constant height as it sweeps over the sample surface, and the tunneling current is imaged.

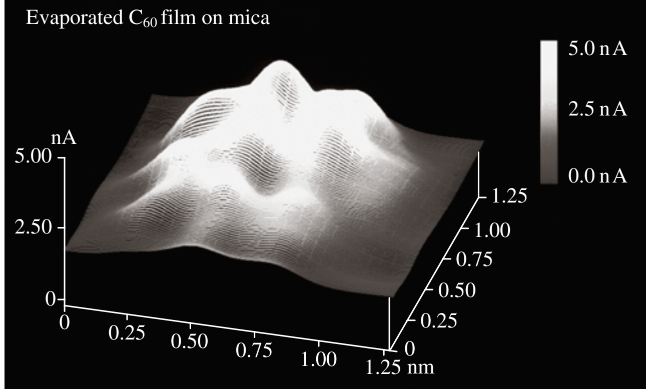
Physically, the Nanoscope STM consists of three main parts: the head which houses the piezoelectric tube scanner for three dimensional motion of the tip and the preamplifier circuit (FET input amplifier) mounted on top of the head for the tunneling current, the base on which the sample is mounted, and the base support, which supports the base and head [11.4]. The base accommodates samples up to 10 mm by 20 mm and 10 mm in thickness. Scan sizes available for the STM are 0.7 µm (for atomic resolution), 12 µm, 75 µm and 125 µm square.

The scanning head controls the three dimensional motion of the tip. The removable head consists of a piezo tube scanner, about 12.7 mm in diameter, mounted into an invar shell used to minimize vertical thermal drifts because of a good thermal match between the piezo tube and the Invar. The piezo tube has separate electrodes for X, Y and Z which are driven by separate drive circuits.

The electrode configuration (Fig. 11.3) provides x and y motions which are perpendicular to each other, minimizes horizontal and vertical coupling, and provides good sensitivity. The vertical motion of the tube is controlled by the Z electrode which is driven by the feedback loop. The x and y scanning motions are each controlled by two electrodes which are driven by voltages of the same magnitude, but opposite signs. These electrodes are called $-Y$, $-X$, $+Y$, and $+X$. Applying complimentary voltages allows a short, stiff tube to provide a good scan range without large voltages. The motion of the tip due to external vibrations is proportional to the square of the ratio of vibration frequency to the resonant frequency of the tube. Therefore, to minimize the tip vibrations, the resonant frequencies of the tube are high at about 60 kHz in the vertical direction and about 40 kHz in the horizontal direction. The tip holder is a stainless steel tube with a 300 μm inner diameter for 250 μm diameter tips, mounted in ceramic in order to keep the mass on the end of the tube low. The tip is mounted either on the front edge of the tube (to keep mounting mass low and resonant frequency high) (Fig. 11.3) or the center of the tube for large range scanners, namely 75 and 125 μm (to preserve the symmetry of the scanning). This commercial STM accepts any tip with a 250 μm diameter shaft. The piezotube requires X-Y calibration which is carried out by imaging an appropriate calibration standard. Cleaved graphite is used for the small-scan length head while two dimensional grids (a gold plated ruling) can be used for longer range heads.

The Invar base holds the sample in position, supports the head, and provides coarse X-Y motion for the sample. A spring-steel sample clip with two thumb screws holds the sample in place. An x-y translation stage built into the base allows the sample to be repositioned under the tip. Three precision screws arranged in a triangular pattern support the head and provide coarse and fine adjustment of the tip height. The base support consists of the base support ring and the motor housing. The stepper motor enclosed in the motor housing allows the tip to be engaged and withdrawn from the surface automatically.

Samples to be imaged with the STM must be conductive enough to allow a few nanoamperes of current to flow from the bias voltage source to the area to be scanned. In many cases, nonconductive samples can be coated with a thin layer of a conductive material to facilitate imaging. The bias voltage and the tunneling current depend on the sample. Usually they are set at a standard value for engagement and fine tuned to enhance the quality of the image. The scan size depends on the sample and the features of interest. A maximum scan rate of 122 Hz can be used. The maximum scan rate is usually related to the scan size. Scan rates above 10 Hz are used for small scans (typically 60 Hz for atomic-scale imaging with a 0.7 μm scanner). The scan rate should be lowered for large scans, especially if the sample surfaces are rough or contain large steps. Moving the tip quickly along the sample surface at high scan rates with large scan sizes will usually lead to a tip crash. Essentially, the scan rate should be inversely proportional to the scan size (typically 2–4 Hz for 1 μm, 0.5–1 Hz for 12 μm, and 0.2 Hz for 125 μm scan sizes). Scan rate in length/time, is equal to scan length divided by the scan rate in Hz. For example, for 10 μm × 10 μm scan size scanned at 0.5 Hz, the scan rate is 10 μm/s. Typically, 256 × 256 data formats are most commonly used. The lateral resolution at larger scans is approximately equal to scan length divided by 256.



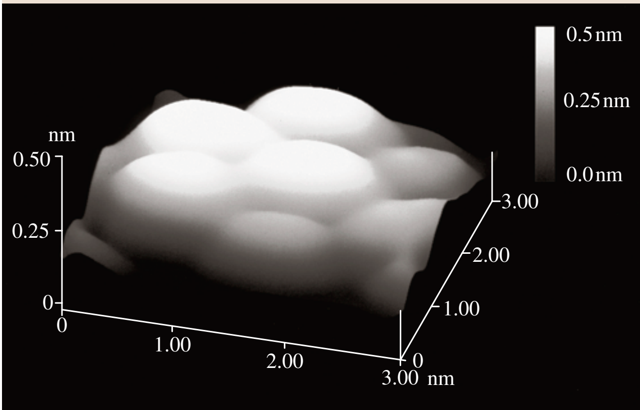


Fig. 11.4 STM images of evaporated C_{60} film on a gold-coated freshly-cleaved mica using a mechanically sheared Pt-Ir (80-20) tip in constant height mode [11.104]

Figure 11.4 shows an example of STM images of an evaporated C_{60} film on a gold-coated freshly-cleaved mica taken at room temperature and ambient pressure [11.104]. Images with atomic resolution at two scan sizes are obtained. Next we describe STM designs which are available for special applications.

Electrochemical STM

The electrochemical STM is used to perform and monitor the electrochemical reactions inside the STM. It includes a microscope base with an integral potentiostat, a short head with a 0.7 μm scan range and a differential preamp and the software required to operate the potentiostat and display the result of the electrochemical reaction.

Standalone STM

The stand alone STMs are available to scan large samples which rest directly on the sample. From Digital instruments, it is available in 12 and 75 μm scan ranges. It is similar to the standard STM except the sample base has been eliminated.

11.1.3 STM Probe Construction

The STM probe should have a cantilever integrated with a sharp metal tip with a low aspect ratio (tip length/tip shank) to minimize flexural vibrations. Ideally, the tip should be atomically sharp, but in practice most tip preparation methods produce a tip with a rather ragged profile that consists of several asperities with the one closest to the surface responsible for tunneling. STM cantilevers with sharp tips are typically fabricated from metal wires of tungsten (W), platinum-iridium (Pt-Ir), or gold (Au) and sharpened by grinding, cutting with a wire cutter or razor blade, field emission/evaporator, ion milling, fracture, or electrochemical polishing/etching [11.105, 106]. The two most commonly used tips are made from either a Pt-Ir (80/20) alloy or tungsten wire. Iridium is used to provide stiffness. The Pt-Ir tips are generally mechanically formed and are readily available. The tungsten tips are etched from tungsten wire with an electrochemical process, for example by using 1 molar KOH solution with a platinum electrode in a electrochemical cell at about 30 V. In general, Pt-Ir tips provide better atomic resolution than tungsten tips, probably due to the lower reactivity of Pt. But tungsten tips are more uniformly shaped and may perform better on samples with steeply sloped features. The tungsten wire diameter used for the cantilever is typically 250 μm with the radius of curvature ranging

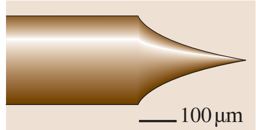

Fig. 11.5 Schematic of a typical tungsten cantilever with a sharp tip produced by electrochemical etching

from 20 to 100 nm and a cone angle ranging from 10 to 60° (Fig. 11.5). The wire can be bent in an *L* shape, if so required, for use in the instrument. For calculations of normal spring constant and natural frequency of round cantilevers, see *Sarid* and *Elings* [11.94].

For imaging of deep trenches, high-aspect-ratio, controlled geometry (CG) Pt-Ir probes are commercially available (Fig. 11.6). These probes are electrochemically etched from Pt-Ir (80/20) wire and polished to a specific shape which is consistent from tip to tip. Probes have a full cone angle of approximately 15°, and a tip radius of less than 50 nm. For imaging of very deep trenches (> 0.25 μm) and nanofeatures, focused ion beam (FIB) milled CG probes with an extremely sharp tip (radius < 5 nm) are used. For electrochemistry, Pt/Ir probes are coated with a nonconducting film (not shown in the figure). These probes are available from Materials Analytical Services, Raleigh, North Carolina.

Pt alloy and W tips are very sharp and have high resolution, but are fragile and sometimes break when contacting a surface. Diamond tips have been used by *Kaneko* and *Oguchi* [11.107]. The diamond tip made conductive by boron ion implantation is found to be chip resistant.

11.2 Atomic Force Microscope

Like the STM, the AFM relies on a scanning technique to produce very high resolution, 3-D images of sample surfaces. The AFM measures ultrasmall forces (less than 1 nN) present between the AFM tip surface and a sample surface. These small forces are measured by measuring the motion of a very flexible cantilever beam having an ultrasmall mass. While STMs require that the surface to be measured be electrically conductive, AFMs are capable of investigating surfaces of both conductors and insulators on an atomic scale if suitable techniques for measurement of cantilever motion are used. In the operation of a high resolution AFM, the sample is generally scanned instead of the tip as with the STM, because the AFM measures the relative displacement between the cantilever surface and reference surface and any cantilever movement would add vibrations. For measurements of large samples, AFMs are available where the tip is scanned and the sample is stationary. As long as the AFM is operated in the so-called contact mode, little if any vibration is introduced.

The AFM combines the principles of the STM and the stylus profiler (Fig. 11.7). In an AFM, the force between the sample and tip is detected, rather than the tunneling current, to sense the proximity of the tip to the sample. The AFM can be used either in a static or dynamic mode. In the static mode, also referred to as repulsive mode or contact mode [11.2], a sharp tip at the end of a cantilever is brought in contact with a sample surface. During initial contact, the atoms at the end of the tip experience a very weak repulsive force due to electronic orbital overlap with the atoms in the sample surface. The force acting on the tip causes a cantilever deflection which is measured by tunneling, capacitive, or optical detectors. The deflection can be measured to within 0.02 nm, so for typical cantilever spring constant of 10 N/m a force as low as 0.2 nN (corresponding normal pressure ∼ 200 MPa for a Si_3N_4 tip with radius of about 50 nm against single-crystal silicon) can be detected. (To put these number in perspective, individual atoms and human hair are typically a fraction of a nanometer and about 75 μm in diameter, respectively, and a drop of water and an eyelash have a mass of about 10 μN and 100 nN, respectively.) In the dynamic mode of operation for the AFM, also referred to as attractive force imaging or noncontact imaging mode, the tip is brought in close proximity (within a few nm) to, and not in contact with the sample. The cantilever is deliberately vibrated either in amplitude modulation (AM) mode [11.65] or frequency modulation (FM) mode [11.65, 94, 108, 109]. Very weak van der Waals attractive forces are present at the tip–sample interface. Although in this technique, the normal pressure exerted at the interface is zero (desirable to avoid any surface deformation), it is slow, and is difficult to use, and is rarely used outside research environments. In the two modes, surface topography is measured by laterally scanning the sample under the tip while simultaneously measuring the separation-dependent force or force gradient (derivative) between the tip and the surface (Fig. 11.7). In the contact (static) mode, the interaction force between tip and sample is measured by measuring the cantilever deflection. In the noncontact (or dynamic) mode, the force gradient is obtained by vibrating the cantilever and measuring the shift of resonant frequency of the cantilever. To obtain topographic information, the interaction force is either recorded directly, or used as a control parameter for a feedback circuit that maintains the force or force derivative at a constant value. With an AFM operated in the contact mode, topographic images with a vertical resolution of less than 0.1 nm (as low as 0.01 nm) and a lateral resolution of about 0.2 nm have been obtained [11.3, 50, 110–114]. With a 0.01 nm displacement sensitivity, 10 nN to 1 pN forces are measurable. These forces are comparable to the forces associated with chemical bonding, e.g., 0.1 μN for an ionic bond and 10 pN for a hydrogen bond [11.2]. For further reading, see [11.94–96, 100, 102, 115–119].

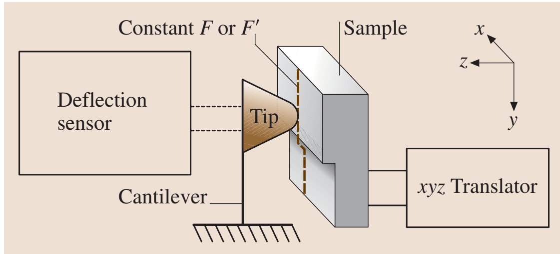

Fig. 11.7 Principle of operation of the AFM. Sample mounted on a piezoelectric tube scanner is scanned against a short tip and the cantilever deflection is measured, mostly, using a laser deflection technique. Force (contact mode) or force gradient (noncontact mode) is measured during scanning

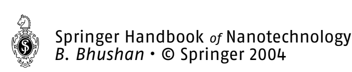
Lateral forces being applied at the tip during scanning in the contact mode, affect roughness measurements [11.120]. To minimize the effects of friction and other lateral forces in the topography measurements



in the contact-mode, and to measure the topography of soft surfaces, AFMs can be operated in the so called tapping mode or force modulation mode [11.32, 121].

The STM is ideal for atomic-scale imaging. To obtain atomic resolution with the AFM, the spring constant of the cantilever should be weaker than the equivalent spring between atoms. For example, the vibration frequencies ω of atoms bound in a molecule or in a crystalline solid are typically 10^{13} Hz or higher. Combining this with the mass of the atoms m, on the order of 10^{-25} kg, gives an interatomic spring constants k, given by $\omega^2 m$, on the order of 10 N/m [11.115]. (For comparison, the spring constant of a piece of household aluminum foil that is 4 mm long and 1 mm wide is about 1 N/m.) Therefore, a cantilever beam with a spring constant of about 1 N/m or lower is desirable. Tips have to be as sharp as possible. Tips with a radius ranging from 5 to 50 nm are commonly available.

Atomic resolution cannot be achieved with these tips at the normal load in the nN range. Atomic structures at these loads have been obtained from lattice imaging or by imaging of the crystal periodicity. Reported data show either perfectly ordered periodic atomic structures or defects on a larger lateral scale, but no well-defined, laterally resolved atomic-scale defects like those seen in images routinely obtained with a STM. Interatomic forces with one or several atoms in contact are 20–40 or 50–100 pN, respectively. Thus, atomic resolution with an AFM is only possible with a sharp tip on a flexible cantilever at a net repulsive force of 100 pN or lower [11.122]. Upon increasing the force from 10 pN, *Ohnesorge* and *Binnig* [11.122] observed that monoatomic steplines were slowly wiped away and a perfectly ordered structure was left. This observation explains why mostly defect-free atomic resolution has been observed with AFM. Note that for atomic-resolution measurements, the cantilever should not be too soft to avoid jumps. Further note that measurements in the noncontact imaging mode may be desirable for imaging with atomic resolution.

The key component in an AFM is the sensor for measuring the force on the tip due to its interaction with the sample. A cantilever (with a sharp tip) with extremely low spring constant is required for high vertical and lateral resolutions at small forces (0.1 nN or lower) but at the same time a high resonant frequency is desirable (about 10 to 100 kHz) in order to minimize the sensitivity to vibration noise from the building which is near 100 Hz. This requires a spring with extremely low vertical spring constant (typically 0.05 to 1 N/m) as well as low mass (on the order of 1 ng). Today, the most advanced AFM cantilevers are microfabricated from silicon or silicon nitride using photolithographic techniques. (For further details on cantilevers, see a later section). Typical lateral dimensions are on the order of 100 μm, with the thicknesses on the order of 1 μm. The force on the tip due to its interaction with the sample is sensed by detecting the deflection of the compliant lever with a known spring constant. This cantilever deflection (displacement smaller than 0.1 nm) has been measured by detecting a tunneling current similar to that used in the STM in the pioneering work of *Binnig* et al. [11.2] and later used by *Giessibl* et al. [11.56], by capacitance detection [11.123, 124], piezoresistive detection [11.125, 126], and by four optical techniques namely (1) by optical interferometry [11.5, 6, 127, 128] with the use of optical fibers [11.57, 129] (2) by optical polarization detection [11.72, 130], (3) by laser diode feedback [11.131] and (4) by optical (laser) beam deflection [11.7, 8, 53, 111, 112]. Schematics of the four more commonly used detection systems are shown in Fig. 11.8. The tunneling method originally used by *Binnig* et al. [11.2] in the first version of the AFM, uses a second tip to monitor the deflection of the cantilever with its force sensing tip. Tunneling is rather sensitive to contaminants and the interaction between the tunneling tip and the rear side of the cantilever can become comparable to the interaction between the tip and sample. Tunneling is rarely used and is mentioned first for historical purposes. *Giessibl* et al. [11.56] have used it for a low temperature AFM/STM design. In contrast to tunneling, other deflection sensors are far

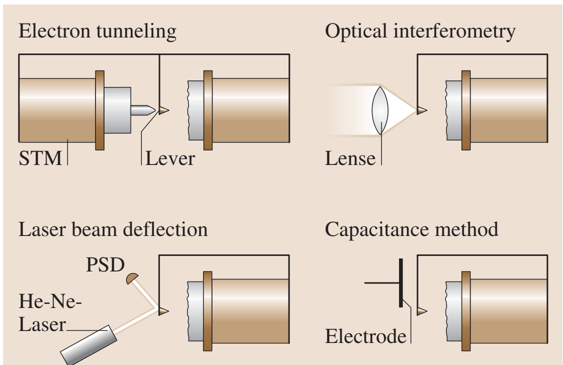


Fig. 11.8 Schematics of the four more commonly used detection systems for measurement of cantilever deflection. In each set up, the sample mounted on piezoelectric body is shown on the right, the cantilever in the middle, and the corresponding deflection sensor on the left [11.118]

Springer Handbook *of* Nanotechnology
B. Bhushan • © Springer 2004

away from the cantilever at distances of microns to tens of mm. The optical techniques are believed to be more sensitive, reliable and easily implemented detection methods than others [11.94, 118]. The optical beam deflection method has the largest working distance, is insensitive to distance changes and is capable of measuring angular changes (friction forces), therefore, it is most commonly used in the commercial SPMs.

Almost all SPMs use piezo translators to scan the sample, or alternatively, to scan the tip. An electric field applied across a piezoelectric material causes a change in the crystal structure, with expansion in some directions and contraction in others. A net change in volume also occurs [11.132]. The first STM used a piezo tripod for scanning [11.1]. The piezo tripod is one way to generate three-dimensional movement of a tip attached to its center. However, the tripod needs to be fairly large (~ 50 mm) to get a suitable range. Its size and asymmetric shape makes it susceptible to thermal drift. The tube scanners are widely used in AFMs [11.133]. These provide ample scanning range with a small size. Control electronics systems for AFMs can use either analog or digital feedback. Digital feedback circuits are better suited for ultra low noise operation.

Images from the AFMs need to be processed. An ideal AFM is a noise free device that images a sample with perfect tips of known shape and has a perfectly linear scanning piezo. In reality, scanning devices are affected by distortions and these distortions must be corrected for. The distortions can be linear and nonlinear. Linear distortions mainly result from imperfections in the machining of the piezo translators causing cross talk between the Z-piezo to the X- and Y-piezos, and vice versa. Nonlinear distortions mainly result because of the presence of a hysteresis loop in piezoelectric ceramics. These may also result if the scan frequency approaches the upper frequency limit of the X- and Y-drive amplifiers or the upper frequency limit of the feedback loop (z-component). In addition, electronic noise may be present in the system. The noise is removed by digital filtering in real space [11.134] or in the spatial frequency domain (Fourier space) [11.135].

Processed data consists of many tens of thousand of points per plane (or data set). The output of the first STM and AFM images were recorded on an X-Y chart recorder, with z-value plotted against the tip position in the fast scan direction. Chart recorders have slow response so computers are used to display the data. The data are displayed as a wire mesh display or gray scale display (with at least 64 shades of gray).

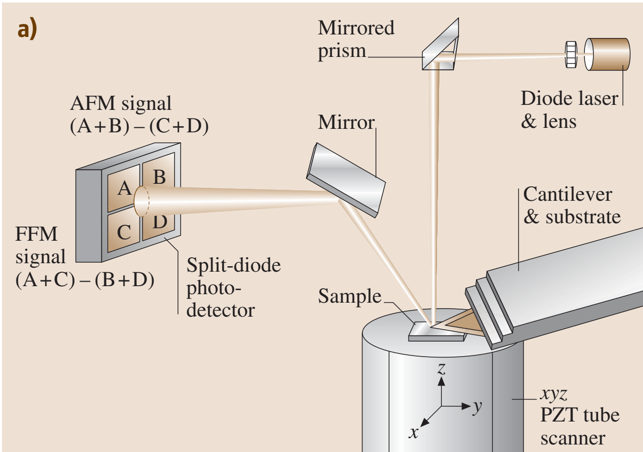
11.2.1 Binnig et al.'s Design

In the first AFM design developed by *Binnig* et al. [11.2], AFM images were obtained by measurement of the force on a sharp tip created by the proximity to the surface of the sample mounted on a 3-D piezoelectric scanner. Tunneling current between STM tip and the backside of the cantilever beam with attached tip was measured to obtain the normal force. This force was kept at a constant level with a feedback mechanism. The STM tip was also mounted on a piezoelectric element to maintain the tunneling current at a constant level.

11.2.2 Commercial AFM

A review of early designs of AFMs is presented by *Bhushan* [11.4]. There are a number of commercial AFMs available on the market. Major manufacturers of AFMs for use in an ambient environment are: Digital Instruments Inc., a subsidiary of Veeco Instruments, Inc., Santa Barbara, California; Topometrix Corp., a subsidiary of Veeco Instruments, Inc., Santa Clara, California; other subsidiaries of Veeco Instruments Inc., Woodbury, New York; Molecular Imaging Corp., Phoenix, Arizona; Quesant Instrument Corp., Agoura Hills, California; Nanoscience Instruments Inc., Phoenix, Arizona; Seiko Instruments, Japan; and Olympus, Japan. AFM/STMs for use in UHV environments are manufactured by Omicron Vakuumphysik GMBH, Taunusstein, Germany.

We describe here two commercial AFMs – small sample and large sample AFMs – for operation in the contact mode, produced by Digital Instruments, Inc., Santa Barbara, CA, with scanning lengths ranging from about 0.7 μm (for atomic resolution) to about 125 μm [11.9, 111, 114, 136]. The original design of these AFMs comes from *Meyer* and *Amer* [11.53]. Basically the AFM scans the sample in a raster pattern while outputting the cantilever deflection error signal to the control station. The cantilever deflection (or the force) is measured using laser deflection technique (Fig. 11.9). The DSP in the workstation controls the z position of the piezo based on the cantilever deflection error signal. The AFM operates in both the "constant height" and "constant force" modes. The DSP always adjusts the height of the sample under the tip based on the cantilever deflection error signal, but if the feedback gains are low the piezo remains at a nearly "constant height" and the cantilever deflection data is collected. With the high gains the piezo height changes to keep the cantilever deflection nearly constant (therefore the force is



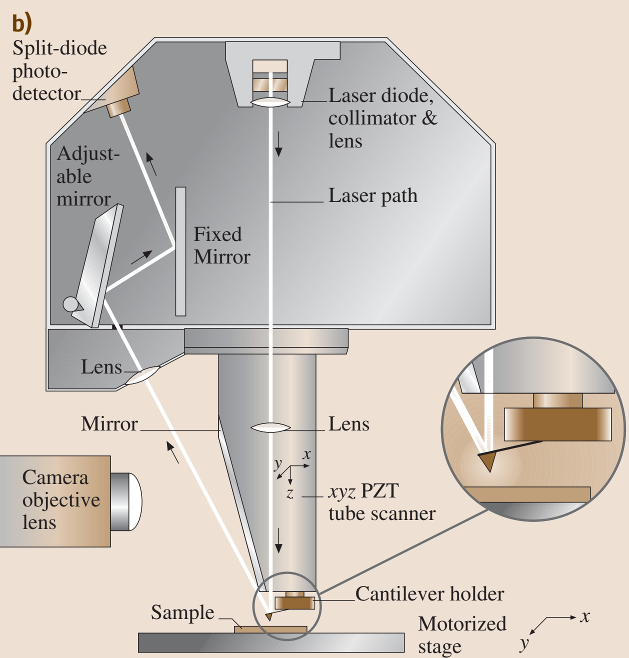


Fig. 11.9a,b Principles of operation of **(a)** a commercial small sample AFM/FFM, and **(b)** a large sample AFM/FFM

constant) and the change in piezo height is collected by the system.

To further describe the principle of operation of the commercial small sample AFM shown in Fig. 11.9a, the sample, generally no larger than 10 mm × 10 mm, is mounted on a PZT tube scanner which consists of separate electrodes to scan precisely the sample in the *x*-*y* plane in a raster pattern and to move the sample in the vertical (*z*) direction. A sharp tip at the free end of a flexible cantilever is brought in contact with the sample. Features on the sample surface cause the cantilever to deflect in the vertical and lateral directions as the sample moves under the tip. A laser beam from a diode laser (5 mW max peak output at 670 nm) is directed by a prism onto the back of a cantilever near its free end, tilted downward at about 10° with respect to the horizontal plane. The reflected beam from the vertex of the cantilever is directed through a mirror onto a quad photodetector (split photodetector with four quadrants) (commonly called position-sensitive detector or PSD, produced by Silicon Detector Corp., Camarillo, California). The differential signal from the top and bottom photodiodes provides the AFM signal which is a sensitive measure of the cantilever vertical deflection. Topographic features of the sample cause the tip to deflect in the vertical direction as the sample is scanned under the tip. This tip deflection will change the direction of the reflected laser beam, changing the intensity difference between the top and bottom sets of photodetectors (AFM signal). In the AFM operating mode called the height mode, for topographic imaging or for any other operation in which the applied normal force is to be kept a constant, a feedback circuit is used to modulate the voltage applied to the PZT scanner to adjust the height of the PZT, so that the cantilever vertical deflection (given by the intensity difference between the top and bottom detector) will remain constant during scanning. The PZT height variation is thus a direct measure of the surface roughness of the sample.

In a large sample AFM, both force sensors using optical deflection methods and scanning unit are mounted on the microscope head (Fig. 11.9b). Because of vibrations added by cantilever movement, lateral resolution of this design is somewhat poorer than the design in Fig. 11.9a in which the sample is scanned instead of the cantilever beam. The advantage of the large sample AFM is that large samples can be measured readily.

Most AFMs can be used for topography measurements in the so-called tapping mode (intermittent contact mode), also referred to as dynamic force microscopy. In the tapping mode, during scanning over the surface, the cantilever/tip assembly is sinusoidally vibrated by a piezo mounted above it, and the oscillating tip slightly taps the surface at the resonant frequency of the cantilever (70–400 Hz) with a constant (20–100 nm) oscillating amplitude introduced in the vertical direction with a feedback loop keeping the average normal force constant (Fig. 11.10). The oscillating amplitude is kept

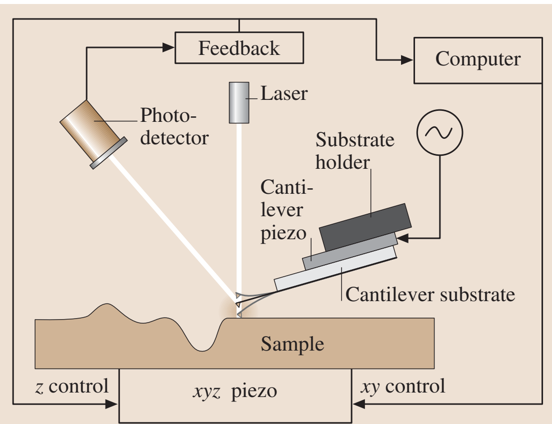

Fig. 11.10 Schematic of tapping mode used for surface roughness measurements

large enough so that the tip does not get stuck to the sample because of adhesive attractions. The tapping mode is used in topography measurements to minimize effects of friction and other lateral forces to measure the topography of soft surfaces.

Topographic measurements are made at any scanning angle. At a first instance, scanning angle may not appear to be an important parameter. However, the friction force between the tip and the sample will affect the topographic measurements in a parallel scan (scanning along the long axis of the cantilever). Therefore a perpendicular scan may be more desirable. Generally, one picks a scanning angle which gives the same topographic data in both directions; this angle may be slightly different than that for the perpendicular scan.

For measurement of the friction force being applied at the tip surface during sliding, the left hand and right hand sets of quadrants of the photodetector are used. In the so-called friction mode, the sample is scanned back and forth in a direction orthogonal to the long axis of the cantilever beam. A friction force between the sample and the tip will produce a twisting of the cantilever. As a result, the laser beam will be reflected out of the plane defined by the incident beam and the beam reflected vertically from an untwisted cantilever. This produces an intensity difference of the laser beam received in the left hand and right hand sets of quadrants of the photodetector. The intensity difference between the two sets of detectors (FFM signal) is directly related to the degree of twisting and hence to the magnitude of the friction force. This method provides three-dimensional maps of the friction force. One problem associated with this method is that any misalignment between the laser beam and the photodetector axis would introduce error in the measurement. However, by following the procedures developed by *Ruan* and *Bhushan* [11.136], in which the average FFM signal for the sample scanned in two opposite directions is subtracted from the friction profiles of each of the two scans, the misalignment effect is eliminated. By following the friction force calibration procedures developed by *Ruan* and *Bhushan* [11.136], voltages corresponding to friction forces can be converted to force units. The coefficient of friction is obtained from the slope of friction force data measured as a function of normal loads typically ranging from 10 to 150 nN. This approach eliminates any contributions due to the adhesive forces [11.10]. For calculation of the coefficient of friction based on a single point measurement, friction force should be divided by the sum of applied normal load and intrinsic adhesive force. Furthermore, it should be pointed out that for a single asperity contact, the coefficient of friction is not independent of load. For further details, refer to a later section.

The tip is scanned in such a way that its trajectory on the sample forms a triangular pattern (Fig. 11.11). Scanning speeds in the fast and slow scan directions depend on the scan area and scan frequency. Scan sizes ranging from less than 1 nm × 1 nm to 125 μm × 125 μm and scan rates from less than 0.5 to 122 Hz typically can be used. Higher scan rates are used for smaller scan lengths. For example, scan rates in the fast and slow scan directions for an area of 10 μm × 10 μm scanned at 0.5 Hz are 10 μm/s and 20 nm/s, respectively.

We now describe the construction of a small sample AFM in more detail. It consists of three main parts: the optical head which senses the cantilever deflection, a PZT tube scanner which controls the scanning motion of the sample mounted on its one end, and the base

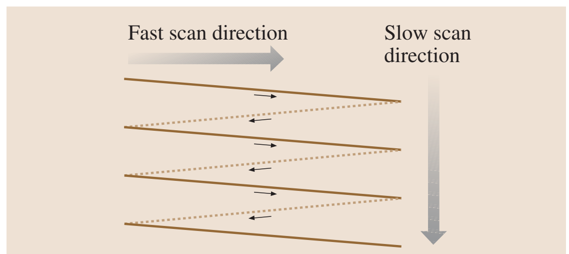

Fig. 11.11 Schematic of triangular pattern trajectory of the AFM tip as the sample is scanned in two dimensions. During imaging, data are recorded only during scans along the solid scan lines

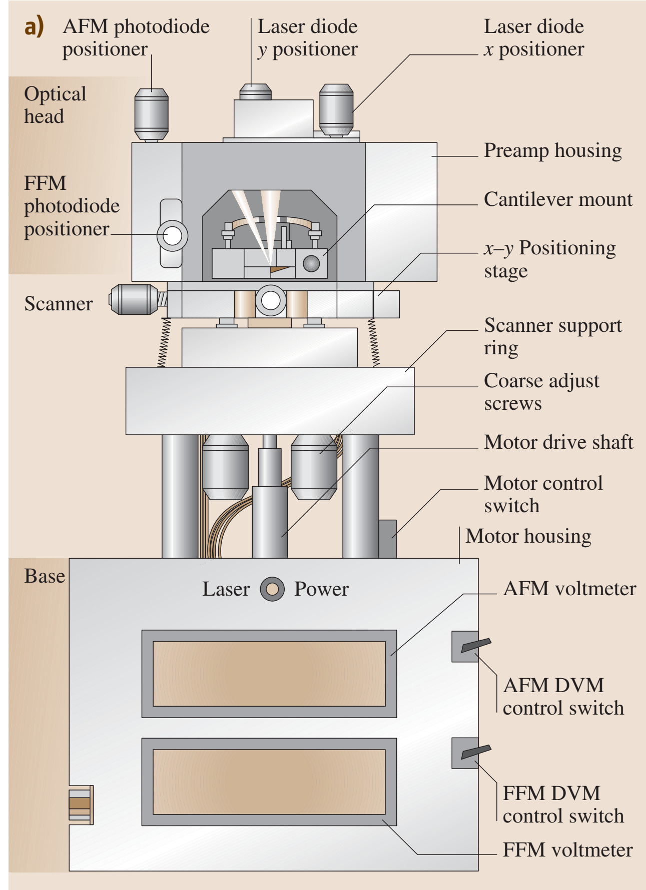

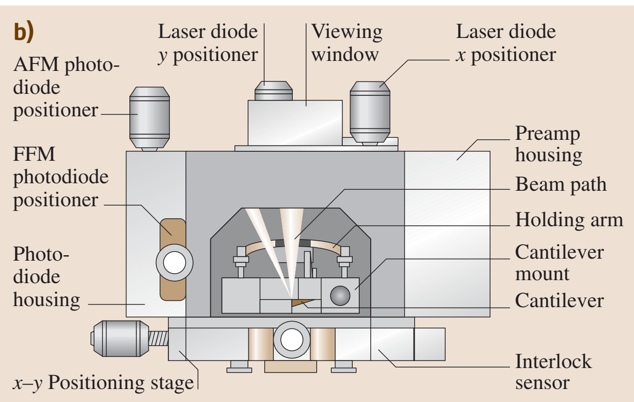

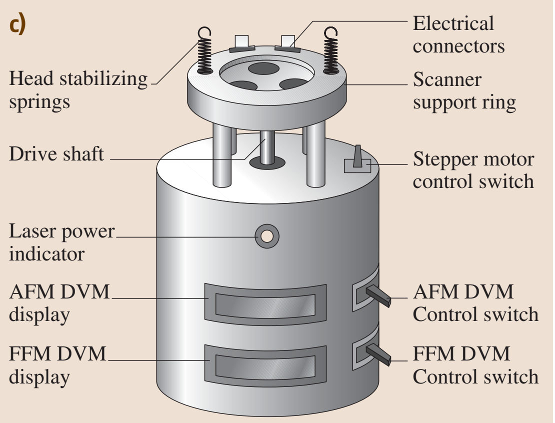

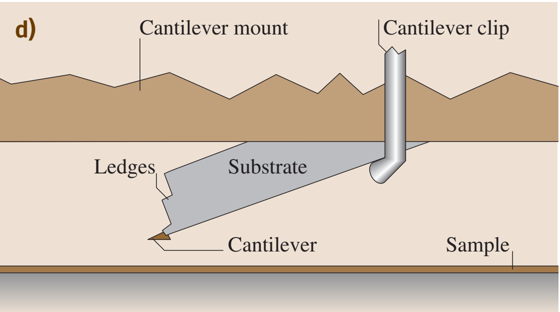

Fig. 11.12a–d Schematics of a commercial AFM/FFM made by Digital Instruments Inc. **(a)** front view, **(b)** optical head, **(c)** base, and **(d)** cantilever substrate mounted on cantilever mount (not to scale)

which supports the scanner and head and includes circuits for the deflection signal (Fig. 11.12a). The AFM connects directly to a control system. The optical head consists of laser diode stage, photodiode stage preamp board, cantilever mount and its holding arm, and deflection beam reflecting mirror (Fig. 11.12b). The laser diode stage is a tilt stage used to adjust the position of the laser beam relative to the cantilever. It consists of the laser diode, collimator, focusing lens, baseplate, and the X and Y laser diode positioners. The positioners are used to place the laser spot on the end of the cantilever. The photodiode stage is an adjustable stage used to position the photodiode elements relative to the reflected laser beam. It consists of the split photodiode, the base plate, and the photodiode positioners. The deflection beam reflecting mirror is mounted on the upper left in the interior of the head which reflects the deflected beam toward the photodiode. The cantilever mount is a metal (for operation in air) or glass (for operation in water) block which holds the cantilever firmly at the proper angle (Fig. 11.12d). Next, the tube scanner con-

sists of an Invar cylinder holding a single tube made of piezoelectric crystal which provides the necessary three-dimensional motion to the sample. Mounted on top of the tube is a magnetic cap on which the steel sample puck is placed. The tube is rigidly held at one end with the sample mounted on the other end of the tube. The scanner also contains three fine-pitched screws which form the mount for the optical head. The optical head rests on the tips of the screws which are used to adjust the position of the head relative to the sample. The scanner fits into the scanner support ring mounted on the base of the microscope (Fig. 11.12c). The stepper motor is controlled manually with the switch on the upper surface of the base and automatically by the computer during the tip engage and tip-withdraw processes.

The scan sizes available for these instruments are 0.7 μm, 12 μm and 125 μm. The scan rate must be decreased as the scan size is increased. A maximum scan rate of 122 Hz can be used. Scan rates of about 60 Hz should be used for small scan lengths (0.7 μm). Scan rates of 0.5 to 2.5 Hz should be used for large scans on samples with tall features. High scan rates help reduce drift, but they can only be used on flat samples with small scan sizes. Scan rate, or scanning speed in length/time in the fast scan direction, is equal to twice the scan length times the scan rate in Hz, and in the slow direction, it is equal to scan length times the scan rate in Hz divided by number of data points in the transverse direction. For example, for 10 μm × 10 μm scan size scanned at 0.5 Hz, the scan rates in the fast and slow scan directions are 10 μm/s and 20 nm/s, respectively. Normally 256 × 256 data points are taken for each image. The lateral resolution at larger scans is approximately equal to scan length divided by 256. The piezo tube requires x-y calibration which is carried out by imaging an appropriate calibration standard. Cleaved graphite is used for small scan heads while two-dimensional grids (a gold plating ruling) can be used for longer range heads.

Examples of AFM images of freshly-cleaved highly-oriented pyrolytic (HOP) graphite and mica surfaces are shown in Fig. 11.13 [11.50, 110, 114]. Images with near atomic resolution are obtained.

The force calibration mode is used to study interactions between the cantilever and the sample surface. In the force calibration mode, the X and Y voltages applied to the piezo tube are held at zero and a sawtooth voltage is applied to the Z electrode of the piezo tube, Fig. 11.14a. The force measurement starts with the sample far away and the cantilever in its rest position. As a result of the applied voltage, the sample is moved up and down relative to the stationary cantilever tip. As the

Part B | 11.2

piezo moves the sample up and down, the cantilever deflection signal from the photodiode is monitored. The force–distance curve, a plot of the cantilever tip deflection signal as a function of the voltage applied to the piezo tube, is obtained. Figure 11.14b shows a typical force–distance curve showing the various features of the curve. The arrow heads reveal the direction of piezo travel. As the piezo extends, it approaches the tip, which is at this point in free air and hence shows no deflection. This is indicated by the flat portion of the curve. As the tip approaches the sample within a few nanometers (point A), an attractive force exists between the atoms of the tip surface and the atoms of the sample surface. The tip is pulled towards the sample and contact occurs at point B on the graph. From this point on, the tip is in contact with the surface and as the piezo further extends, the tip gets further deflected. This is represented by the sloped portion of the curve. As the piezo retracts, the tip goes beyond the zero deflection (flat) line because of attractive forces (van der Waals forces and long range meniscus forces), into the adhesive regime. At point C in the graph, the tip snaps free of the adhesive forces, and is again in free air. The horizontal distance between point B and C along the retrace line gives the distance moved by the tip in the adhesive regime. This distance multiplied by the stiffness of the cantilever gives the adhesive force. Incidentally, the horizontal shift between the loading and unloading curves results from the hysteresis in the PZT tube [11.4].

Multimode Capabilities

The multimode AFM can be used for topography measurements in the contact mode and tapping mode, described earlier, and for measurements of lateral (friction) force, electric force gradients and magnetic force gradients.

The multimode AFM, used with a grounded conducting tip, can measure electric field gradients by oscillating the tip near its resonant frequency. When the lever encounters a force gradient from the electric field, the effective spring constant of the cantilever is altered, changing its resonant frequency. Depending on which side of the resonance curve is chosen, the oscillation amplitude of the cantilever increases or decreases due to the shift in the resonant frequency. By recording the amplitude of the cantilever, an image revealing the strength of the electric field gradient is obtained.

In the magnetic force microscope (MFM) used with a magnetically-coated tip, static cantilever deflection is detected which occurs when a magnetic field exerts a force on the tip and the MFM images of magnetic materials can be produced. MFM sensitivity can be enhanced by oscillating the cantilever near its resonant frequency. When the tip encounters a magnetic force gradient, the effective spring constant, and hence the resonant frequency, is shifted. By driving the cantilever above or below the resonant frequency, the oscillation amplitude varies as the resonance shifts. An image of magnetic field gradients is obtained by recording the oscillation amplitude as the tip is scanned over the sample.

Topographic information is separated from the electric field gradients and magnetic field images by using a so-called lift mode. Measurements in lift mode are taken in two passes over each scan line. On the first pass, topographical information is recorded in the standard tapping mode where the oscillating cantilever lightly taps the surface. On the second pass, the tip is lifted to a user-selected separation (typically 20–200 nm) between the tip and local surface topography. By using the stored topographical data instead of the standard feedback, the separation remains constant without sensing the surface. At this height, cantilever amplitudes are sensitive to electric field force gradients or relatively weak but long-range magnetic forces without being influenced by topographic features. Two-pass measurements are taken for every scan line, producing separate topographic and magnetic force images.

Electrochemical AFM

This option allows one to perform electrochemical reactions on the AFM. It includes a potentiostat, a fluid cell with a transparent cantilever holder and electrodes, and the software required to operate the potentiostat and display the results of the electrochemical reaction.

11.2.3 AFM Probe Construction

Various probes (cantilevers and tips) are used for AFM studies. The cantilever stylus used in the AFM should meet the following criteria: (1) low normal spring constant (stiffness), (2) a high resonant frequency, (3) a high quality factor of the cantilever Q, (4) high lateral spring constant (stiffness), (5) short cantilever length, (6) incorporation of components (such as mirror) for deflection sensing, and (7) a sharp protruding tip [11.137]. In order to register a measurable deflection with small forces, the cantilever must flex with a relativly low force (on the order of few nN) requiring vertical spring constants of 10^{-2} to 10^{2} N/m for atomic resolution in the contact profiling mode. The data rate or imaging rate in the AFM is limited by the mechanical resonant frequency

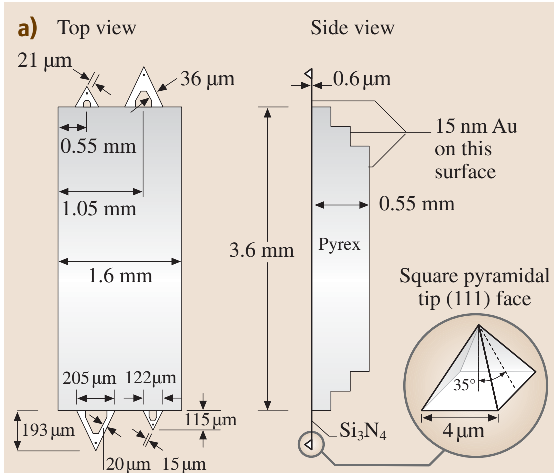
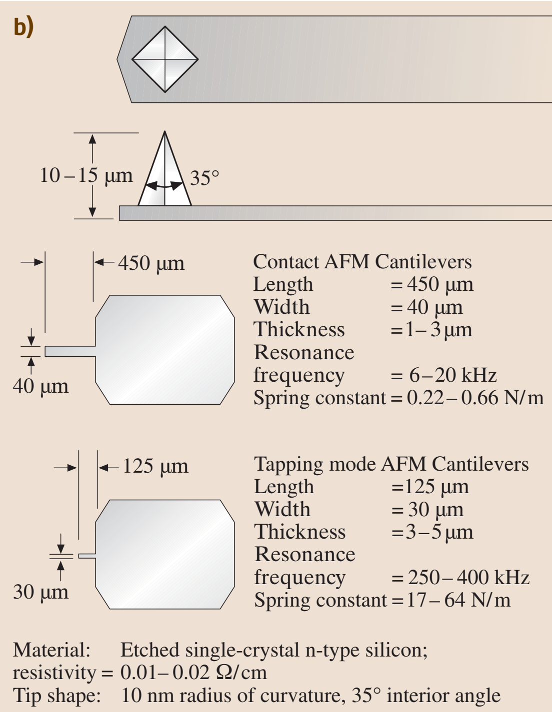
of the cantilever. To achieve a large imaging bandwidth, the AFM cantilever should have a resonant frequency greater than about 10 kHz (30–100 kHz is preferable) in order to make the cantilever the least sensitive part of the system. Fast imaging rates are not just a matter of convenience, since the effects of thermal drifts are more pronounced with slow-scanning speeds. The combined requirements of a low spring constant and a high resonant frequency is met by reducing the mass of the cantilever. The quality factor Q $(= \omega_R/(c/m)$, where ω_R is the resonant frequency of the damped oscillator and c is the damping constant and m is the mass of the oscillator) should have a high value for some applications. For example, resonance curve detection is a sensitive modulation technique for measuring small force gradients in noncontact imaging. Increasing the Q increases the sensitivity of the measurements. Mechanical Q values of 100–1,000 are typical. In contact modes, the Q is of less importance. High lateral spring constant in the cantilever is desirable to reduce the effect of lateral forces in the AFM as frictional forces can cause appreciable lateral bending of the cantilever. Lateral bending results in error in the topography measurements. For friction measurements, cantilevers with less lateral rigidity is preferred. A sharp protruding tip must be formed at the end of the cantilever to provide a well defined interaction with sample over a small area. The tip radius should be much smaller than the radii of corrugations in the sample in order for these to be measured accurately. The lateral spring constant depends critically on the tip length. Additionally, the tip should be centered at the free end.

In the past, cantilevers have been cut by hand from thin metal foils or formed from fine wires. Tips for these cantilevers were prepared by attaching diamond fragments to the ends of the cantilevers by hand, or in the case of wire cantilevers, electrochemically etching the wire to a sharp point. Several cantilever geometries for wire cantilevers have been used. The simplest geometry is the L-shaped cantilever, usually made by bending a wire at a 90° angle. Other geometries include single-V and double-V geometries with a sharp tip attached at the apex of V, and double-X configuration with a sharp tip attached at the intersection [11.31, 138]. These cantilevers can be constructed with high vertical spring constants. For example, double-cross cantilever with an effective spring constant of 250 N/m was used by *Burnham* and *Colton* [11.31]. The small size and low mass needed in the AFM make hand fabrication of the cantilever a difficult process with poor reproducibility. Conventional microfabrication techniques are ideal for constructing planar thin-film structures which have submicron lateral dimensions. The triangular (V-shaped) cantilevers have improved (higher) lateral spring constant in comparison to rectangular cantilevers. In terms of spring constants, the triangular cantilevers are approximately equivalent to two rectangular cantilevers in parallel [11.137]. Although the macroscopic radius of a photolithographically patterned corner is seldom much less than about 50 nm, microscopic asperities on the etched surface provide tips with near atomic dimensions.

Cantilevers have been used from a whole range of materials. Most commonly are cantilevers made of Si_3N_4, Si, and diamond. Young's modulus and the density are the material parameters which determine the resonant frequency, besides the geometry. Table 11.2 shows the relevant properties and the speed of sound, indicative of the resonant frequency for a given shape. Hardness is important to judge the durability of the cantilevers, and is also listed in the table. Materials used for STM cantilevers are also included.

Silicon nitride cantilevers are less expensive than those made of other materials. They are very rugged and well suited to imaging in almost all environments. They are especially compatible to organic and biological materials. Microfabricated silicon nitride triangular beams with integrated square pyramidal tips made of plasma-enhanced chemical vapor deposition (PECVD) are most commonly used [11.137]. Four cantilevers with different





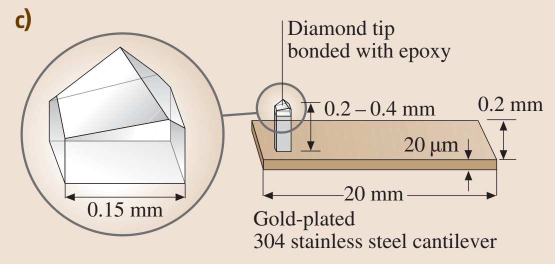


Fig. 11.15a–c Schematics of **(a)** triangular cantilever beam with square pyramidal tips made of PECVD Si_3N_4, **(b)** rectangular cantilever beams with square pyramidal tips made of etched single-crystal silicon, and **(c)** rectangular cantilever stainless steel beam with three-sided pyramidal natural diamond tip

sizes and spring constants on each cantilever substrate made of boron silicate glass (Pyrex), marketed by Digital Instruments, are shown in Figs. 11.15a and 11.16. Two pairs of the cantilevers on each substrate measure about 115 and 193 µm from the substrate to the apex of the triangular cantilever with base widths of 122 and 205 µm, respectively. Both cantilever legs, with the same thickness (0.6 µm) of all the cantilevers, are available with wide and narrow legs. Only one cantilever is selected and used from each substrate. Calculated spring constant and measured natural frequencies for each of the configurations are listed in Table 11.3. The most commonly used cantilever beam is the 115-µm long, wide-legged cantilever (vertical spring constant = 0.58 N/m). Cantilevers with smaller spring constants should be used on softer samples. The pyramidal tips are highly symmetric with its end having a radius of about 20–50 nm. The

Table 11.3 Measured vertical spring constants and natural frequencies of triangular (V-shaped) cantilevers made of PECVD Si_3N_4 (Data provided by Digital Instruments, Inc.)

Cantilever dimension	Spring constant (k_z) (N/m)	Natural frequency (ω_0) (kHz)
115-μm long, narrow leg	0.38	40
115-μm long, wide leg	0.58	40
193-μm long, narrow leg	0.06	13–22
193-μm long, wide leg	0.12	13–22

Table 11.4 Vertical (k_z), lateral (k_y), and torsional (k_{yT}) spring constants of rectangular cantilevers made of Si (IBM) and PECVD Si_3N_4 (Veeco Instruments, Inc.)

Dimensions/stiffness	Si cantilever	Si_3N_4 cantilever
Length (L) (μm)	100	100
Width (b) (μm)	10	20
Thickness (h) (μm)	1	0.6
Tip length (ℓ) (μm)	5	3
k_z (N/m)	0.4	0.15
k_y (N/m)	40	175
k_{yT} (N/m)	120	116
ω_0 (kHz)	~ 90	~ 65

Note: $k_z = Ebh^3/4L^3$, $k_y = Eb^3h/4\ell^3$, $k_{yT} = Gbh^3/3L\ell^2$, and $\omega_0 = [k_z/(m_c + 0.24bhL\rho)]^{1/2}$, where E is Young's modulus, G is the modulus of rigidity [$= E/2(1+\nu)$, ν is Poisson's ratio], ρ is the mass density of the cantilever, and m_c is the concentrated mass of the tip (~ 4 ng) [11.94]. For Si, $E = 130$ GPa, $\rho g = 2{,}300\ \mathrm{kg/m^3}$, and $\nu = 0.3$. For Si_3N_4, $E = 150$ GPa, $\rho g = 3{,}100\ \mathrm{kg/m^3}$, and $\nu = 0.3$

tip side walls have a slope of 35 deg and the length of the edges of the tip at the cantilever base is about 4 μm.

An alternative to silicon nitride cantilevers with integrated tips are microfabricated single-crystal silicon cantilevers with integrated tips. Si tips are sharper than Si_3N_4 tips because they are directly formed by the anisotropic etch in single-crystal Si rather than using an etch pit as a mask for deposited materials [11.139]. Etched single-crystal n-type silicon rectangular cantilevers with square pyramidal tips with a lower radius of less than 10 nm for contact and tapping mode (tapping-mode etched silicon probe or TESP) AFMs are commercially available from Digital Instruments and Nanosensors GmbH, Aidlingen, Germany, Figs. 11.15b and 11.16. Spring constants and resonant frequencies are also presented in the Fig. 11.15b.

Commercial triangular Si_3N_4 cantilevers have a typical width-thickness ratio of 10 to 30 which results in 100 to 1000 times stiffer spring constants in the lateral direction compared to the normal direction. Therefore these cantilevers are not well suited for torsion. For friction measurements, the torsional spring constant should be minimized in order to be sensitive to the lateral forces. Rather long cantilevers with small thickness and large tip length are most suitable. Rectangular beams have lower torsional spring constants in comparison to the triangular (V-shaped) cantilevers. Table 11.4 lists the spring constants (with full length of the beam used) in three directions of the typical rectangular beams. We note that lateral and torsional spring constants are about two orders of magnitude larger than the normal spring constants. A cantilever beam required for the tapping mode is quite stiff and may not be sensitive enough for friction measurements. *Meyer* et al. [11.140] used a specially designed rectangular silicon cantilever with length = 200 μm, width = 21 μm, thickness = 0.4 μm, tip length = 12.5 μm, and shear modulus = 50 GPa, giving a normal spring constant of 0.007 N/m and torsional spring constant of 0.72 N/m which gives a lateral force sensitivity of 10 pN and an angle of resolution of 10^{-7} rad. With this particular geometry, sensitivity to lateral forces could be improved by about a factor of 100 compared with commercial V-shaped Si_3N_4 or rectangular Si or Si_3N_4 cantilevers used by *Meyer* and *Amer* [11.8] with torsional spring constant of ~ 100 N/m. *Ruan* and *Bhushan* [11.136] and *Bhushan* and *Ruan* [11.9] used 115-μm long, wide-legged V-shaped cantilevers made of Si_3N_4 for friction measurements.

For scratching, wear, and indentation studies, single-crystal natural diamond tips ground to the shape of a three-sided pyramid with an apex angle of either 60° or 80° whose point is sharpened to a radius of about 100 nm are commonly used [11.4, 10] (Figs. 11.15c and 11.16). The tips are bonded with conductive epoxy to a gold-plated 304 stainless steel spring sheet (length = 20 mm, width = 0.2 mm, thickness = 20 to 60 μm) which acts as a cantilever. The free length of the spring is varied to change the beam stiffness. The normal spring con-

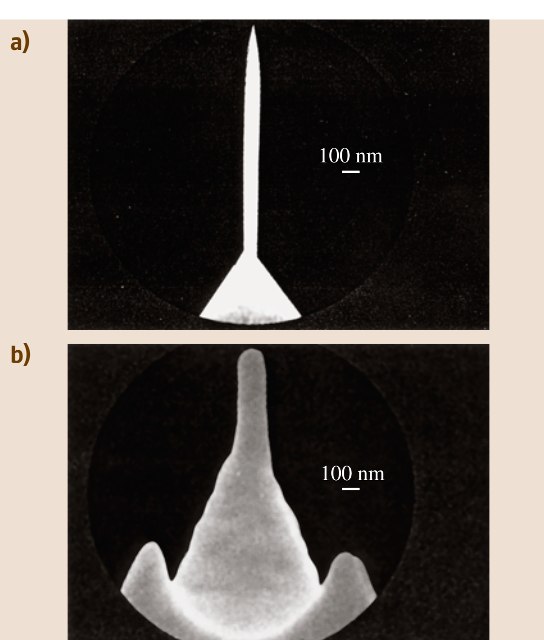

Fig. 11.17a,b Schematics of **(a)** HART Si_3N_4 probe, and **(b)** FIB milled Si_3N_4 probe

stant of the beam ranges from about 5 to 600 N/m for a 20 μm thick beam. The tips are produced by R-DEC Co., Tsukuba, Japan.

For imaging within trenches by an AFM, high aspect ratio tips are used. Examples of the two probes are shown in Fig. 11.17. The high-aspect ratio tip (Hart) probes are produced by starting with a conventional Si_3N_4 pyramidal probe. Through a combination of focused ion beam (FIB) and high resolution scanning electron microscopy (SEM) techniques, a thin filament is grown at the apex of the pyramid. The probe filament is approximately 1 μm long and 0.1 μm in diameter. It tapers to an extremely sharp point (radius better than the resolution of most SEMs). The long thin shape and sharp radius make it ideal for imaging within "vias" of microstructures and trenches (> 0.25 μm). Because of flexing of the probe, it is unsuitable for imaging structures at the atomic level since the flexing of the probe can create image artifacts. For atomic-scale imaging, a FIB-milled probe is used which is relatively stiff yet allows for closely spaced topography. These probes start out as conventional Si_3N_4 pyramidal probes but the pyramid is FIB milled until a small cone shape is formed which has a high aspect ratio with 0.2–0.3 μm in length. The milled probes allow nanostructure resolution without sacrificing rigidity. These types of probes are manufactured by various manufacturers including Materials Analytical Services, Raleigh, North Carolina.

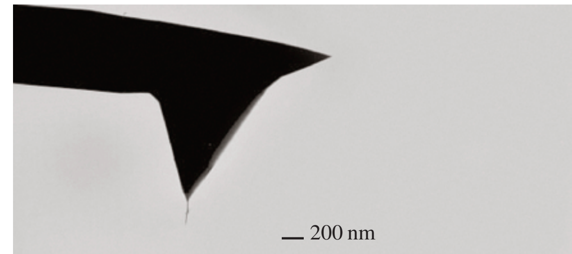

Fig. 11.18 SEM micrograph of a multi-walled carbon nanotube (MWNT) tip physically attached on the single-crystal silicon, square-pyramidal tip (Courtesy Piezomax Technologies, Inc.)

Carbon nanotube tips having small diameter and high aspect ratio are used for high resolution imaging of surfaces and of deep trenches, in the tapping mode or noncontact mode. Single-walled carbon nanotubes (SWNT) are microscopic graphitic cylinders that are 0.7 to 3 nm in diameter and up to many microns in length. Larger structures called multi-walled carbon nanotubes (MWNT) consist of nested, concentrically arranged SWNT and have diameters ranging from 3 to 50 nm. MWNT carbon nanotube AFM tips are produced by manual assembly [11.141], chemical vapor deposition (CVD) synthesis, and hybrid fabrication process [11.142]. Figure 11.18 shows TEM micrograph of a carbon nanotube tip, ProbeMax^{TM}, commercially produced by mechanical assembly by Piezomax Technologies, Inc., Middleton, Wisconsin. For production of these tips, MWNT nanotubes are produced by carbon arc. They are physically attached on the single-crystal silicon, square-pyramidal tips in the SEM using a manipulator and the SEM stage to control the nanotubes and the tip independently. Once the nanotube is attached to the tip, it is usually too long to image with. It is shortened by using an AFM and applying voltage between the tip and the sample. Nanotube tips are also commercially produced by CVD synthesis by NanoDevices, Santa Barbara, California.

11.2.4 Friction Measurement Methods

Based on the work by *Ruan* and *Bhushan* [11.136], the two methods for friction measurements are now described in more detail. (Also see [11.8].) A scanning angle is defined as the angle relative to the y-axis in Fig. 11.19a. This is also the long axis of the cantilever.

A zero degree scanning angle corresponds to the sample scanning in the y direction, and a 90 degree scanning angle corresponds to the sample scanning perpendicular to this axis in the xy plane (along x axis). If the scanning direction is in both the y and $-y$ directions, we call this "parallel scan". Similarly, a "perpendicular scan" means the scanning direction is in the x and $-x$ directions. The sample traveling direction for each of these two methods is illustrated in Fig. 11.19b.

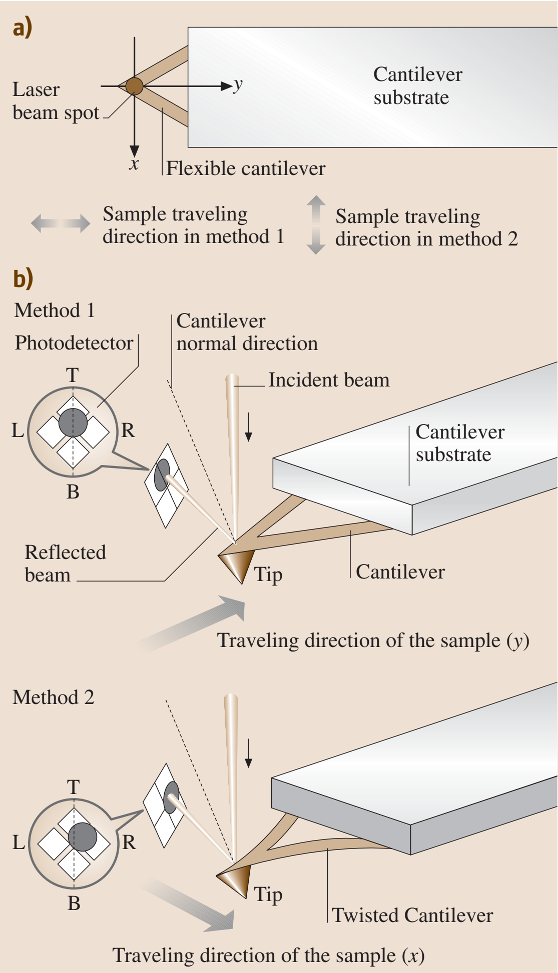

Fig. 11.19 (a) Schematic defining the x- and y-directions relative to the cantilever, and showing the sample traveling direction in two different measurement methods discussed in the text, **(b)** schematic of deformation of the tip and cantilever shown as a result of sliding in the x- and y-directions. A twist is introduced to the cantilever if the scanning is in the x-direction (**(b)**, *lower part*) [11.136]

In method 1 (using "height" mode with parallel scans) in addition to topographic imaging, it is also possible to measure friction force when the scanning direction of the sample is parallel to the y direction (parallel scan). If there were no friction force between the tip and the moving sample, the topographic feature would be the only factor which cause the cantilever to be deflected vertically. However, friction force does exist on all contact surfaces where one object is moving relative to another. The friction force between the sample and the tip will also cause a cantilever deflection. We assume that the normal force between the sample and the tip is W_0 when the sample is stationary (W_0 is typically in the range of 10 nN to 200 nN), and the friction force between the sample and the tip is W_f as the sample scans against the tip. The direction of friction force (W_f) is reversed as the scanning direction of the sample is reversed from positive (y) to negative ($-y$) directions ($\vec{W}_{f(y)} = -\vec{W}_{f(-y)}$).

When the vertical cantilever deflection is set at a constant level, it is the total force (normal force and friction force) applied to the cantilever that keeps the cantilever deflection at this level. Since the friction force is in opposite directions as the traveling direction of the sample is reversed, the normal force will have to be adjusted accordingly when the sample reverses its traveling direction, so that the total deflection of the cantilever will remain the same. We can calculate the difference of the normal force between the two traveling directions for a given friction force W_f. First, by means of a constant deflection, the total moment applied to the cantilever is constant. If we take the reference point to be the point where the cantilever joins the cantilever holder (substrate), point P in Fig. 11.20, we have the following relationship:

$$(W_0 - \Delta W_1)L + W_f \ell = (W_0 + \Delta W_2)L - W_f \ell \quad (11.1)$$

or

$$(\Delta W_1 + \Delta W_2)L = 2W_f \ell \,. \quad (11.2)$$

Thus

$$W_f = (\Delta W_1 + \Delta W_2)L/(2\ell)\,, \quad (11.3)$$

where ΔW_1 and ΔW_2 are the absolute value of the changes of normal force when the sample is traveling in $-y$ and y directions, respectively, as shown in Fig. 11.20; L is the length of the cantilever; ℓ is vertical distance between the end of the tip and point P. The coefficient of

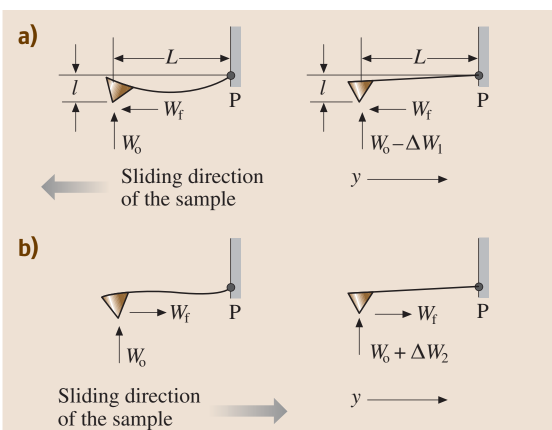

Fig. 11.20 **(a)** Schematic showing an additional bending of the cantilever – due to friction force when the sample is scanned in the y- or $-y$-direction (*left*). **(b)** This effect will be canceled by adjusting the piezo height by a feedback circuit (*right*) [11.136]

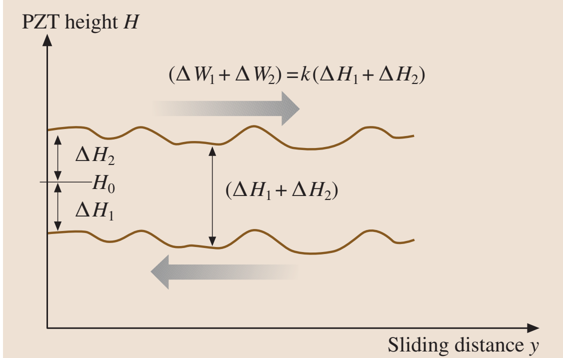

Fig. 11.21 Schematic illustration of the height difference of the piezoelectric tube scanner as the sample is scanned in y and $-y$ directions

friction (μ) between the tip and the sample is then given as

$$\mu = \frac{W_f}{W_0} = \left(\frac{(\Delta W_1 + \Delta W_2)}{W_0}\right)\left(\frac{L}{2\ell}\right) . \tag{11.4}$$

In all circumstances, there are adhesive and interatomic attractive forces between the cantilever tip and the sample. The adhesive force can be due to water from the capillary condensation and other contaminants present at the surface which form meniscus bridges [11.4, 143, 144] and the interatomic attractive force includes van der Waals attraction [11.18]. If these forces (and indentation effect as well, which is usually small for rigid samples) can be neglected, the normal force W_0 is then equal to the initial cantilever deflection H_0 multiplied by the spring constant of the cantilever. $(\Delta W_1 + \Delta W_2)$ can be measured by multiplying the same spring constant by the height difference of the piezo tube between the two traveling directions (y and $-y$ directions) of the sample. This height difference is denoted as $(\Delta H_1 + \Delta H_2)$, shown schematically in Fig. 11.21. Thus, (11.4) can be rewritten as

$$\mu = \frac{W_f}{W_0} = \left(\frac{(\Delta H_1 + \Delta H_2)}{H_0}\right)\left(\frac{L}{2\ell}\right) . \tag{11.5}$$

Since the piezo tube vertical position is affected by the surface topographic profile of the sample in addition to the friction force being applied at the tip, this difference has to be taken point by point at the same location on the sample surface as shown in Fig. 11.21. Subtraction of point by point measurements may introduce errors, particularly for rough samples. We will come back to this point later. In addition, precise measurement of L and ℓ (which should include the cantilever angle) are also required.

If the adhesive forces between the tip and the sample are large enough that it can not be neglected, one should include it in the calculation. However, there could be a large uncertainty in determining this force, thus an uncertainty in using (11.5). An alternative approach is to make the measurements at different normal loads and to use $\Delta(H_0)$ and $\Delta(\Delta H_1 + \Delta H_2)$ from the measurements in (11.5). Another comment on (11.5) is that, since only the ratio between $(\Delta H_1 + \Delta H_2)$ and H_0 comes into this equation, the piezo tube vertical position H_0 and its position difference $(\Delta H_1 + \Delta H_2)$ can be in the units of volts as long as the vertical traveling distance of the piezo tube and the voltage applied to it has a linear relationship. However, if there is a large nonlinearity between the piezo tube traveling distance and the applied voltage, this nonlinearity must be included in the calculation.

It should also be pointed out that (11.4) and (11.5) are derived under the assumption that the friction force W_f is the same for the two scanning directions of the sample. This is an approximation since the normal force is slightly different for the two scans and there may also be a directionality effect in friction. However, this difference is much smaller than W_0 itself. We can ignore the second order correction.

Method 2 ("aux" mode with perpendicular scan) to measure friction was suggested by *Meyer* and *Amer* [11.8]. The sample is scanned perpendicular to

the long axis of the cantilever beam (i. e., to scan along the x or $-x$ direction in Fig. 11.19a) and the output of the horizontal two quadrants of the photodiode-detector is measured. In this arrangement, as the sample moves under the tip, the friction force will cause the cantilever to twist. Therefore the light intensity between the left and right (L and R in Fig. 11.19b, right) detectors will be different. The differential signal between the left and right detectors is denoted as FFM signal $[(\mathrm{L}-\mathrm{R})/(\mathrm{L}+\mathrm{R})]$. This signal can be related to the degree of twisting, hence to the magnitude of friction force. Again, because of a possible error in determining normal force due to the presence of an adhesive force at the tip–sample interface, the slope of the friction data (FFM signal vs. normal load) needs to be taken for an accurate value of the coefficient of friction.

While friction force contributes to the FFM signal, friction force may not be the only contributing factor in commercial FFM instruments (for example, NanoScope IV). One can notice this fact by simply engaging the cantilever tip with the sample. Before engaging, the left and right detectors can be balanced by adjusting the position of the detectors so that the intensity difference between these two detectors is zero (FFM signal is zero). Once the tip is engaged with the sample, this signal is no longer zero even if the sample is not moving in the xy plane with no friction force applied. This would be a detrimental effect. It has to be understood and eliminated from the data acquisition before any quantitative measurement of friction force becomes possible.

One of the fundamental reasons for this observation is the following. The detectors may not have been properly aligned with respect to the laser beam. To be precise, the vertical axis of the detector assembly (the line joining T-B in Fig. 11.22) is not in the plane defined by the incident laser beam and the beam reflected from an untwisted cantilever (we call this plane the "beam plane"). When the cantilever vertical deflection changes due to a change of applied normal force (without having the sample scanned in the xy plane), the laser beam will be reflected up and down and form a projected trajectory on the detector. (Note that this trajectory is in the defined beam plane.) If this trajectory is not coincident with the vertical axis of the detector, the laser beam will not evenly bisect the left and right quadrants of the detectors, even under the condition of no torsional motion of the cantilever, see Fig. 11.22. Thus when the laser beam is reflected up and down due a change of the normal force, the intensity difference between the left and right detectors will also change. In other words, the FFM signal will change as the normal force applied to

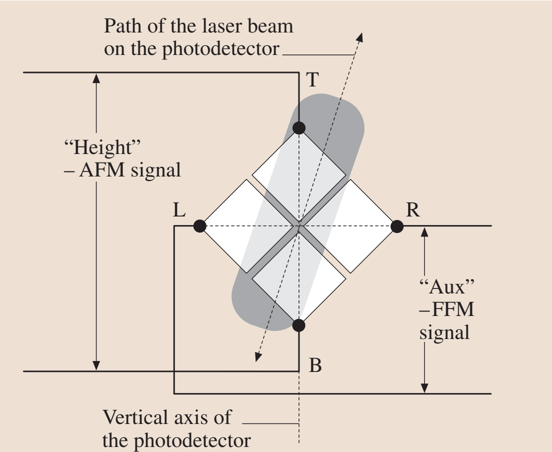

Fig. 11.22 The trajectory of the laser beam on the photodetectors in as the cantilever is vertically deflected (with no torsional motion) for a misaligned photodetector with respect to the laser beam. For a change of normal force (vertical deflection of the cantilever), the laser beam is projected at a different position on the detector. Due to a misalignment, the projected trajectory of the laser beam on the detector is not parallel with the detector vertical axis (the line joint T-B) [11.136]

the tip is changed, even if the tip is not experiencing any friction force. This (FFM) signal is unrelated to friction force or to the actual twisting of the cantilever. We will call this part of FFM signal "$\mathrm{FFM_F}$", and the part which is truly related to friction force "$\mathrm{FFM_T}$".

The $\mathrm{FFM_F}$ signal can be eliminated. One way of doing this is as follows. First the sample is scanned in both x and $-x$ directions and the FFM signal for scans in each direction is recorded. Since friction force reverses its directions when the scanning direction is reversed from x to $-x$ direction, the $\mathrm{FFM_T}$ signal will have opposite signs as the scanning direction of the sample is reversed ($\mathrm{FFM_T}(x) = -\mathrm{FFM_T}(-x)$). Hence the $\mathrm{FFM_T}$ signal will be canceled out if we take the sum of the FFM signals for the two scans. The average value of the two scans will be related to $\mathrm{FFM_F}$ due to the misalignment,

$$\mathrm{FFM}(x) + \mathrm{FFM}(-x) = 2\mathrm{FFM_F}\,. \tag{11.6}$$

This value can therefore be subtracted from the original FFM signals of each of these two scans to obtain the true FFM signal ($\mathrm{FFM_T}$). Or, alternately, by taking the difference of the two FFM signals, one directly gets the $\mathrm{FFM_T}$ value

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

$$\mathrm{FFM}(x)-\mathrm{FFM}(-x)=\mathrm{FFM_T}(x)-\mathrm{FFM_T}(-x)$$
$$=2\mathrm{FFM_T}(x)\,. \quad (11.7)$$

Ruan and *Bhushan* [11.136] have shown that the error signal ($\mathrm{FFM_F}$) can be very large compared to the friction signal $\mathrm{FFM_T}$, thus correction is required.

Now we compare the two methods. The method of using "height" mode and parallel scan (method 1) is very simple to use. Technically, this method can provide 3-D friction profiles and the corresponding topographic profiles. However, there are some problems with this method. Under most circumstances, the piezo scanner displays a hysteresis when the traveling direction of the sample is reversed. Therefore the measured surface topographic profiles will be shifted relative to each other along the y-axis for the two opposite (y and $-y$) scans. This would make it difficult to measure the local height difference of the piezo tube for the two scans. However, the average height difference between the two scans and hence the average friction can still be measured. The measurement of average friction can serve as an internal means of friction force calibration. Method 2 is a more desirable approach. The subtraction of $\mathrm{FFM_F}$ signal from FFM for the two scans does not introduce error to local friction force data. An ideal approach in using this method would be to add the average value of the two profiles in order to get the error component ($\mathrm{FFM_F}$) and then subtract this component from either profiles to get true friction profiles in either directions. By making measurements at various loads, we can get the average value of the coefficient of friction which then can be used to convert the friction profile to the coefficient of friction profile. Thus any directionality and local variations in friction can be easily measured. In this method, since topography data are not affected by friction, accurate topography data can be measured simultaneously with friction data and a better localized relationship between the two can be established.

11.2.5 Normal Force and Friction Force Calibrations of Cantilever Beams

Based on *Ruan* and *Bhushan* [11.136], we now discuss normal force and friction force calibrations. In order to calculate the absolute value of normal and friction forces in Newtons using the measured AFM and $\mathrm{FFM_T}$ voltage signals, it is necessary to first have an accurate value of the spring constant of the cantilever (k_c). The spring constant can be calculated using the geometry and the physical properties of the cantilever material [11.8,94,137]. However, the properties of the PECVD Si_3N_4 (used in fabricating cantilevers) could be different from those of the bulk material. For example, by using an ultrasonic measurement, we found the Young's modulus of the cantilever beam to be about 238 ± 18 GPa which is less than that of bulk Si_3N_4 (310 GPa). Furthermore the thickness of the beam is nonuniform and difficult to measure precisely. Since the stiffness of a beam goes as the cube of thickness, minor errors in precise measurements of thickness can introduce substantial stiffness errors. Thus one should experimentally measure the spring constant of the cantilever. *Cleveland* et al. [11.145] measured the normal spring constant by measuring resonant frequencies of the beams.

For normal spring constant measurement, *Ruan* and *Bhushan* [11.136] used a stainless steel spring sheet of known stiffness (width = 1.35 mm, thickness = 15 µm, free hanging length = 5.2 mm). One end of the spring was attached to the sample holder and the other end was made to contact with the cantilever tip during the measurement, see Fig. 11.23. They measured the piezo traveling distance for a given cantilever deflection. For a rigid sample (such as diamond), the piezo traveling distance Z_t (measured from the point where the tip touches the sample) should equal the cantilever deflection. To keep the cantilever deflection at the same level using a flexible spring sheet, the new piezo traveling distance $Z_{t'}$ would be different from Z_t. The difference between $Z_{t'}$ and Z_t corresponds to the deflection of the spring

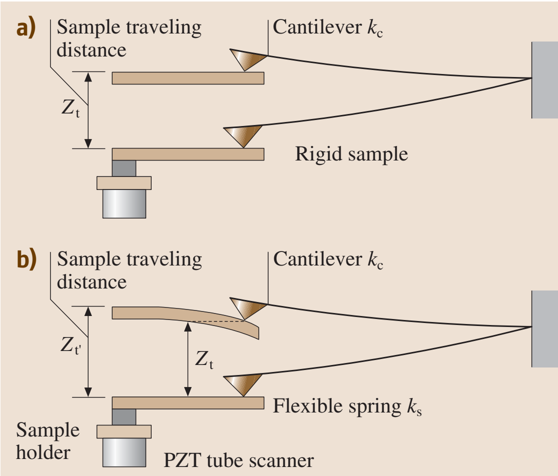

Fig. 11.23a,b Illustration showing the deflection of cantilever as it is pushed by **(a)** a rigid sample or by **(b)** a flexible spring sheet [11.136]

sheet. If the spring constant of the spring sheet is k_s, the spring constant of the cantilever k_c can be calculated by

$$(Z_{t'} - Z_t)k_s = Z_t k_c$$

or

$$k_c = k_s(Z_{t'} - Z_t)/Z_t\,. \quad (11.8)$$

The spring constant of the spring sheet (k_s) used in this study is calculated to be 1.54 N/m. For a wide-legged cantilever used in our study (length = 115 µm, base width = 122 µm, leg width = 21 µm, and thickness = 0.6 µm), k_c was measured to be 0.40 N/m instead of 0.58 N/m reported by its manufacturer – Digital Instruments Inc. To relate photodiode detector output to the cantilever deflection in nm, they used the same rigid sample to push against the AFM tip. Since for a rigid sample the cantilever vertical deflection equals the sample traveling distance measured from the point where the tip touches the sample, the photodiode output as the tip is pushed by the sample can be converted directly to cantilever deflection. For these measurements, they found the conversion factor to be 20 nm/V.

The normal force applied to the tip can be calculated by multiplying the cantilever vertical deflection by the cantilever spring constant for samples which have very small adhesive force with the tip. If the adhesive force between the sample and the tip is large, it should be included in the normal force calculation. This is particularly important in atomic-scale force measurement because in this region, the typical normal force that is measured is in the range of a few hundreds of nN to a few mN. The adhesive force could be comparable to the applied force.

The conversion of friction signal (from FFM_T to friction force) is not as straightforward. For example, one can calculate the degree of twisting for a given friction force using the geometry and the physical properties of the cantilever [11.53, 144]. One would need the information on the detectors such as the quantum efficiency of the detector, the laser power, the instrument's gain, etc. in order to be able convert the signal into the degree of twisting. Generally speaking, this procedure can not be accomplished without having some detailed information about the instrument. This information is not usually provided by the manufactures. Even if this information is readily available, error may still occur in using this approach because there will always be variations as a result of the instrumental set up. For example, it has been noticed that the measured FFM_T signal could be different for the same sample when different AFM microscopes of the same kind are used. The essence is that, one can not calibrate the instrument experimentally using this calculation. *O'Shea* et al. [11.144] did perform a calibration procedure in which the torsional signal was measured as the sample is displaced a known distance laterally while ensuring that the tip does not slide over the surface. However, it is difficult to verify that tip sliding does not occur.

Apparently, a new method of calibration is required. There is a more direct and simpler way of doing this. The first method described (method 1) to measure friction can directly provide an absolute value of the coefficient of friction. It can therefore be used just as an internal means of calibration for the data obtained using method 2. Or for a polished sample which introduces least error in friction measurement using method 1, method 1 can be used to obtain calibration for friction force for method 2. Then this calibration can be used for measurement on all samples using method 2. In method 1, the length of the cantilever required can be measured using an optical microscope; the length of the tip can be measured using a scanning electron microscope. The relative angle between the cantilever and the horizontal sample surface can be measured directly. Thus the coefficient of friction can be measured with few unknown parameters. The friction force can then be calculated by multiplying the coefficient of friction by the normal load. The FFM_T signal obtained using method 2 can then be converted into friction force. For their instrument, they found the conversion to be 8.6 nN/V.

11.3 AFM Instrumentation and Analyses

The performance of AFMs and the quality of AFM images greatly depend on the instrument available and the probes (cantilever and tips) in use. This section describes the mechanics of cantilevers, instrumentation and analysis of force detection systems for cantilever deflections, and scanning and control systems.

11.3.1 The Mechanics of Cantilevers

Stiffness and Resonances of Lumped Mass Systems

Any one of the building blocks of an AFM, be it the body of the microscope itself or the force measuring can-

tilevers, are mechanical resonators. These resonances can be excited either by the surroundings or by the rapid movement of the tip or the sample. To avoid problems due to building or air induced oscillations, it is of paramount importance to optimize the design of AFMs for high resonant frequencies. This usually means decreasing the size of the microscope [11.146]. By using cube-like or sphere-like structures for the microscope, one can considerably increase the lowest eigenfrequency. The fundamental natural frequency, ω_0, of any spring is given by

$$\omega_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m_{\text{eff}}}}\,, \tag{11.9}$$

where k is the spring constant (stiffness) in the normal direction and m_{eff} is the effective mass. The spring constant k of a cantilever beam with uniform cross section (Fig. 11.24) is given by [11.147]

$$k = \frac{3EI}{L^3}\,, \tag{11.10}$$

where E is the Young's modulus of the material, L is the length of the beam and I is the moment of inertia of the cross section. For a rectangular cross section with a width b (perpendicular to the deflection) and a height h one obtains an expression for I

$$I = \frac{bh^3}{12}\,. \tag{11.11}$$

Combining (11.9), (11.10) and (11.11) we get an expression for ω_0

$$\omega_0 = \sqrt{\frac{Ebh^3}{4L^3 m_{\text{eff}}}}\,. \tag{11.12}$$

The effective mass can be calculated using Raleigh's method. The general formula using Raleigh's method for the kinetic energy T of a bar is

$$T = \frac{1}{2}\int_0^L \frac{m}{L}\left(\frac{\partial z(x)}{\partial t}\right)^2 \mathrm{d}x\,. \tag{11.13}$$

For the case of a uniform beam with a constant cross section and length L one obtains for the deflection $z(x) = z_{\max}\left[1-(3x/2L)+(x^3/2L^3)\right]$. Inserting $z_{\max}$ into (11.13) and solving the integral gives

$$T = \frac{1}{2}\int_0^L \frac{m}{L}\left[\frac{\partial z_{\max}(x)}{\partial t}\left(1-\frac{3x}{2L}\right)+\left(\frac{x^3}{L^3}\right)\right]^2 \mathrm{d}x$$
$$= \frac{1}{2}m_{\text{eff}}(z_{\max}t)^2\,,$$

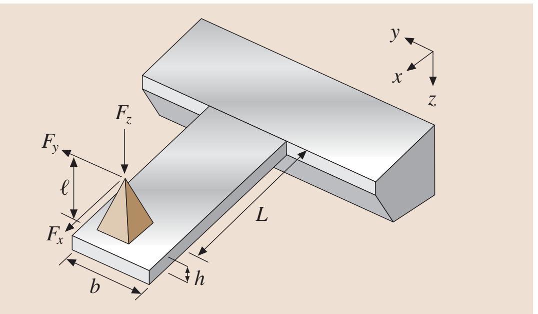

Fig. 11.24 A typical AFM cantilever with length L, width b, and height h. The height of the tip is ℓ. The material is characterized by Young's modulus E, the shear modulus G and a mass density ρ. Normal (F_z), axial (F_x), and lateral (F_y) forces exist at the end of the tip

which gives

$$m_{\text{eff}} = \frac{9}{20}m\,. \tag{11.14}$$

Substituting (11.14) into (11.12) and noting that $m = \rho Lbh$, where ρ is the mass density, one obtains the following expression

$$\omega_0 = \left(\frac{\sqrt{5}}{3}\sqrt{\frac{\mathrm{E}}{\rho}}\right)\frac{\mathrm{h}}{L^2}\,. \tag{11.15}$$

It is evident from (11.15), that one way to increase the natural frequency is to choose a material with a high ratio E/ρ; see Table 11.2 for typical values of $\sqrt{E/\rho}$ of various commonly used materials. Another way to increase the lowest eigenfrequency is also evident in (11.15). By optimizing the ratio h/L^2, one can increase the resonant frequency. However it does not help to make the length of the structure smaller than the width or height. Their roles will just be interchanged. Hence the optimum structure is a cube. This leads to the design rule, that long, thin structures like sheet metal should be avoided. For a given resonant frequency, the quality factor Q should be as low as possible. This means that an inelastic medium such as rubber should be in contact with the structure to convert kinetic energy into heat.

Stiffness and Resonances of Cantilevers

Cantilevers are mechanical devices specially shaped to measure tiny forces. The analysis given in the previous section is applicable. However, to understand better the intricacies of force detection systems we will discuss the

example of a cantilever beam with uniform cross section, Fig. 11.24. The bending of a beam due to a normal load on the beam is governed by the Euler equation [11.147]

$$M = EI(x)\,\frac{d^2 z}{dx^2}\,, \tag{11.16}$$

where M is the bending moment acting on the beam cross section. $I(x)$ the moment of inertia of the cross section with respect to the neutral axis defined by

$$I(x) = \int_z \int_y z^2\,dy\,dz\,. \tag{11.17}$$

For a normal force F_z acting at the tip,

$$M(x) = (L - x)\,F_z \tag{11.18}$$

since the moment must vanish at the endpoint of the cantilever. Integrating (11.16) for a normal force F_z acting at the tip and observing that EI is a constant for beams with a uniform cross section, one gets

$$z(x) = \frac{L^3}{6EI}\left(\frac{x}{L}\right)^2\left(3 - \frac{x}{L}\right)F_z\,. \tag{11.19}$$

The slope of the of the beam is

$$z'(x) = \frac{Lx}{2EI}\left(2 - \frac{x}{L}\right)F_z\,. \tag{11.20}$$

From (11.19) and (11.20), at the end of the cantilever, i. e. for $x = L$, for a rectangular beam, and by using an expression for I in (11.11), one gets,

$$z(L) = \frac{4}{Eb}\left(\frac{L}{h}\right)^3 F_z\,, \tag{11.21}$$

$$z'(L) = \frac{3}{2}\left(\frac{z}{L}\right)\,. \tag{11.22}$$

Now the stiffness in the normal (z) direction, k_z, is

$$k_z = \frac{F_z}{z(L)} = \frac{Eb}{4}\left(\frac{h}{L}\right)^3\,. \tag{11.23}$$

and a change in angular orientation of the end of cantilever beam is

$$\Delta\alpha = \frac{3}{2}\frac{z}{L} = \frac{6}{Ebh}\left(\frac{L}{h}\right)^2 F_z\,. \tag{11.24}$$

Now we ask what will, to first order, happen if we apply a lateral force F_y to the end of the tip (Fig. 11.24). The cantilever will bend sideways and it will twist. The stiffness in the lateral (y) direction, k_y, can be calculated with (11.23) by exchanging b and h

$$k_y = \frac{Eh}{4}\left(\frac{b}{L}\right)^3\,. \tag{11.25}$$

Therefore the bending stiffness in lateral direction is larger than the stiffness for bending in the normal direction by $(b/h)^2$. The twisting or torsion on the other hand is more complicated to handle. For a wide, thin cantilever ($b \gg h$) we obtain torsional stiffness along y axis, k_{yT}

$$k_{yT} = \frac{Gbh^3}{3L\ell^2}\,, \tag{11.26}$$

where G is the modulus of rigidity ($= E/2(1+\nu)$, where ν is the Poisson's ratio). The ratio of the torsional stiffness to the lateral bending stiffness is

$$\frac{k_{yT}}{k_y} = \frac{1}{2}\left(\frac{\ell b}{hL}\right)^2\,, \tag{11.27}$$

where we assume $\nu = 0.333$. We see that thin, wide cantilevers with long tips favor torsion while cantilevers with square cross sections and short tips favor bending. Finally we calculate the ratio between the torsional stiffness and the normal bending stiffness,

$$\frac{k_{yT}}{k_z} = 2\left(\frac{L}{\ell}\right)^2\,. \tag{11.28}$$

Equations (11.26) to (11.28) hold in the case where the cantilever tip is exactly in the middle axis of the cantilever. Triangular cantilevers and cantilevers with tips not on the middle axis can be dealt with by finite element methods.

The third possible deflection mode is the one from the force on the end of the tip along the cantilever axis, F_x (Fig. 11.24). The bending moment at the free end of the cantilever is equal to the $F_x\ell$. This leads to the following modification of (11.18) for the case of forces F_z and F_x

$$M(x) = (L - x)\,F_z + F_x\ell\,. \tag{11.29}$$

Integration of (11.16) now leads to

$$z(x) = \frac{1}{2EI}\left[Lx^2\left(1 - \frac{x}{3L}\right)F_z + \ell x^2 F_x\right] \tag{11.30}$$

and

$$z'(x) = \frac{1}{EI}\left[\frac{Lx}{2}\left(2 - \frac{x}{L}\right)F_z + \ell x F_x\right]\,. \tag{11.31}$$

Evaluating (11.30) and (11.31) at the end of the cantilever, we get the deflection and the tilt

$$z(L) = \frac{L^2}{EI}\left(\frac{L}{3}F_z - \frac{\ell}{2}F_x\right)\,,$$

$$z'(L) = \frac{L}{EI}\left(\frac{L}{2}F_z + \ell F_x\right)\,. \tag{11.32}$$

From these equations, one gets

$$F_z = \frac{12EI}{L^3}\left[z(L) - \frac{Lz'(L)}{2}\right],$$
$$F_x = \frac{2EI}{\ell L^2}\left[2Lz'(L) - 3z(L)\right]. \quad (11.33)$$

A second class of interesting properties of cantilevers is their resonance behavior. For cantilever beams one can calculate the resonant frequencies [11.147, 148]

$$\omega_n^{\text{free}} = \frac{\lambda_n^2}{2\sqrt{3}}\frac{h}{L^2}\sqrt{\frac{E}{\rho}} \quad (11.34)$$

with $\lambda_0 = (0.596864\ldots)\pi$, $\lambda_1 = (1.494175\ldots)\pi$, $\lambda_n \to (n+1/2)\pi$. The subscript n represents the order of the frequency, e.g., fundamental, second mode, and the nth mode.

A similar equation to (11.34) holds for cantilevers in rigid contact with the surface. Since there is an additional restriction on the movement of the cantilever, namely the location of its end point, the resonant frequency increases. Only the λ_n's terms change to [11.148]

$$\lambda_0' = (1.2498763\ldots)\pi, \quad \lambda_1' = (2.2499997\ldots)\pi,$$
$$\lambda_n' \to (n+1/4)\pi. \quad (11.35)$$

The ratio of the fundamental resonant frequency in contact to the fundamental resonant frequency not in contact is 4.3851.

For the torsional mode we can calculate the resonant frequencies as

$$\omega_0^{\text{tors}} = 2\pi\frac{h}{Lb}\sqrt{\frac{G}{\rho}}. \quad (11.36)$$

For cantilevers in rigid contact with the surface, we obtain the expression for the fundamental resonant frequency [11.148]

$$\omega_0^{\text{tors, contact}} = \frac{\omega_0^{\text{tors}}}{\sqrt{1+3(2L/b)^2}}. \quad (11.37)$$

The amplitude of the thermally induced vibration can be calculated from the resonant frequency using

$$\Delta z_{\text{therm}} = \sqrt{\frac{k_B T}{k}}, \quad (11.38)$$

where k_B is Boltzmann's constant and T is the absolute temperature. Since AFM cantilevers are resonant structures, sometimes with rather high Q, the thermal noise is not evenly distributed as (11.38) suggests. The spectral noise density below the peak of the response curve is [11.148]

$$z_0 = \sqrt{\frac{4k_B T}{k\omega_0 Q}} \quad (\text{in m}/\sqrt{\text{Hz}}), \quad (11.39)$$

where Q is the quality factor of the cantilever, described earlier.

11.3.2 Instrumentation and Analyses of Detection Systems for Cantilever Deflections

A summary of selected detection systems was provided in Fig. 11.8. Here we discuss in detail pros and cons of various systems.

Optical Interferometer Detection Systems

Soon after the first papers on the AFM [11.2] appeared, which used a tunneling sensor, an instrument based on an interferometer was published [11.149]. The sensitivity of the interferometer depends on the wavelength of the light employed in the apparatus. Figure 11.25 shows the principle of such an interferometeric design. The light incident from the left is focused by a lens on the cantilever. The reflected light is collimated by the same lens and interferes with the light reflected at the flat. To separate the reflected light from the incident light a $\lambda/4$ plate converts the linear polarized incident light to circular polarization. The reflected light is made linear polarized again by the $\lambda/4$-plate, but with a polarization orthogonal to that of the incident light. The polarizing

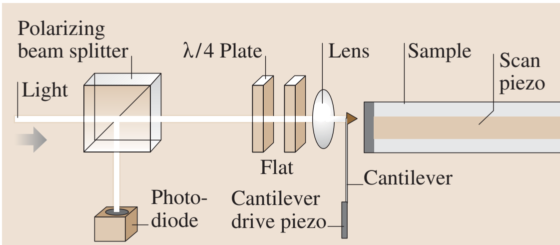

Fig. 11.25 Principle of an interferometric AFM. The light of the laser light source is polarized by the polarizing beam splitter and focused on the back of the cantilever. The light passes twice through a quarter wave plate and is hence orthogonally polarized to the incident light. The second arm of the interferometer is formed by the flat. The interference pattern is modulated by the oscillating cantilever

beam splitter then deflects the reflected light to the photo diode.

Homodyne Interferometer. To improve the signal to noise ratio of the interferometer the cantilever is driven by a piezo near its resonant frequency. The amplitude Δz of the cantilever as a function of driving frequency Ω is

$$\Delta z\,(\Omega) = \Delta z_0 \frac{\Omega_0^2}{\sqrt{\left(\Omega^2-\Omega_0^2\right)^2+\frac{\Omega^2\Omega_0^2}{Q^2}}}\,, \qquad (11.40)$$

where Δz_0 is the constant drive amplitude and Ω_0 the resonant frequency of the cantilever. The resonant frequency of the cantilever is given by the effective potential

$$\Omega_0 = \sqrt{\left(k+\frac{\partial^2 U}{\partial z^2}\right)\frac{1}{m_{\mathrm{eff}}}}\,, \qquad (11.41)$$

where U is the interaction potential between the tip and the sample. Equation (11.41) shows that an attractive potential decreases Ω_0. The change in Ω_0 in turn results in a change of the Δz (see (11.40)). The movement of the cantilever changes the path difference in the interferometer. The light reflected from the cantilever with the amplitude $A_{\ell,0}$ and the reference light with the amplitude $A_{r,0}$ interfere on the detector. The detected intensity $I(t) = [A_\ell(t)+A_r(t)]^2$ consists of two constant terms and a fluctuating term

$$2A_\ell\,(t)\,A_r\,(t) = A_{\ell,0}A_{r,0}\sin\left[\omega t+\frac{4\pi\delta}{\lambda}+\frac{4\pi\,\Delta z}{\lambda}\sin\,(\Omega t)\right]\sin\,(\omega t)\;. \qquad (11.42)$$

Here ω is the frequency of the light, λ is the wavelength of the light, δ is the path difference in the interferometer, and Δz is the instantaneous amplitude of the cantilever, given according to (11.40) and (11.41) as a function of Ω, k, and U. The time average of (11.42) then becomes

$$\begin{aligned}\langle 2A_\ell\,(t)\,A_r\,(t)\rangle_T &\propto \cos\left[\frac{4\pi\delta}{\lambda}+\frac{4\pi\,\Delta z}{\lambda}\sin\,(\Omega t)\right]\\ &\approx \cos\left(\frac{4\pi\delta}{\lambda}\right)-\sin\left[\frac{4\pi\,\Delta z}{\lambda}\sin\,(\Omega t)\right]\\ &\approx \cos\left(\frac{4\pi\delta}{\lambda}\right)-\frac{4\pi\,\Delta z}{\lambda}\sin\,(\Omega t)\;. \end{aligned} \qquad (11.43)$$

Here all small quantities have been omitted and functions with small arguments have been linearized. The amplitude of Δz can be recovered with a lock-in technique. However, (11.43) shows that the measured amplitude is also a function of the path difference δ in the interferometer. Hence this path difference δ must be very stable. The best sensitivity is obtained when $\sin(4\delta/\lambda)\approx 0$.

Heterodyne Interferometer. This influence is not present in the heterodyne detection scheme shown in Fig. 11.26. Light incident from the left with a frequency ω is split in a reference path (upper path in Fig. 11.26) and a measurement path. Light in the measurement path is shifted in frequency to $\omega_1 = \omega + \Delta\omega$ and focused on the cantilever. The cantilever oscillates at the frequency Ω, as in the homodyne detection scheme. The reflected light $A_\ell(t)$ is collimated by the same lens and interferes on the photo diode with the reference light $A_r(t)$. The fluctuating term of the intensity is given by

$$\begin{aligned}2A_\ell\,(t)\,A_r\,(t) = A_{\ell,0}A_{r,0}\sin\Big[(\omega+\Delta\omega)\,t+\frac{4\pi\delta}{\lambda}\\ +\frac{4\pi\,\Delta z}{\lambda}\sin\,(\Omega t)\Big]\sin\,(\omega t)\;,\end{aligned} \qquad (11.44)$$

where the variables are defined as in (11.42). Setting the path difference $\sin(4\pi\delta/\lambda)\approx 0$ and taking the time average, omitting small quantities and linearizing functions with small arguments we get

$$\langle 2A_\ell\,(t)\,A_r\,(t)\rangle_{\mathrm{T}} \propto \cos\left[\Delta\omega t+\frac{4\pi\delta}{\lambda}+\frac{4\pi\,\Delta z}{\lambda}\sin\,(\Omega t)\right]$$

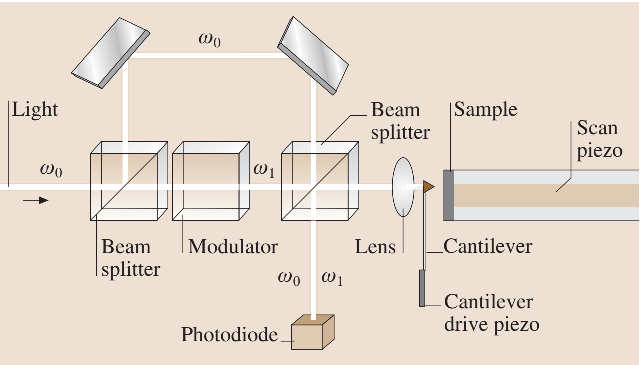

Fig. 11.26 Principle of a heterodyne interferometric AFM. Light with the frequency ω_0 is split into a reference path (upper path) and a measurement path. The light in the measurement path is frequency shifted to ω_1 by an acousto-optical modulator (or an electro-optical modulator) The light reflected from the oscillating cantilever interferes with the reference beam on the detector

$$= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\cos\left[\frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right]$$
$$- \sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin\left[\frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right]$$
$$\approx \cos\left(\frac{4\pi\delta}{\lambda}\right) - \sin\left[\frac{4\pi\Delta z}{\lambda}\sin(\Omega t)\right]$$
$$\approx \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\left[1 - \frac{8\pi^2\Delta z^2}{\lambda^2}\sin(\Omega t)\right]$$
$$- \frac{4\pi\Delta z}{\lambda}\sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t)$$
$$= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right) - \frac{8\pi^2\Delta z^2}{\lambda^2}\cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)$$
$$\times \sin(\Omega t) - \frac{4\pi\Delta z}{\lambda}\sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t)$$
$$= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right) - \frac{4\pi^2\Delta z^2}{\lambda^2}\cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)$$
$$+ \frac{4\pi^2\Delta z^2}{\lambda^2}\cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\cos(2\Omega t)$$
$$- \frac{4\pi\Delta z}{\lambda}\sin\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\sin(\Omega t)$$
$$= \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)\left(1 - \frac{4\pi^2\Delta z^2}{\lambda^2}\right)$$
$$+ \frac{2\pi^2\Delta z^2}{\lambda^2}\left\{\cos\left[(\Delta\omega + 2\Omega)t + \frac{4\pi\delta}{\lambda}\right]\right.$$
$$\left. + \cos\left[(\Delta\omega - 2\Omega)t + \frac{4\pi\delta}{\lambda}\right]\right\}$$
$$+ \frac{2\pi\Delta z}{\lambda}\left\{\cos\left[(\Delta\omega + \Omega)t + \frac{4\pi\delta}{\lambda}\right]\right.$$
$$\left. + \cos\left[(\Delta\omega - \Omega)t + \frac{4\pi\delta}{\lambda}\right]\right\}. \quad (11.45)$$

Multiplying electronically the components oscillating at $\Delta\omega$ and $\Delta\omega + \Omega$ and rejecting any product except the one oscillating at Ω we obtain

$$A = \frac{2\Delta z}{\lambda}\left(1 - \frac{4\pi^2\Delta z^2}{\lambda^2}\right)\cos\left[(\Delta\omega + 2\Omega)t + \frac{4\pi\delta}{\lambda}\right]$$
$$\times \cos\left(\Delta\omega t + \frac{4\pi\delta}{\lambda}\right)$$
$$= \frac{\Delta z}{\lambda}\left(1 - \frac{4\pi^2\Delta z^2}{\lambda^2}\right)\left\{\cos\left[(2\Delta\omega + \Omega)t + \frac{8\pi\delta}{\lambda}\right]\right.$$
$$\left. + \cos(\Omega t)\right\}$$
$$\approx \frac{\pi\Delta z}{\lambda}\cos(\Omega t). \quad (11.46)$$

Unlike in the homodyne detection scheme the recovered signal is independent from the path difference δ of the interferometer. Furthermore a lock-in amplifier with the reference set $\sin(\Delta\omega t)$ can measure the path difference δ independent of the cantilever oscillation. If necessary, a feedback circuit can keep $\delta = 0$.

Fiber-optical Interferometer. The fiber-optical interferometer [11.129] is one of the simplest interferometers to build and use. Its principle is sketched in Fig. 11.27. The light of a laser is fed into an optical fiber. Laser diodes with integrated fiber pigtails are convenient light sources. The light is split in a fiber-optic beam splitter into two fibers. One fiber is terminated by index matching oil to avoid any reflections back into the fiber. The end of the other fiber is brought close to the cantilever in the AFM. The emerging light is partially reflected back into the fiber by the cantilever. Most of the light, however, is lost. This is not a big problem since only 4% of the light is reflected at the end of the fiber, at the glass-air interface. The two reflected light waves interfere with each other. The product is guided back into the fiber coupler and again split into two parts. One half is analyzed by the photodiode. The other half is fed back into the laser. Communications grade laser diodes are sufficiently resistant against feedback to be operated in this environment. They have, however, a bad coherence length, which in this case does not matter, since the optical path difference is in any case no larger than 5 µm. Again the end of the fiber has to be positioned on a piezo drive to set the distance between the fiber and the cantilever to $\lambda(n + 1/4)$.

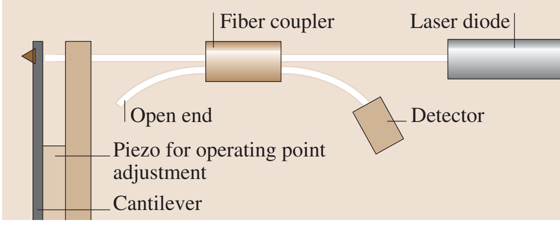

Fig. 11.27 A typical setup for a fiber optic interferometer readout

Nomarski-Interferometer. Another solution to minimize the optical path difference is to use the Nomarski interferometer [11.130]. Figure 11.28 shows a schematic of the microscope. The light of a laser is focused on the cantilever by lens. A birefringent crystal (for instance calcite) between the cantilever and the lens with its optical axis 45° off the polarization direction of the light

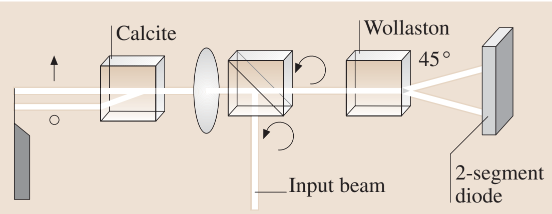

Fig. 11.28 Principle of Nomarski AFM. The circular polarized input beam is deflected to the left by a non-polarizing beam splitter. The light is focused onto a cantilever. The calcite crystal between the lens and the cantilever splits the circular polarized light into two spatially separated beams with orthogonal polarizations. The two light beams reflected from the lever are superimposed by the calcite crystal and collected by the lens. The resulting beam is again circular polarized. A Wollaston prism produces two interfering beams with $\pi/2$ phase shift between them. The minimal path difference accounts for the excellent stability of this microscope

splits the light beam into two paths, offset by a distance given by the length of the crystal. Birefringent crystals have varying indexes of refraction. In calcite, one crystal axis has a lower index than the other two. This means, that certain light rays will propagate at a different speed through the crystal than the others. By choosing a correct polarization, one can select the ordinary ray, the extraordinary ray or one can get any distribution of the intensity amongst those two rays. A detailed description of birefringence can be found in textbooks (e.g., [11.150]). A calcite crystal deflects the extraordinary ray at an angle of 6° within the crystal. By choosing a suitable length of the calcite crystal, any separation can be set.

The focus of one light ray is positioned near the free end of the cantilever while the other is placed close to the clamped end. Both arms of the interferometer pass through the same space, except for the distance between the calcite crystal and the lever. The closer the calcite crystal is placed to the lever, the less influence disturbances like air currents have.

Sarid [11.116] has given values for the sensitivity of the different interferometeric detection systems. Table 11.5 presents a summary of his results.

Optical Lever

The most common cantilever deflection detection system is the optical lever [11.53, 111]. This method, depicted in Fig. 11.29, employs the same technique as light beam deflection galvanometers. A fairly well collimated light beam is reflected off a mirror and projected to a receiving target. Any change in the angular position of the mirror will change the position, where the light ray hits the target. Galvanometers use optical path lengths of several meters and scales projected to the target wall as a read-out help.

For the AFM using the optical lever method a photodiode segmented into two (or four) closely spaced devices detects the orientation of the end of the cantilever. Initially, the light ray is set to hit the photodiodes in the middle of the two sub-diodes. Any deflection of

Table 11.5 Noise in Interferometers. F is the finesse of the cavity in the homodyne interferometer, P_{i} the incident power, P_{d} is the power on the detector, η is the sensitivity of the photodetector and RIN is the relative intensity noise of the laser. P_{R} and P_{S} are the power in the reference and sample beam in the heterodyne interferometer. P is the power in the Nomarski interferometer, $\delta\theta$ is the phase difference between the reference and the probe beam in the Nomarski interferometer. B is the bandwidth, e is the electron charge, λ is the wavelength of the laser, k the cantilever stiffness, ω_0 is the resonant frequency of the cantilever, Q is the quality factor of the cantilever, T is the temperature, and δi is the variation of current i

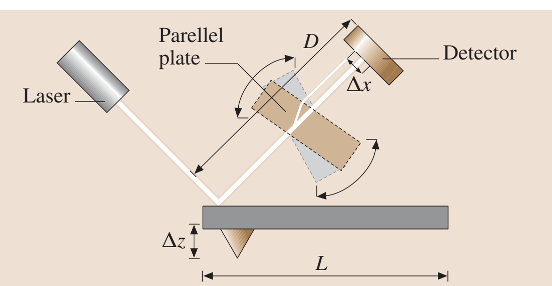

Fig. 11.29 The setup of optical lever detection microscope

the cantilever will cause an imbalance of the number of photons reaching the two halves. Hence the electrical currents in the photodiodes will be unbalanced too. The difference signal is further amplified and is the input signal to the feedback loop. Unlike the interferometeric AFMs, where often a modulation technique is necessary to get a sufficient signal to noise ratio, most AFMs employing the optical lever method are operated in a static mode. AFMs based on the optical lever method are universally used. It is the simplest method for constructing an optical readout and it can be confined in volumes smaller than 5 cm on the side.

The optical lever detection system is a simple yet elegant way to detect normal and lateral force signals simultaneously [11.7, 8, 53, 111]. It has the additional advantage that it is the fact that it is a remote detection system.

Implementations. Light from a laser diode or from a super luminescent diode is focused on the end of the cantilever. The reflected light is directed onto a quadrant diode that measures the direction of the light beam. A Gaussian light beam far from its waist is characterized by an opening angle β. The deflection of the light beam by the cantilever surface tilted by an angle α is 2α. The intensity on the detector then shifts to the side by the product of 2α and the separation between the detector and the cantilever. The readout electronics calculates the difference of the photocurrents. The photocurrents in turn are proportional to the intensity incident on the diode.

The output signal is hence proportional to the change in intensity on the segments

$$I_{\text{sig}} \propto 4\frac{\alpha}{\beta} I_{\text{tot}} . \quad (11.47)$$

For the sake of simplicity, we assume that the light beam is of uniform intensity with its cross section increasing proportional to the distance between the cantilever and the quadrant detector. The movement of the center of the light beam is then given by

$$\Delta x_{\text{Det}} = \Delta z \frac{D}{L} . \quad (11.48)$$

The photocurrent generated in a photodiode is proportional to the number of incoming photons hitting it. If the light beam contains a total number of N_0 photons then the change in difference current becomes

$$\Delta\left(I_{\text{R}} - I_{\text{L}}\right) = \Delta I = \text{const}\ \Delta z\ D\ N_0 . \quad (11.49)$$

Combining (11.48) and (11.49), one obtains that the difference current ΔI is independent of the separation of the quadrant detector and the cantilever. This relation is true, if the light spot is smaller than the quadrant detector. If it is greater, the difference current ΔI becomes smaller with increasing distance. In reality the light beam has a Gaussian intensity profile. For small movements Δx (compared to the diameter of the light spot at the quadrant detector), (11.49) still holds. Larger movements Δx, however, will introduce a nonlinear response. If the AFM is operated in a constant force mode, only small movements Δx of the light spot will occur. The feedback loop will cancel out all other movements.

The scanning of a sample with an AFM can twist the microfabricated cantilevers because of lateral forces [11.5, 7, 8] and affect the images [11.120]. When the tip is subjected to lateral forces, it will twist the cantilever and the light beam reflected from the end of the cantilever will be deflected perpendicular to the ordinary deflection direction. For many investigations this influence of lateral forces is unwanted. The design of the triangular cantilevers stems from the desire, to minimize the torsion effects. However, lateral forces open up a new dimension in force measurements. They allow, for instance, a distinction of two materials because of the different friction coefficient, or the determination of adhesion energies. To measure lateral forces the original optical lever AFM has to be modified. The only modification compared with Fig. 11.29 is the use of a quadrant detector photodiode instead of a two-segment photodiode and the necessary readout electronics, see Fig. 11.9a. The electronics calculates the following signals:

$$\begin{aligned} U_{\text{Normal Force}} &= \alpha\left[\left(I_{\text{Upper Left}} + I_{\text{Upper Right}}\right)\right. \\ &\quad \left.- \left(I_{\text{Lower Left}} + I_{\text{Lower Right}}\right)\right] , \\ U_{\text{Lateral Force}} &= \beta\left[\left(I_{\text{Upper Left}} + I_{\text{Lower Left}}\right)\right. \\ &\quad \left.- \left(I_{\text{Upper Right}} + I_{\text{Lower Right}}\right)\right] . \end{aligned} \quad (11.50)$$

The calculation of the lateral force as a function of the deflection angle does not have a simple solution

for cross-sections other than circles. An approximate formula for the angle of twist for rectangular beams is [11.151]

$$\theta = \frac{M_t L}{\beta G b^3 h}\,, \tag{11.51}$$

where $M_t = F_y \ell$ is the external twisting moment due to lateral force, F_y, and β a constant determined by the value of h/b. For the equation to hold, h has to be larger than b.

Inserting the values for a typical microfabricated cantilever with integrated tips

$$\begin{aligned}
b &= 6\times10^{-7}\,\text{m}\,,\\
h &= 10^{-5}\,\text{m}\,,\\
L &= 10^{-4}\,\text{m}\,,\\
\ell &= 3.3\times10^{-6}\,\text{m}\,,\\
G &= 5\times10^{10}\,\text{Pa}\,,\\
\beta &= 0.333
\end{aligned} \tag{11.52}$$

into (11.51) we obtain the relation

$$F_y = 1.1\times10^{-4}\,\text{N}\times\theta\,. \tag{11.53}$$

Typical lateral forces are of order 10^{-10} N.

Sensitivity. The sensitivity of this setup has been calculated in various papers [11.116, 148, 152]. Assuming a Gaussian beam the resulting output signal as a function of the deflection angle is dispersion like. Equation (11.47) shows that the sensitivity can be increased by increasing the intensity of the light beam I_{tot} or by decreasing the divergence of the laser beam. The upper bound of the intensity of the light I_{tot} is given by saturation effects on the photodiode. If we decrease the divergence of a laser beam we automatically increase the beam waist. If the beam waist becomes larger than the width of the cantilever we start to get diffraction. Diffraction sets a lower bound on the divergence angle. Hence one can calculate the optimal beam waist w_{opt} and the optimal divergence angle β [11.148, 152]

$$\begin{aligned}
w_{opt} &\approx 0.36b\,,\\
\theta_{opt} &\approx 0.89\frac{\lambda}{b}\,.
\end{aligned} \tag{11.54}$$

The optimal sensitivity of the optical lever then becomes

$$\varepsilon\,[\text{mW/rad}] = 1.8\frac{b}{\lambda}I_{tot}\,[\text{mW}]\,. \tag{11.55}$$

The angular sensitivity optical lever can be measured by introducing a parallel plate into the beam. A tilt of the parallel plate results in a displacement of the beam, mimicking an angular deflection.

Additional noise sources can be considered. Of little importance is the quantum mechanical uncertainty of the position [11.148, 152], which is, for typical cantilevers at room temperature

$$\Delta z = \sqrt{\frac{\hbar}{2m\omega_0}} = 0.05\,\text{fm}\,, \tag{11.56}$$

where $\hbar$ is the Planck constant ($= 6.626\times10^{-34}$ J s). At very low temperatures and for high frequency cantilevers this could become the dominant noise source. A second noise source is the shot noise of the light. The shot noise is related to the particle number. We can calculate the number of photons incident on the detector

$$n = \frac{I\tau}{\hbar\omega} = \frac{I\lambda}{2\pi B\hbar c} = 1.8\times10^{9}\,\frac{I[\text{W}]}{B[\text{Hz}]}\,, \tag{11.57}$$

where I is the intensity of the light, τ the measurement time, $B = 1/\tau$ the bandwidth, and c the speed of light. The shot noise is proportional to the square root of the number of particles. Equating the shot noise signal with the signal resulting for the deflection of the cantilever one obtains

$$\Delta z_{shot} = 68\frac{L}{w}\sqrt{\frac{B\,[\text{kHz}]}{I\,[\text{mW}]}}\,[\text{fm}]\,, \tag{11.58}$$

where w is the diameter of the focal spot. Typical AFM setups have a shot noise of 2 pm. The thermal noise can be calculated from the equipartition principle. The amplitude at the resonant frequency is

$$\Delta z_{therm} = 129\sqrt{\frac{B}{k\,[\text{N/m}]\,\omega_0 Q}}\,[\text{pm}]\,. \tag{11.59}$$

A typical value is 16 pm. Upon touching the surface, the cantilever increases its resonant frequency by a factor of 4.39. This results in a new thermal noise amplitude of 3.2 pm for the cantilever in contact with the sample.

Piezoresistive Detection

Implementation. An alternative detection system which is not as widely used as the optical detection schemes are piezoresistive cantilevers [11.125, 126, 132]. These cantilevers are based on the fact that the resistivity of certain materials, in particular of Si, changes with the applied stress. Figure 11.30 shows a typical implementation of a piezo-resistive cantilever. Four

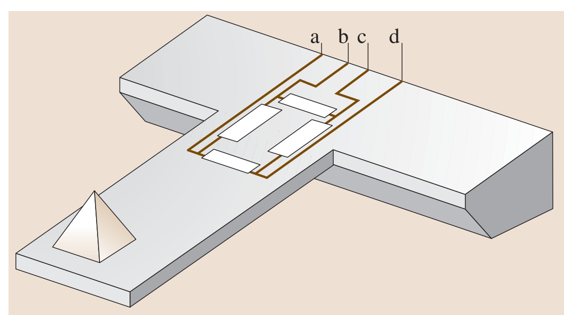

Fig. 11.30 A typical setup for a piezoresistive readout

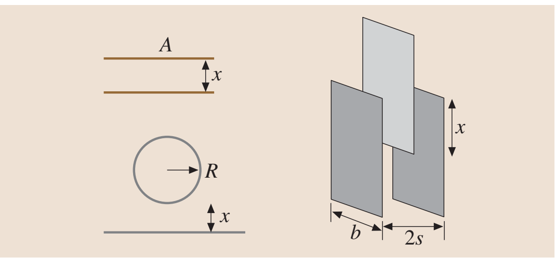

Fig. 11.31 Three possible arrangements of a capacitive readout. The *upper left* shows the cross section through a parallel plate capacitor. The *lower left* shows the geometry of sphere versus plane. The *right side* shows the more complicated, but linear capacitive readout

resistances are integrated on the chip, forming a Wheatstone bridge. Two of the resistors are in unstrained parts of the cantilever, the other two are measuring the bending at the point of the maximal deflection. For instance when an AC voltage is applied between terminals a and c one can measure the detuning of the bridge between terminals b and d. With such a connection the output signal varies only due to bending, but not due to changing of the ambient temperature and thus the coefficient of the piezoresistance.

Sensitivity. The resistance change is [11.126]

$$\frac{\Delta R}{R_0} = \Pi\delta\,, \tag{11.60}$$

where Π is the tensor element of the piezo-resistive coefficients, δ the mechanical stress tensor element and R_0 the equilibrium resistance. For a single resistor they separate the mechanical stress and the tensor element in longitudinal and transverse components

$$\frac{\Delta R}{R_0} = \Pi_t\delta_t + \Pi_l\delta_l\,. \tag{11.61}$$

The maximum value of the stress components are $\Pi_t = -64.0\times10^{-11}\,\mathrm{m^2/N}$ and $\Pi_l = -71.4\times10^{-11}\,\mathrm{m^2/N}$ for a resistor oriented along the (110) direction in silicon [11.126]. In the resistor arrangement of Fig. 11.30 two of the resistors are subject to the longitudinal piezoresistive effect and two of them are subject to the transversal piezo-resistive effect. The sensitivity of that setup is about four times that of a single resistor, with the advantage that temperature effects cancel to first order. The resistance change is then calculated as

$$\frac{\Delta R}{R_0} = \Pi\frac{3Eh}{2L^2}\Delta z = \Pi\frac{6L}{bh^2}F_z\,, \tag{11.62}$$

where $\Pi = 67.7\times10^{-11}\,\mathrm{m^2/N}$ is the averaged piezoresistive coefficient. Plugging in typical values for the dimensions (Fig. 11.24) ($L = 100\,\mu\mathrm{m}$, $b = 10\,\mu\mathrm{m}$, $h = 1\,\mu\mathrm{m}$) one obtains

$$\frac{\Delta R}{R_0} = \frac{4\times10^{-5}}{\mathrm{nN}}F_z\,. \tag{11.63}$$

The sensitivity can be tailored by optimizing the dimensions of the cantilever.

Capacitance Detection

The capacitance of an arrangement of conductors depends on the geometry. Generally speaking, the capacitance increases for decreasing separations. Two parallel plates form a simple capacitor (see Fig. 11.31, upper left), with the capacitance

$$C = \frac{\varepsilon\varepsilon_0 A}{x}\,, \tag{11.64}$$

where A is the area of the plates, assumed equal, and x is the separation. Alternatively one can consider a sphere versus an infinite plane (see Fig. 11.31, lower left). Here the capacitance is [11.116]

$$C = 4\pi\varepsilon_0 R\sum_{n=2}^{\infty}\frac{\sinh(\alpha)}{\sinh(n\alpha)} \tag{11.65}$$

where R is the radius of the sphere, and α is defined by

$$\alpha = \ln\left(1 + \frac{z}{R} + \sqrt{\frac{z^2}{R^2} + 2\frac{z}{R}}\right)\,. \tag{11.66}$$

One has to keep in mind that capacitance of a parallel plate capacitor is a nonlinear function of the separation. Using a voltage divider one can circumvent this problem.

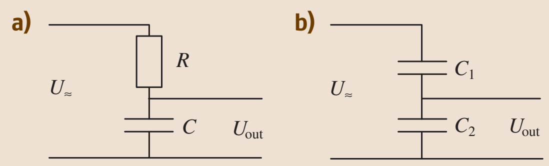

Fig. 11.32a,b Measuring the capacitance. The *left side*, **(a)**, shows a low pass filter, the *right side*, **(b)**, shows a capacitive divider. C (*left*) or C_2 (*right*) are the capacitances under test

Figure 11.32a shows a low pass filter. The output voltage is given by

$$U_{out} = U_{\approx} \frac{\frac{1}{j\omega C}}{R + \frac{1}{j\omega C}} = U_{\approx} \frac{1}{j\omega CR + 1} \cong \frac{U_{\approx}}{j\omega CR} . \quad (11.67)$$

Here C is given by (11.64), ω is the excitation frequency and j is the imaginary unit. The approximate relation in the end is true when $\omega CR \gg 1$. This is equivalent to the statement that C is fed by a current source, since R must be large in this setup. Plugging (11.64) into (11.67) and neglecting the phase information one obtains

$$U_{out} = \frac{U_{\approx} x}{\omega R \varepsilon \varepsilon_0 A} , \quad (11.68)$$

which is linear in the displacement x.

Figure 11.32b shows a capacitive divider. Again the output voltage U_{out} is given by

$$U_{out} = U_{\approx} \frac{C_1}{C_2 + C_1} = U_{\approx} \frac{C_1}{\frac{\varepsilon\varepsilon_0 A}{x} + C_1} . \quad (11.69)$$

If there is a stray capacitance C_s then (11.69) is modified as

$$U_{out} = U_{\approx} \frac{C_1}{\frac{\varepsilon\varepsilon_0 A}{x} + C_s + C_1} . \quad (11.70)$$

Provided $C_s + C_1 \ll C_2$ one has a system which is linear in x. The driving voltage $U_{\approx}$ has to be large (more than 100 V) to have the output voltage in the range of 1 V. The linearity of the readout depends on the capacitance C_1 (Fig. 11.33).

Another idea is to keep the distance constant and to change the relative overlap of the plates (see Fig. 11.31, right side). The capacitance of the moving center plate versus the stationary outer plates becomes

$$C = C_s + 2\frac{\varepsilon\varepsilon_0 bx}{s} , \quad (11.71)$$

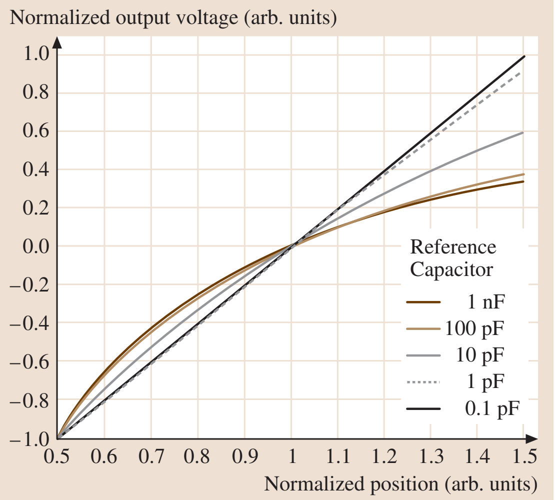

Fig. 11.33 Linearity of the capacitance readout as a function of the reference capacitor

where the variables are defined in Fig. 11.31. The stray capacitance comprises all effects, including the capacitance of the fringe fields. When the length x is comparable to the width b of the plates one can safely assume that the stray capacitance is constant and independent of x. The main disadvantage of this setup is that it is not as easily incorporated in a microfabricated device as the others.

Sensitivity. The capacitance itself is not a measure of the sensitivity, but its derivative is indicative of the signals one can expect. Using the situation described in Fig. 11.31, upper left, and in (11.64) one obtains for the parallel plate capacitor

$$\frac{dC}{dx} = -\frac{\varepsilon\varepsilon_0 A}{x^2} . \quad (11.72)$$

Assuming a plate area A of 20 µm by 40 µm and a separation of 1 µm one obtains a capacitance of 31 fF (neglecting stray capacitance and the capacitance of the connection leads) and a dC/dx of 3.1×10^{-8} F/m = 31 fF/µm. Hence it is of paramount importance to maximize the area between the two contacts and to minimize the distance x. The latter however is far from being trivial. One has to go to the limits of microfabrication to achieve a decent sensitivity.

If the capacitance is measured by the circuit shown in Fig. 11.32 one obtains for the sensitivity

$$\frac{dU_{out}}{U_{\approx}} = \frac{dx}{\omega R \varepsilon \varepsilon_0 A} . \quad (11.73)$$

Using the same value for A as above, setting the reference frequency to 100 kHz, and selecting $R = 1\,G\Omega$, we get the relative change of the output voltage U_{out} to

$$\frac{dU_{out}}{U_{\approx}} = \frac{22.5 \times 10^{-6}}{Å} \times dx . \quad (11.74)$$

A driving voltage of 45 V then translates to a sensitivity of 1 mV/Å. A problem in this setup is the stray capacitances. They are in parallel to the original capacitance and decrease the sensitivity considerably.

Alternatively one could build an oscillator with this capacitance and measure the frequency. RC-oscillators typically have an oscillation frequency of

$$f_{res} \propto \frac{1}{RC} = \frac{x}{R \varepsilon \varepsilon_0 A} . \quad (11.75)$$

Again the resistance R must be of the order of $1\,G\Omega$, when stray capacitances C_s are neglected. However C_s is of the order of 1 pF. Therefore one gets $R = 10\,M\Omega$. Using these values the sensitivity becomes

$$d f_{res} = \frac{C\,dx}{R\,(C + C_s)^2\,x} \approx \frac{0.1\,Hz}{Å}\,dx . \quad (11.76)$$

The bad thing is that the stray capacitances have made the signal nonlinear again. The linearized setup in Fig. 11.31 has a sensitivity of

$$\frac{dC}{dx} = 2\frac{\varepsilon \varepsilon_0 b}{s} . \quad (11.77)$$

Substituting typical values, $b = 10\,\mu m$, $s = 1\,\mu m$ one gets $dC/dx = 1.8 \times 10^{-10}$ F/m. It is noteworthy that the sensitivity remains constant for scaled devices.

Implementations. The readout of the capacitance can be done in different ways [11.123, 124]. All include an alternating current or voltage with frequencies in the 100 kHz to the 100 MHz range. One possibility is to build a tuned circuit with the capacitance of the cantilever determining the frequency. The resonance frequency of a high quality Q tuned circuit is

$$\omega_0 = (LC)^{-1/2} . \quad (11.78)$$

where L is the inductance of the circuit. The capacitance C includes not only the sensor capacitance but also the capacitance of the leads. The precision of a frequency measurement is mainly determined by the ratio of L and C

$$Q = \left(\frac{L}{C}\right)^{1/2} \frac{1}{R} . \quad (11.79)$$

Here R symbolizes the losses in the circuit. The higher the quality the more precise the frequency measurement. For instance a frequency of 100 MHz and a capacitance of 1 pF gives an inductance of 250 μH. The quality becomes then 2.5×10^8. This value is an upper limit, since losses are usually too high.

Using a value of $dC/dx = 31$ fF/μm one gets $\Delta C/Å = 3.1$ aF/Å. With a capacitance of 1 pF one gets

$$\frac{\Delta\omega}{\omega} = \frac{1}{2}\frac{\Delta C}{C} ,$$
$$\Delta\omega = 100\,MHz \times \frac{1}{2}\frac{3.1\,aF}{1\,pF} = 155\,Hz . \quad (11.80)$$

This is the frequency shift for 1 Å deflection. The calculation shows, that this is a measurable quantity. The quality also indicates that there is no physical reason why this scheme should not work.

11.3.3 Combinations for 3-D-Force Measurements

Three dimensional force measurements are essential if one wants to know all the details of the interaction between the tip and the cantilever. The straightforward attempt to measure three forces is complicated, since force sensors such as interferometers or capacitive sensors need a minimal detection volume, which often is too large. The second problem is that the force-sensing tip has to be held by some means. This implies that one of the three Cartesian axes is stiffer than the others.

However by the combination of different sensors one can achieve this goal. Straight cantilevers are employed for these measurements, because they can be handled analytically. The key observation is, that the optical lever method does not determine the position of the end of the cantilever. It measures the orientation. In the previous sections, one has always made use of the fact, that for a force along one of the orthogonal symmetry directions at the end of the cantilever (normal force, lateral force, force along the cantilever beam axis) there is a one to one correspondence of the tilt angle and the deflection. The problem is, that the force along the cantilever beam axis and the normal force create a deflection in the same direction. Hence what is called the normal force component is actually a mixture of two forces. The deflection of the cantilever is the third quantity, which is not considered in most of the AFMs. A fiber optic interferometer in parallel to the optical lever measures the deflection. Three measured quantities then allow the separation of the three orthonormal force directions, as is evident from (11.27) and (11.33) [11.12–16].

Alternatively one can put the fast scanning direction along the axis of the cantilever. Forward and backward scans then exert opposite forces F_x. If the piezo movement is linearized, both force components in AFM based on the optical lever detection can be determined. In this case, the normal force is simply the average of the forces in the forward and backward direction. The force, F_x, is the difference of the forces measured in forward and backward direction.

11.3.4 Scanning and Control Systems

Almost all SPMs use piezo translators to scan the tip or the sample. Even the first STM [11.1, 103] and some of the predecessor instruments [11.153, 154] used them. Other materials or setups for nano-positioning have been proposed, but were not successful [11.155, 156].

Piezo Tubes

A popular solution is tube scanners (Fig. 11.34). They are now widely used in SPMs due to their simplicity and their small size [11.133, 157]. The outer electrode is segmented in four equal sectors of 90 degrees. Opposite sectors are driven by signals of the same magnitude, but opposite sign. This gives, through bending, a two-dimensional movement on, approximately, a sphere. The inner electrode is normally driven by the z signal. It is possible, however, to use only the outer electrodes for scanning and for the z-movement. The main drawback of applying the z-signal to the outer electrodes is, that the applied voltage is the sum of both the x- or y-movement and the z-movement. Hence a larger scan size effectively reduces the available range for the z-control.

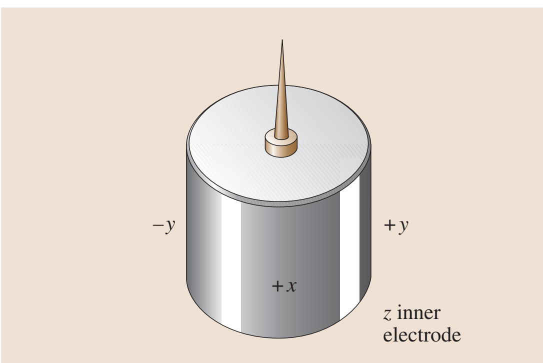

Fig. 11.34 Schematic drawing of a piezoelectric tube scanner. The piezo ceramic is molded into a tube form. The outer electrode is separated into four segments and connected to the scanning voltages. The z-voltage is applied to the inner electrode

Piezo Effect

An electric field applied across a piezoelectric material causes a change in the crystal structure, with expansion in some directions and contraction in others. Also, a net volume change occurs [11.132]. Many SPMs use the transverse piezo electric effect, where the applied electric field $\boldsymbol{E}$ is perpendicular to the expansion/contraction direction.

$$\Delta L = L\,(\boldsymbol{E}\cdot\boldsymbol{n})\,d_{31} = L\frac{V}{t}d_{31}\,, \qquad (11.81)$$

where d_{31} is the transverse piezoelectric constant, V is the applied voltage, t is the thickness of the piezo slab or the distance between the electrodes where the voltage is applied, L is the free length of the piezo slab, and $\boldsymbol{n}$ is the direction of polarization. Piezo translators based on the transverse piezoelectric effect have a wide range of sensitivities, limited mainly by mechanical stability and breakdown voltage.

Scan Range

The calculation of the scanning range of a piezotube is difficult [11.157–159]. The bending of the tube depends on the electric fields and the nonuniform strain induced. A finite element calculation where the piezo tube was divided into 218 identical elements was used [11.158] to calculate the deflection. On each node the mechanical stress, stiffness, strain and piezoelectric stress was calculated when a voltage was applied on one electrode. The results were found to be linear on the first iteration and higher-order corrections were very small even for large electrode voltages. It was found that to first order the x- and z-movement of the tube could be reasonably well approximated by assuming that the piezo tube is a segment of a torus. Using this model one obtains

$$\mathrm{d}x = (V_+ - V_-)\,|d_{31}|\,\frac{L^2}{2t\,\mathrm{d}}\,, \qquad (11.82)$$

$$\mathrm{d}z = (V_+ + V_- - 2V_z)\,|d_{31}|\,\frac{L}{2t}\,, \qquad (11.83)$$

where $|d_{31}|$ is the coefficient of the transversal piezoelectric effect, L is tube's free length, t is tube's wall thickness, d is tube's diameter, V_+ is voltage on positive outer electrode while V_- is voltage of the opposite quadrant negative electrode, and V_z is voltage of the inner electrode.

The cantilever or sample mounted on the piezotube has an additional lateral movement because the point of

measurement is not in the end plane of the piezotube. The additional lateral displacement of the end of the tip is $\ell \sin\varphi \approx \ell\varphi$, where ℓ is the tip length and φ is the deflection angle of the end surface. Assuming that the sample or cantilever are always perpendicular to the end of the walls of the tube and calculating with the torus model one gets for the angle

$$\varphi = \frac{L}{R} = \frac{2\,\mathrm{d}x}{L}\,, \tag{11.84}$$

where R is the radius of curvature the piezo tube. Using the result of (11.84) one obtains for the additional x-movement

$$\begin{aligned}\mathrm{d}x_{\mathrm{add}} &= \ell\varphi = \frac{2\,\mathrm{d}x\ell}{L}\\ &= (V_+ - V_-)\,|d_{31}|\,\frac{\ell L}{td}\end{aligned} \tag{11.85}$$

and for the additional z-movement due to the x-movement

$$\begin{aligned}\mathrm{d}z_{\mathrm{add}} &= \ell - \ell\cos\varphi = \frac{\ell\varphi^2}{2} = \frac{2\ell\,(\mathrm{d}x)^2}{L^2}\\ &= (V_+ - V_-)^2\,|d_{31}|^2\,\frac{\ell L^2}{2t^2d^2}\,.\end{aligned} \tag{11.86}$$

Carr [11.158] assumed for his finite element calculations that the top of the tube was completely free to move and, as a consequence, the top surface was distorted, leading to a deflection angle about half that of the geometrical model. Depending on the attachment of the sample or the cantilever this distortion may be smaller, leading to a deflection angle in-between that of the geometrical model and the one of the finite element calculation.

Nonlinearities and Creep

Piezo materials with a high conversion ratio, i. e. a large d_{31} or small electrode separations, with large scanning ranges are hampered by substantial hysteresis resulting in a deviation from linearity by more than 10%. The sensitivity of the piezo ceramic material (mechanical displacement divided by driving voltage) decreases with reduced scanning range, whereas the hysteresis is reduced. A careful selection of the material for the piezo scanners, the design of the scanners, and of the operating conditions is necessary to get optimum performance.

Passive Linearization: Calculation. The analysis of images affected by piezo nonlinearities [11.160–163] shows that the dominant term is

$$x = AV + BV^2\,, \tag{11.87}$$

where x is the excursion of the piezo, V the applied voltage and A and B two coefficients describing the sensitivity of the material. Equation (11.87) holds for scanning from $V = 0$ to large V. For the reverse direction the equation becomes

$$x = \tilde{A}V - \tilde{B}\,(V - V_{\mathrm{max}})^2\,, \tag{11.88}$$

where $\tilde{A}$ and $\tilde{B}$ are the coefficients for the back scan and V_{max} is the applied voltage at the turning point. Both equations demonstrate that the true x-travel is small at the beginning of the scan and becomes larger towards the end. Therefore images are stretched at the beginning and compressed at the end.

Similar equations hold for the slow scan direction. The coefficients, however, are different. The combined action causes a greatly distorted image. This distortion can be calculated. The data acquisition systems record the signal as a function of V. However the data is measured as a function of x. Therefore we have to distribute the x-values evenly across the image this can be done by inverting an approximation of (11.87). First we write

$$x = AV\left(1 - \frac{B}{A}V\right)\,. \tag{11.89}$$

For $B \ll A$ we can approximate

$$V = \frac{x}{A}\,. \tag{11.90}$$

We now substitute (11.90) into the nonlinear term of (11.89). This gives

$$\begin{aligned}x &= AV\left(1 + \frac{Bx}{A^2}\right)\,,\\ V &= \frac{x}{A}\,\frac{1}{(1 + Bx/A^2)} \approx \frac{x}{A}\left(1 - \frac{Bx}{A^2}\right)\,.\end{aligned} \tag{11.91}$$

Hence an equation of the type

$$\begin{aligned}&x_{\mathrm{true}} = x\,(\alpha - \beta x/x_{\mathrm{max}})\\ &\text{with}\quad 1 = \alpha - \beta\end{aligned} \tag{11.92}$$

takes out the distortion of an image. α and β are dependent on the scan range, the scan speed and on the scan history and have to be determined with exactly the same settings as for the measurement. x_{max} is the maximal scanning range. The condition for α and β guarantees that the image is transformed onto itself.

Similar equations as the empirical one shown above (11.92) can be derived by analyzing the movements of domain walls in piezo ceramics.

Passive Linearization: Measuring the Position. An alternative strategy is to measure the position of the piezo translators. Several possibilities exist.

1. The interferometers described above can be used to measure the elongation of the piezo elongation. The fiber optic interferometer is especially easy to implement. The coherence length of the laser only limits the measurement range. However the signal is of a periodic nature. Hence a direct use of the signal in a feedback circuit for the position is not possible. However as a measurement tool and, especially, as a calibration tool the interferometer is without competition. The wavelength of the light, for instance in a HeNe laser, is so well defined that the precision of the other components determines the error of the calibration or measurement.
2. The movement of the light spot on the quadrant detector can be used to measure the position of a piezo [11.164]. The output current changes by $0.5\,\mathrm{A/cm} \times P(\mathrm{W})/R(\mathrm{cm})$. Typical values ($P = 1\,\mathrm{mW}$, $R = 0.001\,\mathrm{cm}$) give $0.5\,\mathrm{A/cm}$. The noise limit is typically $0.15\,\mathrm{nm} \times \sqrt{\Delta f(\mathrm{Hz})/H(\mathrm{W/cm^2})}$. Again this means that the laser beam above would have a 0.1 nm noise limitation for a bandwidth of 21 Hz. The advantage of this method is that, in principle, one can linearize two axes with only one detector.
3. A knife-edge blocking part of a light beam incident on a photodiode can be used to measure the position of the piezo. This technique, commonly used in optical shear force detection [11.75, 165], has a sensitivity of better than 0.1 nm.
4. The capacitive detection [11.166, 167] of the cantilever deflection can be applied to the measurement of the piezo elongation. Equations (11.64) to (11.79) apply to the problem. This technique is used in some commercial instruments. The difficulties lie in the avoidance of fringe effects at the borders of the two plates. While conceptually simple, one needs the latest technology in surface preparation to get a decent linearity. The electronic circuits used for the readout are often proprietary.
5. Linear Variable Differential Transformers (LVDT) are a convenient means to measure positions down to 1 nm. They can be used together with a solid state joint setup, as often used for large scan range stages. Unlike the capacitive detection there are few difficulties in implementation. The sensors and the detection circuits LVDTs are available commercially.
6. A popular measurement technique is the use of strain gauges. They are especially sensitive when mounted on a solid state joint where the curvature is maximal. The resolution depends mainly on the induced curvature. A precision of 1 nm is attainable. The signals are low – a Wheatstone bridge is needed for the readout.

Active Linearization. Active linearization is done with feedback systems. Sensors need to be monotonic. Hence all the systems described above, with the exception of the interferometers are suitable. The most common solutions include the strain gauge approach, the capacitance measurement or the LVDT, which are all electronic solutions. Optical detection systems have the disadvantage that the intensity enters into the calibration.

Alternative Scanning Systems

The first STMs were based on piezo tripods [11.1]. The piezo tripod (Fig. 11.35) is an intuitive way to generate the three dimensional movement of a tip attached to its center. However, to get a suitable stability and scanning range, the tripod needs to be fairly large (about 50 mm). Some instruments use piezo stacks instead of monolithic piezoactuators. They are arranged in the tripod arrangement. Piezo stacks are thin layers of piezoactive materials glued together to form a device with up to 200 μm of actuation range. Preloading with a suitable metal casing reduces the nonlinearity.

If one tries to construct a homebuilt scanning system, the use of linearized scanning tables is recommended. They are built around solid state joints and actuated by piezo stacks. The joints guarantee that the movement is parallel with little deviation from the predefined scanning plane. Due to the construction it is easy to add measurement devices such as capacitive sensors, LVDTs

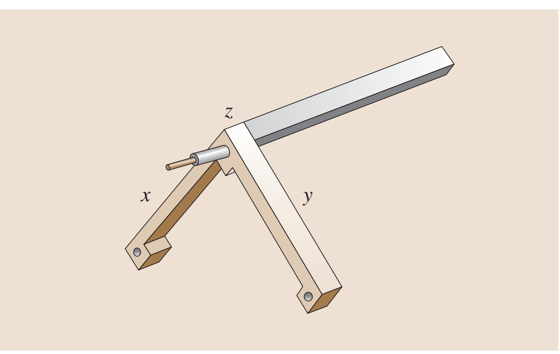

Fig. 11.35 An alternative type of piezo scanners: the tripod

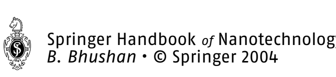

or strain gauges which are essential for a closed loop linearization. Two-dimensional tables can be bought from several manufacturers. They have a linearity of better than 0.1% and a noise level of 10^{-4} to 10^{-5} of the maximal scanning range.

Control Systems

Basics. The electronics and software play an important role in the optimal performance of an SPM. Control electronics and software are supplied with commercial SPMs. Control electronic systems can use either analog or digital feedback. While digital feedback offers greater flexibility and the ease of configuration, analog feedback circuits might be better suited for ultralow noise operation. We will describe here the basic setups for AFMs.

Figure 11.36 shows a block schematic of a typical AFM feedback loop. The signal from the force transducer is fed into the feedback loop consisting mainly of a subtraction stage to get an error signal and an integrator. The gain of the integrator (high gain corresponds to short integration times) is set as high as possible without generating more than 1% overshoot. High gain minimizes the error margin of the current and forces the tip to follow the contours of constant density of states as well as possible. This operating mode is known as Constant Force Mode. A high voltage amplifier amplifies the outputs of the integrator. As AFMs using piezotubes usually require ±150 V at the output, the output of the integrator needs to be amplified by a high voltage amplifier.

In order to scan the sample, additional voltages at high tension are required to drive the piezo. For example, with a tube scanner, four scanning voltages are required, namely $+V_x$, $-V_x$, $+V_y$ and $-V_y$. The x- and y-scanning voltages are generated in a scan generator (analog or computer controlled). Both voltages are input to the two respective power amplifiers. Two inverting amplifiers generate the input voltages for the other two power amplifiers. The topography of the sample surface is determined by recording the input-voltage to the high voltage amplifier for the z-channel as a function of x and y (Constant Force Mode).

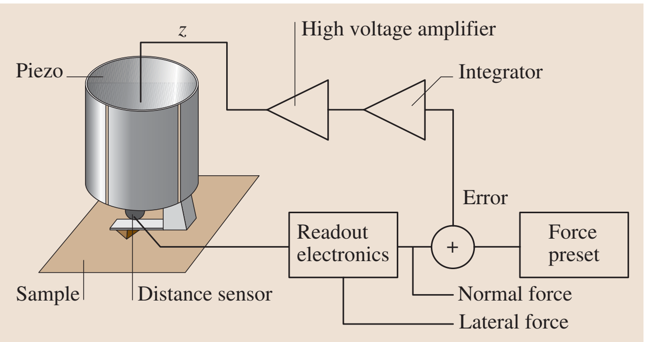

Fig. 11.36 Block schematic of the feedback control loop of an AFM

Another operating mode is the Variable Force Mode. The gain in the feedback loop is lowered and the scanning speed increased such that the force on the cantilever is no longer constant. Here the force is recorded as a function of x and y.

Force Spectroscopy. Four modes of spectroscopic imaging are in common use with force microscopes: measuring lateral forces, $\partial F/\partial z$, $\partial F/\partial x$ spatially resolved, and measuring force versus distance curves. Lateral forces can be measured by detecting the deflection of a cantilever in a direction orthogonal to the normal direction. The optical lever deflection method most easily does this. Lateral force measurements give indications of adhesion forces between the tip and the sample.

$\partial F/\partial z$ measurements probe the local elasticity of the sample surface. In many cases the measured quantity originates from a volume of a few cubic nanometers. The $\partial F/\partial z$ or local stiffness signal is proportional to Young's modulus, as far as one can define this quantity. Local stiffness is measured by vibrating the cantilever by a small amount in the z-direction. The expected signal for very stiff samples is zero: for very soft samples one gets, independent of the stiffness, also a constant signal. This signal is again zero for the optical lever deflection and equal to the driving amplitude for interferometeric measurements. The best sensitivity is obtained when the compliance of the cantilever matches the stiffness of the sample.

A third spectroscopic quantity is the lateral stiffness. It is measured by applying a small modulation in the x-direction on the cantilever. The signal is again optimal when the lateral compliance of the cantilever matches the lateral stiffness of the sample. The lateral stiffness is, in turn, related to the shear modulus of the sample.

Detailed information on the interaction of the tip and the sample can be gained by measuring force versus distance curves. It is necessary to have cantilevers with high enough compliance to avoid instabilities due to the attractive forces on the sample.

Using the Control Electronics as a Two-Dimensional Measurement Tool. Usually the control electronics of an AFM is used to control the x- and y-piezo signals while several data acquisition channels record the po-

Springer Handbook of Nanotechnology

sition dependent signals. The control electronics can be used in another way: it can be viewed as a two-dimensional function generator. What is normally the x- and y-signal can be used to control two independent variables of an experiment. The control logic of the AFM then ensures that the available parameter space is systematically probed at equally spaced points. An example is friction force curves measured along a line across a step on graphite.

Figure 11.37 shows the connections. The z-piezo is connected as usual, like the x-piezo. However the y-output is used to command the desired input parameter. The offset of the y-channel determines the position of the tip on the sample surface, together with the x-channel.

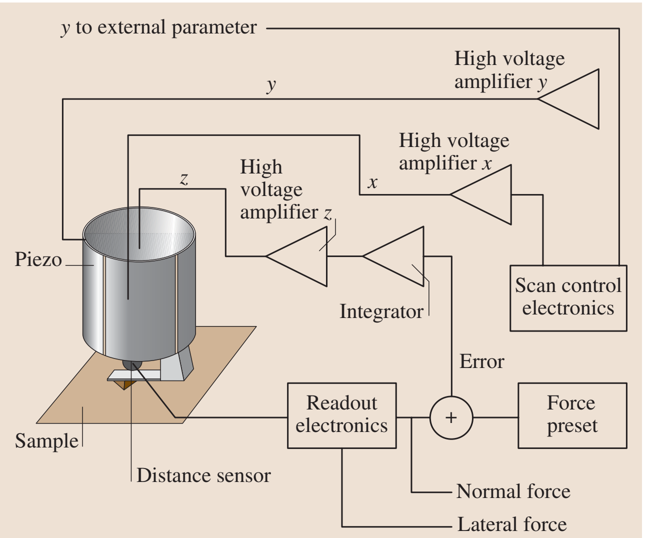

Fig. 11.37 Wiring of an AFM to measure friction force curves along a line

Some Imaging Processing Methods

The visualization and interpretation of images from AFMs is intimately connected to the processing of these images. An ideal AFM is a noise-free device that images a sample with perfect tips of known shape and has perfect linear scanning piezos. In reality, AFMs are not that ideal. The scanning device in AFMs is affected by distortions. The distortions are both linear and nonlinear. Linear distortions mainly result from imperfections in the machining of the piezotranslators causing crosstalk from the Z-piezo to the X- and Y-piezos, and vice versa. Among the linear distortions, there are two kinds which are very important. First, scanning piezos invariably have different sensitivities along the different scan axes due to the variation of the piezo material and uneven sizes of the electrode areas. Second, the same reasons might cause the scanning axes not to be orthogonal. Furthermore, the plane in which the piezoscanner moves for constant height z is hardly ever coincident with the sample plane. Hence, a linear ramp is added to the sample data. This ramp is especially bothersome when the height z is displayed as an intensity map.

The nonlinear distortions are harder to deal with. They can affect AFM data for a variety of reasons. First, piezoelectric ceramics do have a hysteresis loop, much like ferromagnetic materials. The deviations of piezoceramic materials from linearity increase with increasing amplitude of the driving voltage. The mechanical position for one voltage depends on the previously applied voltages to the piezo. Hence, to get the best positional accuracy, one should always approach a point on the sample from the same direction. Another type of nonlinear distortion of the images occurs when the scan frequency approaches the upper frequency limit of the X- and Y-drive amplifiers or the upper frequency limit of the feedback loop (z-component). This distortion, due to feedback loop, can only be minimized by reducing the scan frequency. On the other hand, there is a simple way to reduce distortions due to the X- and Y-piezo drive amplifiers. To keep the system as simple as possible, one normally uses a triangular waveform for driving the scanning piezos. However, triangular waves contain frequency components as multiples of the scan frequency. If the cutoff frequency of the X- and Y-drive electronics or of the feedback loop is too close to the scanning frequency (two or three times the scanning frequency), the triangular drive voltage is rounded off at the turning points. This rounding error causes, first, a distortion of the scan linearity and, second, through phase lags, the projection of part of the backward scan onto the forward scan. This type of distortion can be minimized by carefully selecting the scanning frequency and by using driving voltages for the X- and Y-piezos with waveforms like trapezoidal waves, which are closer to a sine wave. The values measured for X, Y, or Z piezos are affected by noise. The origin of this noise can be either electronic, some disturbances, or a property of the sample surface due to adsorbates. In addition to this incoherent noise, interference with main and other equipment nearby might be present. Depending on the type of noise, one can filter it in the real space or in Fourier space. The most important part of image processing is to visualize the measured data. Typical AFM data sets can consist of many thousands to over a million points per plane. There may be more than one image plane present.

The AFM data represents a topography in various data spaces.

Most commercial data acquisition systems use implicitly some kind of data processing. Since the original data is commonly subject to slopes on the surface, most programs use some kind of slope correction. The least disturbing way is to substrate a plane $z(x, y) = Ax + By + C$ from the data. The coefficients are determined by fitting $z(x, y)$ to the data. Another operation is to subtract a second order function such as $z(x, y) = Ax^2 + By^2 + Cxy + Dx + Ey + F$. Again, the parameters are determined with a fit. This function is appropriate for almost planar data, where the nonlinearity of the piezos caused such a distortion.

In the image processing software from Digital Instruments, up to three operations are performed on the raw data. First, a zero-order flatten is applied. The flatten operation is used to eliminate image bow in the slow scan direction (caused by a physical bow in the instrument itself), slope in the slow scan direction, bands in the image (caused by differences in the scan height from one scan line to the next). The flattening operation takes each scan line and subtracts the average value of the height along each scan line from each point in that scan line. This brings each scan line to the same height. Next, a first-order plane-fit is applied in the fast scan direction. The plane-fit operation is used to eliminate bow and slope in the fast scan direction. The plane-fit operation calculated a best-fit plane for the image and subtracts it from the image. This plane has a constant non-zero slope in the fast scan direction. In some cases, a higher-order polynomial "plane" may be required. Depending upon the quality of the raw data, the flattening operation and/or the planefit operation may not be required at all.

12. Probes in Scanning Microscopies

Scanning probe microscopy (SPM) provides nanometer-scale mapping of numerous sample properties in essentially any environment. This unique combination of high resolution and broad applicability has lead to the application of SPM to many areas of science and technology, especially those interested in the structure and properties of materials at the nanometer scale. SPM images are generated through measurements of a tip-sample interaction. A well-characterized tip is the key element to data interpretation and is typically the limiting factor.

Commercially available atomic force microscopy (AFM) tips, integrated with force sensing cantilevers, are microfabricated from silicon and silicon nitride by lithographic and anisotropic etching techniques. The performance of these tips can be characterized by imaging nanometer-scale standards of known dimension, and the resolution is found to roughly correspond to the tip radius of curvature, the tip aspect ratio, and the sample height. Although silicon and silicon nitride tips have a somewhat large radius of curvature, low aspect ratio, and limited lifetime due to wear, the widespread use of AFM today is due in large part to the broad availability of these tips. In some special cases, small asperities on the tip can provide resolution much higher than the tip radius of curvature for low-Z samples such as crystal surfaces and ordered protein arrays.

Several strategies have been developed to improve AFM tip performance. Oxide sharpening improves tip sharpness and enhances tip asperities. For high-aspect-ratio samples such as integrated circuits, silicon AFM tips can be modified by focused ion beam (FIB) milling. FIB tips reach three-degree cone angles over lengths of several microns and can be fabricated at arbitrary angles. Other high resolution and high-aspect-ratio tips are produced by electron beam deposition (EBD) in which a carbon spike is deposited onto the tip apex from the background gases in an electron microscope. Finally, carbon nanotubes have been employed as AFM tips. Their nanometer-scale diameter, long length, high stiffness, and elastic buckling properties make carbon nanotubes possibly the ultimate tip material for AFM. Nanotubes can be manually attached to silicon or silicon nitride AFM tips or "grown" onto tips by chemical vapor deposition (CVD), which should soon make them widely available. In scanning tunneling microscopy (STM), the electron tunneling signal decays exponentially with tip-sample separation, so that in principle only the last few atoms contribute to the signal. STM tips are, therefore, not as sensitive to the nanoscale tip geometry and can be made by simple mechanical cutting or electrochemical etching of metal wires. In choosing tip materials, one prefers hard, stiff metals that will not oxidize or corrode in the imaging environment.

References 383

In scanning probe microscopy (SPM), an image is created by raster scanning a sharp probe tip over a sample and measuring some highly localized tip-sample interaction as a function of position. SPMs are based on several interactions, the major types including scanning tunneling microscopy (STM), which measures an electronic tunneling current; atomic force microscopy (AFM), which measures force interactions; and near-field scan-

ning optical microscopy (NSOM), which measures local optical properties by exploiting near-field effects (Fig. 12.1). These methods allow the characterization of many properties (structural, mechanical, electronic, optical) on essentially any material (metals, semiconductors, insulators, biomolecules) and in essentially any environment (vacuum, liquid, or ambient air conditions). The unique combination of nanoscale resolution, previously the domain of electron microscopy, *and broad applicability* has led to the proliferation of SPM into virtually all areas of nanometer-scale science and technology.

Several enabling technologies have been developed for SPM, or borrowed from other techniques. Piezoelectric tube scanners allow accurate, sub-angstrom positioning of the tip or sample in three dimensions. Optical deflection systems and microfabricated cantilevers can detect forces in AFM down to the picoNewton range. Sensitive electronics can measure STM currents less than 1 picoamp. High transmission fiber optics and sensitive photodetectors can manipulate and detect small optical signals of NSOM. Environmental control has been developed to allow SPM imaging in UHV, cryogenic temperatures, at elevated temperatures, and in fluids. Vibration and drift have been controlled such that a probe tip can be held over a single molecule for hours of observation. Microfabrication techniques have been developed for the mass production of probe tips, making SPMs commercially available and allowing the development of many new SPM modes and combinations with other characterization methods. However, of all this SPM development over the past 20 years, what has received the least attention is perhaps the most important aspect: the probe tip.

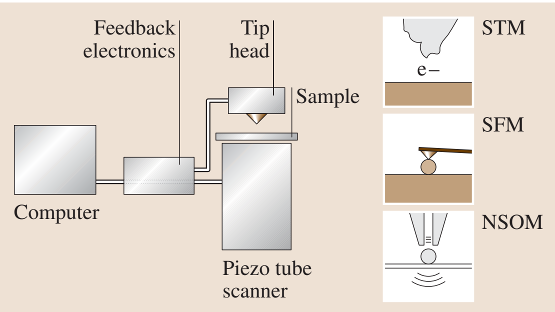

Fig. 12.1 A schematic of the components of a scanning probe microscope and the three types of signals observed: STM senses electron tunneling currents, AFM measures forces, and NSOM measures near-field optical properties via a sub-wavelength aperture

Interactions measured in SPMs occur at the tip-sample interface, which can range in size from a single atom to tens of nanometers. The size, shape, surface chemistry, electronic and mechanical properties of the tip apex will directly influence the data signal and the interpretation of the image. Clearly, the better characterized the tip the more useful the image information. In this chapter, the fabrication and performance of AFM and STM probes will be described.

12.1 Atomic Force Microscopy

AFM is the most widely used form of SPM, since it requires neither an electrically conductive sample, as in STM, nor an optically transparent sample or substrate, as in most NSOMs. Basic AFM modes measure the topography of a sample with the only requirement being that the sample is deposited on a flat surface and rigid enough to withstand imaging. Since AFM can measure a variety of forces, including van der Waals forces, electrostatic forces, magnetic forces, adhesion forces and friction forces, specialized modes of AFM can characterize the electrical, mechanical, and chemical properties of a sample in addition to its topography.

12.1.1 Principles of Operation

In AFM, a probe tip is integrated with a microfabricated force-sensing cantilever. A variety of silicon and silicon nitride cantilevers are commercially available with micron-scale dimensions, spring constants ranging from 0.01 to 100 N/m, and resonant frequencies ranging from 5 kHz to over 300 kHz. The cantilever deflection is detected by optical beam deflection, as illustrated in Fig. 12.2. A laser beam bounces off the back of the cantilever and is centered on a split photodiode. Cantilever deflections areproportional to the difference signal $V_A - V_B$. Sub-angstrom deflections can be deflected and, therefore, forces down to tens of picoNewtons can be measured. A more recently developed method of cantilever deflection measurement is through a piezoelectric layer on the cantilever that registers a voltage upon deflection [12.1].

A piezoelectric scanner rasters the sample under the tip while the forces are measured through deflections of the cantilever. To achieve more controlled imaging con-

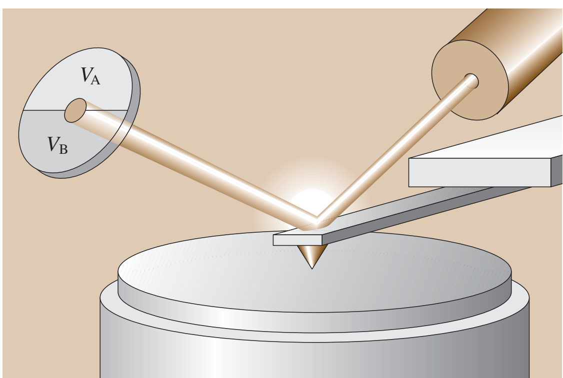

Fig. 12.2 An illustration of the optical beam deflection system that detects cantilever motion in the AFM. The voltage signal $V_A - V_B$ is proportional to the deflection

ditions, a feedback loop monitors the tip-sample force and adjusts the sample Z-position to hold the force constant. The topographic image of the sample is then taken from the sample Z-position data. The mode described is called contact mode, in which the tip is deflected by the sample due to repulsive forces, or "contact". It is generally only used for flat samples that can withstand lateral forces during scanning. To minimize lateral forces and sample damage, two AC modes have been developed. In these, the cantilever is driven into AC oscillation near its resonant frequency (tens to hundreds of kHz) with amplitudes of 5 to tens of s. When the tip approaches the sample, the oscillation is damped, and the reduced amplitude is the feedback signal, rather than the DC deflection. Again, topography is taken from the varying Z-position of the sample required to keep the tip oscillation amplitude constant. The two AC modes differ only in the nature of the interaction. In intermittent contact mode, also called tapping mode, the tip contacts the sample on each cycle, so the amplitude is reduced by ionic repulsion as in contact mode. In non-contact mode, long-range van der Waals forces reduce the amplitude by effectively shifting the spring constant experienced by the tip and changing its resonant frequency.

12.1.2 Standard Probe Tips

In early AFM work, cantilevers were made by hand from thin metal foils or small metal wires. Tips were created by gluing diamond fragments to the foil cantilevers or electrochemically etching the wires to a sharp point. Since these methods were labor intensive and not highly reproducible, they were not amenable to large-scale production. To address this problem, and the need for smaller cantilevers with higher resonant frequencies, batch fabrication techniques were developed (see Fig. 12.3). Building on existing methods to batch fabricate Si_3N_4 cantilevers, *Albrecht* et al. [12.2] etched an array of small square openings in an SiO_2 mask layer over a (100) silicon surface. The exposed square (100) regions were etched with KOH, an anisotropic etchant that terminates at the (111) planes, thus creating pyramidal etch pits in the silicon surface. The etch pit mask was then removed and another was applied to define the cantilever shapes with the pyramidal etch pits at the end. The Si wafer was then coated with a low stress Si_3N_4 layer by LPCVD. The Si_3N_4 fills the etch pit, using it as a mold to create a pyramidal tip. The silicon was later removed by etching to free the cantilevers and tips. Further steps resulting in the attachment of the cantilever to a macroscopic piece of glass are not described here. The resulting pyramidal tips were highly symmetric and had a tip radius of less than 30 nm, as determined by scanning electron microscopy (SEM). This procedure has likely not changed significantly, since commercially available Si_3N_4 tips are still specified to have a curvature radius of 30 nm.

Wolter et al. [12.3] developed methods to batch fabricate single-crystal Si cantilevers with integrated tips. Microfabricated Si cantilevers were first prepared using previously described methods, and a small mask was formed at the end of the cantilever. The Si around the mask was etched by KOH, so that the mask was under cut. This resulted in a pyramidal silicon tip under the mask, which was then removed. Again, this partial description of the full procedure only describes tip fabrication. With some refinements the silicon tips were made

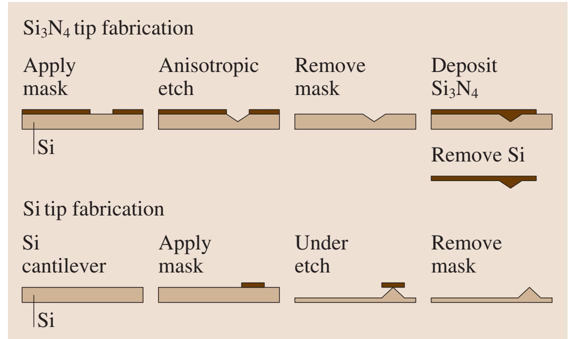

Fig. 12.3 A schematic overview of the fabrication of Si and Si_3N_4 tip fabrication as described in the text

 © Springer 2004

in high yield with curvature radii of less than 10 nm. Si tips are sharper than Si_3N_4 tips, because they are directly formed by the anisotropic etch in single-crystal Si, rather than using an etch pit as a mask for deposited material. Commercially available silicon probes are made by similar refined techniques and provide a curvature typical radius of < 10 nm.

12.1.3 Probe Tip Performance

In atomic force microscopy the question of resolution can be a rather complicated issue. As an initial approximation, resolution is often considered strictly in geometrical terms that assume rigid tip-sample contact. The topographical image of a feature is broadened or narrowed by the size of the probe tip, so the resolution is approximately the width of the tip. Therefore, the resolution of AFM with standard commercially available tips is on the order of 5 to 10 nm. *Bustamante* and *Keller* [12.4] carried the geometrical model further by drawing an analogy to resolution in optical systems. Consider two sharp spikes separated by a distance d to be point objects imaged by AFM (see Fig. 12.4). Assume the tip has a parabolic shape with an end radius R. The tip-broadened image of these spikes will appear as inverted parabolas. There will be a small depression between the images of depth Δz. The two spikes are considered "resolved" if Δz is larger than the instrumental noise in the z direction. Defined in this manner, the resolution d, the minimum separation at which the spikes are resolved, is

$$d = 2\sqrt{2R\,(\Delta z)}\,, \qquad (12.1)$$

where one must enter a minimal detectable depression for the instrument (Δz) to determine the resolution. So for a silicon tip with radius 5 nm and a minimum detectable Δz of 0.5 nm, the resolution is about 4.5 nm. However, the above model assumes the spikes are of equal height. *Bustamante* and *Keller* [12.4] went on to point out that if the height of the spikes is not equal, the resolution will be affected. Assuming a height difference of Δh, the resolution becomes:

$$d = \sqrt{2R}\left(\sqrt{\Delta z} + \sqrt{\Delta z + \Delta h}\right)\,. \qquad (12.2)$$

For a pair of spikes with a 2 nm height difference, the resolution drops to 7.2 nm for a 5 nm tip and 0.5 nm minimum detectable Δz. While geometrical considerations are a good starting point for defining resolution, they ignore factors such as the possible compression and deformation of the tip and sample. *Vesenka* et al. [12.5] confirmed a similar geometrical resolution model by imaging monodisperse gold nanoparticles with tips characterized by transmission electron microscopy (TEM).

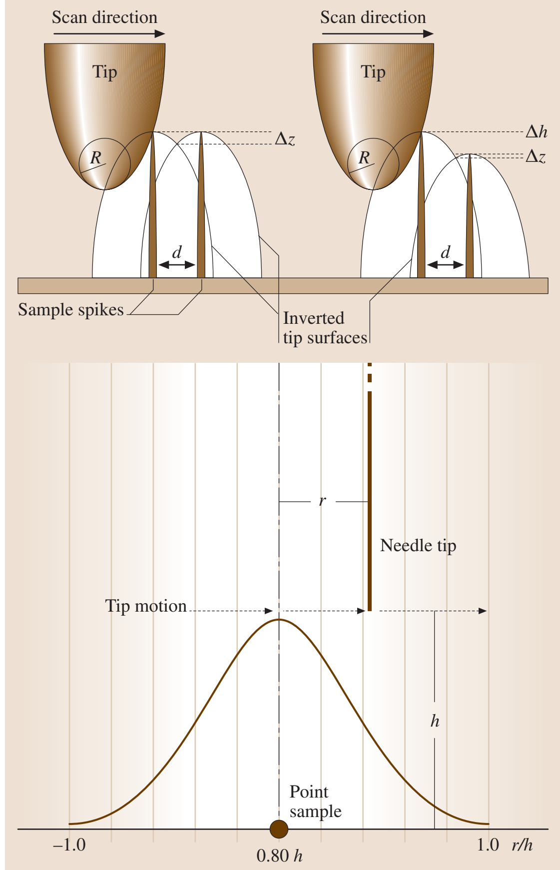

Fig. 12.4 The factors that determine AFM imaging resolution in contact mode (*top*) and noncontact mode (*bottom*), adapted from [12.4]

Noncontact AFM contrast is generated by long-range interactions such as van der Waals forces, so resolution will not simply be determined by geometry because the tip and sample are not in rigid contact. *Bustamante* and *Keller* [12.4] have derived an expression for the resolution in noncontact AFM for an idealized, infinitely thin "line" tip and a point particle as the sample (Fig. 12.4). Noncontact AFM is sensitive to the gradient of long-range forces, so the van der Waals force gradient was calculated as a function of position for the tip

at height h above the surface. If the resolution d is defined as the full width at half maximum of this curve, the resolution is:

$$d = 0.8h\ . \quad (12.3)$$

This shows that even for an ideal geometry, the resolution is fundamentally limited in noncontact mode by the tip-sample separation. Under UHV conditions, the tip-sample separation can be made very small, so atomic resolution is possible on flat, crystalline surfaces. Under ambient conditions, however, the separation must be larger to keep the tip from being trapped in the ambient water layer on the surface. This larger separation can lead to a point where further improvements in tip sharpness do not improve resolution. It has been found that imaging 5 nm gold nanoparticles in noncontact mode with carbon nanotube tips of 2 nm diameter leads to particle widths of 12 nm, larger than the 7 nm width one would expect assuming rigid contact [12.8]. However, in tapping mode operation, the geometrical definition of resolution is relevant, since the tip and sample come into rigid contact. When imaging 5 nm gold particles with 2 nm carbon nanotube tips in tapping mode, the expected 7 nm particle width is obtained [12.9].

The above descriptions of AFM resolution cannot explain the sub-nanometer resolution achieved on crystal surfaces [12.10] and ordered arrays of biomolecules [12.11] in contact mode with commercially available probe tips. Such tips have nominal radii of curvature ranging from 5 nm to 30 nm, an order of magnitude larger than the resolution achieved. A detailed model to explain the high resolution on ordered membrane proteins has been put forth by [12.6]. In this model, the larger part of the silicon nitride tip apex balances the tip-sample interaction through electrostatic forces, while a very small tip asperity interacts with the sample to provide contrast (see Fig. 12.5). This model is supported by measurements at varying salt concentrations to vary the electrostatic interaction strength and the observation of defects in the ordered samples. However, the existence of such asperities has never been confirmed by independent electron microscopy images of the tip. Another model, considered especially applicable to atomic resolution on crystal surfaces, assumes the tip is in contact with a region of the sample much larger than the resolution observed, and that force components matching the periodicity of the sample are transmitted to the tip, resulting in an "averaged" image of the periodic lattice. Regardless of the mechanism, the structures determined are accurate and make this a highly valuable method for membrane proteins. However, this level of

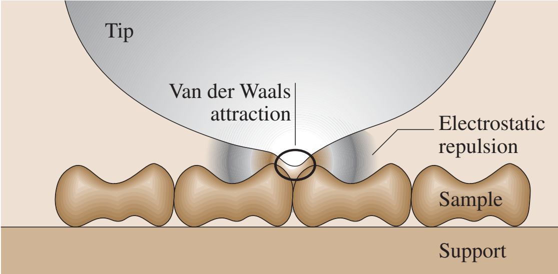

Fig. 12.5 A tip model to explain the high resolution obtained on ordered samples in contact mode, from [12.6]

resolution should not be expected for most biological systems.

12.1.4 Oxide-Sharpened Tips

Both Si and Si_3N_4 tips with increased aspect ratio and reduced tip radius can be fabricated through oxide sharpening of the tip. If a pyramidal or cone-shaped silicon tip is thermally oxidized to SiO_2 at low temperature ($< 1{,}050\,°C$), Si-SiO_2 stress formation reduces the oxidation rate at regions of high curvature. The result is a sharper, higher-aspect-ratio cone of silicon at the high curvature tip apex inside the outer pyramidal layer of SiO_2 (see Fig. 12.6). Etching the SiO_2 layer with HF then leaves tips with aspect ratios up to 10:1 and radii down to 1 nm [12.7], although 5–10 nm is the nominal specification for most commercially available tips. This oxide sharpening technique can also be applied to Si_3N_4 tips by oxidizing the silicon etch pits that are used as molds. As with tip fabrication, oxide sharpening is not quite as effective for Si_3N_4. Si_3N_4 tips were reported to have an

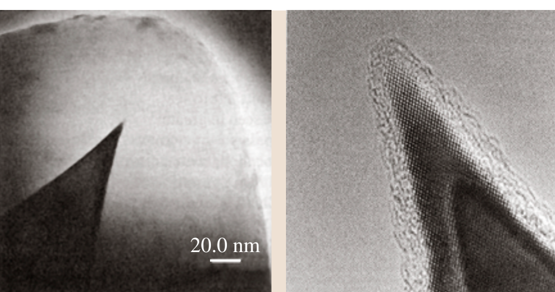

Fig. 12.6 Oxide sharpening of silicon tips. The *left image* shows a sharpened core of silicon in an outer layer of SiO_2. The *right image* is a higher magnification view of such a tip after the SiO_2 is removed. Adapted from [12.7]

11 nm radius of curvature [12.12], while commercially available oxide-sharpened Si_3N_4 tips have a nominal radius of < 20 nm.

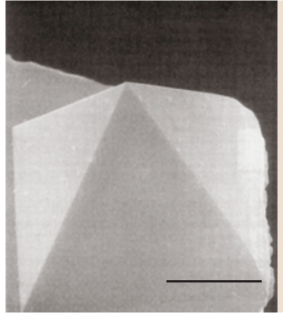
12.1.5 FIB tips

A common AFM application in integrated circuit manufacture and MEMs is to image structures with very steep sidewalls such as trenches. To accurately image these features, one must consider the micron-scale tip structure, rather than the nanometer-scale structure of the tip apex. Since tip fabrication processes rely on anisotropic etchants, the cone half-angles of pyramidal tips are approximately 20 degrees. Images of deep trenches taken with such tips display slanted sidewalls and may not reach the bottom of the trench due to the tip broadening effects. To image such samples more faithfully, high-aspect-ratio tips are fabricated by focused ion beam (FIB) machining a Si tip to produce a sharp spike at the tip apex. Commercially available FIB tips have half cone angles of < 3 degrees over lengths of several microns, yielding aspect ratios of approximately 10:1. The radius of curvature at the tip end is similar to that of the tip before the FIB machining. Another consideration for high-aspect-ratio tips is the tip tilt. To ensure that the pyramidal tip is the lowest part of the tip-cantilever assembly, most AFM designs tilt the cantilever about 15 degrees from parallel. Therefore, even an ideal "line tip" will not give an accurate image of high steep sidewalls, but will produce an image that depends on the scan angle. Due to the versatility of the FIB machining, tips are available with the spikes at an angle to compensate for this effect.

12.1.6 EBD tips

Another method of producing high-aspect-ratio tips for AFM is called electron beam deposition (EBD). First developed for STM tips [12.13, 14], EBD tips were introduced for AFM by focusing an SEM onto the apex of a pyramidal tip arranged so that it pointed along the electron beam axis (see Fig. 12.7). Carbon material was deposited by the dissociation of background gases in the SEM vacuum chamber. *Schiffmann* [12.15] systematically studied the following parameters and how they affected EBD tip geometry:

Deposition time :	0.5 to 8 min
Beam current :	3–300 pA
Beam energy :	1–30 keV
Working distance :	8–48 mm .



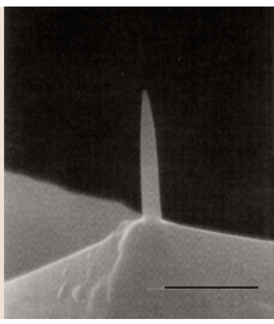


Fig. 12.7 A pyramidal tip before (*left*, 2-µm-scale bar) and after (*right*, 1-µm-scale bar) electron beam deposition, adapted from [12.13]

EBD tips were cylindrical with end radii of 20–40 nm, lengths of 1 to 5 µm, and diameters of 100 to 200 nm. Like FIB tips, EBD tips were found to achieve improved imaging of steep features. By controlling the position of the focused beam, the tip geometry can be further controlled. Tips were fabricated with lengths over 5 µm and aspect ratios greater than 100:1, yet these were too fragile to use as a tip in AFM [12.13].

12.1.7 Carbon Nanotube Tips

Carbon nanotubes are microscopic graphitic cylinders that are nanometers in diameter, yet many microns in length. Single-walled carbon nanotubes (SWNT) consist of single sp^2 hybridized carbon sheets rolled into seamless tubes and have diameters ranging from 0.7 to 3 nm.

Carbon Nanotube Structure

Larger structures called multiwalled carbon nanotubes (MWNT) consist of nested, concentrically arranged SWNT and have diameters ranging from 3 to 50 nm. Figure 12.8 shows a model of nanotube structure, as well as TEM images of a SWNT and a MWNT. The small diameter and high aspect ratio of carbon nanotubes suggests their application as high resolution, high-aspect-ratio AFM probes.

Carbon Nanotube Mechanical Properties

Carbon nanotubes possess exceptional mechanical properties that impact their use as probes. Their lateral stiffness can be approximated from that of a solid elastic rod:

$$k_{lat} = \frac{3\pi Y r^4}{4 l^3} , \tag{12.4}$$

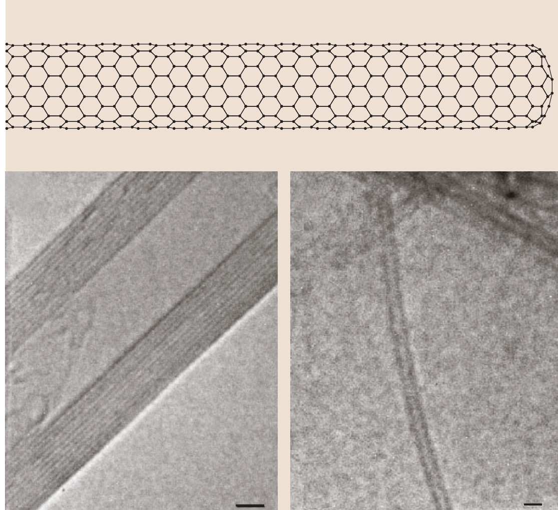

Fig. 12.8 The structure of carbon nanotubes, including TEM images of a MWNT (*left*) and a SWNT (*right*), from [12.16]

where the spring constant k_{lat} represents the restoring force per unit lateral displacement, r is the radius, l is the length, and Y is the Young's modulus (also called the elastic modulus) of the material. For the small diameters and extreme aspect ratios of carbon nanotube tips, the thermal vibrations of the probe tip at room temperature can become sufficient to degrade image resolution. These thermal vibrations can be approximated by equating $\frac{1}{2}k_{\mathrm{B}}T$ of thermal energy to the energy of an oscillating nanotube:

$$\frac{1}{2}k_{\mathrm{B}}T = \frac{1}{2}k_{\mathrm{lat}}a^2 , \qquad (12.5)$$

where k_{B} is Boltzmann's constant, T is the temperature, and a is the vibration amplitude. Substituting for k_{lat} from (12.4) yields:

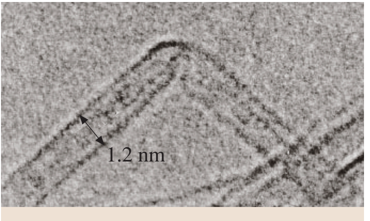
$$a = \sqrt{\frac{4k_{\mathrm{B}}Tl^3}{3\pi Yr^4}} . \qquad (12.6)$$

The strong dependence on radius and length reveals that one must carefully control the tip geometry at this size scale. Equation (12.6) implies that the stiffer the material, i. e., the higher its Young's modulus, the smaller the thermal vibrations and the longer and thinner a tip can be. The Young's moduli of carbon nanotubes have been determined by measurements of the thermal vibration amplitude by TEM [12.18, 19] and by directly measuring the forces required to deflect a pinned carbon nanotube in an AFM [12.20]. These experiments revealed that the Young's modulus of carbon nanotubes is 1–2 TPa, in agreement with theoretical predictions [12.21]. This makes carbon nanotubes the stiffest known material and, therefore, the best for fabricating thin, high-aspect-ratio tips. A more detailed and accurate derivation of the thermal vibration amplitudes was derived for the Young's modulus measurements [12.18, 19].

Carbon nanotubes elastically buckle under large loads, rather than fracture or plastically deform like most materials. Nanotubes were first observed in the buckled state by transmission electron microscopy [12.17], as shown in Fig. 12.9. The first experimental evidence that nanotube buckling is elastic came from the application of nanotubes as probe tips [12.22], described in detail below. A more direct experimental observation of elastic buckling was obtained by deflecting nanotubes pinned to a low friction surface with an AFM tip [12.20]. Both reports found that the buckling force could be approximated with the macroscopic Euler buckling formula for an elastic column:

$$F_{\mathrm{Euler}} = \frac{\pi^3 Yr^4}{4l^2} . \qquad (12.7)$$

The buckling force puts another constraint on the tip length: If the nanotube is too long the buckling force



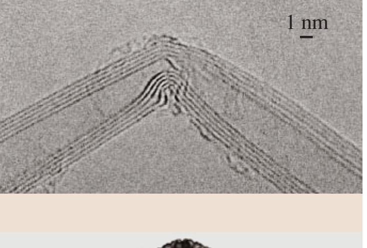


Fig. 12.9 TEM images and a model of a buckled nanotube, adapted from [12.17]

Part B | 12.1

will be too low for stable imaging. The elastic buckling property of carbon nanotubes has significant implications for their use as AFM probes. If a large force is applied to the tip inadvertently, or if the tip encounters a large step in sample height, the nanotube can buckle to the side, then snap back without degraded imaging resolution when the force is removed, making these tips highly robust. No other tip material displays this buckling characteristic.

Manually Assembled Nanotube Probes

The first carbon nanotube AFM probes [12.22] were fabricated by techniques developed for assembling single-nanotube field emission tips [12.23]. This process, illustrated in Fig. 12.10, used purified MWNT material synthesized by the carbon arc procedure. The raw material, which must contain at least a few percent of long nanotubes ($> 10\,\mu m$) by weight, purified by oxidation to approximately 1% of its original mass. A torn edge of the purified material was attached to a micromanipulator by carbon tape and viewed under a high power optical microscope. Individual nanotubes and nanotube bundles were visible as filaments under dark field illumination. A commercially available AFM tip was attached to another micromanipulator opposing the nanotube material. Glue was applied to the tip apex from high vacuum carbon tape supporting the nanotube material. Nanotubes were then manually attached to the tip apex by micromanipulation. As assembled, MWNT tips were often too long for imaging due to thermal vibrations and low buckling forces described in Sect. 12.1.7. Nanotubes tips were shortened by applying 10 V pulses to the tip while it was near a sputtered niobium surface. This process etched ~ 100 nm lengths of nanotube per pulse.

The manually assembled MWNT tips demonstrated several important nanotube tip properties [12.22]. First, the high aspect ratio of the MWNT tips allowed the accurate imaging of trenches in silicon with steep sidewalls, similar to FIB and EBD tips. Second, elastic buckling was observed indirectly through force curves (see Fig. 12.11). Note that as the tip taps the sample, the amplitude drops to zero and a DC deflection is observed, because the nanotube is unbuckled and is essentially rigid. As the tip moves closer, the force on the nanotube eventually exceeds the buckling force. The nanotube buckles, allowing the vibration amplitude to partially recover, and the deflection remains constant. Numeric tip trajectory simulations could only reproduce these force curves if elastic buckling was included in the nanotube response. Finally, the nanotube tips were highly robust. Even after "tip crashes" or hundreds of controlled buckling cycles, the tip retained its resolution and high aspect ratio.

Manual assembly of carbon nanotube probe tips is straightforward, but has several limitations. It is labor intensive and not amenable to mass production. Although MWNT tips have been made commercially available by this method, they are about ten times more expensive than silicon probes. The manual assembly method has also been carried out in an SEM, rather than an optical microscope [12.24]. This eliminates the need for pulse-etching, since short nanotubes can be attached to the tip, and the "glue" can be applied by EBD. But this is still not the key to mass production, since nanotube tips are made individually. MWNT tips provided a modest improvement in resolution on biological samples, but typical MWNT radii are similar to that of silicon tips, so they cannot provide the ultimate resolution possible with a SWNT tip. SWNT bundles can be attached to silicon probes by manual assembly. Pulse etching at times produces very high resolution tips that likely result from exposing a small number of nanotubes from the bundle, but this is not reproducible [12.25]. Even if a sample could be prepared that consisted of individual SWNT for manual assembly, such nanotubes would not be easily visible by optical microscopy or SEM.

CVD Nanotube Probe Synthesis

The problems of manual assembly of nanotube probes discussed above can largely be solved by directly growing nanotubes onto AFM tips by metal-catalyzed chemical vapor deposition (CVD). The key features of the nanotube CVD process are illustrated in Fig. 12.12. Nanometer-scale metal catalyst particles are heated in a gas mixture containing hydrocarbon or CO. The gas molecules dissociate on the metal surface, and carbon is adsorbed into the catalyst particle. When this carbon precipitates, it nucleates a nanotube of similar diameter to the catalyst particle. Therefore, CVD allows control over nanotube size and structure, including the production of SWNTs [12.26] with radii as low as 3.5 Angstrom [12.27].

Several key issues must be addressed to grow nanotube AFM tips by CVD: (1) the alignment of the nanotubes at the tip, (2) the number of nanotubes that grow at the tip, and (3) the length of the nanotube tip. *Li* et al. [12.28] found that nanotubes grow perpendicular to a porous surface containing embedded catalyst. This approach was exploited to fabricate nanotube tips by CVD [12.29] with the proper alignment, as illustrated in Fig. 12.13. A flattened area of approximately 1–5 μm^2 was created on Si tips by scanning in contact mode at high load (1 μN) on a hard, synthetic diamond surface. The tip was then anodized in HF to create 100 nm-diameter pores in this flat surface [12.30]. It is important to only anodize the last 20–40 μm of the cantilever, which includes the tip, so that the rest

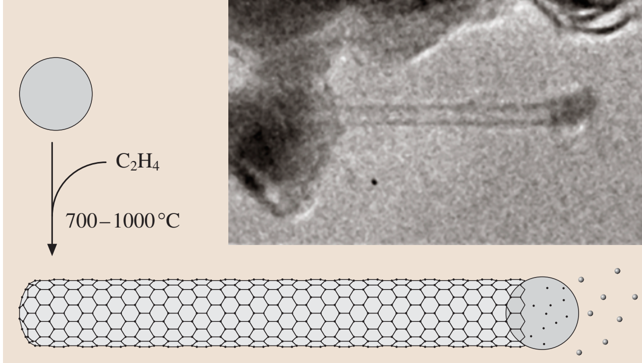

Fig. 12.12 CVD nanotube synthesis. Ethylene reacts with a nanometer-scale iron catalyst particle at high temperature to form a carbon nanotube. The *inset* in the upper right is a TEM image showing a catalyst particle at the end of a nanotube, from [12.16]

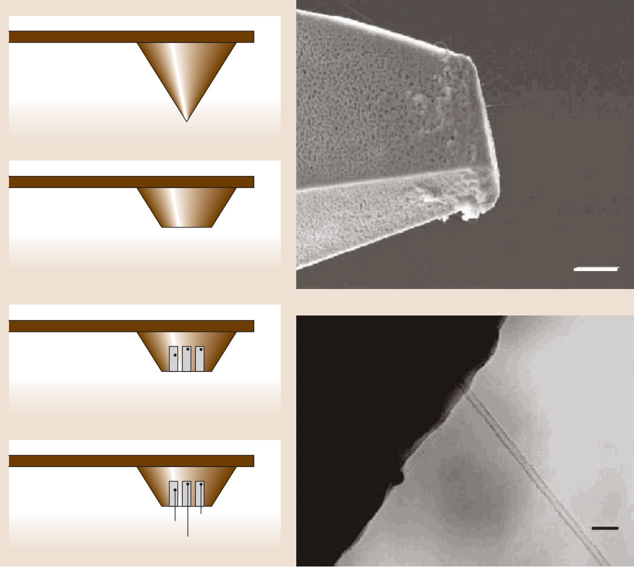

Fig. 12.13 Pore-growth CVD nanotube tip fabrication. The *left panel*, from top to bottom, shows the steps described in the text. The *upper right* is an SEM image of such a tip with a small nanotube protruding from the pores (scale bar is 1 μm). The *lower right* is a TEM of a nanotube protruding from the pores (scale bar is 20 nm), from [12.16]

of the cantilever is still reflective for use in the AFM. This was achieved by anodizing the tip in a small drop of HF under the view of an optical microscope. Next, iron was electrochemically deposited into the pores to form catalyst particles [12.31]. Tips prepared in this way were heated in low concentrations of ethylene at 800 °C, which is known to favor the growth of thin nanotubes [12.26]. When imaged by SEM, nanotubes were found to grow perpendicular to the surface from the pores as desired (Fig. 12.13). TEM revealed that the nanotubes were thin, individual, multiwalled nanotubes with typical radii ranging from 3–5 nm. If nanotubes did not grow in an acceptable orientation, the carbon could be removed by oxidation, and then CVD repeated to grow new nanotube tips.

These "pore-growth" CVD nanotube tips were typically several microns in length – too long for imaging – and were pulse-etched to a usable length of < 500 nm. The tips exhibited elastic buckling behavior and were very robust in imaging. In addition, the thin, individual nanotube tips enabled improved resolution [12.29] on isolated proteins. The pore-growth method demonstrated the potential of CVD to simplify the fabrication of nanotube tips, although there were still limitations. In particular, the porous layer was difficult to prepare and rather fragile.

An alternative approach for CVD fabrication of nanotube tips involves direct growth of SWNTs on the surface of a pyramidal AFM tip [12.32, 33]. In this "surface-growth" approach, an alumina/iron/molybdenum-powdered catalyst known to produce SWNT [12.26] was dispersed in ethanol at 1 mg/mL. Silicon tips were dipped in this solution and allowed to dry, leaving a sparse layer of ~ 100 nm catalyst clusters on the tip. When CVD conditions were applied, single-walled nanotubes grew along the silicon tip surface. At a pyramid edge, nanotubes can either bend to align with the edge, or protrude from the surface. If the energy required to bend the tube and follow the edge is less than the attractive nanotube-surface energy, then the nanotube will follow the pyramid edge to the apex. Therefore, nanotubes were effectively steered toward the tip apex by the pyramid edges. At the apex, the nanotube protruded from the tip, since the energetic cost of bending around the sharp silicon tip was too high. The high aspect ratio at the oxide-sharpened silicon tip apex was critical for good nanotube alignment. A schematic of this approach is shown in Fig. 12.14. Evidence for this model came from SEM investigations that show that a very high yield of tips contains nanotubes only at the apex, with very few protruding elsewhere from the pyramid. TEM analysis demonstrated that the tips typically consist of small SWNT bundles that are formed by nanotubes coming together from different edges of the pyramid to join at the apex, supporting the surface growth model described above (Fig. 12.14). The "surface growth" nanotube tips exhibit a high aspect ratio and high resolution imaging, as well as elastic buckling.

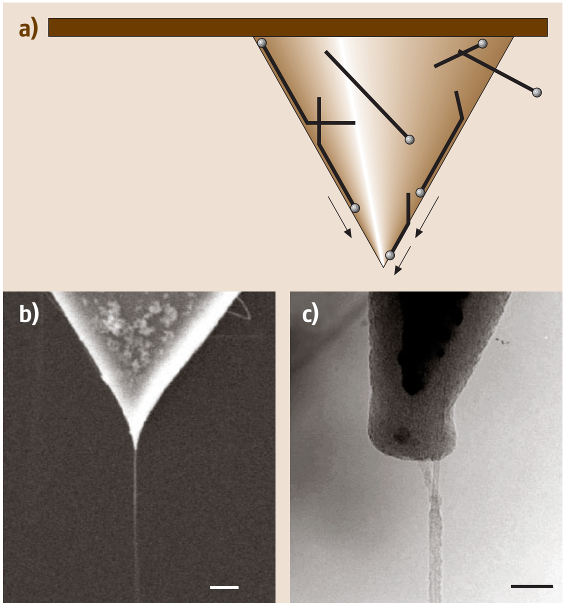

Fig. 12.14a–c Surface-growth nanotube tip fabrication. **(a)** Schematic represents the surface growth process in which nanotubes growing on the pyramidal tip are guided to the tip apex. **(b)**,**(c)** Images show **(b)** SEM (200-nm-scale bar) and **(c)** TEM (20-nm-scale bar) images of a surface growth tip, from [12.16]

The surface growth method has been expanded to include wafer-scale production of nanotube tips with yields of over 90% [12.34], yet one obstacle remains to the mass production of nanotube probe tips. Nanotubes protruding from the tip are several microns long, and since they are so thin, they must be etched to less than 100 nm. While the pulse-etching step is fairly reproducible, it must be carried out on nanotube tips in a serial fashion, so surface growth does not yet represent a true method of batch nanotube tip fabrication.

Hybrid Nanotube Tip Fabrication: Pick-up Tips

Another method of creating nanotube tips is something of a hybrid between assembly and CVD. The motiva-

tion was to create AFM probes that have an *individual* SWNT at the tip to achieve the ultimate imaging resolution. In order to synthesize isolated SWNT, they must be nucleated at sites separated farther than their typical length. The alumina-supported catalyst contains a high density of catalyst particles per 100 nm cluster, so nanotube bundles cannot be avoided. To fabricate completely isolated nanotubes, isolated catalyst particles were formed by dipping a silicon wafer in an isopropyl alcohol solution of $Fe(NO_3)_3$. This effectively left a submonolayer of iron on the wafer, so that when it was heated in a CVD furnace, the iron became mobile and aggregated to form isolated iron particles. During CVD conditions, these particles nucleated and grew SWNTs. By controlling the reaction time, the SWNT lengths were kept shorter than their typical separation, so that the nanotubes never had a chance to form bundles. AFM analysis of these samples revealed 1–3 nm-diameter SWNT and un-nucleated particles on the surface (Fig. 12.15). However, there were tall objects that were difficult to image at a density of about 1 per 50 μm^2. SEM analysis at an oblique angle demonstrated that these were SWNTs that had grown perpendicular to the surface (Fig. 12.15).

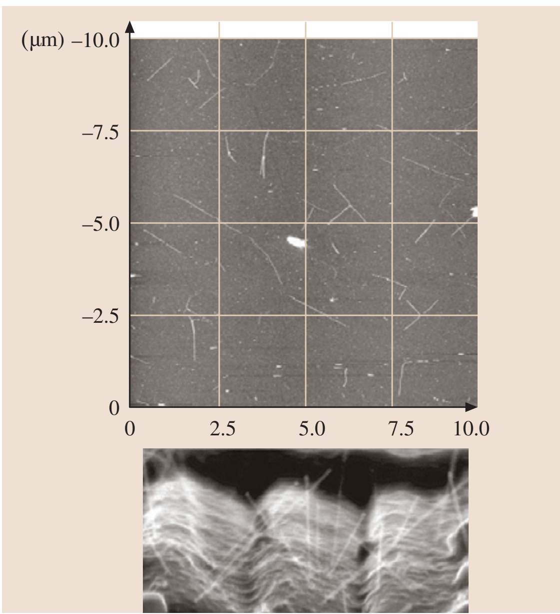

Fig. 12.15 Atomic force microscopy image (*top*) of a wafer with isolated nanotubes synthesized by CVD. The SEM view provides evidence that some of these nanotubes are arranged vertically

In the "pick-up tip" method, these isolated SWNT substrates were imaged by AFM with silicon tips in air [12.9]. When the tip encountered a vertical SWNT, the oscillation amplitude was damped, so the AFM pulled the sample away from the tip. This pulled the SWNT into contact with the tip along its length, so that it became attached to the tip. This assembly process happened automatically when imaging in tapping mode – no special tip manipulation was required. When imaging a wafer with the density shown in Fig. 12.15, one nanotube was attached per 8 μm × 8 μm scan at 512×512 and 2 Hz, so a nanotube tip could be made in about 5 min. Since the as-formed SWNT tip continued to image, there was usually no evidence in the topographic image that a nanotube had been attached. However, the pick-up event was identified when the Z-voltage suddenly stepped to larger tip-

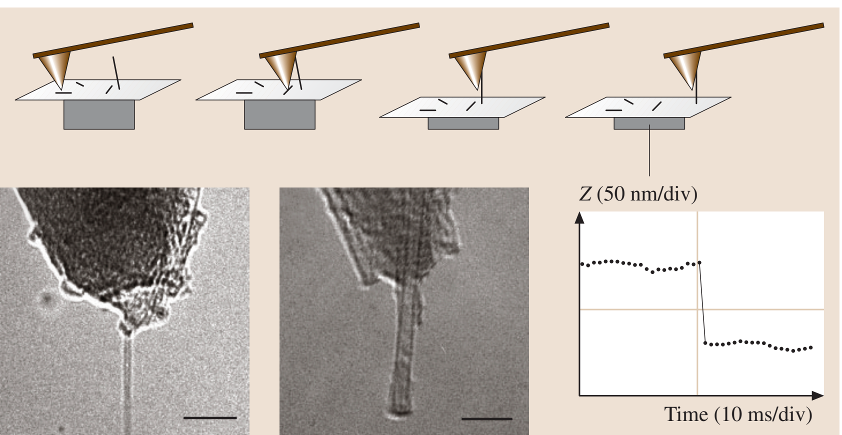

Fig. 12.16 Pick-up tip assembly of nanotube probes. The *top* illustrates the nanotube pick-up process that occurs while imaging vertical nanotubes in an AFM, including a trace of the Z-position during a pick-up event. The *lower left* TEM images show single nanotubes (diameters 0.9 nm and 2.8 nm) on an AFM tip fabricated by this method, adapted from [12.9]

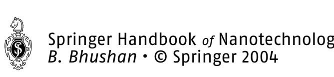

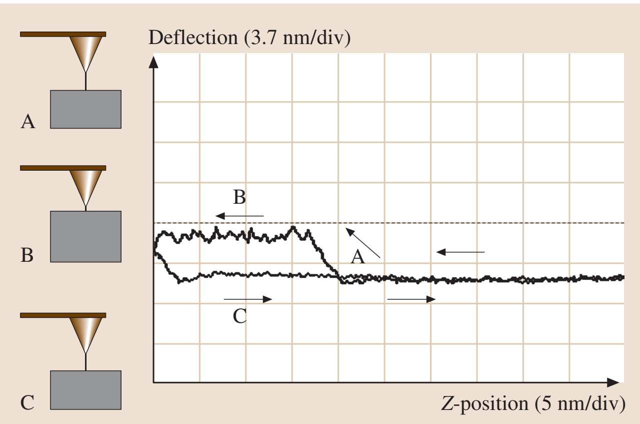

Fig. 12.17 The process by which nanotube tips can be shortened in AFM force curves. The hysteresis in the deflection trace (*bottom*) reveals that ∼ 17 nm were removed

sample separation due to the effective increase in tip length.

Individual SWNT tips must be quite short, typically less than 50 nm in length, for reasons outlined above. Pulse-etching, which removes 50–100 nm of nanotube length at a time, lacked the necessary precision for shortening pick-up tips, so the tips were shortened through force curves. A pick-up tip force curve is shown in Fig. 12.17. When the tip first interacted with the sample, the amplitude decreased to zero, and further approach generated a small deflection that ultimately saturated. However, this saturation was not due to buckling. Note that the amplitude did not recover, as in the buckling curves. This leveling was due to the nanotube sliding on the pyramidal tip, which was confirmed by the hysteresis in the amplitude and deflection curves. If the force curve was repeated, the tip showed no deflection or amplitude drop until further down, because the tip was essentially shorter.

Pick-up SWNT tips achieve the highest resolution of all nanotube tips, since they are always individuals rather than bundles. In tapping mode, they produce images of 5 nm gold particles that have a *full width* of ∼ 7 nm, the expected geometrical resolution for a 2 nm cylindrical probe [12.9]. Although the pick-up method is serial in nature, it may still be the key to the mass production of nanotube tips. Note that the original nanotube tip length can be measured electronically from the size of the Z-piezo step. The shortening can be electronically controlled through the hysteresis in the force curves. Therefore, the entire procedure (including tip exchange) can be automated by computer.

12.2 Scanning Tunneling Microscopy

Scanning tunneling microscopy (STM) was the original scanning probe microscopy and generally produces the highest resolution images, routinely achieving atomic resolution on flat, conductive surfaces. In STM, the probe tip consists of a sharpened metal wire that is held 0.3 to 1 nm from the sample. A potential difference of 0.1 V to 1 V between the tip and sample leads to tunneling currents on the order of 0.1 to 1 nA. As in AFM, a piezo-scanner rasters the sample under the tip, and the Z-position is adjusted to hold the tunneling current constant. The Z-position data represents the “topography”, or in this case the surface, of constant electron density. As with other SPMs, the tip properties and performance greatly depend on the experiment being carried out. Although it is nearly impossible to prepare a tip with a known atomic structure, a number of factors are known to affect tip performance, and several preparation methods have been developed that produce good tips.

The nature of the sample being investigated and the scanning environment will affect the choice of the tip material and how the tip is fabricated. Factors to consider are mechanical properties – a hard material that will resist damage during tip-sample contact is desired. Chemical properties should also be considered – formation of oxides, or other insulating contaminants will affect tip performance. Tungsten is a common tip material because it is very hard and will resist damage, but its use is limited to ultrahigh vacuum (UHV) conditions, since it readily oxidizes. For imaging under ambient conditions an inert tip material such as platinum or gold is preferred. Platinum is typically alloyed with iridium to increase its stiffness.

12.2.1 Mechanically Cut STM Tips

STM tips can be fabricated by simple mechanical procedures such as grinding or cutting metal wires. Such

tips are not formed with highly reproducible shapes and have a large opening angle and a large radius of curvature in the range of 0.1 to 1 μm (see Fig. 12.18a). They are not useful for imaging samples with surface roughness above a few nanometers. However, on atomically flat samples, mechanically cut tips can achieve atomic resolution due to the nature of the tunneling signal, which drops exponentially with tip-sample separation. Since mechanically cut tips contain many small asperities on the larger tip structure, atomic resolution is easily achieved as long as one atom of the tip is just a few angstroms lower than all of the others.

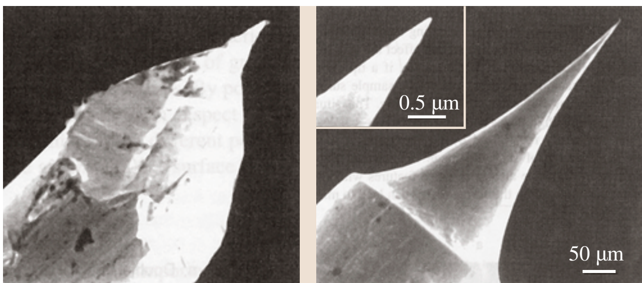

Fig. 12.18 A mechanically cut STM tip (*left*) and an electrochemically etched STM tip (*right*), from [12.35]

12.2.2 Electrochemically Etched STM Tips

For samples with more than a few nanometers of surface roughness, the tip structure in the nanometer-size range becomes an issue. Electrochemical etching can provide tips with reproducible and desirable shapes and sizes (Fig. 12.18), although the exact atomic structure of the tip apex is still not well controlled. The parameters of electrochemical etching depend greatly on the tip material and the desired tip shape. The following is an entirely general description. A fine metal wire (0.1–1 mm diameter) of the tip material is immersed in an appropriate electrochemical etchant solution. A voltage bias of 1–10 V is applied between the tip and a counterelectrode such that the tip is etched. Due to the enhanced etch rate at the electrolyte-air interface, a neck is formed in the wire. This neck is eventually etched thin enough so that it cannot support the weight of the part of the wire suspended in the solution, and it breaks to form a sharp tip. The widely varying parameters and methods will be not be covered in detail here, but many recipes are found in the literature for common tip materials [12.36–39].

13. Noncontact Atomic Force Microscopy and Its Related Topics

The scanning probe microscopy (SPM) such as the STM and the NC-AFM is the basic technology for the nanotechnology and also for the future bottom-up process. In Sect. 13.1, the principles of AFM such as operating modes and the frequency modulation method of the NC-AFM are fully explained. Then, in Sect. 13.2, applications of NC-AFM to semiconductors that make clear its potentials such as spatial resolution and functions are introduced. Next, in Sect. 13.3, applications of NC-AFM to insulators such as alkali halides, fluorides and transition metal oxides are introduced. At last, in Sect. 13.4, applications of NC-AFM to molecules such as carboxylate ($RCOO^-$) with R = H, CH_3, $C(CH_3)_3$ and CF_3 are introduced. Thus, the NC-AFM can observe atoms and molecules on various kinds of surfaces such as semiconductor, insulator and metal oxide with atomic/molecular resolutions. These sections are essential to understand the status of the art and the future possibility of NC-AFM that is the second generation of atom/molecule technology.

The scanning tunneling microscope (STM) is an atomic tool based on an electric method that measures the tunneling current between a conductive tip and a conductive surface. It can electrically observe individual atoms/molecules. It can characterize or analyze the electronic nature around surface atoms/molecules. In addition, it can manipulate individual atoms/molecules. Hence, the STM is the first generation of atom/molecule technology. On the other hand, the atomic force microscope (AFM) is a unique atomic tool based on a mechanical method that can deal with even the insulator surface. Since the invention of noncontactAFM (NC-AFM) in 1995, the NC-AFM and the NC-AFM-based method have rapidly developed into a powerful surface tool on atomic/molecular scales, because the NC-AFM has the following characteristics: (1) it has true atomic resolution, (2) it can measure atomic force (so-called atomic force spectroscopy), (3) it can observe even insulators, and (4) it can measure mechanical responses such as elastic deformation. Thus, the NC-AFM is the second generation of atom/molecule technology. The scanning probe microscopy (SPM) such as the STM and the NC-AFM is the basic technology for nanotechnology and also for the future bottom-up process.

In Sect. 13.1, principles of NC-AFM will be fully introduced. Then, in Sect. 13.2, applications to semi-

conductors will be presented. Next, in Sect. 13.3, applications to insulators will be described. And, in Sect. 13.4, applications to molecules will be introduced. These sections are essential to understanding the status of the art and the future possibility of the NC-AFM.

13.1 Principles of Noncontact Atomic Force Microscope (NC-AFM)

The atomic force microscope (AFM), invented by *Binnig* [13.1] and introduced in 1986 by *Binnig*, *Quate*, and *Gerber* [13.2], is an offspring of the scanning tunneling microscope (STM) [13.3]. The STM is covered in books and review articles, e.g., [13.4–9]. Early on in the development of STM it became evident that relatively strong forces act between a tip in close proximity to a sample. It was found that these forces could be put to good use in the atomic force microscope (AFM). Detailed information about the noncontact AFM can be found in [13.10–12].

13.1.1 Imaging Signal in AFM

Figure 13.1 shows a sharp tip close to a sample. The potential energy between the tip and sample V_{ts} causes a z component of the tip-sample force $F_{ts} = -\partial V_{ts}/\partial z$. Depending on the mode of operation, the AFM uses F_{ts} or some entity derived from F_{ts} as the imaging signal.

Unlike the tunneling current, which has a very strong distance dependence, F_{ts} has long- and short-range contributions. We can classify the contributions by their range and strength. In vacuum, there are van der Waals, electrostatic, and magnetic forces with long-range (up to 100 nm) and short-range chemical forces (fractions of a nm).

The van der Waals interaction is caused by fluctuations in the electric dipole moment of atoms and their mutual polarization. For a spherical tip with radius R next to a flat surface (z is the distance between the plane connecting the centers of the surface atoms and the center of the closest tip atom), the van der Waals potential is given by [13.13]:

$$V_{\mathrm{vdW}} = -\frac{A_{\mathrm{H}}}{6z} \,. \tag{13.1}$$

The "Hamaker constant", A_{H}, depends on the type of materials (atomic polarizability and density) of the tip and sample and is on the order of 1 eV for most solids [13.13].

When the tip and sample are both conductive and have an electrostatic potential difference, $U \neq 0$, electrostatic forces are important. For a spherical tip with radius R, the force is given by [13.14]:

$$F_{\mathrm{electrostatic}} = -\frac{\pi\varepsilon_0 R U^2}{z} \,. \tag{13.2}$$

Chemical forces are more complicated. Empirical model potentials for chemical bonds are the Morse potential (see e.g., [13.13]).

$$V_{\mathrm{Morse}} = -E_{\mathrm{bond}}\left(2\,\mathrm{e}^{-\kappa(z-\sigma)} - \mathrm{e}^{-2\kappa(z-\sigma)}\right) \tag{13.3}$$

and the Lennard-Jones potential [13.13]:

$$V_{\mathrm{Lennard\text{-}Jones}} = -E_{\mathrm{bond}}\left(2\frac{\sigma^6}{z^6} - \frac{\sigma^{12}}{z^{12}}\right) \,. \tag{13.4}$$

These potentials describe a chemical bond with bonding energy E_{bond} and equilibrium distance σ. The Morse potential has an additional parameter – a decay length κ.

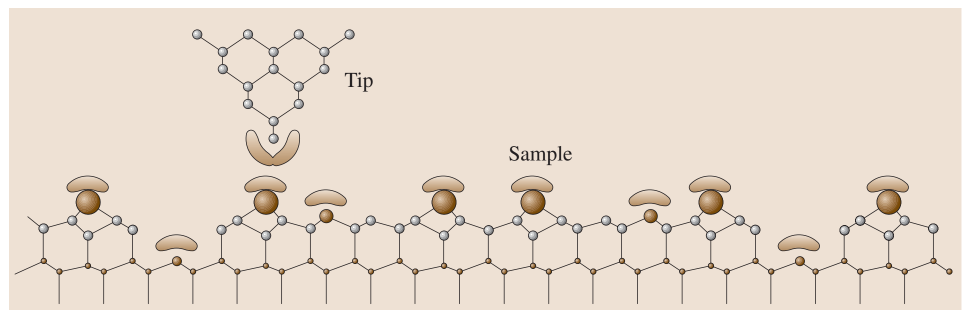

Fig. 13.1 Schematic view of an AFM tip close to a sample

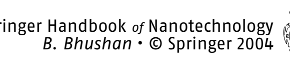

13.1.2 Experimental Measurement and Noise

Forces between the tip and sample are typically measured by recording the deflection of a cantilever beam that has a tip mounted to its end (see Fig. 13.2). Today's microfabricated silicon cantilevers were first created by the *Calvin F. Quate* group [13.15–17] and *Wolter* et al. at IBM [13.18].

The cantilever is characterized by its spring constant k, eigenfrequency f_0, and quality factor Q.

For a rectangular cantilever with dimensions w, t, and L (see Fig. 13.2), the spring constant k is given by [13.6]:

$$k = \frac{E_Y w t^3}{4L^3} , \quad (13.5)$$

where E_Y is Young's modulus. The eigenfrequency f_0 is given by [13.6]:

$$f_0 = 0.162 \frac{t}{L^2} \sqrt{E_Y/\rho} , \quad (13.6)$$

where ρ is the mass density of the cantilever material. The Q-factor depends on the damping mechanisms present in the cantilever. For micromachined cantilevers operated in air, Q is typically a few hundred but can reach hundreds of thousands in vacuum.

In the first AFM, the deflection of the cantilever was measured with an STM – the backside of the cantilever was metalized, and a tunneling tip was brought close to it to measure the deflection [13.2]. Today's designs use optical (interferometer, beam-bounce) or electrical methods (piezoresistive, piezoelectric) for measuring the cantilever deflection. A discussion of the various techniques can be found in [13.19], descriptions of piezoresistive detection schemes are found in [13.17, 20], and piezoelectric methods are explained in [13.21–24].

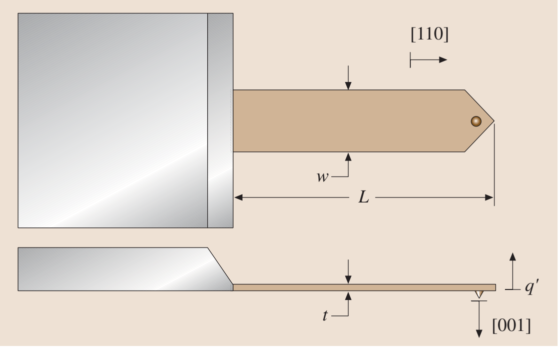

Fig. 13.2 Top view and side view of a microfabricated silicon cantilever (schematic)

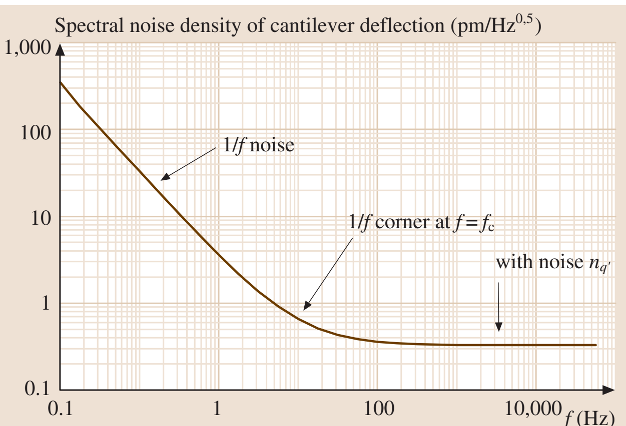

Fig. 13.3 Schematic view of $1/f$ noise apparent in force detectors. Static AFMs operate in a frequency range from 0.01 Hz to a few hundred Hz, while dynamic AFMs operate at frequencies around 10 kHz to a few hundred kHz. The noise of the cantilever deflection sensor is characterized by the $1/f$ corner frequency f_c and the constant deflection noise density $n_{q'}$ for the frequency range where white noise is dominating

The quality of the cantilever deflection measurement can be expressed in a schematic plot of the deflection noise density versus frequency, as in Fig. 13.3.

The noise density has a $1/f$ dependence for low frequency and merges into a constant noise density ("white noise") above the "$1/f$ corner frequency".

13.1.3 Static AFM Operating Mode

In the static mode of operation, the force translates into a deflection $q' = F_{ts}/k$ of the cantilever, yielding images as maps $z(x, y, F_{ts} = \text{const.})$. The noise level of the force measurement is then given by the cantilever's spring constant k times the noise level of the deflection measurement. In this respect, a small value for k increases force sensitivity. On the other hand, instabilities are more likely to occur with soft cantilevers (see Sect. 13.1.5). Because the deflection of the cantilever should be significantly larger than the deformation of the tip and sample, the cantilever should be much softer than the bonds between the bulk atoms in the tip and sample. Inter-atomic force constants in solids are in a range from 10 N/m to about 100 N/m – in biological samples, they can be as small as 0.1 N/m. Thus, typical values for k in the static mode are 0.01–5 N/m.

Even though it has been demonstrated that atomic resolution is possible with static AFM, the method can only be applied in certain cases. The detrimental effects of $1/f$ noise can be limited by working at low temperatures [13.25], where the coefficients of thermal expansion are very small, or by building the AFM of a material with a low thermal expansion coefficient [13.26]. The long-range attractive forces have to be cancelled by immersing the tip and sample in a liquid [13.26], or by partly compensating the attractive force by pulling at the cantilever after jump-to-contact has occurred [13.27]. *Jarvis* et al. have cancelled the long-range attractive force with an electromagnetic force applied to the cantilever [13.28]. Even with these restrictions, static AFM does not produce atomic resolution on reactive surfaces like silicon, as the chemical bonding of the AFM tip and sample pose an unsurmountable problem [13.29, 30].

13.1.4 Dynamic AFM Operating Mode

In the dynamic operation modes, the cantilever is deliberately vibrated. There are two basic methods of dynamic operation: amplitude modulation (AM) and frequency modulation (FM) operation. In AM-AFM [13.31], the actuator is driven by a fixed amplitude A_{drive} at a fixed frequency f_{drive}, where f_{drive} is close to f_0. When the tip approaches the sample, elastic and inelastic interactions cause a change in both the amplitude and the phase (relative to the driving signal) of the cantilever. These changes are used as the feedback signal. While the AM mode was initially used in a noncontact mode, it was later implemented very successfully at a closer distance range in ambient conditions involving repulsive tip-sample interactions.

The change in amplitude in AM mode does not occur instantaneously with a change in the tip-sample interaction, but on a time scale of $\tau_{\text{AM}} \approx 2Q/f_0$, and the AM mode is slow with high-Q cantilevers. However, the use of high Q-factors reduces noise. *Albrecht* et al. found a way to combine the benefits of high Q and high speed by introducing the frequency modulation (FM) mode [13.32], where the change in the eigenfrequency settles on a time scale of $\tau_{\text{FM}} \approx 1/f_0$.

Using the FM mode, the resolution was improved dramatically, and finally atomic resolution [13.33, 34] was obtained by reducing the tip-sample distance and working in vacuum. For atomic studies in vacuum, the FM mode (see Sect. 13.1.6) is now the preferred AFM technique. However, atomic resolution in vacuum can also be obtained with the AM mode, as demonstrated by *Erlandsson* et al. [13.35].

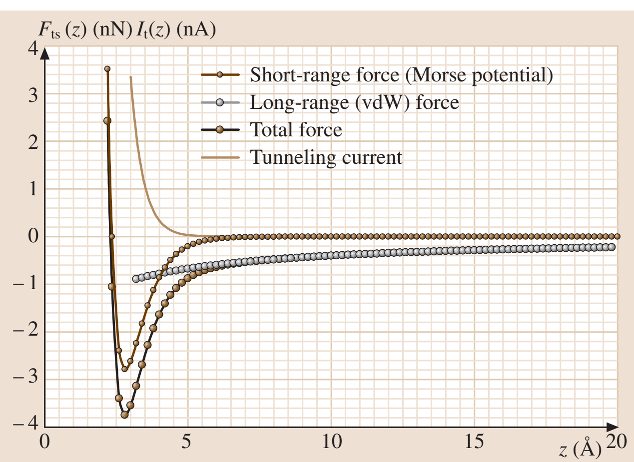

Fig. 13.4 Plot of tunneling current I_t and force F_{ts} (typical values) as a function of distance z between front atom and surface atom layer

13.1.5 The Four Additional Challenges Faced by AFM

Some of the inherent AFM challenges are apparent by comparing the tunneling current and tip-sample force as a function of distance (Fig. 13.4).

The tunneling current is a monotonic function of the tip-sample distance and has a very sharp distance dependence. In contrast, the tip-sample force has long- and short-range components and is not monotonic.

Jump-to-Contact and Other Instabilities

If the tip is mounted on a soft cantilever, the initially attractive tip-sample forces can cause a sudden "jump-to-contact" when the tip approaches the sample. This instability occurs in the quasi-static mode if [13.36, 37]

$$k < \max\left(-\frac{\partial^2 V_{\text{ts}}}{\partial z^2}\right) = k_{\text{ts}}^{\max} . \quad (13.7)$$

Jump-to-contact can be avoided even for soft cantilevers by oscillating it at a large enough amplitude A [13.38]:

$$kA > \max(-F_{\text{ts}}) . \quad (13.8)$$

If hysteresis occurs in the $F_{\text{ts}}(z)$-relation, the energy ΔE_{ts} needs to be supplied to the cantilever for each oscillation cycle. If this energy loss is large compared to the intrinsic energy loss of the cantilever, amplitude control can become difficult. An additional approximate

Springer Handbook of Nanotechnology
B. Bhushan • © Springer 2004

criterion for k and A is then

$$\frac{kA^2}{2} \geq \frac{\Delta E_{\text{ts}} Q}{2\pi} . \tag{13.9}$$

Contribution of Long-Range Forces

The force between tip and sample is composed of many contributions: electrostatic, magnetic, van der Waals, and chemical forces in vacuum. All of these force types except for the chemical forces have strong long-range components that conceal the atomic-force components. For imaging by AFM with atomic resolution, it is desirable to filter out the long-range force contributions and only measure the force components that vary at the atomic scale. While there is no way to discriminate between long- and short-range forces in static AFM, it is possible to enhance the short-range contributions in dynamic AFM through the proper choice of the oscillation amplitude A of the cantilever.

Noise in the Imaging Signal

Measuring the cantilever deflection is subject to noise, especially at low frequencies ($1/f$ noise). In static AFM, this noise is particularly problematic because of the approximate $1/f$ dependence. In dynamic AFM, the low-frequency noise is easily discriminated when using a bandpass filter with a center frequency around f_0.

Non-monotonic Imaging Signal

The tip-sample force is not monotonic. In general, the force is attractive for large distances, and upon decreasing the distance between tip and sample, the force turns repulsive (see Fig. 13.4). Stable feedback is only possible on a monotonic subbranch of the force curve.

Frequency-modulation AFM (FM-AFM) helps to overcome challenges. The non-monotonic imaging signal in AFM is a remaining complication for FM-AFM.

13.1.6 Frequency-Modulation AFM (FM-AFM)

In FM-AFM, a cantilever with eigenfrequency f_0 and spring constant k is subject to controlled positive feedback such that it oscillates with a constant amplitude A [13.32], as shown in Fig. 13.5.

Experimental Setup

The deflection signal is phase shifted, routed through an automatic gain control circuit and fed back to the actuator. The frequency f is a function of f_0, its quality factor Q, and the phase shift ϕ between the mechanical excitation generated at the actuator and the deflection of the cantilever. If $\phi = \pi/2$, the loop oscillates at $f = f_0$.

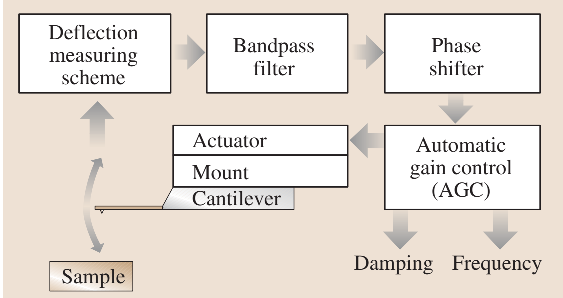

Fig. 13.5 Block diagram of a frequency-modulation force sensor

Three physical observables can be recorded: 1) a change in resonance frequency, Δf, 2) the control signal of the automatic gain control unit as a measure of the tip-sample energy dissipation and 3) an average tunneling current (for conducting cantilevers and tips).

Applications

FM-AFM was introduced by *Albrecht* and coworkers in magnetic force microscopy [13.32]. The noise level and imaging speed were enhanced significantly compared to amplitude modulation techniques. Achieving atomic resolution on the Si(111)-(7×7) surface has been an important step in the development of the STM [13.39], and in 1994, this surface was imaged by AFM with true atomic resolution for the first time [13.33] (see Fig. 13.6).

The initial parameters that provided *true atomic resolution* (see caption of Fig. 13.6) were found empirically. Surprisingly, the amplitude necessary for obtaining good

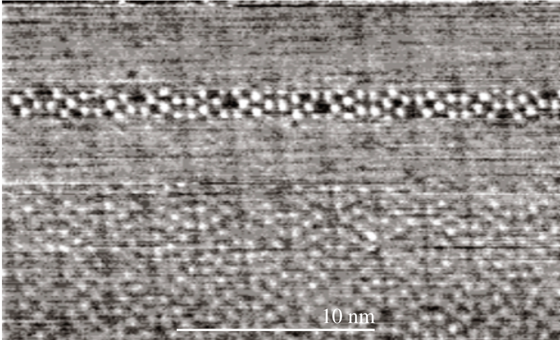

Fig. 13.6 First AFM image of the Si(111)-(7×7) surface. Parameters $k = 17\,\text{Nm}$, $f_0 = 114\,\text{kHz}$, $Q = 28{,}000$, $A = 34\,\text{nm}$, $\Delta f = -70\,\text{Hz}$, $V_t = 0\,\text{V}$

results was very large compared to atomic dimensions. It turned out later that the amplitudes had to be that large in order to fulfill the stability criteria listed in Sect. 13.1.5. Cantilevers with $k \approx 2{,}000\,\mathrm{N/m}$ can be operated with amplitudes in the Å-range [13.24].

13.1.7 Relation Between Frequency Shift and Forces

The cantilever (spring constant k, effective mass m^*) is a macroscopic object and its motion can be described by classical mechanics. Figure 13.7 shows the deflection $q'(t)$ of the tip of the cantilever: It oscillates with an amplitude A at a distance $q(t)$ to a sample.

Generic Calculation

The Hamiltonian of the cantilever is:

$$H = \frac{p^2}{2m^*} + \frac{kq'^2}{2} + V_{\mathrm{ts}}(q) \,, \tag{13.10}$$

where $p = m^* \mathrm{d}q'/\mathrm{d}t$. The unperturbed motion is given by:

$$q'(t) = A\cos(2\Box f_0 t) \,, \tag{13.11}$$

and the frequency is:

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m^*}} \,. \tag{13.12}$$

If the force gradient $k_{\mathrm{ts}} = -\partial F_{\mathrm{ts}}/\partial z = \partial^2 V_{\mathrm{ts}}/\partial z^2$ is constant during the oscillation cycle, the calculation of the frequency shift is trivial:

$$\Delta f = \frac{f_0}{2k} k_{\mathrm{ts}} \,. \tag{13.13}$$

However, in classic FM-AFM, k_{ts} varies in orders of magnitude during one oscillation cycle, and a perturbation approach, as shown below, has to be employed for the calculation of the frequency shift.

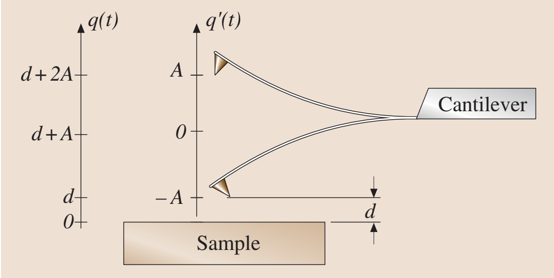

Fig. 13.7 Schematic view of an oscillating cantilever and definition of geometric terms

Hamilton–Jacobi Method

The first derivation of the frequency shift in FM-AFM was achieved in 1997 [13.38] using canonical perturbation theory [13.40]. The result of this calculation is:

$$\begin{aligned}\Delta f &= -\frac{f_0}{kA^2}\left\langle F_{\mathrm{ts}} q' \right\rangle \\ &= -\frac{f_0}{kA^2}\int_0^{1/f_0} F_{\mathrm{ts}}(d + A + q'(t))q'(t)\,\mathrm{d}t \,.\end{aligned} \tag{13.14}$$

The applicability of first-order perturbation theory is justified, because in FM-AFM, E is typically in the range of several keVs, while V_{ts} is on the order of a few eVs. *Dürig* [13.41] has found a generalized algorithm that even allows the reconstruction of the tip-sample potential if not only the frequency shift, but the higher harmonics of the cantilever oscillation are known.

A Descriptive Expression for Frequency Shifts as a Function of the Tip-Sample Forces

With integration by parts, the complicated expression (13.14) transforms into a very simple expression that resembles (13.13) [13.42].

$$\Delta f = \frac{f_0}{2k}\int_{-A}^{A} k_{\mathrm{ts}}(z - q')\frac{\sqrt{A^2 - q'^2}}{\frac{\pi}{2}kA^2}\,\mathrm{d}q' \,. \tag{13.15}$$

This expression is closely related to (13.13): The constant k_{ts} is replaced by a weighted average, where the weight function $w(q', A)$ is a semicircle with radius A divided by the area of the semicircle $\pi A^2/2$ (see Fig. 13.8). For $A \to 0$, $w(q', A)$ is a representation of Dirac's delta function and the trivial zero-amplitude result of (13.13) is immediately recovered. The frequency shift results from a convolution between the tip-sample force gradient and the weight function. This convolution can easily be reversed with a linear transformation, and the tip-sample force can be recovered from the frequency shift versus distance curve [13.42].

The dependence of the frequency shift with amplitude confirms an empirical conjecture: Small amplitudes increase the sensitivity to short-range forces! Adjusting the amplitude in FM-AFM resembles tuning an optical spectrometer to a passing wavelength. When short-range interactions are to be probed, the amplitude should be in the range of the short-range forces. While using amplitudes in the Å-range has been elusive with conventional cantilevers, because of the instability problems described in Sect. 13.1.5, cantilevers with a stiffness on the order of $1{,}000\,\mathrm{N/m}$ like the ones introduced in [13.23] are well suited for small-amplitude operation.

13.1.8 Noise in Frequency-Modulation AFM – Generic Calculation

The vertical noise in FM-AFM is given by the ratio between the noise in the imaging signal and the slope of the imaging signal with respect to z:

$$\delta z = \frac{\delta \Delta f}{\left|\frac{\partial \Delta f}{\partial z}\right|} . \quad (13.16)$$

Figure 13.9 shows a typical frequency shift versus distance curve. Because the distance between the tip and sample is measured indirectly through the frequency shift, it is clearly evident from Fig. 13.9 that the noise in the frequency measurement $\delta \Delta f$ translates into vertical noise δz and is given by the ratio between $\delta \Delta f$ and the slope of the frequency shift curve $\Delta f(z)$ (13.16). Low vertical noise is obtained for a low-noise frequency measurement and a steep slope of the frequency shift curve.

The frequency noise $\delta \Delta f$ is typically inversely proportional to the cantilever amplitude A [13.32, 43]. The derivative of the frequency shift versus distance is constant for $A \ll \lambda$, where λ is the range of the tip-sample interaction and proportional to $A^{-1.5}$ for $A \gg \lambda$ [13.38]. Thus, minimal noise occurs if [13.44]

$$A_{\text{optimal}} \approx \lambda , \quad (13.17)$$

for chemical forces, $\lambda \approx 1$ Å. However, for stability reasons (Sect. 13.1.5), extremely stiff cantilevers are needed for small amplitude operation. The excellent noise performance of the stiff cantilever and small amplitude technique has been verified experimentally [13.24].

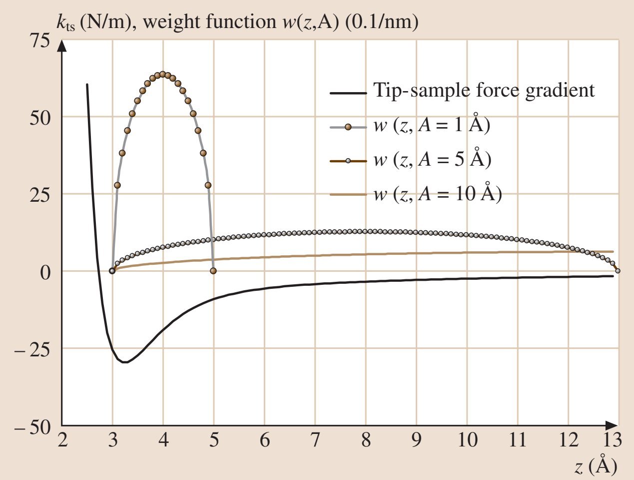

Fig. 13.8 Tip-sample force gradient k_{ts} and weight function for the calculation of the frequency shift

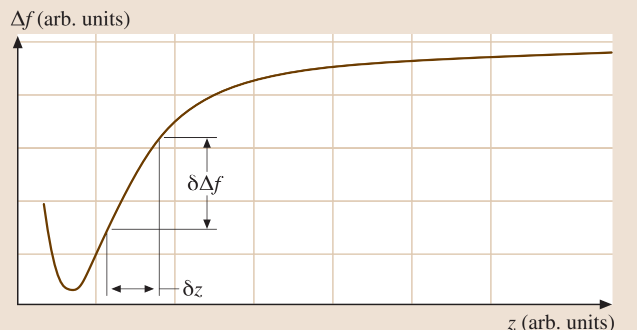

Fig. 13.9 Plot of frequency shift Δf as a function of tip-sample distance z. The noise in the tip-sample distance measurement is given by the noise of the frequency measurement $\delta \Delta f$ divided by the slope of the frequency shift curve

13.1.9 Conclusion

Dynamic force microscopy, in particular frequency-modulation atomic force microscopy, has matured into a viable technique that allows true atomic resolution of conducting and insulating surfaces and spectroscopic measurements on individual atoms [13.10, 45]. Even true atomic resolution in lateral force microscopy is now possible [13.46]. Challenges remain in the chemical composition and structural arrangement of the AFM tip.

13.2 Applications to Semiconductors

For the first time, corner holes and adatoms on Si(111)7×7 surface have been observed at a very local area by *Giessibl* using the pure noncontact AFM in ultrahigh vacuum (UHV) [13.33]. It became the breakthrough for the true atomic resolution imaging on a well-defined clean surface using noncontact AFM. Then, Si(111)7×7 [13.34, 35, 45, 47], InP(110) [13.48], and Si(100)2×1 [13.34] surfaces were successively

resolved with true atomic resolution. Furthermore, thermally induced motion of atoms or atomic-scale point defects on InP(110) surface have been observed at room temperature [13.48]. In this section, we will describe typical results of atomically resolved noncontact AFM imaging of semiconductor surfaces.

13.2.1 Si(111)7×7 Surface

Figure 13.10 shows the atomic resolution images of the Si(111)7×7 surface [13.49]. Here, Fig. 13.10a (TYPE I) was obtained using the Si tip without dangling, which is covered with an inert oxide layer. Fig. 13.10b (TYPE II) was obtained using the Si tip with dangling bond on which the Si atoms were deposited, due to the mechanical soft contact between the tip and the Si surface. The variable frequency shift mode was used. We can see not only adatoms and corner holes, but also missing adatoms described by the dimer-adatom-stacking fault (DAS) model. We can see that the image contrast in Fig. 13.10b is clearly stronger than that in Fig. 13.10a.

Interestingly, by using the Si tip with dangling bond, we observed contrast between inequivalent halves and between inequivalent adatoms of the 7×7 unit cell. Namely, as shown in Fig. 13.11a, the faulted halves surrounded with a solid line show brighter than the unfaulted halves surrounded with a broken line. Here, the positions of the faulted and unfaulted halves were decided from the step direction. From the cross-sectional profile along the long diagonal of the 7×7 unit cell in Fig. 13.11b, the heights of the corner adatoms are slightly higher than those of the adjacent center adatoms in the faulted and unfaulted halves of the unit cell. The measured corrugations are in the following decreasing order:

$$\text{Co-F} > \text{Ce-F} > \text{Co-U} > \text{Ce-U}\,,$$

where Co-F and Ce-F indicate the corner and center adatoms in faulted halves, and Co-U and Ce-U indicate the corner and center adatoms in unfaulted halves, respectively. As averaging over several units, the corrugation height differences are estimated to be 0.25 Å, 0.15 Å, and 0.05 Å for Co-F, Ce-F, and Co-U, respectively, referring to Ce-U. This tendency, that the heights of the corner adatoms are higher than those of the center adatoms, is consistent with the experimental results using a silicon tip [13.47], although they could not determine faulted and unfaulted halves of the unit cell in the measured AFM images. However, this tendency is completely contrary to the experimental results using a tungsten tip [13.35]. This difference may originate from the difference in the materials of the tip, which seems to affect the interaction between the tip and the reactive sample surface. Another possibility is that the tip is in contact with the surface during the small fraction of the oscillating cycle in their experiments [13.35].

We consider that contrast between inequivalent adatoms is not caused by tip artifacts for the following reasons: 1) Each adatom, corner hole and defect were clearly observed; 2) the apparent heights of adatoms are the same whether they are located adjacent to defects or not; 3) the same contrast in several images for the different tips has been observed.

It should be noted that the corrugation amplitude of adatoms ∼ 1.4 Å in Fig. 13.11b is higher than that of 0.8–1.0 Å obtained with the STM, although the depth of corner holes obtained with noncontact AFM is almost the same as that observed with STM. Besides, in noncontact mode AFM images, the corrugation ampli-

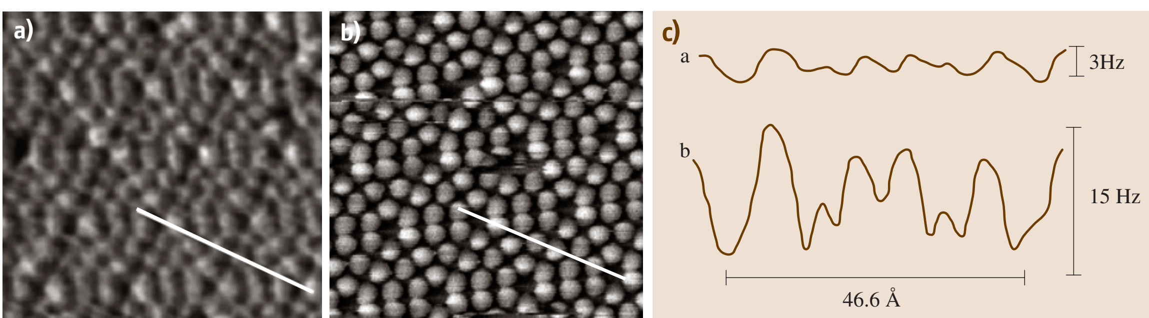

Fig. 13.10a–c Noncontact mode AFM images of Si(111) 7×7 reconstructed surface obtained using the Si tips **(a)** without and **(b)** with dangling bond. The scan area is 99 Å×99 Å. **(c)** The cross sectional profiles along long diagonal of the 7×7 unit cell indicated by *white lines* in **(a)** and **(b)**

tude of adatoms was frequently larger than the depth of the corner holes. The origin of such a large corrugation of adatoms may be due to the effect of the chemical interaction, but that is yet unclear.

The atom positions, surface energies, dynamic properties, and chemical reactivities on the Si(111)7×7 reconstructed surface have been extensively investigated theoretically and experimentally. From these investigations, the possible origins of the contrast between inequivalent adatoms in AFM images are the following: the true atomic heights that correspond to the adatom core positions, the stiffness (spring constant) of inter-atomic bonding with the adatoms that corresponds to the frequencies of the surface mode, the amount of charge of adatom, and the chemical reactivity of adatoms. Table 13.1 summarizes the decreasing orders of the inequivalent adatoms for individual property. From Table 13.1, we can see that the calculated adatom heights and the stiffness of inter-atomic bonding cannot explain the AFM data, while the amount of charge of adatom and the chemical reactivity of adatoms can explain our data. The contrast due to the amount of charge of adatom means that the AFM image originated from the difference of the vdW, or the electrostatic physical interactions between the tip and the valence electrons at the adatoms. The contrast due to the chemical reactivity of adatoms means that the AFM image originated from the difference of covalent bonding chemical interaction between the atoms at the tip apex and the dangling bond of adatoms. Thus, we can see there are two possible interactions that explain the strong contrast between inequivalent adatoms of the 7×7 unit cell observed using the Si tip with dangling bond.

A weak contrast image in Fig. 13.10a is due to vdW and/or electrostatic force interactions. On the other hand, strong contrast images in Figs. 13.10b and 13.11a are due to a covalent bonding formation between the AFM tip with Si atoms and Si adatoms. These results signify the capability of the noncontact mode AFM to image the variation in chemical reactivity of Si adatoms. In the future, by controlling an atomic species at the tip apex, the study of chemical reactivity on an atomic scale will be possible using the noncontact AFM.

13.2.2 Si(100)2×1 and Si(100)2×1:H Monohydride Surfaces

In order to investigate the imaging mechanism of the noncontact AFM, a comparative study between a reactive surface and an insensitive surface using the same tip is very useful. Si(100)2×1:H monohydride surface is a Si(100)2×1 reconstructed surface that is terminated by a hydrogen atom. It does not reconstruct as metal is deposited on the semiconductor surface. The surface structure hardly changes. Thus, Si(100)2×1:H monohydride surface is one of most useful surfaces for a model system to investigate the imaging mechanism, experimentally and theoretically. Furthermore, whether the interaction between a very small atom such as hy-

drogen and a tip apex is observable with noncontact AFM is interesting. Here, we show noncontact AFM images measured on a Si(100)2×1 reconstructed surface with a dangling bond and a Si(100)2×1:H monohydride surface with a dangling bond that is terminated by a hydrogen atom [13.50].

Figure 13.12a shows the atomic resolution image of a Si(100)2×1 reconstructed surface. The paired bright spots arranged like rows with a 2×1 symmetry was observed with clear contrast. Missing pairs of bright spots were observed, as indicated by arrows. Further, pairs of bright spots are shown by the white dashed arc and appear to be the stabilize-buckled asymmetric dimer structure. The distance between paired bright spots is 3.2±0.1 Å.

Figure 13.13a shows the atomic resolution image of a Si(100)2×1:H monohydride surface. Paired bright spots arranged like rows were observed. Missing paired bright spots, as well as those paired in rows and single bright spots were observed, as indicated by arrows. The distance between paired bright spots is 3.5±0.1 Å. This distance is 0.2 Å larger than that of a Si(100)2×1 reconstructed surface. It was found that the distance between bright spots increases in size due to the hydrogen termination.

The bright spots in Fig. 13.12 do not merely image the silicon atom site, because the distance between bright spots forming the dimer structure of Fig. 13.12a (3.2±0.1 Å) is larger than the distance between silicon atoms of every dimer structure model (2.9 Å is the maximum distance between upper silicons on asymmetric dimer structures). This seems to be due to the contribution to imaging of the chemical bonding interaction between the dangling bond out of the silicon tip apex and the dangling bond on the Si(100)2×1 reconstructed surface. The chemical bonding interaction works with strong direction dependence between the dangling bond out of the silicon dimer structure on the Si(100)2×1 reconstructed surface and the dangling bond out of the silicon tip apex, and the dimer structure is obtained with a larger distance than between silicons on the surface.

The bright spots of Fig. 13.13 seem to be located at hydrogen atom sites on a Si(100)2×1:H monohydride surface, because the distance between bright spots forming the dimer structures (3.5±0.1 Å) agrees approximately with the distance between the hydrogen, i.e., 3.52 Å. Thus, noncontact AFM atomically resolves the individual hydrogen atoms on the topmost layer. On this surface, the dangling bond is terminated by a hydrogen atom, and the hydrogen atom on the topmost layer does not have a chemical reactivity. Therefore, the interaction between the hydrogen atom on the top most layer and the silicon tip apex does not contribute to the chemical bonding interaction with strong direction de-

pendence as in a silicon surface, and the bright spots of a noncontact AFM image correspond to the hydrogen atom sites on the topmost layer.

13.2.3 Metal-Deposited Si Surface

In this section, we will introduce the comparative study of force interaction between a Si tip and a metal deposited Si surface and between a metal adsorbed Si tip and a metal-deposited Si surface [13.51, 52]. As for the metal-deposited Si surface, a Si(111)$\sqrt{3}\times\sqrt{3}$-Ag (hereafter referred to as $\sqrt{3}$-Ag) surface was used.

For the $\sqrt{3}$-Ag surface, the honeycomb-chained trimer (HCT) model has been accepted as the appropriate model. As shown in Fig. 13.14, this structure contains Si trimer at the second layer, 0.75 Å below the Ag trimer at the topmost layer. The topmost Ag atoms and the lower Si atoms form covalent bonds. The inter-atomic distances between the nearest neighbor Ag atoms forming Ag trimer and between lower Si atoms forming Si trimer are 3.43 Å and 2.31 Å, respectively. The apexes of Si trimers and Ag trimers face the $[11\bar{2}]$ direction and the direction tilted a little to the $[\bar{1}\bar{1}2]$ direction, respectively.

In Fig. 13.15, we show the noncontact AFM images measured using a normal Si tip at the frequency shift of (a) −37 Hz, (b) −43 Hz, and (c) −51 Hz, respectively. These frequency shifts correspond to the tip-sample distance of about 0–3 Å. We defined the zero position of tip-sample distance, i. e., the contact point, where the vibration amplitude began to decrease. The rhombus indicates the $\sqrt{3}\times\sqrt{3}$ unit cell. When the tip approached the surface, the contrast of the noncontact AFM images became strong and the pattern remarkably changed. That is, by moving the tip toward the sample surface, the hexagonal pattern, the trefoil-like pattern composed of three dark lines, and the triangle pattern can be observed sequentially. In Fig. 13.15a, the distance between the bright spots is 3.9 ± 0.2 Å. In Fig. 13.15c, the distance

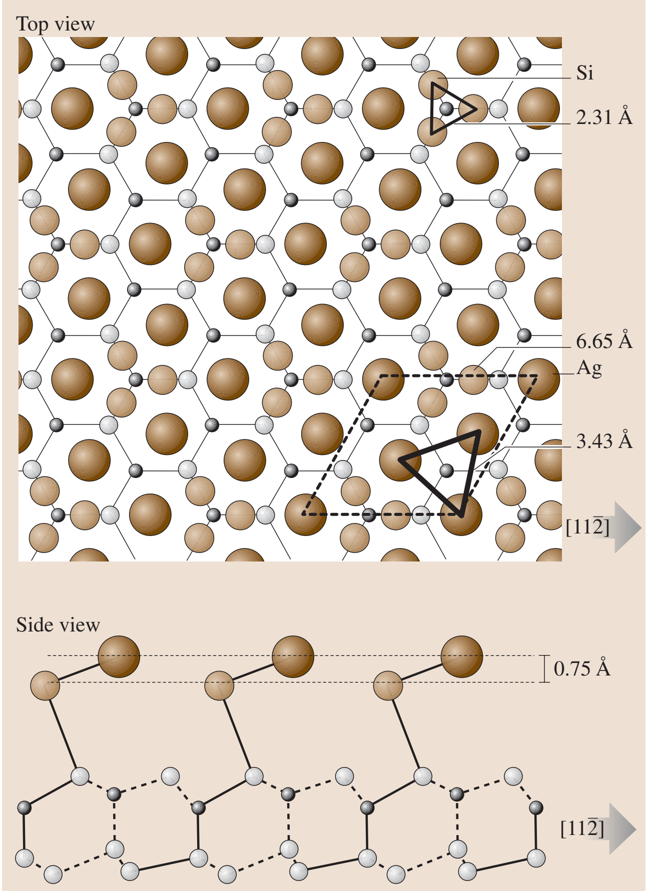

Fig. 13.14 HCT model for the structure of the Si(111)$\sqrt{3}\times\sqrt{3}$-Ag surface. *Black closed circle*, *gray closed circle*, *open circle*, and *closed circle* with *horizontal line* indicate Ag atom at the topmost layer, Si atom at the second layer, Si atom at the third layer, and Si atom at the fourth layer, respectively. *Rhombus* indicates $\sqrt{3}\times\sqrt{3}$ unit cell. *Thick*, *large solid triangle* indicates an Ag trimer. *Thin*, *small, solid triangle* indicates a Si trimer

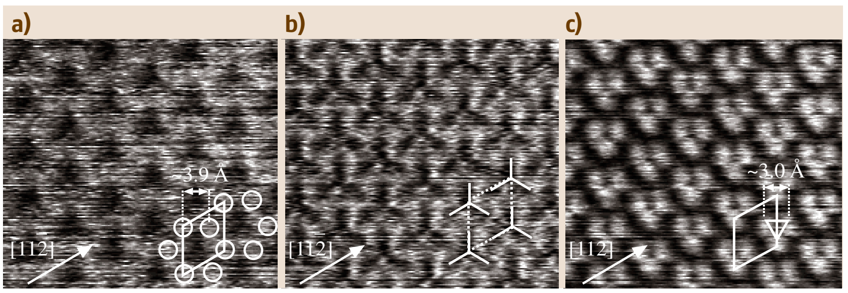

Fig. 13.15a–c Noncontact AFM images obtained at the frequency shifts of **(a)** −37 Hz, **(b)** −43 Hz, and **(c)** −51 Hz on a Si(111)$\sqrt{3}\times\sqrt{3}$-Ag surface. This distance dependence was obtained with the Si tip. Scan area is 38 Å × 34 Å. A *rhombus* indicates $\sqrt{3}\times\sqrt{3}$ unit cell

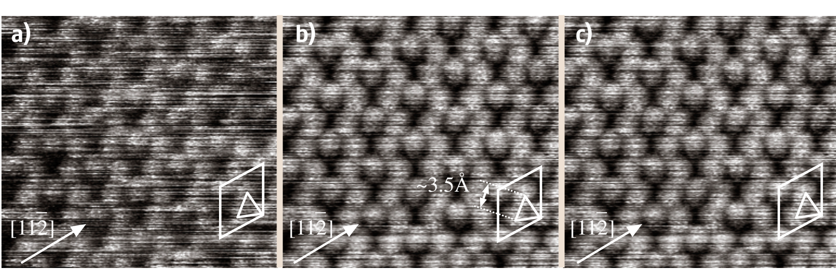

Fig. 13.16a–c Noncontact AFM images obtained at the frequency shifts of **(a)** −4.4 Hz, **(b)** −6.9 Hz, and **(c)** −9.4 Hz on a Si(111)$\sqrt{3}\times\sqrt{3}$-Ag surface. This distance dependence was obtained with the Ag adsorbed tip. Scan area is 38 Å × 34 Å

between the bright spots is 3.0 ± 0.2 Å, and the direction of the apex of all triangles composed of three bright spots is [11$\bar{2}$].

In Fig. 13.16, we show the noncontact AFM images measured by using an Ag adsorbed tip at the frequency shift of (a) −4.4 Hz, (b) −6.9 Hz, and (c) −9.4 Hz, respectively. The tip-sample distances Z are roughly estimated to be $Z = 1.9$ Å, 0.6 Å, and ∼ 0 Å (in noncontact region), respectively. When the tip approached the surface, the pattern of the noncontact AFM images didn't change, although the contrasts became clearer. A triangle pattern can be observed. The distance between the bright spots is 3.5 ± 0.2 Å. The direction of the apex of all triangles composed of three bright spots is tilted a little from the [$\bar{1}\bar{1}$2] direction.

Thus, noncontact AFM images measured on a Si(111)$\sqrt{3}\times\sqrt{3}$-Ag surface showed two types of distance dependence of the image patterns, depending on the atom species on the tip apex.

By using the normal Si tip with dangling bond, as in Fig. 13.15a, the measured distance between the bright spot of 3.9 ± 0.2 Å agrees with the distance of 3.84 Å between the center of the Ag trimer in the HCT model within the experimental error. Furthermore, the hexagonal pattern composed of six bright spots also agrees with the honeycomb structure of the Ag trimer in the HCT model. So the most appropriate site corresponding to the bright spots in Fig. 13.15a is the site of the center of the Ag trimers. In Fig. 13.15c, the measured distance of 3.0 ± 0.2 Å between the bright spots forming the triangle pattern does not agree with either the distance between the Si trimer of 2.31 Å or the distance between the Ag trimer of 3.43 Å in the HCT model, while the direction of the apex of triangles composed of three bright spots agrees with the [11$\bar{2}$] direction of the apex of the Si trimer in the HCT model. So the most appropriate site corresponding to the bright spots in Fig. 13.15c is the intermediate site between Si atoms and Ag atoms. On the other hand, by using the Ag adsorbed tip, the measured distance of 3.5 ± 0.2 Å between the bright spots in Fig. 13.16 agrees with the distance of 3.43 Å between the nearest neighbor Ag atoms forming the Ag trimer at the topmost layer in the HCT model within the experimental error. In addition, the direction of the apex of the triangles composed of three bright spots also agrees with the direction of the apex of the Ag trimer, i. e., tilted [$\bar{1}\bar{1}$2], in the HCT model. So the most appropriate site corresponding to the bright spots in Fig. 13.16 is the site of individual Ag atoms forming the Ag trimer at the topmost layer.

It should be noted that by using the noncontact AFM with an Ag adsorbed tip the individual Ag atom on the $\sqrt{3}$-Ag surface could be resolved in real space for the first time, although it could not be resolved by using the noncontact AFM with a Si tip. So far, the $\sqrt{3}$-Ag surface has been observed by the scanning tunneling microscope (STM) with atomic resolution. However, the STM can measure the local charge density of state near Fermi level on the surface. From the first principle calculation, it was proven that the unoccupied surface state is densely distributed around the center of the Ag trimer. As a result, bright contrast is obtained at the center of the Ag trimer with the STM.

Finally, we consider the origin of the atomic resolution imaging of the individual Ag atoms on the $\sqrt{3}$-Ag surface. Here, we discuss the difference of the force interactions between the Si and the Ag adsorbed tips. As shown in Fig. 13.17a, by using the Si tip, there is the dangling bond out of the topmost Si atom on the Si tip apex. As a result, the force interaction is dominated by the physical bonding interaction such as Coulomb force far from the surface and by chemical bonding interaction very close to the surface. In other words, if the reactive Si tip with dangling bond approaches the surface, at the distance far from the surface, the Coulomb force acts between the electron localized at the dangling bond out of the topmost Si atom on the tip apex and the positive charge distributed around the center of the Ag trimer. At the distance very close to the surface, the chemical bonding interaction will occur due to the onset of the or-

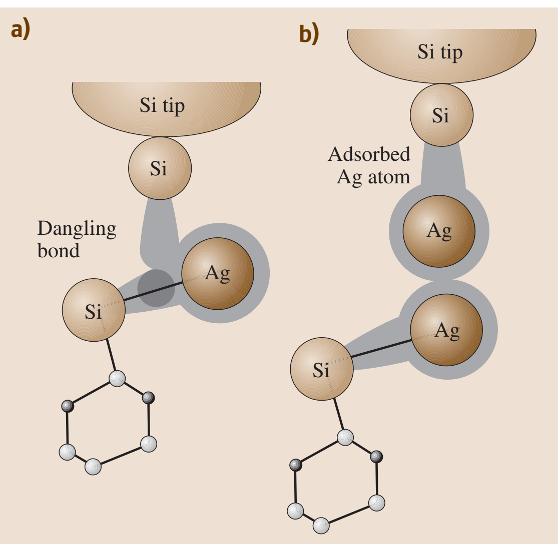

Fig. 13.17a,b Schematic illustration of **(a)** the Si atom with dangling bond and **(b)** the Ag adsorbed tip above the Si-Ag covalent bond on Si(111)$\sqrt{3}\times\sqrt{3}$-Ag surface

bital hybridization between the dangling bond out of the topmost Si atom on the Si tip apex and the Si-Ag covalent bond on the surface. Hence, the individual Ag atoms will not be resolved, the image pattern will change depending on the tip-sample distance. On the other hand, as shown in Fig. 13.17b, by using an Ag adsorbed tip, the dangling bond localized out of the topmost Si atom on the Si tip apex is terminated by the adsorbed Ag atom. As a result, even at very close tip-sample distance, the force interaction is dominated by the physical bonding interaction such as the vdW force interaction. If the Ag adsorbed tip approaches the surface, the vdW force acts between the Ag atom on the tip apex and Ag or Si atom on the surface. Ag atoms at the topmost layer on the $\sqrt{3}$-Ag surface are located higher than the Si atoms at the lower layer. Hence, the individual Ag atoms (or nearly true topography) will be resolved, and the image pattern will not change even at very close tip-sample distance. It should be emphasized that there is a possibility to identify or recognize atom species on a sample surface using the noncontact AFM if we can control an atomic species at the tip apex.

13.3 Applications to Insulators

Insulators such as alkali halides, fluorides, and metal oxides are key materials in many applications, including optics, microelectronics, catalysis, and so on. Surface properties are important in these technologies, but they are usually poorly understood. This is due to their low conductivity, which makes it difficult to investigate them using electron- and ion-based measurement techniques such as low-energy electron diffraction, ion scattering spectroscopy, and scanning tunneling microscopy (STM). Surface imaging by noncontact atomic force microscopy (NC-AFM) does not require the sample to exhibit high conductivity, because NC-AFM detects a force between the tip on the cantilever and the surface of the sample. Since the first report of atomically resolved NC-AFM on a Si(111) 7×7 surface [13.33], several groups have succeeded in obtaining "true" atomic resolution images of insulators, including defects, and it has been shown that NC-AFM is a powerful new tool for the atomic-scale surface investigation of insulators.

In this section, we will describe typical results of atomically resolved NC-AFM imaging of insulators such as alkali halides, fluorides, and metal oxides. For alkali halides and fluorides, we will focus on the contrast formation, which is the most important issue for interpreting atomically resolved images of binary compounds on the basis of experimental and theoretical results. For the metal oxides, typical examples of atomically resolved imaging will be shown. Also, simultaneous imaging using STM and NC-AFM will be described, and the difference between the STM and NC-AFM images will be demonstrated. Finally, we will describe the results obtained when we imaged an antiferromagnetic NiO(001) surface with a ferromagnetic Fe-coated tip in order to explore the possibility of detecting short-range magnetic interaction using the NC-AFM.

13.3.1 Alkali Halides, Fluorides, and Metal Oxides

The surfaces of alkali halides were the first insulating materials to be imaged by NC-AFM with true atomic resolution [13.53]. Up until now, there have been reports on atomically resolved images of (001) cleaved surfaces for single crystal NaF, RbBr, LiF, KI, NaCl [13.54], KBr [13.55], and thin films of NaCl(001) on Cu(111) [13.56]. In this section, we describe the contrast formation of alkali halides surface on the basis of experimental and theoretical results.

Alkali Halides

In experiments of alkali halides, the symmetry of the observed topographic images indicates that the protrusions exhibit only one type of ions, either positively or negatively charged ions. This leads to the conclusion that the atomic contrast is dominantly caused by electrostatic interactions between a charged atom at the tip apex and the surface ions, i. e., the long-range forces between the macroscopic tip and the sample such as van der Waals force is modulated by an alternating short-range electrostatic interaction of the surface ions. Theoretical work employing the atomistic simulation technique has revealed the mechanism for contrast formation on an ionic surface [13.57]. A significant part of the contrast is due to the displacement of ions in the force field, not only enhancing the atomic corrugations, but also contributing to the electrostatic potential by forming dipoles at the surface. The experimentally observed atomic corrugation height is determined by the interplay of the long- and short-range forces. In the case of NaCl, it has been experimentally demonstrated that a more blunt tip produces a larger corrugation when the tip-sample distance is shorter [13.54]. This result shows that the increased long-range forces induced by a blunt tip allow for more stable imaging closer to the surface. The stronger electrostatic short-range interaction and the larger ion displacement produce a more pronounced atomic corrugation.

At steps and kinks of an NaCl thin film on Cu(111), the amplitude of the atomic corrugations has been observed to increase by up to a factor of two, as large as that of atomically flat terraces [13.56]. This increase in the contrast is due to the low coordination of the step-edge and the kinked ions. The low coordination of the ions results in an enhancement of the electrostatic potential over the site and an increase in the displacement induced by the interaction with the tip. These results demonstrate that the short-range interaction dominates the atomic contrast and leads to a considerable displacement of the surface ions from the ideal position.

Theoretical study predicts that the image contrast depends on the chemical species of the tip apex. *Bennewitz* et al. [13.56] have performed the calculations using an MgO tip terminated by oxygen, an Mg ion, and an OH. The magnitude of the atomic contrast for the Mg-terminated tip shows a slight increase in comparison with an oxygen-terminated tip. The atomic contrast with the oxygen-terminated tip is dominated by the attractive electrostatic interaction between the oxygen on the tip apex and the Na ion, but the Mg-terminated tip attractively interacts with the Cl ion. Also, it has been demonstrated that the magnitude of the contrast for an OH-terminated tip is almost an order of magnitude less than for the oxygen- and Mg-terminated tips.

In order to explore the imaging mechanism for the alkali halides, the heterogeneous surface of NaCl crystal containing $(OCN)^-$ molecules as impurities has been observed by NC-AFM [13.58]. In this case, the atomic periodicity of the NaCl lattice is imaged. However, high-resolution investigations of impurities are limited by the convolution between the tip apex and the molecules at the surface. *Bennewitz* et al. [13.59] reported on the heterogeneous surfaces of alkali halide crystals. In this experiment, which was designed to observe the chemically nonhomogeneous alkali halide surface, a mixed crystal composing of 60% KCl and 40% KBr was used as the sample. In this crystal, which is a so-called solid solution, the Cl and Br ions are mixed randomly. The image of the cleaved $KCl_{0.6}Br_{0.4}(001)$ surface indicates that only one type of ion is imaged as protrusions as if it were a pure alkali halide crystal. However, there is a significant difference in comparison with the surface of a pure crystal. The amplitude of atomic corrugation varies strongly between the positions of the ions imaged as depressions. This variation in the corrugations corresponds to the constituents of the crystal, i. e., the Cl and Br ions, and it is concluded that the tip apex is negatively charged. Also, it is demonstrated that a comparison between the distribution of the deep depressions and the composition of the mixed crystal assigns the deep depressions to Br ions. Although an evaluation of the effect of the surface buckling induced by a random distribution of anions is needed in order to understand the contrast mechanism, this result demonstrates that NC-AFM measurement exhibits chemical sensitivity on an atomic scale. For applications to alkali halide surfaces, real space imaging with NC-AFM presents the possibility for chemical discrimination at the surface.

Fluorides

Fluorides are important materials for the progress of atomic-scale resolution NC-AFM imaging on insulators. There are reports in the literature of surface images for single crystal BaF_2, SrF_2 [13.60], and CaF_2 [13.61–63]. Surfaces of fluorite-type crystals are prepared by cleaving along the (111) planes. Their structure is more complex than the structure of alkali halides with the NaCl structure. The complexity is of great interest for atomic-resolution imaging using an NC-AFM and also for theoretical predictions of the interpretation of atomic-scale contrast information.

The first atomically resolved images of a $CaF_2(111)$ surface have been obtained in topographic mode [13.62] in which the tip-sample distance is regulated by maintaining a constant frequency shift. In this imaging mode, the surface ions mostly appear as spherical caps. Similar measurements have been performed on the (111) surfaces of SrF_2 and BaF_2.

Barth et al. [13.64] have found that the $CaF_2(111)$ surface images obtained using the constant height mode, in which the frequency shift is recorded with a very low loop gain, can be categorized into two contrast patterns. In the first, the ions appear as triangles, and in the other, they have the appearance of circles, similar to the contrast obtained in a topographic image. These differences are revealed by comparing the cross sections along the [121] direction. Theoretical studies demonstrated that these two different contrast patterns could be explained as a result of imaging with tips of different polarity [13.64–66]. When imaging with a positively charged (cation-terminated) tip, the triangular pattern appears. In this case, the contrast is dominated by the strong short-range electrostatic attraction between the positive tip and the negative F ions. The cross section along the [121] direction of the triangular image shows two maxima: one is a larger peak over the F ions located in the topmost layer, and the other is a smaller peak at the position of the F ions in the third layer. The minima appear at the position of the Ca ions in the second layer. When imaging with a negatively charged (anion-terminated) tip, the spherical image contrast appears, and the main periodicity is created by the Ca ions in the second layer between the topmost and the third F ion layers. In the cross section along the [121] direction, the large maxima correspond to the Ca sites, because of the strong attraction of the negative tip, and the minima appear at the sites of maximum repulsion over the F ions in the first layer. At a position between two F ions, there are smaller maxima. This reflects the weaker repulsion over the third layer F ion sites compared to the protruding topmost F ion sites and a slower decay in the contrast on one side of the Ca ions. These results demonstrate that the image contrast of a $CaF_2(111)$ surface depends on the state of the tip apex.

The triangular pattern obtained with a positively charged tip appears at relatively large tip-sample distance, as shown in Fig. 13.18a. On the cross section along the [121] direction, experimental results and theoretical studies both demonstrate the large peak and small shoulder characteristic for the triangular pattern image (Fig. 13.18d). When the tip approaches the surface more closely, the triangular pattern of the experimental images is more vivid (Fig. 13.18b), just as predicted in the theoretical works. On the cross section along the [121] direction, as the tip approaches, the amplitude of the shoulder increases until it is equal to that of the main peak, and this feature gives rise to the honeycomb pattern image, as shown Fig. 13.18c. These results demonstrate that there is a more complex process of image contrast formation. Also, from detailed theoretical analysis of the electrostatic potential [13.67], it is suggested that the change in displacement of the ions due to the proximity of the tip plays an important role in the formation of the image contrast. Such a drastic change in image contrast, depending on both the polarity of the terminated tip atom and the tip-sample distance, is inherent in

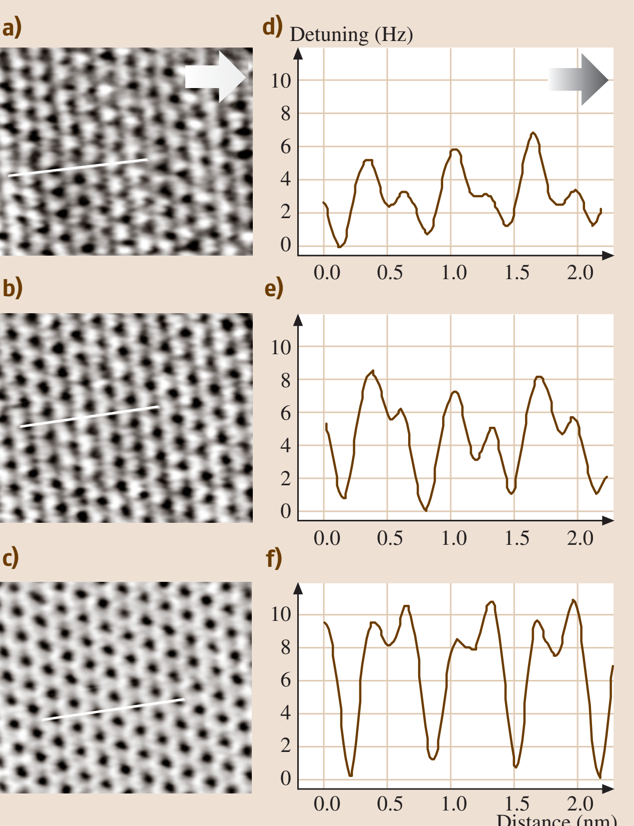

Fig. 13.18 **(a)**–**(c)** $CaF_2(111)$ surface images obtained by using the constant height mode. From **(a)** to **(c)** the frequency shift was lowered. The *white lines* represent the positions of the cross section. **(d)**–**(f)** The cross section extracted from the Fourier-filtered images of **(a)**–**(c)**. the fluoride (111) surface, and this image contrast feature cannot be seen on the (001) surface of alkali halides with a simple crystal structure.

These results have demonstrated that there is good agreement between experiment and theory. However, the results of careful experiments show another feature: The cross sections in the forward and backward scan directions do not yield identical results [13.64]. Also, it is shown that the structures of cross sections taken along the three equivalent [121] directions are different. It is thought that this can be attributed to the asymmetry of the nano-cluster at the tip apex, which leads to different interactions in the equivalent directions. A better understanding of the asymmetric image contrast may require a more complicated modeling of the tip structure. However, the most desirable solution would be the development of the suitable techniques for well-defined tip preparation. In fact, it should be mentioned that perfect tips on an atomic scale can occasionally be obtained. These tips do yield identical results in forward and backward scanning, and cross sections in the three equivalent directions taken with this tip are almost identical [13.68].

The fluoride (111) surface is an excellent standard surface for calibrating tips on an atomic scale. The polarity of the tip-terminated atom can be determined from the image contrast pattern (spherical or triangular pattern). The irregularities in the tip structure can be detected, since the surface structure is highly symmetric. Therefore, once such a tip has been prepared, it can be used as a calibrated tip for imaging unknown surfaces.

The states of the tip apex play an important role in interpreting NC-AFM images of alkali halide and fluoride surfaces. It is expected that the achievement of a good correlation between experimental and theoretical studies will help advance surface imaging for insulators by NC-AFM.

Metal Oxides

Most of the metal oxides that have attracted strong interest for their technological importance are insulative. Therefore, in the case of atomically resolved imaging of metal oxide surfaces by STM, efforts to increase the conductivity of the sample are needed, for example, the introduction of defects of anions or cations, doping with other atoms, and surface observations during heating of the sample. However, in principle, NC-AFM provides the possibility of observing nonconductive metal oxides without these efforts. In cases where the conductivity of the metal oxides is high enough for a tunneling current to flow, it should be noted that most of the surface images obtained by NC-AFM and STM are not identical.

Since the first report of atomically resolved images on a $TiO_2(110)$ surface with oxygen point defects [13.69], they have also been reported on $TiO_2(100)$ [13.70–72], $SnO_2(110)$ [13.73], NiO(001) [13.74, 75], $SrTiO_3(100)$ [13.76], and $CeO_2(111)$ [13.77] surfaces. Also, *Barth* et al. [13.78] have succeeded in obtaining atomically resolved NC-AFM images of a clean α-$Al_2O_3(0001)$ surface, which is impossible to investigate using STM. In this section, we describe typical results of the imaging of metal oxides by NC-AFM.

The α-$Al_2O_3(0001)$ surface exists in several ordered phases that can be reversibly transformed into each other by thermal treatments and oxygen exposure. It is known that the high temperature phase has a large $(\sqrt{31}\times\sqrt{31})R\pm 9°$ unit cell. However, the details of the atomic structure of this surface have not been revealed, and two models are proposed from the results of low-energy electron diffraction and X-ray diffraction studies. Recently, *Barth* et al. [13.78] have directly observed this reconstructed α-$Al_2O_3(0001)$ surface by NC-AFM. They confirmed that the dominant contrast of the low magnification image corresponds to a rhombic grid representing a unit cell of $(\sqrt{31}\times\sqrt{31})R+9°$, as shown in Fig. 13.19a. Also, more details of atomic structures are determined from the higher magnification image (Fig. 13.19b), which was taken at a reduced tip-sample distance. In this atomically resolved image, it is revealed that each side of the rhombus is intersected by 10 atomic rows, and that a hexagonal arrangement of atoms exists in the center of the rhombi (Fig. 13.19c). This feature agrees with the proposed surface structure that predicts order in the center of hexagonal surface domains and disorder at the domain boundaries. Their result is an excellent demonstration of the capabilities of the NC-AFM as a powerful tool for the atomic-scale surface investigation of insulators.

In addition, *Barth* et al. [13.78] have performed observations of the $Al_2O_3(0001)$ surface when it is exposed to water and hydrogen. It is suggested that the region of atomic disorder has an extremely high reactivity. Such investigations of the surface structure of adsorbed insulator substrates can only be provided by NC-AFM. The NC-AFM imaging of metal growth on oxides [13.79] has also been reported. A description of the adsorbed molecular arrangement on a TiO_2 surface can be found in the next section.

The atomic structure of $SrTiO_3(100)$-$(\sqrt{5}\times\sqrt{5})$ $R26.6°$ surface, as well as that of $Al_2O_3(0001)$-$(\sqrt{31}\times\sqrt{31})R\pm 9°$ can be determined on the basis of

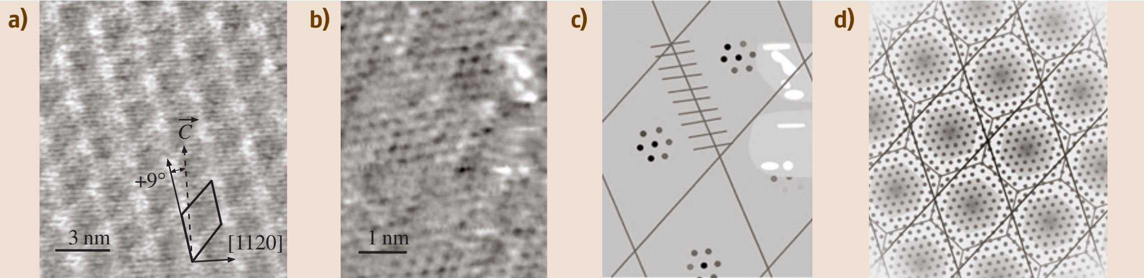

Fig. 13.19 **(a)** Image of the high temperature, reconstructed clean α-Al_2O_3 surface obtained by using the constant height mode. The *rhombus* represents the unit cell of the $(\sqrt{31}\times\sqrt{31})R+9°$ reconstructed surface. **(b)** Higher magnification image of **(a)**. Imaging was performed at a reduced tip-sample distance. **(c)** Schematic representation of the indicating regions of hexagonal order in the center of reconstructed rhombi. **(d)** Superposition of the hexagonal domain with reconstruction rhombi found by NC-AFM imaging. Atoms in *gray shaded regions* are well-ordered. The images and the schematic representations are from [13.78]

the results of NC-AFM imaging [13.76]. $SrTiO_3$ is one of the perovskite oxides and its (100) surface exhibits the many different kinds of reconstructed structures. In the case of the $(\sqrt{5}\times\sqrt{5})R26.6°$ reconstruction, the oxygen vacancy-Ti^{3+}-oxygen model (where the terminated surface is TiO_2 and the observed spots are related to oxygen vacancies) was proposed from the results of STM imaging. As shown in Fig. 13.20, *Kubo* et al. [13.76] have performed measurements using both STM and NC-AFM and have found that the size of the bright spots, as observed by NC-AFM, is always smaller than that for STM measurement and that the dark spots, which are not observed by STM, are arranged along the [001] and [010] directions in the NC-AFM image. A theoretical simulation of the NC-AFM image using first-principles calculations shows that the bright and dark spots correspond to Sr and oxygen atoms, respectively. It has been proposed that the structural model of the reconstructed surface consists of an ordered Sr adatom located at the oxygen fourfold site on the TiO_2-terminated layer (Fig. 13.20c).

Because STM images are related to the spatial distribution of the wave functions near the Fermi level, atoms, which do not have a local density of states near the Fermi level, are generally invisible even on the conductive materials. On the other hand, the NC-AFM image reflects the strength of the tip-sample interaction force originating from chemical, electrostatic interactions, and so on. Therefore, even STM and NC-AFM images obtained using an identical tip and sample will generally differ.

Simultaneous imaging of a $TiO_2(110)$ surface with STM and NC-AFM shows a typical result that differs in terms of the atoms that are visualized [13.72]. For simultaneous imaging, the tip-sample distance is controlled by keeping a constant frequency shift, and the tunneling current between the oscillating cantilever and the surface is measured. The two images show different atomic contrasts, i. e., the atomic corrugation of the

Part B | 13.3

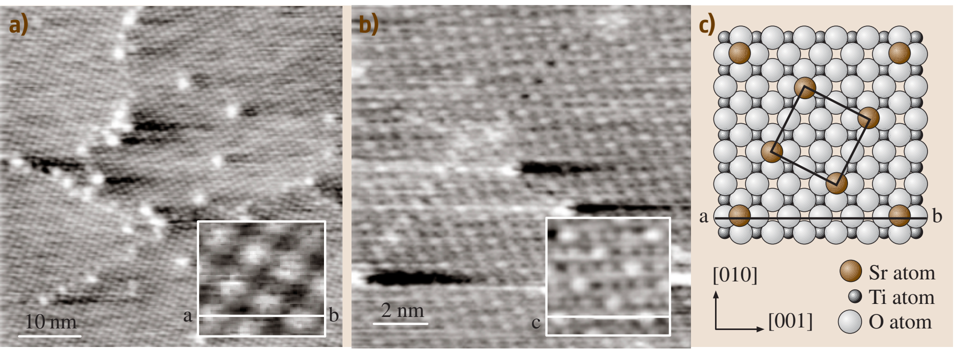

Fig. 13.20 **(a)** STM and **(b)** NC-AFM images of a $SrTiO_3(100)$ surface. **(c)** A proposed model of the $SrTiO_3(100)$-$(\sqrt{5}\times\sqrt{5})R26.6°$ surface reconstruction. The images and the schematic representations are from [13.76]

STM image is in antiphase in the (1×1) and in phase in the (1×2) with respect to the NC-AFM image. In the (1×1), the STM image shows that the dangling bond states at the tip apex overlap with the dangling bonds of the 3*d* states that are protruding from the Ti atom, while the NC-AFM primarily imaged the uppermost oxygen atom. The results of $SrTiO_3$ and TiO_2 surface imaging show that the information obtained by STM and NC-AFM differ, and that the simultaneous imaging of a metal oxide surface enables the investigation of a more detailed surface structure.

13.3.2 Atomically Resolved Imaging of a NiO(001) Surface

The transition metal oxides such as NiO, CoO, and FeO feature the simultaneous existence of an energy gap and unpaired electrons, which gives rise to magnetic properties. Such magnetic insulators are widely used for the exchange biasing in spin valve devices. The NC-AFM enables the direct surface imaging of magnetic insulators on an atomic scale. The forces detected by NC-AFM originate from several kinds of interaction between the surface and the tip, including magnetic interactions in some cases. Theoretical studies predict that short-range magnetic interactions such as the exchange interaction should enable the NC-AFM to image magnetic moments on an atomic scale. In this section, we will describe an imaging of the antiferromagnetic NiO(001) surface using a ferromagnetic Fe-coated tip in order to explore the detection of the short-range magnetic interaction. Also, theoretical studies of the exchange force interaction between a magnetic tip and a sample will be described.

Theoretical Studies of the Exchange Force

The NC-AFM measures various kinds of interaction between tip and sample such as van der Waals, and electrostatic and short-range chemical interactions. In the case of a magnetic tip and sample, the interaction detected by the NC-AFM includes the long-range magnetic dipole interaction and the short-range magnetic interaction. The short-range magnetic interaction between the atoms at the tip apex and the sample surface is governed by a combination of the Coulomb interaction and the Pauli exclusion principle and may be included among the short-range chemical interactions. The magnetic interaction energy depends on the electron spin state of the atoms, and the energy difference in spin alignments (parallel or anti-parallel) is referred to as the exchange interaction energy. Therefore, if the short-range magnetic interaction can be detected, an atomically resolved NC-AFM image, in which the short-range interaction contributes to the atomic protrusions, should reveal the local energy difference in the spin alignment.

In the past, extensive theoretical studies on the short-range magnetic interaction between a ferromagnetic tip and a ferromagnetic sample have been performed by a simple calculation [13.80], a tight-binding approximation [13.81], and first-principles calculations [13.82]. In the calculations performed by *Nakamura* et al. [13.82], three-atomic-layer Fe(001) films, which are separated by a vacuum gap, are used as a model for the tip and sample. The exchange force (F_{ex}) is defined as the difference of the forces (F_P, F_{AP}) in each spin configuration (parallel: P, anti-parallel: AP) of the tip and sample. The tip-sample distance dependency of the exchange force demonstrates that the amplitude of the exchange force is on the order of 10^{-10} N or above and is large enough to be detected by NC-AFM. Also, the site dependency of the exchange force indicates that the discrimination of the exchange force enables the direct imaging of the magnetic moments on an atomic scale. Recently, the interaction between a spin-polarized H atom and a Ni atom on a NiO(001) surface has been investigated theoretically [13.83]. *Foster* and *Shluger* demonstrated that the difference in magnitude of the exchange interaction between opposite spin Ni ions in a NiO surface could be sufficient to be measured in a low temperature NC-AFM experiment. Also, in order to investigate the effect of surface relaxation, they calculated the interaction of different metal tips with the MgO surface used as a model system. The results indicated that the interaction over the oxygen site is stronger than that over the Mg site, and it was pointed out that the tips should be coated in metals that interact weakly with the surface for the detection of the exchange interaction between the atom at the tip apex and the Ni atom on the NiO surface. However, we must take into account another possibility, that is, that a metal atom at the ferromagnetic tip apex may interact with a Ni atom on the second layer through a magnetic interaction mediated by the electrons in an oxygen atom on the surface.

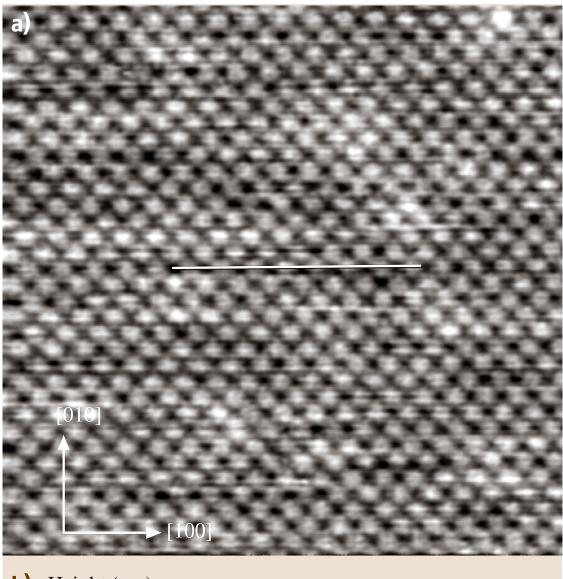
13.3.3 Atomically Resolved Imaging Using Noncoated and Fe-Coated Si Tips

It is thought that the magnetic insulator NiO is one of the best candidates for detecting short-range magnetic interactions such as the exchange interaction, because an experimental configuration of a ferromagnetic tip

and an antiferromagnetic sample minimizes the long-range magnetic dipole interaction that might hinder the detection of the short-range interaction.

Below the Néel temperature of 525 K, NiO is antiferromagnetic and has a rhombohedral structure contracted along the ⟨111⟩ axes. The direction of the spin on nickel atoms in the same {111} plane is parallel, a so-called ferromagnetic sheet. The direction of spin in the adjacent {111} planes is anti-parallel. As a result, the spins at the Ni atoms on the (001) surface are arranged in a checkerboard pattern, i. e., the spin alignment along the ⟨111⟩ direction is antiferromagnetic in order and that along the ⟨1 −1 0⟩ direction is ferromagnetic in order.

Figure 13.21a shows an atomically resolved image of a NiO(001) surface with a ferromagnetic Fe-coated tip [13.84]. The bright protrusions correspond to atoms spaced about 0.42 nm apart, consistent with the expected periodic arrangement of the NiO(001) surface.



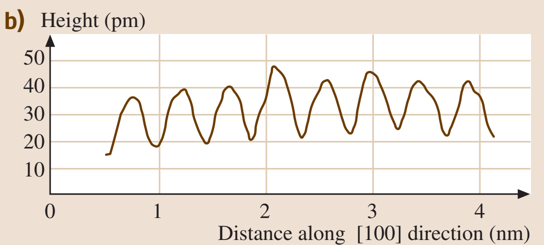


Fig. 13.21 (a) Atomically resolved image obtained with an Fe-coated tip. **(b)** shows the cross sections of the middle part in **(a)**. Their corrugations are about 30 pm

The corrugation amplitude is typically 30 pm, which is comparable to the value previously reported [13.74, 75], as shown in Fig. 13.21b. Also, because of the symmetry of the image, it was concluded that only one type of atom is visualized by NC-AFM. However, from this image, we think that it is difficult to distinguish which of the atoms are observed, oxygen or nickel. The theoretical works indicate that a metal tip interacts strongly with the oxygen atoms on the MgO(001) surface [13.83]. From this result, it is presumed that the bright protrusions correspond to the oxygen atoms. However, it is still questionable which of the atoms are visible with a Fe-coated tip.

If the short-range magnetic interaction is included in the interactions detected by NC-AFM, the corrugation amplitude of the atoms should depend on the direction of the spin at the atom-site. The results of a comparison of the corrugation amplitudes of the same species of atoms with opposite spin can reveal the difference in the short-range magnetic interaction, because the nonmagnetic interactions peculiar to a particular atomic species should be identical. From the results of first-principles calculations [13.82], the contribution of the short-range magnetic interaction to the measured corrugation amplitude is expected to be about a few percent of the total interaction. Discrimination of such small perturbations is therefore needed. In order to reduce the noise, the corrugation amplitude was added on the basis of the periodicity of the NC-AFM image. In addition, the topographical asymmetry, which is the index characterizing the difference in atomic corrugation amplitude, has been defined [13.85]. The result shows that the value of the topographical asymmetry calculated from the image obtained with an Fe-coated Si tip depends on the direction of summing of the corrugation amplitude, and that the dependency corresponds to the antiferromagnetic spin ordering of the NiO(001) surface. With a paramagnetic Si tip, no significant indication of a directional dependency of the topographical asymmetry can be seen. Therefore, it is believed that the results obtained using a Fe-coated tip support the conclusion that the dependency of the topographical asymmetry originates in the short-range magnetic interaction.

The measurements presented here demonstrate the possibility of imaging magnetic structures on an atomic scale by NC-AFM. However, the origin of the detected short-range magnetic interaction is under discussion. Therefore, further experiments such as the measurement of force-distance curves and a theoretical study of the interaction between the ferromagnetic tip and an antiferromagnetic sample are needed.

13.4 Applications to Molecules

In the future, it is expected that electronic, chemical, and medical devices will be downsized to a nanoscale. To achieve this, visualizing and assembling individual molecular components is of fundamental importance. Topographic imaging of nonconductive materials is a challenge for atomic force microscopy (AFM). Nanometer-sized domains of surfactants terminated with different functional groups have been identified by lateral force microscopy (LFM) [13.88] and chemical force microscopy (CFM) [13.89] as extensions of AFM. At a higher resolution, a periodic array of molecules, Langmuir–Blodgett films [13.90] for example, was recognized by AFM. However, it remains difficult to visualize an isolated molecule, molecule vacancy, or the boundary of different periodic domains with a microscope with the tip in contact.

13.4.1 Why Molecules and What Molecules?

The access to individual molecules has not been a trivial task even for noncontact atomic force microscopy (NC-AFM). The force pulling the tip into the surface is less sensitive to the gap width (r), especially when chemically stable molecules cover the surface. The attractive potential between two stable molecules is shallow and exhibits r^{-6} decay [13.13].

High-resolution topography of formate ($HCOO^-$) [13.91] was first reported in 1997 as a molecular adsorbate. The number of imaged molecules is now increasing because of the technological importance of molecular interfaces. To date, the following studies on molecular topography have been published: C_{60} [13.86, 92], DNAs [13.87, 93], adenine and thymine [13.94], alkanethiols [13.94, 95], a perylene-derivative (PTCDA) [13.96], a metal porphyrin (Cu-TBPP) [13.97], glycine sulfate [13.98], polypropylene [13.99], vinylidene fluoride [13.100], and a series of carboxylates ($RCOO^-$) [13.101–107]. Two of these are presented in Figs. 13.22 and 13.23 to demonstrate the current stage of achievement. The proceedings of the annual NC-AFM conference represent a convenient opportunity for us to update the list of molecules imaged.

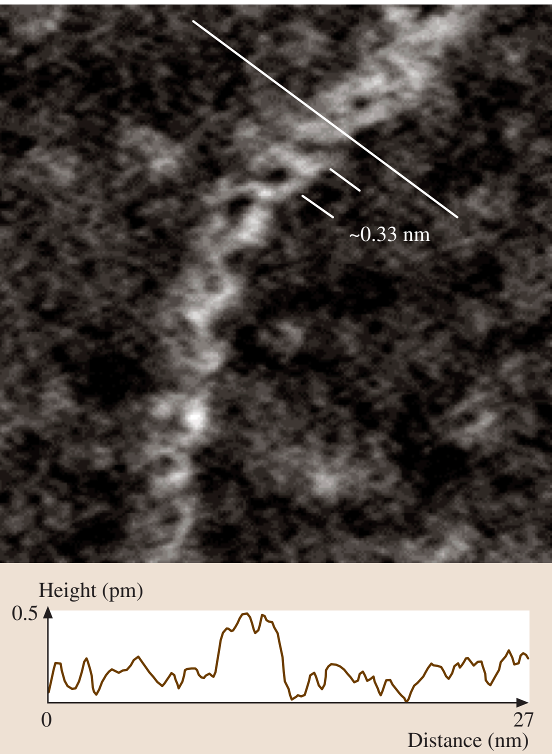

Fig. 13.23 The constant frequency-shift topography of a DNA helix on a mica surface based on [13.87]. Image size: $43 \times 43\ nm^2$. The image revealed features with a spacing of 3.3 nm, consistent with the helix turn of B-DNA

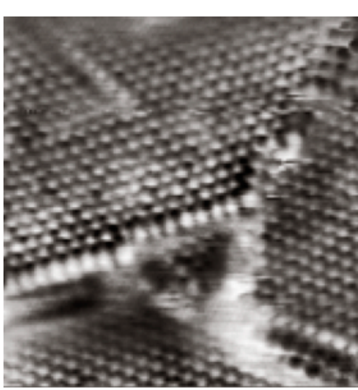

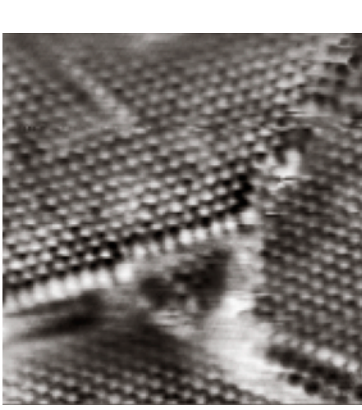

Fig. 13.22 The constant frequency-shift topography of domain boundaries on a C_{60} multilayered film deposited on a Si(111) surface based on [13.86]. Image size: $35 \times 35\ nm^2$

13.4.2 Mechanism of Molecular Imaging

A systematic study on carboxylate ($RCOO^-$) with R = H, CH_3, $C(CH_3)_3$, $C \equiv CH$, and CF_3 revealed that the van der Waals force is responsible for the molecule-dependent microscope topography despite its long-range (r^{-6}) nature. Carboxylates adsorbed on the (110) sur-

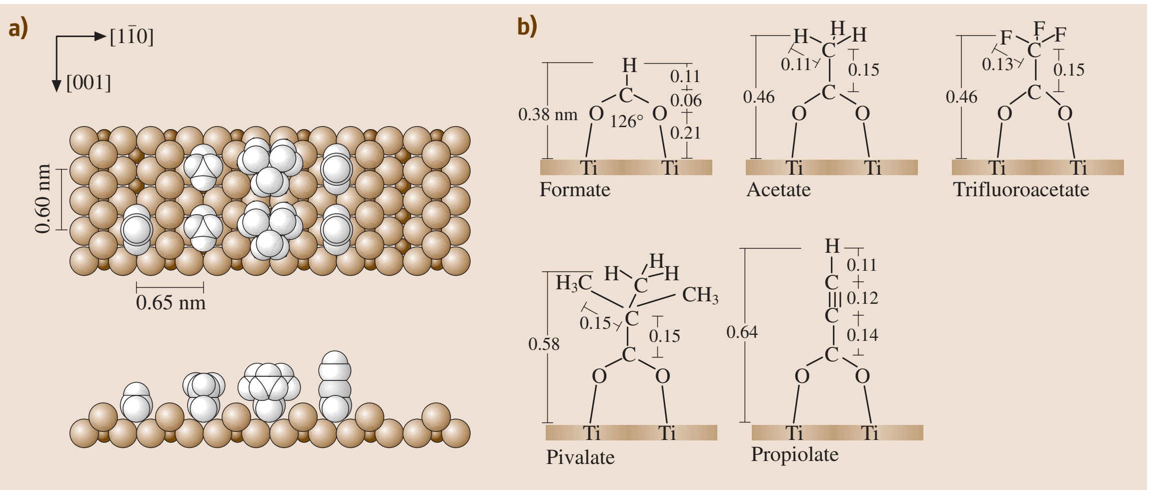

Fig. 13.24a,b The carboxylates and TiO_2 substrate. **(a)** Top and side view ball model. *Small shaded* and *large shaded balls* represent Ti and O atoms in the substrate. Protons yielded in the dissociation reaction are not shown. **(b)** Atom geometry of formate, acetate, pivalate, propiolate, and trifluoroacetate adsorbed on the $TiO_2(110)$ surface. The O-Ti distance and O – C – O angle of the formate were determined in the quantitative analysis of photoelectron diffraction [13.109]

face of rutile TiO_2 have been extensively studied as a prototype of organic materials interfaced with an inorganic metal oxide [13.108]. A carboxylic acid molecule (RCOOH) dissociates on this surface to a carboxylate ($RCOO^-$) and a proton (H^+) at room temperature, as illustrated in Fig. 13.24. The pair of negatively charged oxygen atoms in $RCOO^-$ coordinate two positively charged Ti atoms at the surface. The adsorbed carboxylates create a long-range ordered monolayer. The lateral distances of the adsorbates in the ordered monolayer are regulated at 0.65 and 0.59 nm along the [1$\bar{1}$0] and [001] directions. By scanning a mixed monolayer containing different carboxylates, the microscope topography of the terminal groups can be quantitatively compared while minimizing tip-dependent artifacts.

Figure 13.25 presents the observed constant frequency-shift topography of four carboxylates terminated by different alkyl groups. On the formate-covered surface of panel (a) individual formates (R = H) were resolved as protrusions of a uniform brightness. The dark

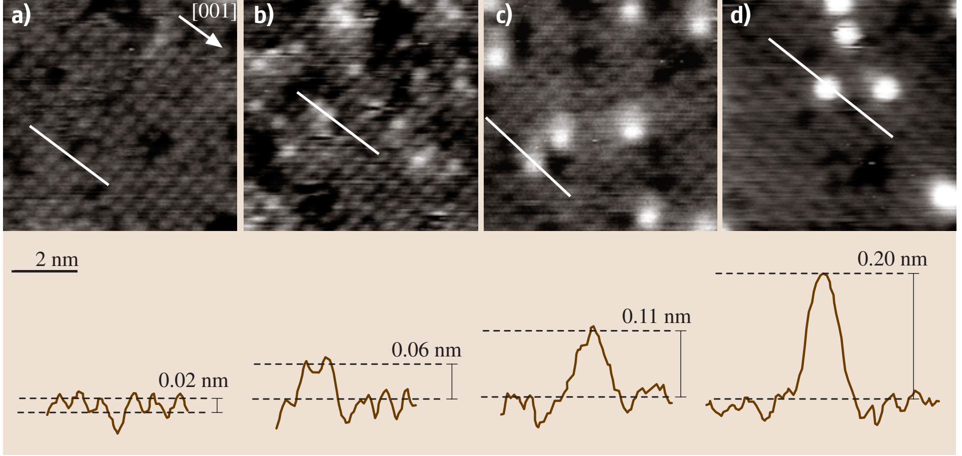

Fig. 13.25a–d The constant frequency-shift topography of carboxylate monolayers prepared on the $TiO_2(110)$ surface based on [13.102, 104, 106]. Image size: $10 \times 10\,nm^2$. **(a)** Pure formate monolayer; **(b)** formate-acetate mixed layer; **(c)** formate-pivalate mixed layer; **(d)** formate-propiolate mixed layer. Cross sections determined on the *lines* are shown in the lower panel

holes represent unoccupied surface sites. The cross section in the lower panel shows that the accuracy of the height measurement was 0.01 nm or better. Brighter particles appeared in the image when the formate monolayer was exposed to acetic acid (CH_3COOH), as shown in panel (b). Some formates were exchanged with acetates ($R = CH_3$) impinging from the gas phase [13.110]. Because the number of brighter spots increased with exposure time to acetic acid, the brighter particle was assigned to the acetate [13.102]. Twenty-nine acetates and 188 formates were identified in the topography. An isolated acetate and its surrounding formates exhibited an image height difference of 0.06 nm. Pivalate is terminated by bulky $R = C(CH_3)_3$. Nine bright pivalates were surrounded by formates of ordinary brightness in the image of panel (c) [13.104]. The image height difference of an isolated pivalate over the formates was 0.11 nm. Propiolate with C≡CH is a needle-like adsorbate of single-atom diameter. That molecule exhibited in panel (d) a microscope topography 0.20 nm higher than that of the formate [13.106].

The image topography of formate, acetate, pivalate, and propiolate followed the order of the size of the alkyl groups. Their physical topography can be assumed on the C−C and C−H bond lengths in the corresponding RCOOH molecules in the gas phase [13.111] and is illustrated in Fig. 13.24. The top hydrogen atom of the formate is located 0.38 nm above the surface plane containing the Ti atom pair, while three equivalent hydrogen atoms of the acetate are more elevated at 0.46 nm. The uppermost H atoms in the pivalate are raised by 0.58 nm relative to the Ti plane. The H atom terminating the triple-bonded carbon chain in the propiolate is at 0.64 nm. Figure 13.26 summarizes the observed image heights relative to the formate as a function of the physical height of the topmost H atoms given in the model. The straight line fitted the four observations [13.104]. When the horizontal axis was scaled with other properties (molecular weight, the number of atoms in a molecule, or the number of electrons in valence states), the correlation became poor.

On the other hand, if the tip apex traced the contour of a molecule composed of hard-sphere atoms, the image topography would reproduce the physical topography in a one-to-one ratio, as shown by the broken line in Fig. 13.26. However, the slope of the fitted line was 0.7. A slope of less than unity is interpreted with the long-range nature of the tip-molecule force. The observable frequency shift reflects the sum of the forces between the tip apex and individual molecules. When the tip passes above a tall molecule embedded in short

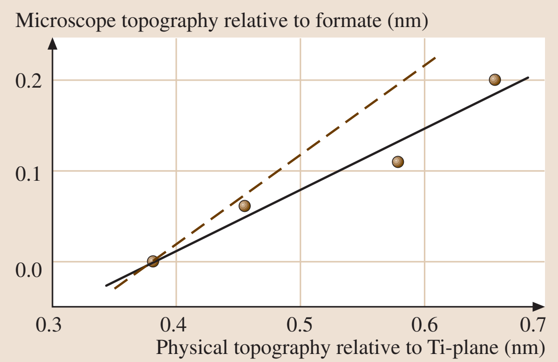

Fig. 13.26 The constant frequency-shift topography of the alkyl-substituted carboxylates as a function of their physical topography given in the model of Fig. 13.3 based on [13.104]

molecules, it is pulled up to compensate for the increased force originating from the tall molecule. Forces between the lifted tip and the short molecules are reduced due to the increased tip-surface distance. Feedback regulation pushes down the probe to restore the lost forces.

This picture predicts that microscope topography is sensitive to the lateral distribution of the molecules, and that was in fact the case. Two-dimensionally clustered acetates exhibited enhanced image height over an isolated acetate [13.102]. The tip-molecule force, therefore, remained non-zero at distances over the lateral separation of the carboxylates on this surface (0.59–0.65 nm). Chemical bond interactions cannot be important across such a wide tip-molecule gap, whereas atom-scale images of Si(111)-(7×7) are interpreted with the fractional formation of tip-surface chemical bonds [13.24, 45, 49]. Instead, the attractive component of the van der Waals force is probable for the observed molecule-dependent topography. The absence of the tip-surface chemical bond is reasonable on the carboxylate-covered surface terminated with stable C−H bonds.

The attractive component of the van der Waals force contains electrostatic terms caused by permanent-dipole/permanent-dipole coupling, permanent-dipole/induced-dipole coupling, and induced-dipole/induced-dipole coupling (dispersion force). The four carboxylates examined are equivalent in terms of their permanent electric dipole, because the alkyl groups are nonpolar. The image contrast of one carboxylate relative to another is thus ascribed to the dispersion force and/or the force created by the coupling between the permanent dipole on the tip and the induced dipole on the molecule. If we further assume that the Si tip used exhibits the smallest

permanent dipole, the dispersion force remains dominant to create the NC-AFM topography dependent on the nonpolar groups of atoms. A numerical simulation on this assumption [13.106] successfully reproduced the propiolate topography of Fig. 13.25d. A calculation that does not include quantum chemical treatments is expected to work, unless the tip approaches the surface too closely, or the molecule possesses a dangling bond.

In addition to the contribution of the dispersion force, the permanent dipole moment of molecules may perturb the microscope topography through electrostatic coupling with the tip. Its possible role was demonstrated by imaging a fluorine-substituted acetate. The strongly polarized C−F bonds were expected to perturb the electrostatic field over the molecule. The constant frequency-shift topography of acetate ($R = CH_3$) and trifluoroacetate ($R = CF_3$) was indeed sensitive to the fluorine substitution. The acetate was observed 0.05 nm higher than the trifluoroacetate [13.103], although the F atoms in the trifluoroacetate, as well as the H atoms in the acetate were lifted by 0.46 nm from the surface plane, as illustrated in Fig. 13.24.

13.4.3 Perspectives

Experimental results summarized in this section prove the feasibility of NC-AFM in identifying individual molecules. A systematic study on the constant frequency-shift topography of carboxylates with R = H, CH_3, $C(CH_3)_3$, C≡CH, and CF_3 has revealed the mechanism behind the high-resolution imaging of the chemically stable molecules. The dispersion force is primarily responsible for the molecule-dependent topography. The permanent dipole moment of the imaged molecule, if it exists, perturbs the topography through the electrostatic coupling with the tip. A tiny calculation containing empirical force fields works in simulating the microscope topography.

These results make us optimistic about analyzing physical and chemical properties of nanoscale supramolecular assemblies constructed on a solid surface. If the accuracy of topographic measurement is developed by one more order of magnitude, which is not an unrealistic concept, it may be possible to identify structural isomers, chiral isomers, and conformational isomers of a molecule. Kelvin probe force microscopy (KPFM), an extension of NC-AFM, provides a nanoscale analysis of molecular electronic properties [13.99, 100]. Force spectroscopy with chemically modified tips seems promising for the detection of a selected chemical force. Operation in a liquid atmosphere [13.112] is demanded to observe biochemical materials in the raw.

14. Low Temperature Scanning Probe Microscopy

This chapter is dedicated to scanning probe microscopy, one of the most important techniques in nanotechnology. In general, scanning probe techniques allow the measurement of physical properties down to the nanometer scale. Some techniques, such as the scanning tunneling microscope and the scanning force microscope even go down to the atomic scale. The properties that are accessible are various. Most importantly, one can image the arrangement of atoms on conducting surfaces by scanning tunneling microscopy and on insulating substrates by scanning force microscopy. But also the arrangement of electrons (scanning tunneling spectroscopy), the force interaction between different atoms (scanning force spectroscopy), magnetic domains (magnetic force microscopy), the local capacitance (scanning capacitance microscopy), the local temperature (scanning thermo microscopy), and local light-induced excitations (scanning near-field microscopy) can be measured with high spatial resolution. In addition, some techniques even allow the manipulation of atomic configurations.

Probably the most important advantage of the low-temperature operation of scanning probe techniques is that they lead to a significantly better signal-to-noise ratio than measuring at room temperature. This is why many researchers work below 100 K. However, there are also physical reasons to use low-temperature equipment. For example, the manipulation of atoms or scanning tunneling spectroscopy with high energy resolution can only be realized at low temperatures. Moreover, some physical effects such as superconductivity or the Kondo effect are restricted to low temperatures. Here, we describe the design criteria of low-temperature scanning probe equipment and summarize some of the most spectacular results achieved since the invention of the method about 20 years ago. We first focus on the scanning tunneling microscope, giving examples of atomic manipulation and the analysis of electronic properties in different material arrangements. Afterwards, we describe results obtained by scanning force microscopy, showing atomic-scale imaging on insulators, as well as force spectroscopy analysis. Finally, the magnetic force microscope, which images domain patterns in ferromagnets and vortex patterns in superconductors, is discussed. Although this list is far from complete, we feel that it gives an adequate impression of the fascinating possibilities of low-temperature scanning probe instruments.

In this chapter low temperatures are defined as lower than about 100 K and are normally achieved by cooling with liquid nitrogen or liquid helium. Applications in which SPMs are operated close to 0 °C are not covered in this chapter.

References ... 442

More than two decades ago, the first design of an experimental setup was presented where a sharp tip was systematically scanned over a sample surface in order to obtain local information on the tip-sample interaction down to the atomic scale. This original instrument used the tunneling current between a conducting tip and a conducting sample as a feedback signal and was named *scanning tunneling microscope* accordingly [14.1]. Soon after this historic breakthrough, it became widely recognized that virtually any type of tip-sample interaction can be used to obtain local information on the sample by applying the same general principle, provided that the selected interaction was reasonably short-ranged. Thus, a whole variety of new methods has been introduced, which are denoted collectively as *scanning probe methods*. An overview is given by *Wiesendanger* [14.2].

The various methods, especially the above mentioned scanning tunneling microscopy (STM) and scanning force microscopy (SFM) – which is often further classified into subdisciplines such as the topography-reflecting atomic force microscopy (AFM), the magnetic force microscopy (MFM), or the electrostatic force microscopy (EFM) – have been established as standard methods for surface characterization on the nanometer scale. The reason is that they feature extremely high resolution (often down to the atomic scale for STM and AFM), despite a principally simple, compact, and comparatively inexpensive design.

A side effect of the simple working principle and the compact design of many scanning probe microscopes (SPMs) is that they can be adapted to different environments such as air, all kinds of gaseous atmospheres, liquids, or vacuum with reasonable effort. Another advantage is their ability to work within a wide temperature range. A microscope operation at higher temperatures is chosen to study surface diffusion, surface reactivity, surface reconstructions that only manifest at elevated temperatures, high-temperature phase transitions, or to simulate conditions as they occur, e.g., in engines, catalytic converters, or reactors. Ultimately, the upper limit for the operation of an SPM is determined by the stability of the sample, but thermal drift, which limits the ability to move the tip in a controlled manner over the sample, as well as the depolarization temperature of the piezoelectric positioning elements might further restrict successful measurements.

On the other hand, low-temperature (LT) application of SPMs is much more widespread than operation at high temperatures. Essentially five reasons make researchers adapt their experimental setups to low-temperature compatibility. These are: (1) the reduced thermal drift, (2) lower noise levels, (3) enhanced stability of tip and sample, (4) the reduction in piezo hysteresis/creep, and (5) probably the most obvious, the fact that many physical effects are restricted to low temperature. Reasons (1) to (4) only apply unconditionally if the whole microscope body is kept at low temperature (typically in or attached to a bath cryostat, see Sect. 14.2). Setups in which only the sample is cooled may show considerably less favorable operating characteristics. As a result of (1) to (4), ultrahigh resolution and long-term stability can be achieved on a level that significantly exceeds what can be accomplished at room temperature even under the most favorable circumstances. Typical examples for (5) are superconductivity [14.3] and the Kondo effect [14.4].

14.1 Microscope Operation at Low Temperatures

Nevertheless, before we devote ourselves to a small overview of experimental LTSPM work, we will take a closer look at the specifics of microscope operation at low temperatures, including a discussion of the corresponding instrumentation.

14.1.1 Drift

Thermal drift originates from thermally activated movements of the individual atoms, which are reflected by the thermal expansion coefficient. At room temperature, typical values for solids are on the order of $(1-50)\times10^{-6}\,\mathrm{K}^{-1}$. If the temperature could be kept precisely constant, any thermal drift would vanish, regardless of the absolute temperature of the system. The close coupling of the microscope to a large temperature bath that keeps a constant temperature ensures a significant reduction in thermal drift and allows for distortion-free, long-term measurements. Microscopes that are efficiently attached to sufficiently large bath cryostats, therefore, show a one- to two-order-of-magnitude increase in thermal stability compared with non-stabilized setups operated at room temperature.

A second effect also helps suppress thermally induced drift of the probing tip relative to a specific

location on the sample surface. The thermal expansion coefficients are at liquid helium temperature two or more orders of magnitude smaller than at room temperature. Consequently, the thermal drift during low-temperature operation decreases accordingly.

For some specific scanning probe methods, there may be additional ways a change in temperature can affect the quality of the data. In *frequency-modulation SFM* (FM-SFM), for example, the measurement principle relies on the accurate determination of the eigenfrequency of the cantilever, which is determined by its spring constant and its effective mass. However, the spring constant changes with temperature due to both thermal expansion (i. e., the resulting change in the cantilever dimensions) and the variation of Young's modulus with temperature. Assuming drift rates of about 2 mK/min, as is typical for room temperature measurements, this effect might have a significant influence on the obtained data.

14.1.2 Noise

The theoretically achievable resolution in SPMs often increases with decreasing temperature due to a decrease in thermally induced noise. An example is the thermal noise in SFMs, which is proportional to the square root of the temperature [14.5, 6]. Lowering the temperature from $T = 300\,\mathrm{K}$ to $T = 10\,\mathrm{K}$ thus results in a reduction of the thermal frequency noise of more than a factor of five. Graphite, e.g., has been imaged atomically resolved only at low temperatures due to its extremely low corrugation, which was below the room temperature noise level [14.7, 8].

Another, even more striking, example is the spectroscopic resolution in *scanning tunneling spectroscopy* (STS). It depends linearly on the temperature [14.2] and is consequently reduced even more at LT than the thermal noise in AFM. This provides the opportunity to study structures or physical effects not accessible at room temperature such as spin and Landau levels in semiconductors [14.9].

Finally, it might be worth mentioning that the enhanced stiffness of most materials at low temperatures (increased Young's modulus) leads to a reduced coupling to external noise. Even though this effect is considered small [14.6], it should not be ignored.

14.1.3 Stability

There are two major stability issues that considerably improve at low temperature. First, low temperatures close to the temperature of liquid helium inhibit most of the thermally activated diffusion processes. As a consequence, the sample surfaces show a significantly increased long-term stability, since defect motion or adatom diffusion is massively suppressed. Most strikingly, even single xenon atoms deposited on suitable substrates can be successfully imaged [14.10, 11], or even manipulated [14.12]. In the same way, the low temperatures also stabilize the atomic configuration at the tip end by preventing sudden jumps of the most loosely bound foremost tip atom(s). Second, the large cryostat that usually surrounds the microscope acts as an effective cryo pump. Thus samples can be kept clean for several weeks, which is a multiple of the corresponding time at room temperature (about 3–4 h).

14.1.4 Piezo Relaxation and Hysteresis

The last important benefit from low-temperature operation of SPMs is that artifacts given by the response of the piezoelectric scanners are substantially reduced. After applying a voltage ramp to one electrode of a piezoelectric scanner, its immediate initial deflection, l_0, is followed by a much slower relaxation, Δl, with a logarithmic time dependence. This effect, known as piezo relaxation or "creep", diminishes substantially at low temperatures, typically by a factor of ten or more. As a consequence, piezo nonlinearities and piezo hysteresis decrease accordingly. Additional information is given by *Hug* et al. [14.13].

14.2 Instrumentation

The two main design criteria for all vacuum-based scanning probe microscope systems are (1) to provide an efficient decoupling of the microscope from the vacuum system and other sources of external vibrations, and (2) to avoid most internal noise sources through a high mechanical rigidity of the microscope body itself. In vacuum systems designed for low-temperature applications, a significant degree of complexity is added, since, on the one hand, close thermal contact of the SPM and cryogen is necessary to ensure the (approximately)

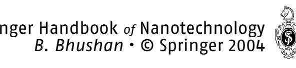
drift-free conditions described above, while, on the other hand, a good vibration isolation (both from the outside world, as well as from the boiling or flowing cryogen) has to be maintained.

Plenty of microscope designs have been presented in the last ten to 15 years, predominantly in the field of STM. Due to the variety of the different approaches, we will, somewhat arbitrarily, give two examples on different levels of complexity that might serve as illustrative model designs.

14.2.1 A Simple Design for a Variable Temperature STM

A simple design for a variable temperature STM system is presented in Fig. 14.1 (Similar systems are also offered by Omicron (Germany) or Jeol (Japan)). It should give an impression of what the minimum requirements are, if samples are to be investigated successfully at low temperatures. It features a single ultrahigh vacuum (UHV) chamber that houses the microscope in its center. The general idea to keep the setup simple is that only the sample is cooled by means of a flow cryostat that ends in the small liquid nitrogen (LN) reservoir. This reservoir is connected to the sample holder with copper braids. The role of the copper braids is to thermally attach the LN reservoir to the sample located on the sample holder in an effective manner, while vibrations due to the flow of the cryogen should be blocked as much as possible. In this way, a sample temperature of about 100 K is reached. Alternatively, with liquid helium

Fig. 14.1 One chamber UHV system with variable temperature STM based on a flow cryostat design. (Courtesy of RHK Technology, USA)



operation, a base temperature of below 30 K can be achieved, while a heater that is integrated into the sample stage enables high-temperature operation up to 1,000 K.

A typical experiment would run as follows: First, the sample is brought into the system by placing it in the so-called *load-lock*. This small part of the chamber can be separated from the rest of the system by a valve, so that the main part of the system can remain under vacuum at all times (i. e., even if the load-lock is opened for introducing the sample). After vacuum is re-established, the sample is transferred to the main chamber using the transfer arm. A linear motion feedthrough enables the storage of sample holders or, alternatively, specialized holders that carry replacement tips for the STM. Extending the transfer arm further, the sample can be placed on the sample stage and subsequently cooled down to the desired temperature. The scan head, which carries the STM tip, is then lowered with the scan head manipulator onto the sample holder (see Fig. 14.2). The special design of the scan head (see [14.14] for details) allows not only a flexible positioning of the tip on any desired location on the sample surface, but also compensates to a certain degree for thermal drift that inevitably occurs in such a design due to temperature gradients.

In fact, thermal drift is often much more prominent in LT-SPM designs, where only the sample is cooled, than in room temperature designs. Therefore, to fully benefit from the high stability conditions described in the introduction, it is mandatory to keep the whole microscope at the exact same temperature. This is mostly realized by using bath cryostats, which add a certain degree of complexity.

14.2.2 A Low Temperature SFM Based on a Bath Cryostat

As an example for an LT-SPM setup based on a bath cryostat, let us take a closer look at the LT-SFM system sketched in Fig. 14.3, which has been used to acquire the images on graphite, xenon, NiO, and InAs presented in Sect. 14.4. The force microscope is

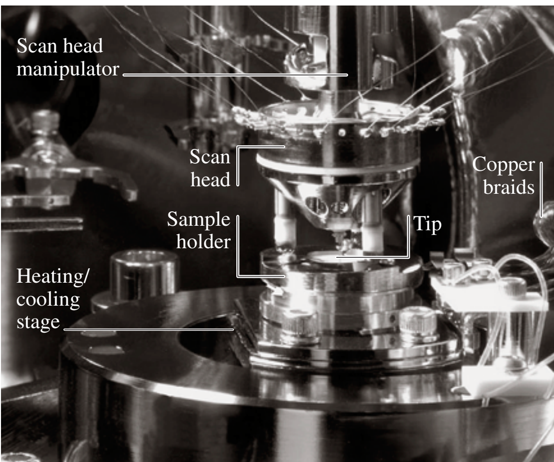


Fig. 14.2 Photograph of the STM located inside the system sketched in Fig. 14.1. After the scan head has been lowered onto the sample holder, it is fully decoupled from the scan head manipulator and can be moved laterally using the three piezo legs it stands on. (Courtesy of RHK Technology, USA)

built into a UHV system that comprises three vacuum chambers: one for cantilever and sample preparation, which also serves as a transfer chamber, one for analysis purposes, and a main chamber that houses the microscope. A specially designed vertical transfer mechanism based on a double chain allows the lowering of the microscope into a UHV compatible bath cryostat attached underneath the main chamber. To damp the system, it is mounted on a table carried by pneumatic damping legs, which, in turn, stand on a separate foundation to decouple it from building vibrations. The cryostat and dewar are separated from the rest of the UHV system by a bellow. In addition, the dewar is surrounded by sand for acoustic isolation.

In this design, tip and sample are exchanged at room temperature in the main chamber. After the transfer into the cryostat, the SFM can be cooled by either liquid nitrogen or liquid helium, reaching temperatures down to 10 K. An all-fiber interferometer as the detection mechanism for the cantilever deflection ensures high resolution, while simultaneously allowing the construction of a comparatively small, rigid, and symmetric microscope.

Figure 14.4 highlights the layout of the SFM body itself. Along with the careful choice of materials, the symmetric design eliminates most of the problems with drift inside the microscope encountered when cooling or warming it up. The microscope body has an overall cylindrical shape with a 13 cm height and a 6 cm diameter and exact mirror symmetry along the cantilever axis. The main body is made of a single block of macor, a machinable glass ceramic, which ensures a rigid and stable design. For most of the metallic parts titanium was used, which has a temperature coefficient similar to macor. The controlled but stable accomplishment of movements, such as coarse approach and lateral positioning in other microscope designs, is a difficult task at low temperatures. The present design uses a special type of piezo motor that moves a sapphire prism (see the "fiber approach" and the "sample approach" signs in Fig. 14.3). It is described in detail in [14.15]. More information regarding this design is given in [14.16].

14.3 Scanning Tunneling Microscopy and Spectroscopy

In this section, we review some of the most important results achieved by LTSTM. After summarizing the results with emphasis on the necessity of LT equipment, we turn to details of the different experiments and the physical meaning of the obtained results.

As described in Sect. 14.1, the LT equipment has basically three advantages for scanning tunneling microscopy (STM) and spectroscopy (STS). First, the instruments are much more stable with respect to thermal drift and the coupling to external noise, allowing the establishment of new functionalities of the instrument. In particular, the LTSTM has been used to move atoms on a surface [14.12], cut molecules in pieces [14.17], reform bonds [14.18], and, consequently, establish new structures on the nanometer scale. Also, the detection of light resulting from tunneling into a particular atom [14.19] and the visualization of thermally induced atomic movements [14.20] partly require LT instrumentation.

Second, the spectroscopic resolution in STS depends linearly on temperature and is, therefore, considerably reduced at LT. This provides the opportunity to study physical effects unaccessible at room temperature. Obvious examples are the resolution of spin and Landau levels in semiconductors [14.9], or the investigation of lifetime broadening effects of particular electronic states on the nanometer scale [14.21]. More spectacular, electronic wave functions have been imaged for the first time in real space using an LTSTM [14.22], and vibrational levels giving rise to additional inelastic tunneling have been detected [14.23] and localized within particular molecules [14.24].

Third and most obvious, many physical effects, in particular, effects guided by electronic correlations, are restricted to low temperature. Typical examples are superconductivity [14.3], the Kondo effect [14.4], and many of the electron phases found in semiconductors [14.25]. Here, the LTSTM provides the possibility to study electronic effects on a local scale, and intensive work has been done in this field, the most elaborate with respect to high temperature superconductivity [14.26].

14.3.1 Atomic Manipulation

Although manipulation of surfaces on the atomic scale can be achieved at room temperature [14.27], only the use of LTSTMs allow the placement of individual atoms at desired atomic positions [14.28].

The usual technique to manipulate atoms is to increase the current above a certain atom, which reduces the tip-atom distance, then to move the tip with the atom to a desired position, and finally to reduce the current again in order to decouple atom and tip. The first demonstration of this technique was performed by Eigler and Schweizer (1990), who used Xe atoms on a Ni(110) surface to write the three letters “IBM” (their employer) on the atomic scale (Fig. 14.5a). Nowadays, many laboratories are able to move different kinds of atoms and molecules on different surfaces with high precision. An example featuring CO molecules on Cu(110) is shown in Fig. 14.5b–g. Basic modes of controlled motion, pushing, pulling, and sliding of the molecules have been established that depend on the tunneling current, i. e., the distance and the particular molecule-substrate combination [14.29]. It is believed that the electric field between tip and molecule is the strongest force moving the molecules, but other mechanisms such as electromigration caused by the high current density [14.28] or modifications of the surface potential due to the presence of the tip [14.30] have been put forth as important for some of the manipulation modes.

Meanwhile, other types of manipulation on the atomic scale have been developed. Some of them require inelastic tunneling into vibrational or rotational modes of molecules or atoms. They lead to controlled desorption [14.31], diffusion [14.32], pick-up of molecules by the tip [14.18], or rotation of individual entities [14.33, 34]. Also, dissociation of molecules by voltage pulses [14.17], conformational changes induced by dramatic change of tip-molecule distance [14.35], and association of pieces into larger molecules by reducing their lateral distance [14.18] have been shown. Fig. 14.5h–m shows the production of biphenyl from two iodobenzene molecules [14.36]. The iodine is abstracted by voltage pulses (Fig. 14.5i,j), then the iodine is moved to the terrace by the pulling mode (Fig. 14.5k,l), and finally the two phenyl parts are slid along the step edge until they are close enough to react (Fig. 14.5m). The chemical identification of the components is not deduced straightforwardly from STM images and partly requires detailed calculations of their apparent shape.

Low temperatures are not always required in these experiments, but they increase the reproducibility because of the higher stability of the instrument, as discussed in Sect. 14.1. Moreover, rotation or diffusion of entities could be excited at higher temperatures, making the intentionally produced configurations unstable.

14.3.2 Imaging Atomic Motion

Since individual manipulation processes last seconds to minutes, they probably cannot be used to manufacture large and repetitive structures. A possibility to construct such structures is self-assembled growth. It partly relies on the temperature dependence of different diffusion processes on the surface. A detailed knowledge of the diffusion parameters is required, which can be deduced from sequences of STM images measured at temperatures close to the onset of the process of interest [14.37]. Since many diffusion processes set on at LT, LT are partly required [14.20]. Consecutive images of so-called HtBDC molecules on Cu(110) recorded at $T = 194\,\mathrm{K}$ are shown in Fig. 14.6a–c [14.38]. As indicated by the arrows, the position of the molecules changes with time,

The constant hopping rate of H below 65 K indicates a non-thermal diffusion process, probably tunneling (courtesy of Ho, Irvine)

implying diffusion. Diffusion parameters are obtained from Arrhenius plots of the determined hopping rate h, as shown in Fig. 14.6d. Of course, one must make sure that the diffusion process is not influenced by the presence of the tip, since it is known from manipulation experiments that the presence of the tip can move a molecule. However, particularly at low tunneling voltages these conditions can be fulfilled.

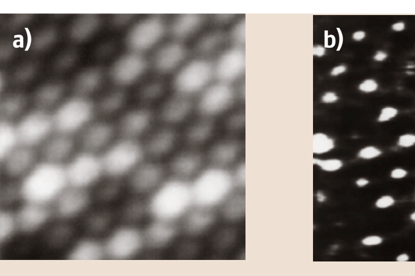
Besides the determination of diffusion parameters, studies of the diffusion of individual molecules showed the importance of mutual interactions in diffusion, which can lead to concerted motion of several molecules [14.20], or, very interestingly, the influence of quantum tunneling [14.39]. The latter is deduced from the Arrhenius plot of hopping rates of H and D on Cu(001), as shown in Fig. 14.6e. The hopping rate of H levels off at about 65 K, while the hopping rate of the heavier D atom goes down to nearly zero, as expected from thermally induced hopping.

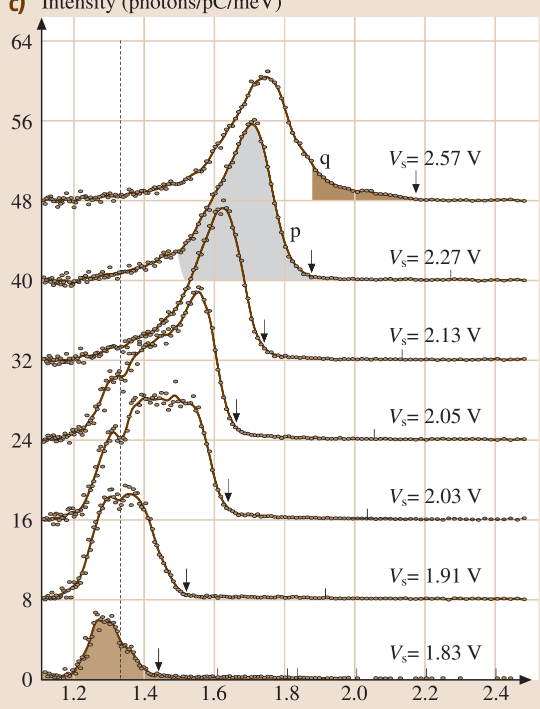
Other diffusion processes such as the movement of surface vacancies [14.40] or of bulk interstitials close to the surface [14.41], and the Brownian motion of vacancy islands [14.42] have also been displayed.

14.3.3 Detecting Light from Single Atoms and Molecules

It had already been realized in 1988 that STM experiments are accompanied by light emission [14.43]. The fact that molecular resolution in the light intensity was achieved at LT (Fig. 14.7a,b) [14.19] raised the hope of performing quasi-optical experiments on the molecular scale. Meanwhile, it is clear that the basic emission process observed on metals is the decay of a local plasmon induced in the area around the tip by inelastic tunneling processes [14.44, 45]. Thus, the molecular resolution is basically a change in the plasmon environment, largely given by the increased height of the tip with respect to the surface above the molecule [14.46]. However, the electron can, in principle, also decay via single-particle excitations. Indeed, signatures of single-particle levels are observed. Figure 14.7c shows light spectra measured at different tunneling voltage V above a nearly complete Na monolayer on Cu(111) [14.47]. The plasmon mode peak energy (arrow) is found, as usual, to be proportional to V, but an additional peak that does not move with V appears at 1.6 eV (p). Plotting the light intensity as a function of photon energy and V (Fig. 14.7d) clearly shows that this additional peak is fixed in photon energy and corresponds to the separation of quantum well levels of the Na ($E_n - E_m$).

Light has also been detected from semiconductors [14.48], including heterostructures [14.49]. There, the light is mostly caused by single-particle relaxation





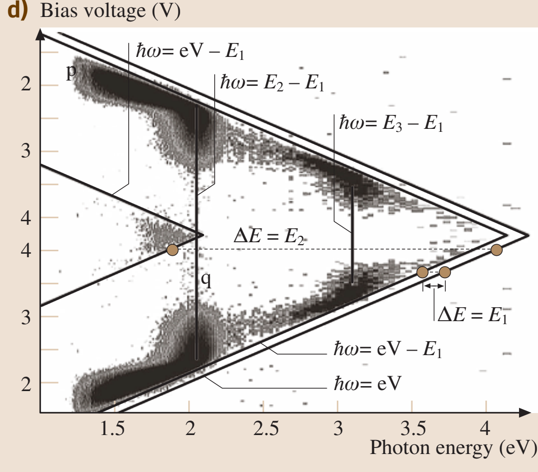


Fig. 14.7 **(a)** STM image of C_{60} molecules on Au(110) imaged at $T = 50$ K. **(b)** STM-induced photon intensity map of the same area; all photons from 1.5 eV to 2.8 eV contribute to the image, tunneling voltage $V = -2.8$ V (**(a)**,**(b)** courtesy of Berndt, Kiel). **(c)** STM-induced photon spectrum measured on 0.6 monolayer of Na on Cu(111) at different tunneling voltages as indicated. Besides the shifting plasmon mode marked by an *arrow*, an energetically constant part named p is recognizable. **(d)** Greyscale map of photon intensity as a function of tunnelling voltage and photon energy measured on 2.0 monolayer Na on Cu(111). The energetically constant photons are identified with intersubband transitions of the Na quantum well, as marked by $E_n - E_m$ (**(c)**,**(d)** courtesy of Hoffmann, Hamburg)

of the injected electrons, allowing a very local source of electron injection.

14.3.4 High Resolution Spectroscopy

One of the most important modes of LTSTM is STS. It detects the differential conductivity $\mathrm{d}I/\mathrm{d}V$ as a function of the applied voltage V and the position (x, y). The $\mathrm{d}I/\mathrm{d}V$-signal is basically proportional to the local density of states (LDOS) of the sample, the sum over squared single-particle wave functions Ψ_i [14.2]

$$\frac{\mathrm{d}I}{\mathrm{d}V}(V, x, y) \propto \mathrm{LDOS}(E, x, y) = \sum_{\Delta E} |\Psi_i(E, x, y)|^2 \,, \quad (14.1)$$

where ΔE is the energy resolution of the experiment. In simple terms, each state corresponds to a tunneling channel if it is located between the Fermi levels (E_F) of the tip and the sample. Thus, all states located in this energy interval contribute to I, while $\mathrm{d}I/\mathrm{d}V(V)$ detects only the states at the energy E corresponding to V. The local intensity of each channel depends further on the LDOS of the state at the corresponding surface position and its decay length into vacuum. For s-like tip states, *Tersoff* and *Hamann* have shown that it is simply proportional to the LDOS at the position of the tip [14.50]. Therefore, as long as the decay length is spatially constant, one measures the LDOS at the surface (14.1). Note that the contributing states are not only surface states, but also bulk states. However, surface states usually dominate if present. *Chen* has shown that higher orbital tip states lead to the so-called derivation rule [14.51]: p_z-type tip states detect $\mathrm{d}(\mathrm{LDOS})/\mathrm{d}z$, d_z^2-states detect $\mathrm{d}^2(\mathrm{LDOS})/\mathrm{d}z^2$, and

so on. As long as the decay into vacuum is exponential and spatially constant, this leads only to an additional factor in dI/dV. Thus, it is still the LDOS that is measured (14.1). The requirement of a spatially constant decay is usually fulfilled on larger length scales, but not on the atomic scale [14.51]. There, states located close to the atoms show a stronger decay into vacuum than the less localized states in the interstitial region. This effect can lead to corrugations that are larger than the real LDOS corrugations [14.52].

The voltage dependence of dI/dV is sensitive to a changing decay length with V, which increases with V. Additionally, $dI/dV(V)$-curves might be influenced by possible structures in the DOS of the tip, which also contributes to the number of tunneling channels [14.53]. However, these structures can usually be identified, and only tips free of characteristic DOS structures are used for quantitative experiments.

Importantly, the energy resolution ΔE is largely determined by temperature. It is defined as the smallest energy distance of two δ-peaks in the LDOS that can still be resolved as two individual peaks in $dI/dV(V)$-curves and is $\Delta E = 3.3\,\mathrm{kT}$ [14.2]. The temperature dependence is nicely demonstrated in Fig. 14.8, where the tunneling gap of the superconductor Nb is measured at different temperatures [14.54]. The peaks at the rim of the gap get wider at temperatures well below the critical temperature of the superconductor ($T_c = 9.2\,\mathrm{K}$).

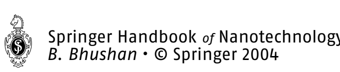
Lifetime Broadening

Besides ΔE, intrinsic properties of the sample lead to a broadening of spectroscopic features. Basically, the finite lifetime of the electron or hole in the corresponding state broadens its energetic width. Any kind of interaction such as electron-electron interaction can be responsible. Lifetime broadening has usually been measured by photoemission spectroscopy (PES), but it turned out that lifetimes of surface states on noble metal surfaces determined by STS (Fig. 14.9a,b) are up to a factor of three larger than the ones measured by PES [14.55]. The reason is probably that defects broaden the PES spectrum. Defects are unavoidable in a spatially integrating technique such as PES, thus, STS has the advantage of choosing a particularly clean area for lifetime measurements. The STS results can be successfully compared to theory, highlighting the dominating influence of intraband transitions for the surface state lifetime on Au(111) and Cu(111), at least close to the onset of the surface band [14.21].

With respect to band electrons, the analysis of the width of the band onset in $dI/dV(V)$-curves has the disadvantage of being restricted to the onset energy. Another method circumvents this problem by measuring the decay of standing electron waves scattered from a step edge as a function of energy [14.56]. Figure 14.9c,d shows the resulting oscillating dI/dV-signal measured for two different energies. To deduce the coherence length L_Φ, which is inversely proportional to the lifetime τ_Φ, one has to consider that the finite ΔE in the experiment also leads to a decay of the standing wave away from the step edge. The dotted fit line using $L_\Phi = \infty$ indicates this effect and, more importantly, shows a discrepancy with the measured curve. Only including a finite coherence length of 6.2 nm results in good agreement, which, in turn, determines L_Φ and thus τ_Φ, as displayed in Fig. 14.9c. The found $1/E^2$-dependence of τ_Φ points to a dominating influence of electron-electron interactions at higher energies in the surface band.

Landau and Spin Levels

Moreover, the increased energy resolution at LT allows the resolution of electronic states that are not resolvable at RT. For example, Landau and spin quantization appearing in magnetic field B have been probed on InAs(110) [14.9, 57]. The corresponding quantization



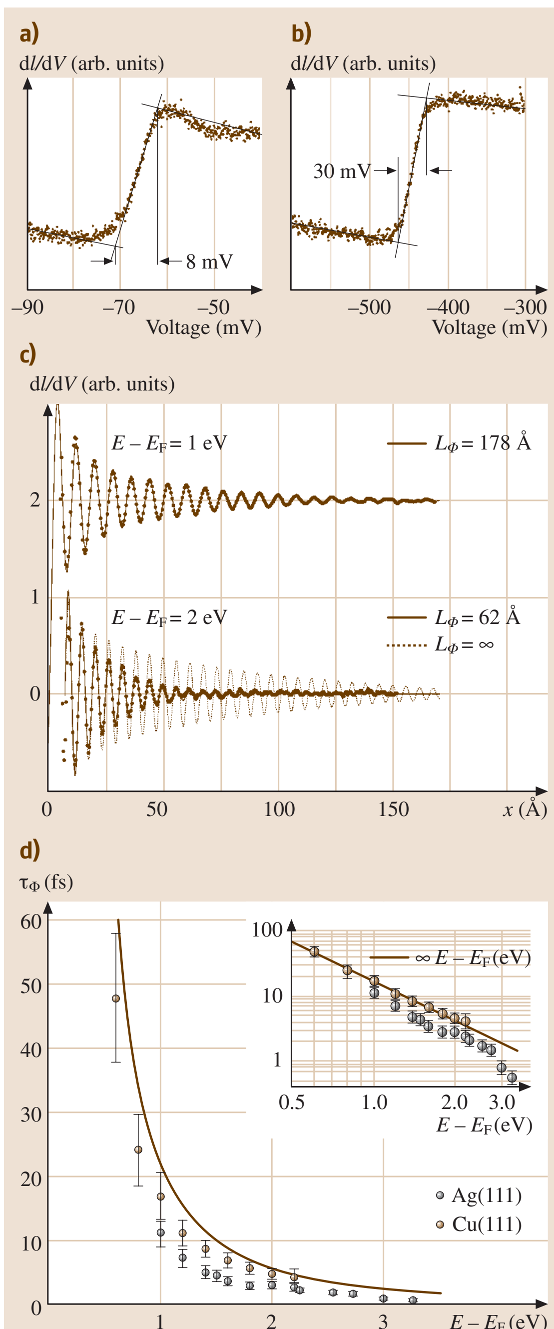


Fig. 14.9 **(a)**,**(b)** spatially averaged $dI/dV(V)$-curves of Ag(111) and Cu(111); both surfaces exhibit a surface state with parabolic dispersion starting at -65 meV and -430 meV, respectively. The lines are drawn to determine the energetic width of the onset of these surface bands (**(a)**,**(b)** courtesy of Berndt, Kiel); **(c)** dI/dV-intensity as a function of position away from a step edge of Cu(111) measured at the voltages $(E - E_F)$, as indicated (*points*); the lines are fits assuming standing electron waves with a phase coherence length L_Φ as marked; **(d)** resulting phase coherence time as a function of energy for Ag(111) and Cu(111). *Inset* shows the same data on a double logarithmic scale evidencing the E^{-2}-dependence (*line*) (**(c)**,**(d)** courtesy of Brune, Lausanne)

energies are given by $E_{\text{Landau}} = \hbar e B / m_{\text{eff}}$ and $E_{\text{spin}} = g\mu B$. Thus InAs is a good choice, since it exhibits a low effective mass $m_{\text{eff}}/m_e = 0.023$ and a high g-factor of 14 in the bulk conduction band. The values in metals are $m_{\text{eff}}/m_e \approx 1$ and $g \approx 2$, resulting in energy splittings of only 1.25 meV and 1.2 meV at $B = 10$ T. This is obviously lower than the typical lifetime broadenings discussed in the previous section and also close to $\Delta E = 1.1$ meV achievable at $T = 4$ K.

Fortunately, the electron density in doped semiconductors is much lower, and thus the lifetime increases significantly. Figure 14.10a shows a set of spectroscopy curves obtained on InAs(110) in different magnetic fields [14.9]. Above E_F, oscillations with increasing intensity and energy distance are observed. They show the separation expected from Landau quantization. In turn, they can be used to deduce m_{eff} from the peak separation (Fig. 14.10b). An increase of m_{eff} with increasing E has been found as expected from theory. Also, at high fields spin quantization is observed (Fig. 14.10c). It is larger than expected from the bare g-factor due to contributions from exchange enhancement [14.58]. A detailed discussion of the peaks revealed that they belong to the so-called tip-induced quantum dot resulting from the work function difference between tip and sample.

Vibrational Levels

As discussed with respect to light emission in STM, inelastic tunneling processes contribute to the tunneling current. The coupling of electronic states to vibrational levels is one source of inelastic tunneling [14.23]. It provides additional channels contributing to $dI/dV(V)$ with final states at energies different from V. The final energy is simply shifted by the energy of the vibrational level. If only discrete vibrational energy levels couple to a smooth electronic DOS, one expects a peak in d^2I/dV^2 at the vibrational energy. This situation appears for molecules on noble metal surfaces. As usual, the isotope effect on the vibrational energy can be used

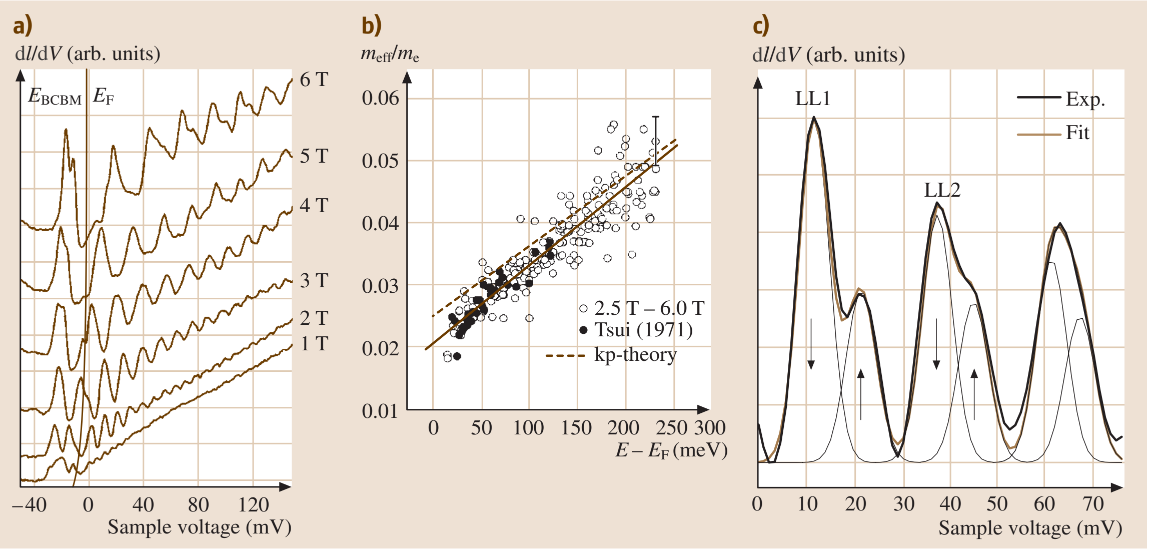

Fig. 14.10 **(a)** $\mathrm{d}I/\mathrm{d}V$-curves of n-InAs(110) at different magnetic fields as indicated; E_{BCBM} marks the bulk conduction band minimum; oscillations above E_{BCBM} are caused by Landau quantization; the double peaks at $B = 6\,\mathrm{T}$ are caused by spin quantization. **(b)** Effective mass data deduced from the distance of adjacent Landau peaks ΔE according to $\Delta E = h\,\mathrm{e}B/m_{eff}$ (*open symbols*); *filled symbols* are data from planar tunnel junctions (Tsui), the *solid line* is a mean-sqare fit of the data and the *dashed line* is the expected effective mass of InAs according to kp-theory. **(c)** Magnification of a $\mathrm{d}I/\mathrm{d}V$-curve at $B = 6\,\mathrm{T}$ exhibiting spin splitting; the Gaussian curves marked by *arrows* are the fitted spin levels

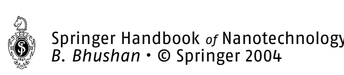
to verify the vibrational origin of the peak. First indications of vibrational levels have been found for H_2O and D_2O on TiO_2 [14.59], and completely convincing work has been performed for C_2H_2 and C_2D_2 on Cu(001) [14.23] (Fig. 14.11a). The technique can be used to identify individual molecules on the surface by their characteristic vibrational levels. In particular, surface reactions, as described in Fig. 14.5h–m, can be directly verified. Moreover, the orientation of complexes with respect to the surface can be determined to a certain extent, since the vibrational excitation depends on the position of the tunneling current within the molecule. Finally, the excitation of certain molecular levels can induce such corresponding motions as hopping [14.32], rotation [14.34] (Fig. 14.11b–e), or desorption [14.31], leading to additional possibilities for manipulation on the atomic scale.

Kondo Resonance

A rather intricate interaction effect is the Kondo effect. It results from a second order scattering process between itinerate states and a localized state [14.60]. The two states exchange some degree of freedom back and forth, leading to a divergence of the scattering probability at the Fermi level of the itinerate states. Due to the divergence, the effect strongly modifies sample properties. For example, it leads to an unexpected increase in resistance with decreasing temperature for metals containing magnetic impurities [14.4]. Here, the exchanged degree of freedom is the spin. A spectroscopic signature of the Kondo effect is a narrow peak in the DOS at the Fermi level disappearing above a characteristic temperature (Kondo temperature). STS provides the opportunity to study this effect on the local scale [14.61, 62].

Figure 14.12a–d shows an example of Co clusters deposited on a carbon nanotube [14.63]. While a small dip at the Fermi level, which is probably caused by curvature influences on the π-orbitals, is observed without Co (Fig. 14.12b) [14.64], a strong peak is found around a Co cluster deposited on top of the tube (Fig. 14.12a, arrow). The peak is slightly shifted with respect to $V = 0\,\mathrm{mV}$ due to the so-called Fano resonance [14.65], which results from interference of the tunneling processes into the localized Co-level and the itinerant nanotube levels. The resonance disappears within a several nanometer distance from the cluster, as shown in Fig. 14.12d.

The Kondo effect has also been detected for different magnetic atoms deposited on noble metal sur-



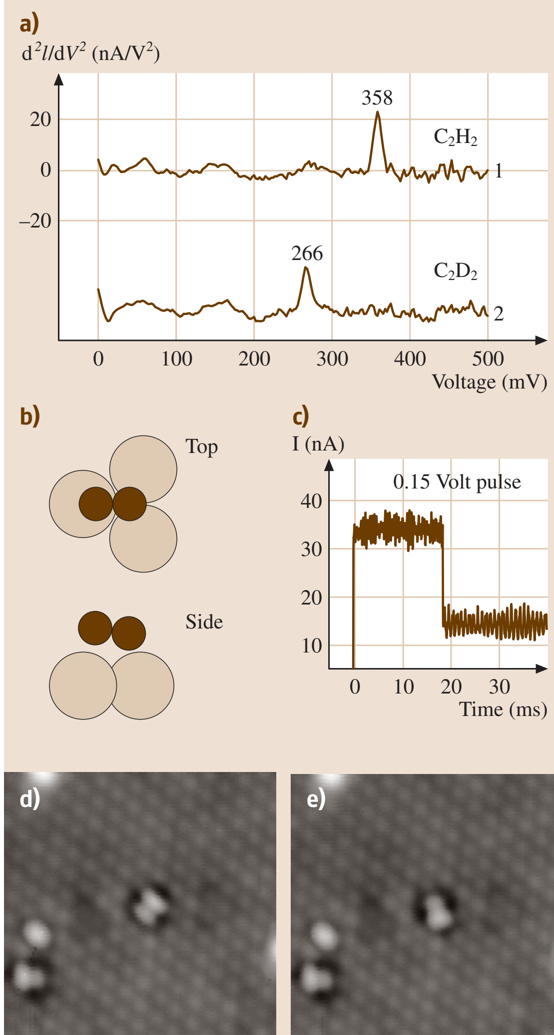


Fig. 14.11 **(a)** d^2I/dV^2-curves taken above a C_2H_2 and a C_2D_2 molecule on Cu(100); the peaks correspond to the C-H, respectively, C-D stretch mode energy of the molecule. **(b)** Sketch of O_2 molecule on Pt(111). **(c)** Tunnelling current above an O_2 molecule on Pt(111) during a voltage pulse of 0.15 V; the jump in current indicates rotation of the molecule. **(d)**, **(e)** STM image of an O_2 molecule on Pt(111) ($V = 0.05$ V) prior and after rotation induced by a voltage pulse to 0.15 V (**(a)–(e)** courtesy of Ho, Irvine)

faces [14.61,62]. There, it disappears at about 1 nm away from the magnetic impurity, and the effect of the Fano resonance is more pronounced, contributing to dips in $dI/dV(V)$-curves instead of peaks.

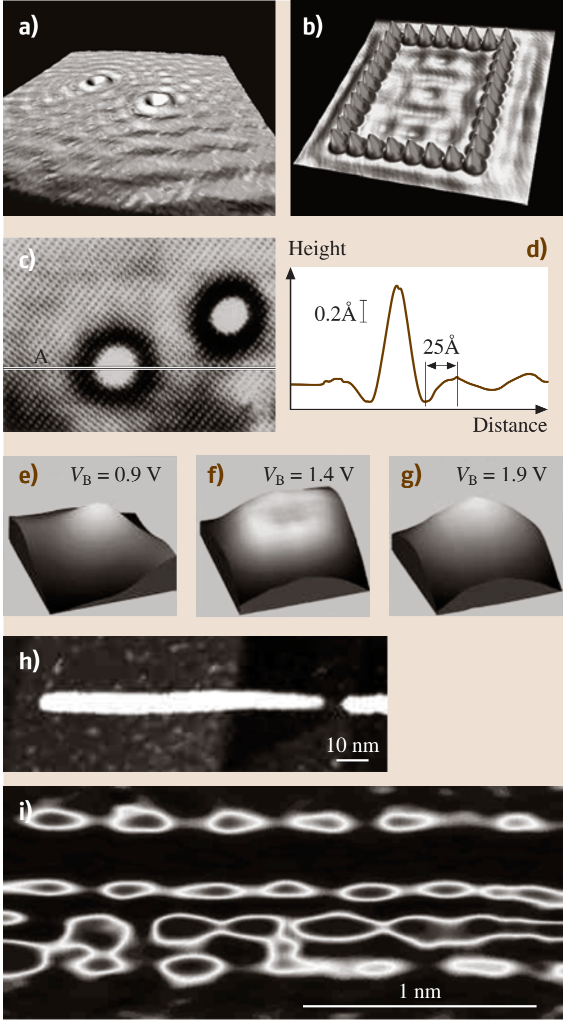

Fig. 14.13 **(a)** Low voltage STM image of Cu(111), including two defect atoms; the waves are electronic Bloch waves scattered at the defects. **(b)** Low voltage STM image of a rectangular quantum corral made from single atoms on Cu(111); the pattern inside the corral is the confined state of the corral close to E_F; (**(a)**,**(b)** courtesy of Eigler, Almaden). **(c)** STM image of GaAs(110) around a Si donor, $V = -2.5$ V; the line scan along A shown in **(d)** exhibits an additional oscillation around the donor caused by a standing Bloch wave; the grid like pattern corresponds to the atomic corrugation of the Bloch wave (**(c)**,**(d)** courtesy of van Kempen, Nijmegen). **(e)–(g)** STM images of an InAs/ZnSe-core/shell-nanocluster at different V. A fascinating experiment has been performed by *Manoharan* et al. [14.66], who used manipulation to form an elliptic cage for the surface states of Cu(111) (Fig. 14.12e, bottom). This cage was constructed to have a quantized level at E_F. Then, a cobalt atom was placed in one focus of the elliptic cage, producing a Kondo resonance. Surprisingly, the same resonance reappeared in the opposite focus, but not away from the focus (Fig. 14.12e, top). This shows amazingly that complex local effects such as the Kondo resonance can be guided to remote points.

Orbital scattering as a source of the Kondo resonance has also been found around a defect on Cr(001) [14.67]. Here, it is believed that itinerate sp-levels scatter at a localized d-level to produce the Kondo peak.

14.3.5 Imaging Electronic Wave Functions

Since STS measures the sum of squared wave functions (14.1), it is an obvious task to measure the local appearance of the most simple wave functions in solids, namely, the Bloch waves.

Bloch Waves

The atomically periodic part of the Bloch wave is always measured if atomic resolution is achieved (inset of Fig. 14.14a). However, the long-range, wavy part requires the presence of scatterers. The electron wave impinges on the scatterer and gets reflected, leading to self-interference. In other words, the phase of the Bloch wave gets fixed by the scatterer.

Such self-interference patterns were first found on Graphite(0001) [14.68] and later on noble metal surfaces, where adsorbates or step edges scatter the surface states (Fig. 14.13a) [14.22]. Fourier transforms of the real-space images reveal the k-space distribution of the corresponding states [14.69], which may include additional contributions besides the surface state [14.70]. Using particular geometries as the so-called quantum corrals to form a cage for the electron wave, the scatter-

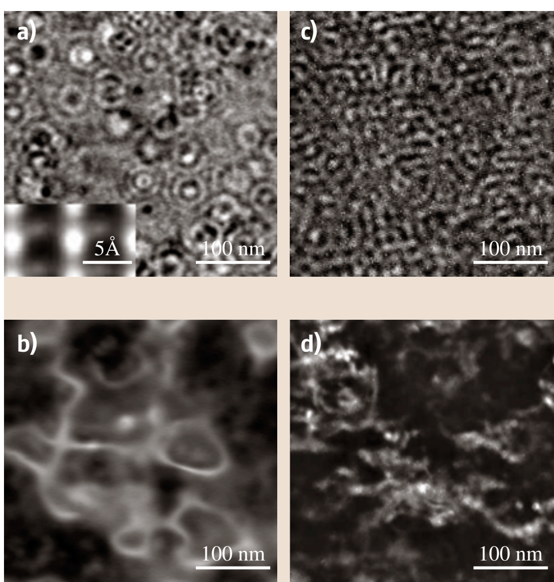

Fig. 14.14 **(a)** $\mathrm{d}I/\mathrm{d}V$-image of InAs(110) at $V = 50\,\mathrm{mV}$, $B = 0\,\mathrm{T}$; circular wave patterns corresponding to standing Bloch waves around each S donor are visible; inset shows a magnification revealing the atomically periodic part of the Bloch wave. **(b)** Same as **(a)**, but at $B = 6\,\mathrm{T}$; the stripe structures are drift states. **(c)** $\mathrm{d}I/\mathrm{d}V$-image of a 2-D electron system on InAs(110) induced by the deposition of Fe, $B = 0\,\mathrm{T}$. **(d)** Same as **(c)** but at $B = 6\,\mathrm{T}$; note that the contrast in **(a)** is increased by a factor of ten with respect to **(b)**–**(d)**

ing state can be rather complex (Fig. 14.13b). Anyway, it can usually be reproduced by simple calculations involving single-particle states [14.71].

Bloch waves in semiconductors scattered at charged dopants (Fig. 14.13c,d) [14.72], Bloch states confined in semiconductor quantum dots (Fig. 14.13e–g) [14.73], and Bloch waves confined in short-cut carbon nanotubes (Fig. 14.13h,i) [14.74, 75] have been visualized.

Drift States

More complex wave functions result from interactions. A nice playground to study such interactions are doped semiconductors. The reduced electron density with respect to metals increases the importance of electron interactions with potential disorder and other electrons. Applying a magnetic field quenches the kinetic energy, further enhancing the importance of interactions. A dramatic effect can be observed on InAs(110), where 3-D bulk states are displayed. While the usual scattering states around individual dopants are observed at $B = 0\,\mathrm{T}$ (Fig. 14.14a) [14.76], stripe structures are found in high magnetic field (Fig. 14.14b) [14.77]. They run along equipotential lines of the disorder potential. This can be understood by recalling that the electron tries to move in a cyclotron orbit, which is accelerated and decelerated in electrostatic potential, leading to a drift motion along an equipotential line [14.78].

The same effect has been found in 2-D electron systems (2-DES) of the same substrate, where the scattering states at $B = 0\,\mathrm{T}$ are, however, found to be more complex (Fig. 14.14c) [14.79]. The reason is the tendency of a 2-DES to exhibit closed scattering paths [14.80]. Consequently, the self-interference does not result from scattering at individual scatterers, but from complicated self-interference paths involving many scatterers. But drift states are also observed in the 2-DES at high magnetic fields (Fig. 14.14d) [14.81].

Charge Density Waves

Another interaction modifying the LDOS is the electron-phonon interaction. Phonons scatter electrons between different Fermi points. If the wave vectors connecting Fermi points exhibit a preferential orientation, a so-called Peierls instability occurs [14.82]. The corresponding phonon energy goes to zero, the atoms are slightly displaced with the periodicity of the corresponding wave vector, and a charge density wave (CDW) with the same periodicity appears. Essentially, the CDW increases the overlap of the electronic states with the phonon by phase fixing with respect to the atomic lattice. The Peierls transition naturally occurs in 1-D systems, where only two Fermi points are present, and, hence, preferential orientation is pathological. It can also occur in 2-D systems if large areas of the Fermi line run in parallel.

STS studies of CDWs are numerous (e.g., [14.83, 84]). Examples of a 1-D CDW on a quasi 1-D-like bulk material and of a 2-D CDW are shown in Fig. 14.15a–d and Fig. 14.15e, respectively [14.85, 86]. In contrast to usual scattering states where LDOS corrugations are only found close to the scatterer, the corrugations of CDWs are continous across the surface. Heating the substrate toward the transition temperature leads to a melting of the CDW lattice, as shown in Fig. 14.15f–h.

CDWs have also been found on monolayers of adsorbates such as a monolayer of Pb on Ge(111) [14.87]. These authors performed a nice temperature-dependent study revealing that the CDW is nucleated by scattering states around defects as one might expect [14.88]. 1-D systems have also been prepared on surfaces show-

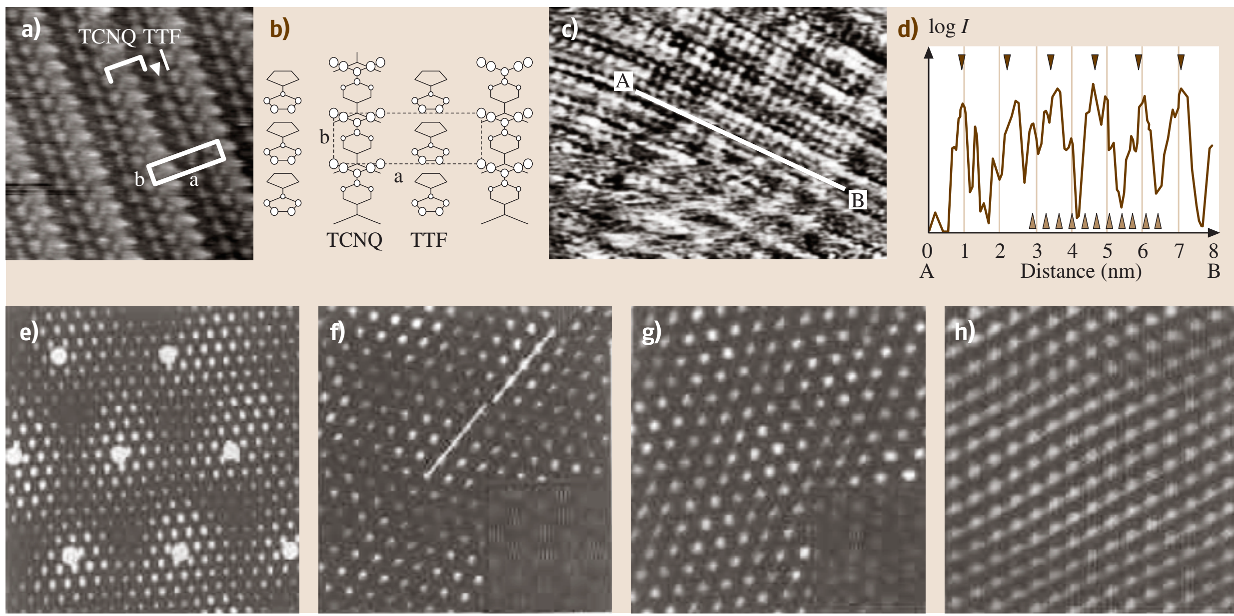

Fig. 14.15 **(a)** STM image of the ab-plane of the organic quasi 1-D conductor TTF-TCNQ, $T = 300$ K; while the TCNQ chains are conducting, the TTF chains are insulating. **(b)** Stick and ball model of the ab-plane of TTF-TCNQ. **(c)** STM image taken at $T = 61$ K, the additional modulation due to the Peierls-transition is visible in the profile along line A shown in **(d)**; the *open triangles* mark the atomic periodicity and the *filled triangles* the expected CDW periodicity (**(a)–(d)** courtesy of Kageshima, Kanagawa). **(e)–(h)** Low voltage STM-images of the two-dimensional CDW-system 1 T-TaS_2 at $T = 242$ K **(e)**, 298 K **(f)**, 349 K **(g)**, 357 K **(h)**. A long-range, hexagonal modulation is visible besides the atomic spots; its periodicity is highlighted by *big white dots* in **(e)**; the additional modulation obviously weakens with increasing T, but is still apparent in **(f)** and **(g)**, as evidenced in the lower magnification images in the insets (**(e)–(h)** courtesy of Lieber, Cambridge)

ing Peierls transitions [14.89,90]. Finally, the energy gap occurring at the transition has been studied by measuring $\mathrm{d}I/\mathrm{d}V(V)$-curves [14.91].

Superconductors

An intriguing effect resulting from electron-phonon interaction is superconductivity. Here, the attractive part of the electron-phonon interaction leads to the coupling of electronic states with opposite wave vector and mostly opposite spin [14.92]. Since the resulting Cooper pairs are bosons, they can condense at LT, forming a coherent many-particle phase, which can carry current without resistance. Interestingly, defect scattering does not influence the condensate if the coupling along the Fermi surface is homogeneous (s-wave superconductor). The reason is that the symmetry of the scattering of the two components of a Cooper pair effectively leads to a scattering from one Cooper pair state to another without affecting the condensate. This is different if the scatterer is magnetic, since the different spin components of the pair are scattered differently, leading to an effective pair breaking visible as a single-particle excitation within the superconducting gap. On a local scale, the effect has first been demonstrated by putting Mn, Gd, and Ag atoms on a Nb(110) surface [14.93]. While the nonmagnetic Ag does not modify the gap shown in Fig. 14.16a, it is modified in an asymmetric fashion close to Mn or Gd adsorbates, as shown in Fig. 14.16b. The asymmetry of the additional intensity is caused by the breaking of the particle-hole symmetry due to the exchange interaction between the localized Mn state and the itinerate Nb states.

Another important local effect is caused by the relatively large coherence length of the condensate. At a material interface, the condensate wave function cannot stop abruptly, but laps into the surrounding material (proximity effect). Consequently, a superconducting gap can be measured in areas of non-superconducting material. Several studies have shown this effect on the

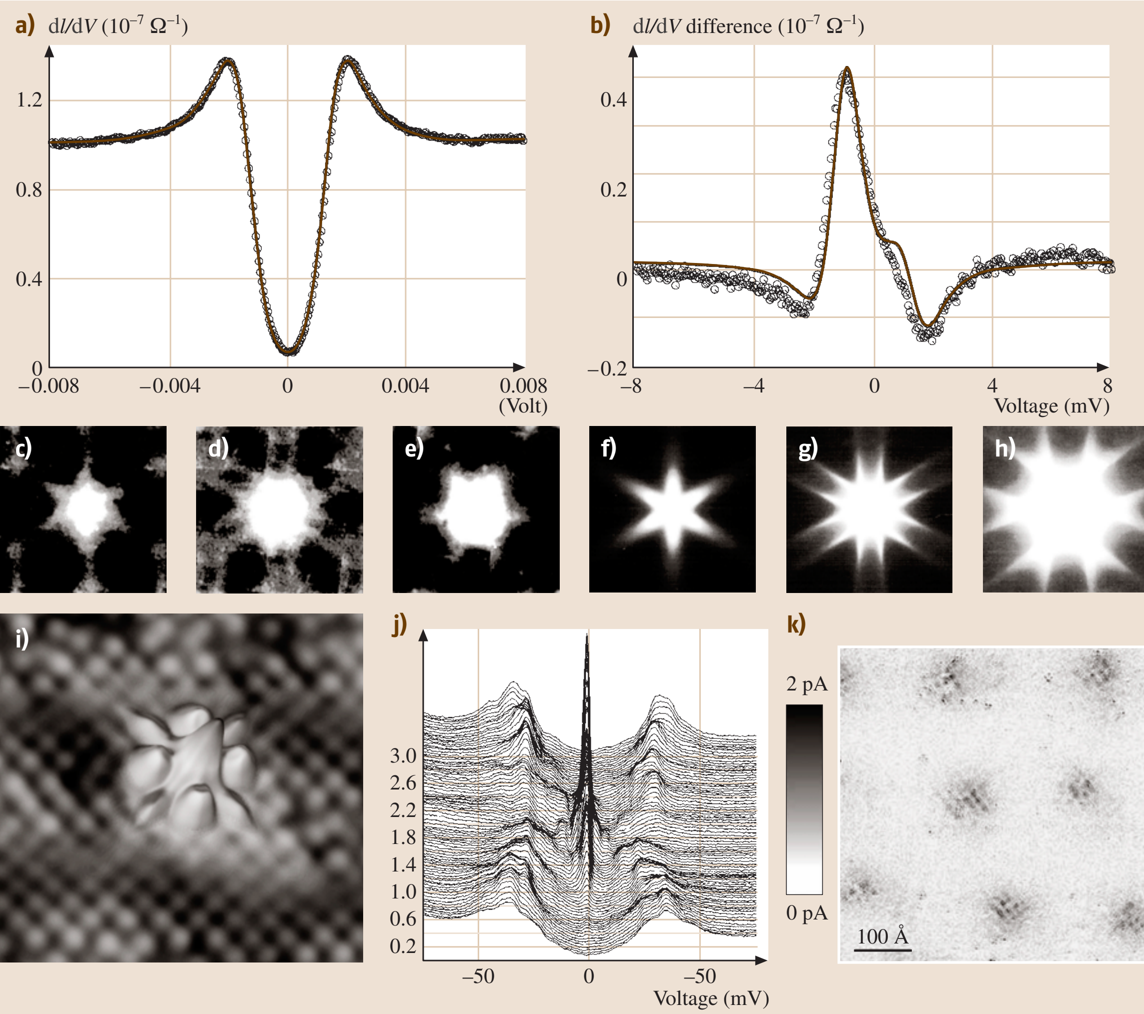

Fig. 14.16 **(a)** $\mathrm{d}I/\mathrm{d}V$-curve of Nb(110) at $T = 3.8$ K (*symbols*) in comparison with a BCS-fit of the superconducting gap of Nb (*line*). **(b)** Difference between the $\mathrm{d}I/\mathrm{d}V$-curve taken directly above a Mn-atom on Nb(110) and the $\mathrm{d}I/\mathrm{d}V$-curve taken above the clean Nb(110) (*symbols*) in comparison with a fit using the Bogulubov-de Gennes equations (*line*) (**(a)**,**(b)** courtesy of Eigler, Almaden). **(c)**–**(e)** $\mathrm{d}I/\mathrm{d}V$-images of a vortex core in the type-II superconductor 2H-$NbSe_2$ at 0 mV **(c)**, 0.24 mV **(d)**, and 0.48 mV **(e)** (**(c)**–**(e)** courtesy of H. F. Hess). **(f)**–**(h)** Corresponding calculated LDOS images within the Eilenberger framework (**(f)**–**(h)** courtesy of Machida, Okayama). **(i)** Overlap of an STM image at $V = -100$ mV (backround 2-D image) and a $\mathrm{d}I/\mathrm{d}V$-image at $V = 0$ mV (overlapped 3-D image) of optimally doped $Bi_2Sr_2CaCu_2O_{8+\delta}$ containing 0.6% Zn impurities. The STM image shows the atomic structure of the cleavage plane, while the $\mathrm{d}I/\mathrm{d}V$-image shows a bound state within the superconducting gap, which is located around a single Zn impurity. The fourfold symmetry of the bound state reflects the d-like symmetry of the superconducting pairing function; **(j)** $\mathrm{d}I/\mathrm{d}V$-curves taken at different positions across the Zn impurity; the bound state close to 0 mV is visible close to the Zn atom; **(k)** LDOS in the vortex core of slightly overdoped $Bi_2Sr_2CaCu_2O_{8+\delta}$, $B = 5$ T; the $\mathrm{d}I/\mathrm{d}V$-image taken at $B = 5$ T is integrated over $V = 1$–12 mV, and the corresponding $\mathrm{d}I/\mathrm{d}V$-image at $B = 0$ T is subtracted to highlight the LDOS induced by the magnetic field. The checkerboard pattern within the seven vortex cores exhibits a periodicity, which is fourfold with respect to the atomic lattice shown in **(i)** and is thus assumed to be a CDW (**(i)**–**(k)** courtesy of S. Davis, Cornell and S. Uchida, Tokyo)

local scale using metals and doped semiconductors as surrounding materials [14.94, 95].

While the classical type-I superconductors are ideal diamagnets, the so-called type-II superconductors can contain magnetic flux. The flux forms vortices, each containing one flux quantum. These vortices are accompanied by a disappearance of the superconducting gap and, therefore, can be probed by STS [14.96]. LDOS maps measured inside the gap lead to bright features in the area of the vortex core. Importantly, the length scale of these features is different from the length scale of the magnetic flux due to the difference between London's penetration depth and coherence length. Thus, STS probes another property of the vortex than the usual magnetic imaging techniques (see Sect. 14.4.4). Surprisingly, first measurements of the vortices on $NbSe_2$ revealed vortices shaped as a sixfold star [14.97] (Fig. 14.16c). With increasing voltage inside the gap, the orientation of the star rotates by 30° (Fig. 14.16d,e). The shape of these stars could finally be reproduced by theory, assuming an anisotropic pairing of electrons in the superconductor (Fig. 14.16f–h) [14.98]. Additionally, bound states inside the vortex core, which result from confinement by the surrounding superconducting material, are found [14.97]. Further experiments investigated the arrangement of the vortex lattice, including transitions between hexagonal and quadratic lattices [14.99], the influence of pinning centers [14.100], and the vortex motion induced by current [14.101].

An important topic is still the understanding of high temperature superconductivity (HTCS). An almost accepted property of HTCS is its d-wave pairing symmetry. In contrast to s-wave superconductors, scattering can lead to pair breaking, since the Cooper pair density vanishes in certain directions. Indeed, scattering states (bound states in the gap) around nonmagnetic Zn impurities have been observed in $Bi_2Sr_2CaCu_2O_{8+\delta}$ (BSCCO) (Fig. 14.16i,j) [14.26]. They reveal a d-like symmetry, but not the one expected from simple Cooper pair scattering. Other effects such as magnetic polarization in the environment probably have to be taken into account [14.102]. Moreover, it has been found that magnetic Ni impurities exhibit a weaker scattering structure than Zn impurities [14.103]. Thus, BSCCO shows exactly the opposite behavior of the Nb discussed above (Fig. 14.16a,b). An interesting topic is the importance of inhomogeneities in HTCS materials. Evidence for inhomogeneities has indeed been found in underdoped materials, where puddles of the superconducting phase are shown to be embedded in non-superconducting areas [14.104].

Of course, vortices have also been investigated in HTCS materials [14.105]. Bound states are found, but at energies that are in disagreement with simple models, assuming a BCS-like d-wave superconductor [14.106, 107]. Theory predicts, instead, that the bound states are magnetic-field-induced spin-density waves stressing the competition between anti-ferromagnetic order and superconductivity in HTCS materials [14.108]. Since the spin density wave is accompanied by a charge density wave of half wavelength, it can be probed by STS [14.109]. Indeed, a checkerboard pattern of the right periodicity has been found in and around vortex cores in BSCCO (Fig. 14.16k). It exceeds the width of an individual vortex core, implying that the superconducting coherence length is different from the anti-ferromagnetic one.

Complex Systems (Manganites)

Complex phase diagrams are not restricted to HTCS materials (cuprates). They exist with similar complexity for other doped oxides such as manganites. Only a few studies of these materials have been performed by STS, mainly showing the inhomogeneous evolution of metallic and insulating phases [14.110, 111]. Similarities to the granular case of an underdoped HTCS material are obvious. Since inhomogeneities seem to be crucial in many of these materials, a local method such as STS might continue to be important for the understanding of their complex properties.

14.3.6 Imaging Spin Polarization: Nanomagnetism

Conventional STS couples to the LDOS, i. e., the charge distribution of the electronic states. Since electrons also have spin, it is desirable to also probe the spin distribution of the states. This can be achieved if the tunneling tip is covered by a ferromagnetic material [14.112]. The coating acts as a spin filter or, more precisely, the tunneling current depends on the relative angle α_{ij} between the spins of the tip and the sample according to $\cos(\alpha_{ij})$. In ferromagnets, the spins mostly have one preferential orientation along the so-called easy axis, i. e., a particular tip is not sensitive to spin orientations of the sample perpendicular to the spin orientation of the tip. Different tips have to be prepared to detect different spin orientations of the sample. Moreover, the magnetic stray field of the tip can perturb the spin orientation of the sample. To avoid this, a technique

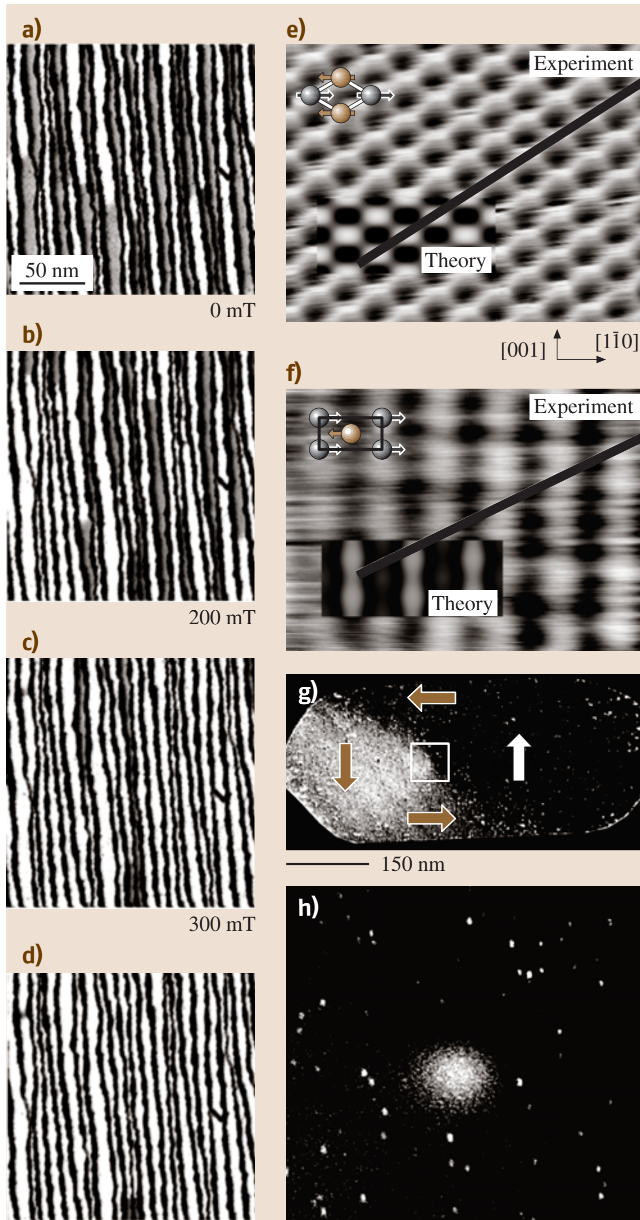

Fig. 14.17 (a)–(d) Spin-polarized STM images of 1.65 monolayer of Fe deposited on a stepped W(110) surface measured at different B-fields, as indicated. Double layer and monolayer Fe stripes are formed on the W substrate; only the double layer stripes exhibit magnetic contrast with an out-of-plane sensitive tip as used here. *White* and *grey areas* correspond to different domains. Note that more white areas appear with increasing field. **(e)** STM image of an antiferromagnetic Mn monolayer on W(110). **(f)** Spin-polarized STM-image of the same surface (in-plane tip). The insets in **(e)** and **(f)** show the calculated STM and spin-polarized STM images, respectively, and the stick and ball models symbolize the atomic and the magnetic unit cell (**(a)–(f)** courtesy of M. Bode, Hamburg). **(g)** Spin-polarized STM image of a 6-nm-high Fe island on W(110) (in-plane tip). Four different areas are identified as four different domains with domain orientations as indicated by the *arrows*. **(h)** Spin-polarized STM image of the central area of an island; the size of the area is indicated by the rectangle in **(g)**; the measurement is performed with an out-of-plane sensitive tip showing that the magnetization turns out-of-plane in the center of the island

using anti-ferromagnetic Cr as a tip coating material has been developed [14.113]. This avoids stray fields, but still provides a preferential spin orientation of the few atoms at the tip apex that dominate the tunneling current. Depending on the thickness of the Cr coating, spin orientations perpendicular or parallel to the sample surface are prepared.

So far, the described technique has been used to image the evolution of magnetic domains with increasing B-field(Fig. 14.17a–d) [14.114], the anti-ferromagnetic order of a Mn monolayer on W(110) (Fig. 14.17e,f) [14.115], and the out-of-plane orientation predicted for a magnetic vortex core as it exists in the center of a Fe island exhibiting four domains in the flux closure configuration (Fig. 14.17g,h) [14.116].

Besides the obvious strong impact on nanomagnetism, the technique might also be used to investigate other electronic phases such as the proposed spin density wave around a HTCS vortex core.

14.4 Scanning Force Microscopy and Spectroscopy

SFSThe examples discussed in the previous section show the wide variety of physical questions that have been tackled with the help of LTSTM. Here, we turn to the other prominent scanning probe method that is applied at low temperatures, namely, SFM, which gives complementary information on sample properties on the atomic scale.

The ability to sensitively detect *forces* with spatial resolution down to the atomic scale is of great interest, since force is one of the most fundamental quantities in physics. Mechanical force probes usually consist of a cantilever with a tip at its free end that is brought close to the sample surface. The cantilever can be mounted parallel or perpendicular to the surface (general aspects of force probe designs are described in Chapt. 12). Basically, two methods exist to detect forces with cantilever-based probes – the *static* and the *dynamic* mode (see Chapt. 11). They can be used to generate a laterally resolved image (*microscopy* mode) or determine its distance dependence (*spectroscopy* mode). One can argue about the terminology, since spectroscopy is usually related to energies and not to distance dependences. Nevertheless, we will use it throughout the text, because it avoids lenghty paraphrases and is established in this sense throughout the literature.

In the static mode, a force that acts on the tip bends the cantilever. By measuring its deflection Δz the tip-sample force F_{ts} can be directly calculated with Hooke's law: $F_{ts} = c_z \cdot \Delta z$, where c_z denotes the spring constant of the cantilever. In the various dynamic modes, the cantilever is oscillated with amplitude A at or near its eigenfrequency f_0, but in some applications also off resonance. At ambient pressures or in liquids, amplitude modulation (AM-SFM) is used to detect amplitude changes or the phase shift between driving force and cantilever oscillation. In vacuum, the frequency shift Δf of the cantilever due to a tip-sample interaction is measured by frequency modulation technique (FM-SFM). The nomenclature is not standardized. Terms like tapping mode or intermittent contact mode are used instead of AM-SFM, and NC-AFM (noncontact atomic force microscopy) or DFM (dynamic force microscopy) instead of FM-SFM or FM-AFM. However, all these modes are *dynamic*, i. e., they involve an oscillating cantilever and can be used in the noncontact, as well as in the contact regime. Therefore, we believe that the best and most consistent way is to distinguish them by their different detection schemes. Converting the measured quantity (amplitude, phase, or frequency shift) into a physically meaningful quantity, e.g., the tip-sample interaction force F_{ts} or the force gradient $\partial F_{ts}/\partial z$, is not always straightforward and requires an analysis of the equation of motion of the oscillating tip (see Chaps. 15, 13).

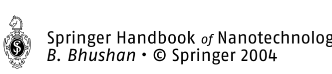
Whatever method is used, the resolution of a cantilever-based force detection is fundamentally limited by its intrinsic *thermomechanical* noise. If the cantilever is in thermal equilibrium at a temperature T, the equipartition theorem predicts a thermally induced *root mean square* (rms) motion of the cantilever in z direction of $z_{rms} = (k_B T/c_{eff})^{1/2}$, where k_B is the Boltzmann constant and $c_{eff} = c_z + \partial F_{ts}/\partial z$. Note that usually $dF_{ts}/dz \gg c_z$ in contact and $dF_{ts}/dz < c_z$ in noncontact. Evidently, this fundamentally limits the force resolution in the static mode, particularly if operated in noncontact. Of course, the same is true for the different dynamic modes, because the thermal energy $k_B T$ excites the eigenfrequency f_0 of the cantilever. Thermal noise is *white* noise, i. e., its spectral density is flat. However, if the cantilever transfer function is taken into account, one can see that the thermal energy mainly excites f_0. This explains the term "thermo" in thermomechanical noise, but what is the "mechanical" part?

A more detailed analysis reveals that the thermally induced cantilever motion is given by

$$z_{rms} = \sqrt{\frac{2k_B TB}{\pi c_z f_0 Q}}\,, \tag{14.2}$$

where B is the measurement bandwidth and Q is the quality factor of the cantilever. Analog expressions can be obtained for all quantities measured in dynamic modes, because the deflection noise translates, e.g., into frequency noise [14.5]. Note that f_0 and c_z are correlated with each other via $2\pi f_0 = (c_z/m_{eff})^{1/2}$, where the effective mass m_{eff} depends on the geometry, density, and elasticity of the material. The Q-factor of the cantilever is related to the external damping of the cantilever motion in a medium and on the intrinsic damping within the material. This is the "mechanical" part of the fundamental cantilever noise.

It is possible to operate a low temperature force microscope directly immersed in the cryogen [14.117,118] or in the cooling gas [14.119], whereby the cooling is simple and very effective. However, it is evident from (14.2) that the smallest fundamental noise is achievable



in vacuum, where the Q-factors are more than 100 times larger than in air, and at low temperatures.

The best force resolution up to now, which is better than $1\times10^{-18}\,\mathrm{N/Hz^{1/2}}$, has been achieved by *Mamin* et al. [14.120] in vacuum at a temperature below 300 mK. Due to the reduced thermal noise and the lower thermal drift, which results in a higher stability of the tip-sample gap and a better signal-to-noise ratio, the highest resolution is possible at low temperatures in ultrahigh vacuum with FM-SFM. A vertical rms-noise below 2 pm [14.121, 122] and a force resolution below 1 aN [14.120] have been reported.

Besides the reduced noise, the application of force detection at low temperatures is motivated by the increased stability and the possibility to observe phenomena, which appear below a certain critical temperature T_c, as outlined at page 414. The experiments, which have been performed at low temperatures up until now, were motivated by at least one of these reasons and can be roughly divided into four groups: (i) atomic-scale imaging, (ii) force spectroscopy, (iii) investigation of quantum phenomena by measuring electrostatic forces, and (iv) utilizing magnetic probes to study ferromagnets, superconductors, and single spins. In the following, we describe some exemplary results.

14.4.1 Atomic-Scale Imaging

In a simplified picture, the dimensions of the tip end and its distance to the surface limit the lateral resolution of force microscopy, since it is a near-field technique. Consequently, atomic resolution requires a stable single atom at the tip apex that has to be brought within a distance of some tenths of a nanometer to an atomically flat surface. Both conditions can be fulfilled by FM-AFM, and nowadays *true* atomic resolution is routinely obtained (see Chapt. 13). However, the above statement says nothing about the nature and the underlying processes of imaging with atomic resolution. Si(111)-(7×7) was the first surface on which true atomic resolution was achieved [14.123], and several studies have been performed at low temperatures on this well-known material [14.124–126]. First principle simulations performed on semiconductors with a silicon tip revealed that *chemical* interactions, i. e., a significant charge redistribution between the dangling bonds of tip and sample, dominate the atomic-scale contrast [14.127–129]. On V-III semiconductors, it was found that only one atomic species, the group V atoms, is imaged as protrusions with a silicon tip [14.128, 129]. Furthermore, these simulations revealed that the sample, as well as the tip atoms are noticeably displaced from their equilibrium position due to the interaction forces. At low temperatures, both aspects could be observed with silicon tips on indium arsenide [14.121, 130].

Chemical Sensitivity of Force Microscopy

The (110) surface of the III-V semiconductor indium arsenide exhibits both atomic species in the top layer (see Fig. 14.18a). Therefore, this sample is well suited to study the chemical sensitivity of force microscopy [14.121]. In Fig. 14.18b, the usually observed atomic-scale contrast on InAs(110) is displayed. As predicted, the arsenic atoms, which are shifted by 80 pm above the indium layer due to the (1×1) relaxation, are imaged as protrusions. While this general appearance was similar for most tips, two other distinctively different contrasts were also observed: a second protru-

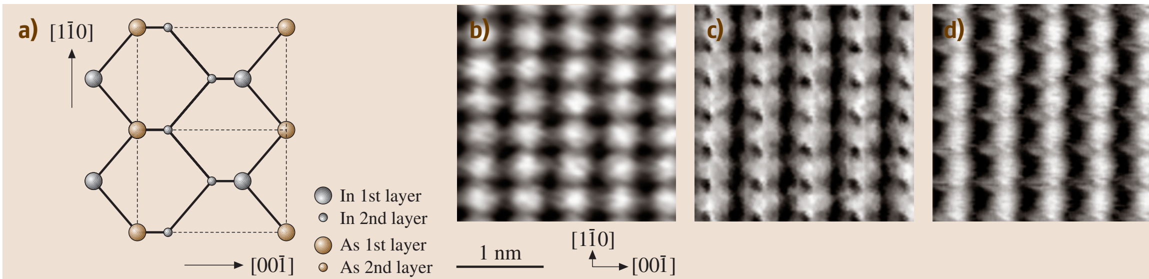


Fig. 14.18a–d The structure of InAs(110) as seen from top **(a)** and three FM-AFM images of this surface obtained with different tips at 14 K **(b)–(d)**. In **(b)**, only the arsenic atoms are imaged as protrusions, as predicted for a silicon tip. The two features in **(c)** and **(d)** corresponds to the zigzag arrangement of the indium and arsenic atoms. Since force microscopy is sensitive to short-range chemical forces, the appearance of the indium atoms can be associated with a chemically different tip apex

sion (c) and a sharp depression (d). The arrangement of these two features corresponds well to the zigzag configuration of the indium and arsenic atoms along the [1$\bar{1}$0]-direction. A sound explanation would be as follows: The contrast usually obtained with one feature per surface unit cell corresponds to a silicon-terminated tip, as predicted by simulations. A different atomic species at the tip apex, however, can result in a very different charge redistribution. Since the atomic-scale contrast is due to a chemical interaction, the two other contrasts would then correspond to a tip that has been accidentally contaminated with sample material (arsenic or indium-terminated tip apex). Nevertheless, this explanation has not yet been verified by simulations for this material.

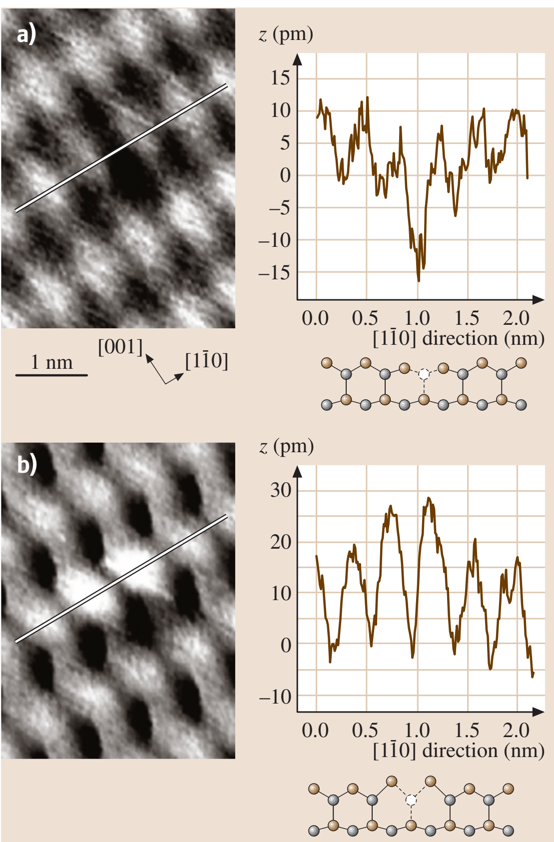

Fig. 14.19a,b Two FM-AFM images of the identical indium-site point defect (presumably an indium vacancy) recorded at 14 K. If the tip is relatively far away, the theoretically predicted inward relaxation of two arsenic atoms adjacent to an indium vacancy is visible **(a)**. At a closer tip-sample distance **(b)**, the two arsenic atoms are pulled farther toward the tip compared to the other arsenic atoms, since they have only two instead of three bonds

Tip-Induced Atomic Relaxation

Schwarz et al. [14.121] were able to directly visualize the predicted tip-induced relaxation during atomic-scale imaging near a point defect. Figure 14.19 shows two FM-AFM images of the same point defect recorded with different constant frequency shifts on InAs(110), i. e., the tip was closer to the surface in (b) compared to (a). The arsenic atoms are imaged as protrusions with the used silicon tip. From the symmetry of the defect, an indium-site defect can be inferred, since the distance-dependent contrast is consistent with what has to be expected for an indium vacancy. This expectation is based on calculations performed for the similar III-V semiconductor GaP(110), where the two surface gallium atoms around a P-vacancy were found to relax downward [14.131]. This corresponds to the situation in Fig. 14.19a, where the tip is relatively far away and an inward relaxation of the two arsenic atoms is observed. The considerably larger attractive force in Fig. 14.19b, however, pulls the two arsenic atoms toward the tip. All other arsenic atoms are also pulled, but they are less displaced, because they have three bonds to the bulk, while the two arsenic atoms in the neighborhood of an indium vacancy have only two bonds. This direct experimental proof of the presence of tip-induced relaxations is also relevant for STM measurements, because the tip-sample distances are similar during atomic resolution imaging. Moreover, the result demonstrates that FM-AFM can probe elastic properties on an atomic level.

Imaging of Weakly Interacting van der Waals Surfaces

For weakly interacting van der Waals surfaces like the (0001) surface of graphite, much smaller atomic corrugation amplitudes are expected compared to strongly interacting surfaces such as semiconductors. In graphite, a layered material, the carbon atoms are covalently bonded and arranged in a honeycomb structure within the (0001) plane. Individual layers of (0001) planes (*ABA*... stacking) stick together only by weak van der Waals forces. Three distinctive sites exist on the surface: carbon atoms with (*A*-type) and without (*B*-type) a neighbor in the next graphite layer and the *hollow site* (H-site) in the hexagon center. Neither static contact force microscopy nor STM can resolve the three different sites. For both methods, the contrast is well understood and exhibits protrusions with a sixfold sym-

metry and a periodicity of 246 pm. In high resolution FM-AFM images acquired at low temperatures, a large maximum and two different minima have been resolved (see Fig. 14.20a). A simulation using the Lennard-Jones potential, in which the attractive part is given by the short-range interatomic van der Waals force, reproduced these three features very well. By comparison with the experimental data (cf. the solid and the dotted line in the section of Fig. 14.20a), the large maximum could be assigned to the hollow site, while the two different minima represent *A*- and *B*-type carbon atoms [14.132]. Note that the image contrast is inverted with respect the arrangement of the atoms, i. e., the minima correspond to the position of the carbon atoms. The carbon-carbon distance of only 142 pm is the smallest interatomic distance that has been resolved with FM-AFM so far. Moreover, the weak tip-sample interaction results in typical corrugation amplitudes around 10 pm peak-to-peak, i. e., just above the noise level [14.7].

While experiments on graphite basically gain advantages from the increased stability and signal-to-noise ratio at low temperatures, solid xenon (melting temperature $T_m = 161$ K) can only be observed at sufficiently low temperatures [14.8]. In addition, xenon is a pure van der Waals crystal, and since it is an insulator, FM-AFM is the only real space method available today that allows the study of solid xenon on the atomic scale.

Allers et al. [14.8] adsorbed a well-ordered xenon film on cold graphite(0001) ($T < 55$ K) and subsequently studied it at 22 K by FM-AFM (see Fig. 14.20b). The six-fold symmetry and the distance between the protrusions correspond well with the nearest neighbor distance in the closed, packed (111) plane of bulk xenon, which crystallizes in the face-centered cubic structure. A comparison between experiment and simulation confirmed that the protrusions correspond to the position of the xenon atoms [14.133]. However, the simulated corrugation amplitudes do not fit as well as for graphite (see sections in Fig. 14.20b). A possible reason is that tip-induced relaxations, which were not considered in the simulations, are more important for this pure van der Waals crystal xenon than they are for graphite, because in-plane graphite exhibits strong covalent bonds. Nevertheless, the results demonstrated that a weakly bonded van der Waals crystal could be imaged nondestructively on the atomic scale for the first time.

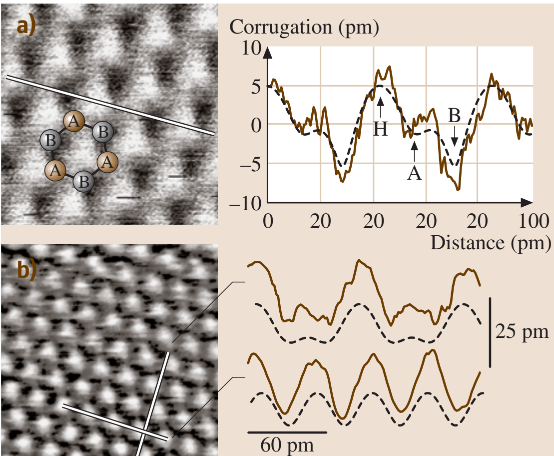

Fig. 14.20a,b FM-AFM images of graphite(0001) **(a)** and Xe(111) **(b)** recorded at 22 K. On the right side, line sections taken from the experimental data (*solid lines*) are compared to simulations (*dotted lines*). *A*- and *B*-type carbon atoms, as well as the hollow site (H-site) on graphite can be distinguished, but are imaged with inverted contrast, i. e., the carbon sites are displayed as minima. Such an inversion does not occur on Xe(111)

14.4.2 Force Spectroscopy

A wealth of information about the nature of the tip-sample interaction can be obtained by measuring its distance dependence. This is usually done by recording the measured quantity (deflection, frequency shift, amplitude change, phase shift) and applying an appropriate voltage ramp to the *z*-electrode of the scanner piezo, while the *z*-feedback is switched off. According to (14.2), low temperatures and high *Q*-factors (vacuum) considerably increase the force resolution. In the static mode, long-range forces and contact forces can be examined. Force measurements at small tip-sample distances are inhibited by the *jump-to-contact* phenomenon: If the force gradient $\partial F_{ts}/\partial z$ becomes larger than the spring constant c_z, the cantilever cannot resist the attractive tip-sample forces and the tip snaps onto the surface. Sufficiently large spring constants prevent this effect, but reduce the force resolution. In the dynamic modes, the jump-to-contact can be avoided due to the additional restoring force ($c_z A$) at the lower turnaround point. The highest sensitivity can be achieved in vacuum by using the FM technique, i. e., by recording $\Delta f(z)$-curves. An alternative FM spectroscopy method, the recording of $\Delta f(A)$-curves, has been suggested by *Hölscher* et al. [14.134]. Note that if the amplitude is much larger than the characteristic decay length of the tip-sample force, the frequency shift cannot simply be converted into force gradients by

using $\partial F_{ts}/\partial z = 2c_z \cdot \Delta f/f_0$ [14.135]. Several methods have been published to convert $\Delta f(z)$ data into the tip-sample potential $V_{ts}(z)$ and tip-sample force $F_{ts}(z)$ (see, e.g., [14.136, 137]).

Measurement of Interatomic Forces at Specific Atomic Sites

FM force spectroscopy has been successfully used to measure and determine quantitatively the short-range chemical force between the foremost tip atom and specific surface atoms [14.109, 138, 139]. Figure 14.21 displays an example for the quantitative determination of the short-range force. Figure 14.21a shows two $\Delta f(z)$-curves measured with a silicon tip above a corner hole and above an adatom. Their position is indicated by arrows in the inset, which displays the atomically resolved Si(111)-(7×7) surface. The two curves differ from each other only for small tip-sample distances, because the long-range forces do not contribute to the atomic-scale contrast. The low, thermally induced lateral drift and the high stability at low temperatures were required to precisely address the two specific sites. To extract the short-range force, the long-range van der Waals and/or electrostatic forces can be subtracted from the total force. The grey curve in Fig. 14.21b has been reconstructed from the $\Delta f(z)$-curve recorded above an adatom and represents the total force. After removing the long-range contribution from the data, the much steeper black line is obtained, which corresponds to the short-range force between the adatom and the atom at the tip apex. The measured maximum attractive force (−2.1 nN) agrees well with first principle calculations (−2.25 nN).

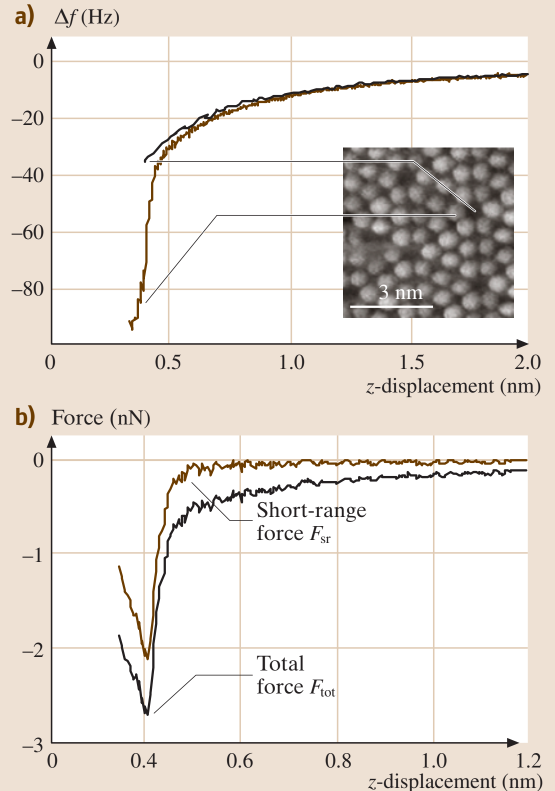

Fig. 14.21a,b FM force spectroscopy on specific atomic sites at 7.2 K. In **(a)**, an FM-SFM image of the Si(111)-(7×7) surface is displayed together with two $\Delta f(z)$-curves, which have been recorded at the positions indicated by the *arrows*, i. e., above the cornerhole (*brown*) and above an adatom (*black*). In **(b)**, the total force above an adatom (*brown line*) has been recovered from the $\Delta f(z)$-curve. After subtraction of the long-range part, the short-range force can be determined (*black line*) (courtesy of H. J. Hug; cf. [14.138])

Three-dimensional Force Field Spectroscopy

Further progress with the FM technique has been made by *Hölscher* et al. [14.140]. They acquired a complete 3-D force field on NiO(001) with atomic resolution (*3-D force field spectroscopy*). In Fig. 14.22a, the atomically resolved FM-AFM image of NiO(001) is shown together with the used coordinate system and the tip to illustrate the measurement principle. NiO(001) crystallizes in the rock salt structure. The distance between the protrusions corresponds to the lattice constant of 417 pm, i. e., only one type of atom (most likely the oxygen) is imaged as protrusion. In an area of 1 nm × 1 nm, 32 × 32 individual $\Delta f(z)$-curves have been recorded at every (x, y) image point and converted into $F_{ts}(z)$-curves. The $\Delta f(x, y, z)$ data set is thereby converted into the 3-D force field $F_{ts}(x, y, z)$. Figure 14.22b, where a specific x-z-plane is displayed, demonstrates that atomic resolution is achieved. It represents a 2-D cut $F_{ts}(x, y = \text{const}, z)$ along the [100]-direction (corresponding to the shaded slice marked in Fig. 14.22a). Since a large number of curves have been recorded, *Langkat* et al. [14.139] could evaluate the whole data set by standard statistical means to extract the long- and short-range forces. A possible future application of 3-D force field spectroscopy could be to map the short-range forces of complex molecules with functionalized tips in order to locally resolve their chemical reactivity.

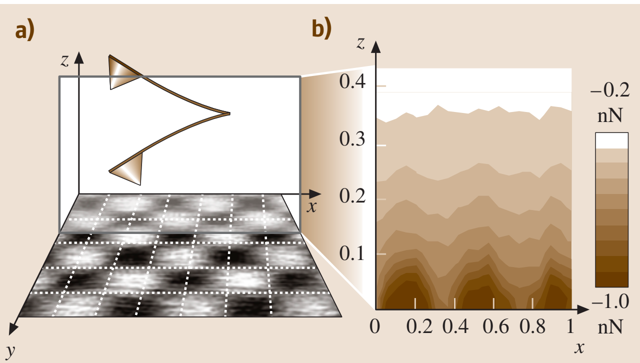

Fig. 14.22a,b Principle of the 3-D force filed spectroscopy method **(a)** and a 2-D cut through the 3-D force field $F_{ts}(x,y,z)$ recorded at 14 K **(b)**. At all 32×32 image points of the 1 nm × 1 nm large scan area on NiO(001), a $\Delta f(z)$-curve has been recorded. The obtained $\Delta f(x, y, z)$ data set is then converted into the 3-D tip-sample force field $F_{ts}(x, y, z)$. The *shaded slice* $F_{ts}(x, y = \text{const}, z)$ in **(a)** corresponds to a cut along the [100]-direction and demonstrates that atomic resolution has been obtained, because the distance between the protrusions corresponds well to the lattice constant of nickel oxide

Noncontact Friction

Another approach to achieve small tip-sample distances in combination with high force sensitivity is to use soft springs in a perpendicular configuration. The much higher cantilever stiffness along the cantilever axis prevents the jump-to-contact, but the lateral resolution is limited by the magnitude of the oscillation amplitude. However, with such a setup at low temperatures, *Stipe* et al. [14.141] measured the distance dependence of the very small force due to noncontact friction between tip and sample in vacuum. The effect was attributed to electric charges, which are moved parallel to the surface by the oscillating tip. Since the topography was not recorded in situ, the influence of contaminants or surface steps remained unknown.

Part B | 14.4

14.4.3 Electrostatic Force Microscopy

Electrostatic forces are readily detectable by a force microscope, because tip and sample can be regarded as two electrodes of a capacitor. If they are electrically connected via their back sides and have different work functions, electrons will flow between tip and sample until their Fermi levels are equalized. As a result, an electric field and, consequently, an attractive electrostatic force exists between them at zero bias. This *contact potential difference* can be balanced by applying an appropriate bias voltage. It has been demonstrated that individual doping atoms in semiconducting materials can be detected by electrostatic interactions due to the local variation of the surface potential around them [14.142, 143].

Detection of Edge Channels in the Quantum Hall Regime

At low temperatures, electrostatic force microscopy has been used to measure the electrostatic potential in the quantum Hall regime of a *two-dimensional electron gas* (2-DEG) buried in epitaxially grown GaAs/AlGaAs heterostructures [14.144–147]. In the 2-DEG, electrons can move freely in the x-y-plane, but they cannot move in z-direction. Electrical transport properties of a 2-DEG are very different compared to normal metallic conduction. Particularly, the Hall resistance $R_H = h/ne^2$ (where h represents Planck's constant, e is the electron charge, and $n = 1, 2, \ldots$) is quantized in the quantum Hall regime, i. e., at sufficiently low temperatures ($T < 4$ K) and high magnetic fields (up to 20 T). Under these conditions, theoretical calculations predict the existence of *edge channels* in a Hall bar. A Hall bar is a strip conductor that is contacted in a specific way to allow longitudinal and transversal transport measurements in a perpendicular magnetic field. The current is not evenly distributed over the cross section of the bar, but passes mainly along rather thin paths close to the edges. This prediction has been verified by measuring profiles of the electrostatic potential across a Hall bar in different perpendicular external magnetic fields [14.144–146].

Figure 14.23a shows the experimental setup used to observe these edge channels on top of a Hall bar with a force microscope. The tip is positioned above the surface of a Hall bar under which the 2-DEG is buried. The direction of the magnetic field is oriented perpendicular to the 2-DEG. Note that although the 2-DEG is located several tens of nanometers below the surface, its influence on the electrostatic surface potential can be detected. In Fig. 14.23b, the results of scans perpendicular to the Hall bar are plotted against the magnitude of the external magnetic field. The value of the electrostatic potential is grey-coded in arbitrary units. In certain field ranges, the potential changes linearly across the Hall bar, while in other field ranges the potential drop is confined to the edges of the Hall bar. The predicted edge channels can explain this behavior. The periodicity of the phenomenon is related to the filling factor ν, i. e., the number of Landau levels that are filled with electrons (see also Sect. 14.3.4). Its value depends on $1/B$

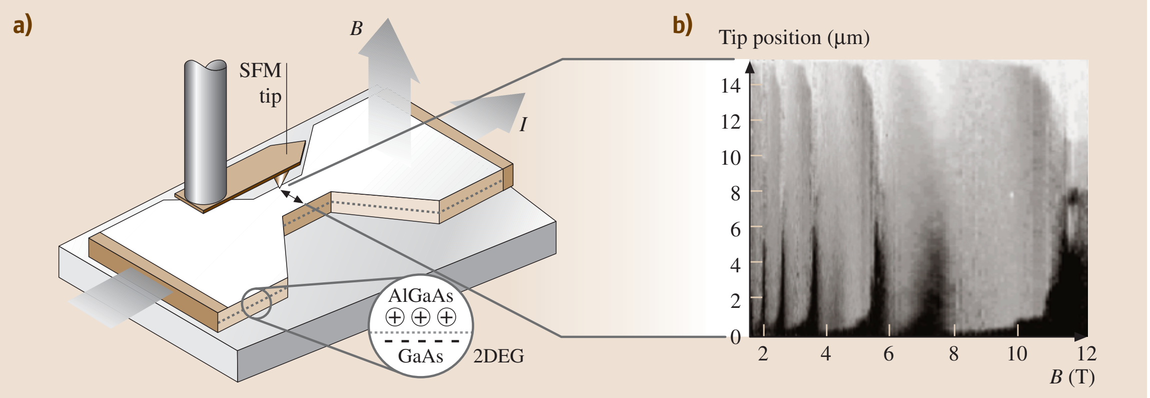

Fig. 14.23a,b Configuration of the Hall bar within a low temperature ($T < 1$ K) force microscope **(a)** and profiles (y-axis) at different magnetic field (x-axis) of the electrostatic potential across a 14-µm-wide Hall bar in the quantum Hall regime **(b)**. The external magnetic field is oriented perpendicular to the 2-DEG, which is buried below the surface. *Bright* and *dark regions* reflect the characteristic changes of the electrostatic potential across the Hall bar at different magnetic fields and can be explained by the existence of the theoretically predicted edge channels (courtesy of E. Ahlswede; cf. [14.146])

and is proportional to the electron concentration n_e in the 2-DEG ($\nu = n_e h/eB$, where h represents Planck's constant and e the electron charge).

14.4.4 Magnetic Force Microscopy

To detect magnetostatic tip-sample interactions with magnetic force microscopy (MFM), a ferromagnetic probe has to be used. Such probes are readily prepared by evaporating a thin magnetic layer, e.g., 10 nm iron, onto the tip. Due to the in-plane shape anisotropy of thin films, the magnetization of such tips lies predominantly along the tip axis, i. e., perpendicular to the surface. Since magnetostatic interactions are long-range, they can be separated from the topography by scanning in a certain constant height (typically around 20 nm) above the surface, where the z-component of the sample stray field is probed (see Fig. 14.24a). Therefore, MFM is always operated in noncontact. The signal from the cantilever is directly recorded while the z-feedback is switched off. MFM can be operated in the static mode or in the dynamic modes (AM-MFM at ambient pressures and FM-MFM in vacuum). A lateral resolution below 50 nm can be routinely obtained.

Observation of Domain Patterns

MFM is widely used to visualize domain patterns of ferromagnetic materials. At low temperatures, *Moloni* et al. [14.148] observed the domain structure of magnetite below its Verwey transition temperature ($T_V = 122$ K), but most of the work concentrated on thin films of $La_{1-x}Ca_xMnO_3$ [14.149–151]. Below T_V, the conductivity decreases by two orders of magnitude and a small structural distortion is observed. The domain structure of this mixed valence manganite is of great interest, because its resistivity strongly depends on the external magnetic field, i. e., it exhibits a large colossal magneto resistive effect. To investigate the field dependence of domain patterns in ambient conditions, electromagnets have to be used. They can cause severe thermal drift problems due to Joule-heating of the coils by large currents. Field on the order of 100 mT can be achieved. In contrast, much larger fields (more than 10 T) can be rather easily produced by implementing a superconducting magnet in low temperature setups. With such a design, *Liebmann* et al. [14.151] recorded the domain structure along the major hysteresis loop of $La_{0.7}Ca_{0.3}MnO_3$ epitaxially grown on $LaAlO_3$ (see Fig. 14.24b–f). The film geometry (thickness is 100 nm) favors an in-plane magnetization, but the lattice mismatch with the substrate induces an out-of-plane anisotropy. Thereby, an irregular pattern of strip domains appears in zero field. If the external magnetic field is increased, the domains with anti-parallel orientation shrink and finally disappear in saturation (see Fig. 14.24b,c). The residual contrast in saturation (d) reflects topographic features. If the field is decreased after saturation (see Fig. 14.24e,f), cylindrical domains first nucleate and then start to grow. At zero field, the maze-type domain pattern has been evolved again.

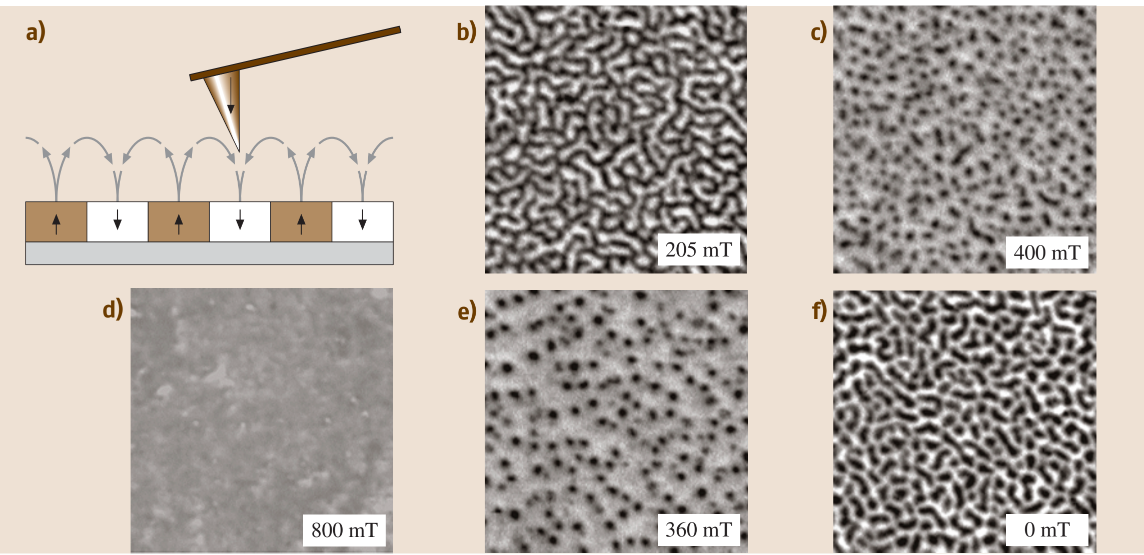

Fig. 14.24a–f Principle of MFM operation **(a)** and field-dependent domain structure of a ferromagnetic thin film **(b)–(f)** recorded at 5.2 K with FM-MFM. All images were recorded on the same 4 μm×4 μm large scan area. The $La_{0.7}Ca_{0.3}MnO_3/LaAlO_3$ system exhibits a substrate-induced out-of-plane anisotropy. *Bright* and *dark areas* are visible and correspond to attractive and repulsive magnetostatic interactions, respectively. The series shows how the domain pattern evolves along the major hysteresis loop from, i. e., zero field to saturation at 600 mT and back to zero field

Such data sets can be used to analyze domain nucleation and the domain growth mode. Moreover, due to the negligible drift, domain structure and surface morphology can be directly compared, because every MFM can be used as a regular topography-imaging force microscope.

Detection of Individual Vortices in Superconductors

Numerous low temperature MFM experiments have been performed on superconductors [14.152–159]. Some basic features of superconductors have been mentioned already in Sect. 14.3.5. The main difference of STM/STS compared to MFM is the high sensitivity to the electronic properties of the surface. Therefore, careful sample preparation is a prerequisite. This is not so important for MFM experiments, since the tip is scanned at a certain distance above the surface.

Superconductors can be divided into two classes with respect to their behavior in an external magnetic field. For type-I superconductors, any magnetic flux is entirely excluded below their critical temperature T_c (Meissner effect), while for type-II superconductors, cylindrical inclusions (*vortices*) of normal material exist in a superconducting matrix (*vortex* state). The radius of the vortex *core*, where the Cooper pair density decreases to zero, is on the order of the coherence length ξ. Since the superconducting gap vanishes in the core, they can be detected by STS (see Sect. 14.3.5). Additionally, each vortex contains one magnetic quantum flux $\Phi = h/2e$ (where h represents Planck's constant and e the electron charge). Circular supercurrents around the core screen the magnetic field associated with a vortex; their radius is given by the London penetration depth λ of the material. This magnetic field of the vortices can be detected by MFM. Investigations have been performed on the two most popular copper oxide high-T_c superconductors, $YBa_2Cu_3O_7$ [14.152, 153, 155] and $Bi_2Sr_2CaCu_2O_8$ [14.153, 159], on the only elemental conventional type-II superconductor Nb [14.156, 157], and on the layered compound crystal $NbSe_2$ [14.154, 156].

Most often, vortices have been generated by cooling the sample from the normal state to below T_c in an external magnetic field. After such a *field cooling* procedure, the most energetically favorable vortex arrangement is a regular triangular Abrikosov lattice. *Volodin* et al. [14.154] were able to observe such an Abrikosov lattice on $NbSe_2$. The intervortex distance d is related to the external field during B cool down

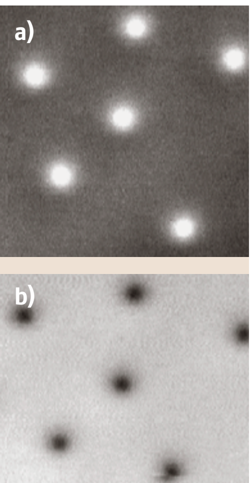

Fig. 14.25a,b Two $5\,\mu\text{m} \times 5\,\mu\text{m}$ FM-MFM images of vortices in a niobium thin film after field-cooling at 0.5 mT **(a)** and −0.5 mT **(b)**, respectively. Since the external magnetic field was parallel in **(a)** and antiparallel in **(b)** with respect to the tip magnetization, the vortices exhibit reversed contrast. Strong pinning dominates the position of the vortices, since they appear at identical locations in **(a)** and **(b)** and are not arranged in a regular Abrikosov lattice (courtesy of P. Grütter; cf. [14.157])

via $d = (4/3)^{1/4}(\Phi/B)^{1/2}$. Another way to introduce vortices into a type-II superconductor is vortex penetration from the edge by applying a magnetic field at temperatures below T_c. According to the Bean model, a vortex density gradient exists under such conditions within the superconducting material. *Pi* et al. [14.159] slowly increased the external magnetic field until the vortex front approaching from the edge reached the scanning area.

If the vortex configuration is dominated by the *pinning* of vortices at randomly distributed structural defects, no Abrikosov lattice emerges. The influence of pinning centers can be studied easily by MFM, because every MFM can be used to scan the topography in its AFM mode. This has been done for natural growth defects by *Moser* et al. [14.155] on $YBa_2Cu_3O_7$ and for $YBa_2Cu_3O_7$ and niobium thin films, respectively, by *Volodin* et al. [14.158]. *Roseman* et al. [14.160] investigated the formation of vortices in the presence of an artificial structure on niobium films, while *Pi* et al. [14.159] produced columnar defects by heavy ion bombardment in a $Bi_2Sr_2CaCu_2O_8$ single crystal to study the strong pinning at these defects.

Figure 14.25 demonstrates that MFM is sensitive to the polarity of vortices. In Fig. 14.25a, six vortices have been produced in a niobium film by field cooling in +0.5 mT. External magnetic field and tip magnetization are parallel, and, therefore, the tip-vortex interaction is attractive (bright contrast). To remove the vortices, the niobium was heated above T_c (≈ 9 K). Thereafter, vortices of opposite polarity were produced by field cooling in −0.5 mT, which appear dark in Fig. 14.25b. The vortices are probably bound to strong pinning sites, because the vortex positions are identical in both images of Fig. 14.25. By imaging the vortices at different scanning heights, *Roseman* et al. [14.157] tried to extract values for the London penetration depth from the scan height dependence of their profiles. While good qualitative agreement with theoretical predictions has been found, the absolute values do not agree with published literature values. The disagreement was attributed to the convolution between tip and vortex stray field. Better values might be obtained with calibrated tips.

Toward Single Spin Detection

So far, only collective magnetic phenomena like ferromagnetic domains have been observed via magnetostatic tip-sample interactions detected by MFM. However, magnetic ordering exists due to the exchange interaction between the electron spins of neighboring atoms in a solid. The most energetically favorable situation can be either ferromagnetic (parallel orientation) or anti-ferromagnetic (anti-parallel orientation) ordering. It has been predicted that the exchange force between an individual spin of a magnetically ordered sample and the spin of the foremost atom of a magnetic tip can be detected at sufficiently small tip-sample distances [14.161, 162].

The experimental realization, however, is very difficult, because the exchange force is about a factor of ten weaker and of even shorter range than the chemical interactions that are responsible for the atomic-scale contrast. FM-AFM experiments with a ferromagnetic tip have been performed on the anti-ferromagnetic NiO(001) surface at room temperature [14.163] and with a considerable better signal-to-noise ratio at low temperatures [14.122]. Although it was possible to achieve atomic resolution, a periodic contrast that could be attributed to the anti-ferromagnetically ordered spins of the nickel atoms could not be observed.

Even more ambitious is the proposed detection of individual nuclear spins by magnetic resonance force microscopy (MRFM) using a magnetic tip [14.164, 165]. The interest in this technique is driven by the possibility of reaching subsurface true 3-D imaging with atomic resolution and chemical specificity. The idea of MRFM is to combine aspects of force microscopy (atomic resolution capability) with nuclear magnetic resonance (3-D imaging and elemental selectivity). Low temperatures are required, because the forces are extremely small.

Up until now, no individual spins have been detected by MRFM. However, electron spin resonance [14.166, 167], nuclear magnetic resonance [14.168], and ferromagnetic resonance [14.169] experiments of spin ensembles have been performed with micrometer resolution. On the way toward single spin detection, the design of ultrasensitive cantilevers made considerable progress, and the detection of forces below 1×10^{-18} N has been achieved [14.120].

15. Dynamic Force Microscopy

This chapter presents an introduction to the concept of the dynamic operational mode of the atomic force microscope (dynamic AFM). While the static, or contact mode AFM is a widespread technique to obtain nanometer resolution images on a wide variety of surfaces, true atomic resolution imaging is routinely observed only in the dynamic mode. We will explain the jump-to-contact phenomenon encountered in static AFM and present the dynamic operational mode as a solution to overcome this effect. The dynamic force microscope is modeled as a harmonic oscillator to gain a basic understanding of the underlying physics in this mode.

Dynamic AFM comprises a whole family of operational modes. A systematic overview of the different modes typically encountered in force microscopy is presented, and special care is taken to explain the distinct features of each mode. Two modes of operation dominate the application of dynamic AFM. First, the amplitude modulation mode (also called tapping mode) is shown to exhibit an instability, which separates the purely attractive force interaction regime from the attractive–repulsive regime. Second, the self-excitation mode is derived and its experimental realization is outlined. While the first is primarily used for imaging in air and liquid, the second dominates imaging in UHV (ultrahigh vacuum) for atomic resolution imaging. In particular, we explain the influence of different forces on spectroscopy curves obtained in dynamic force microscopy. A quantitative link between the measurement values and the interaction forces is established.

Force microscopy in air suffers from small quality factors of the force sensor (i. e., the cantilever beam), which are shown to limit the achievable resolution. Also, the above mentioned instability in amplitude modulation mode often hinders imaging of soft and fragile samples. A combination of the amplitude modulation with the self-excitation mode is shown to increase the quality, or Q-factor, and extend the regime of stable operation, making the so-called Q-control module a valuable tool. Apart from the advantages of dynamic force microscopy as a nondestructive, high-resolution imaging method, it can also be used to obtain information about energy dissipation phenomena at the nanometer scale. This measurement channel can provide crucial information on electric and magnetic surface properties. Even atomic resolution imaging has been obtained in the dissipation mode. Therefore, in the last section, the quantitative relation between the experimental measurement values and the dissipated power is derived.

15.1 Motivation: Measurement of a Single Atomic Bond

The direct measurement of the force interaction between two distinct molecules has been the motivation for scientists for many years now. The fundamental forces responsible for the solid state of matter can be directly investigated, ultimately between defined single molecules. But it has not been until very recently that the chemical forces could be quantitatively measured for a single atomic bond [15.1]. How can we reliably measure forces that may be as small as one billionth of 1 N? How can we identify one single pair of atoms as the source of the force interaction?

The same mechanical principle that is used to measure the gravitational force exerted by your body weight (e.g., with the scale in your bathroom) can be employed to measure the forces between single atoms. A spring with a defined elasticity is compressed by an arbitrary force (e.g., your weight). The compression Δz of the spring (with spring constant k) is a direct measure of the force F exerted, which in the regime of elastic deformation obeys Hooke's law:

$$F = k\Delta z \,. \tag{15.1}$$

The only difference with regard to your bathroom scale is the sensitivity of the measurement. Typically springs with a stiffness of 0.1 N/m to 10 N/m are used, which will be deflected by 0.1 nm to 10 nm upon application of an interatomic force of some nN. Experimentally, a laser deflection technique is used to measure the movement of the spring. The spring is a bendable cantilever microfabricated from silicon wafers. If a sufficiently sharp tip, usually directly attached to the cantilever, is approached toward a surface within some nanometers, we can measure the interacting forces through changes in the deflected laser beam. This is a static measurement; hence it is called *static AFM*. Alternatively, the cantilever can be excited to vibrate at its resonant frequency. Under the influence of tip-sample forces the resonant frequency (and consequently also amplitude and phase) of the cantilever will change and serve as measurement parameters. This is called the *dynamic AFM*. Due to the multitude of possible operational modes, expressions like noncontact mode, intermittent-contact mode, tapping mode, FM-mode, AM-mode, self-excitation, constant-excitation, or constant-amplitude mode AFM are found in the literature, which will be systematically categorized in the following paragraphs.

In fact, the first AFMs were operated in the dynamic mode. In 1986, *Binnig*, *Quate* and *Gerber* presented the concept of the atomic force microscope [15.2]. The deflection of the cantilever with the tip was measured with sub-angstrom precision by an additional scanning tunneling microscope (STM). While the cantilever was externally oscillated close to its resonant frequency, the amplitude and phase of the oscillation were measured. If the tip is approached toward the surface, the oscillation parameters, amplitude and phase, are influenced by the tip-surface interaction, and can, therefore, be used as feedback channels. A certain set-point, for example, the amplitude, is given, and the feedback loop will adjust the tip-sample distance such that the amplitude remains constant. The controller parameter is recorded as a function of the lateral position of the tip with respect to the sample, and the scanned image essentially represents the surface topography.

What then is the difference between the static and the dynamic mode of operation for the AFM? The static deflection AFM directly gives the interaction force between tip and sample using (15.1). In the dynamic mode, we find that the resonant frequency, amplitude, and phase of the oscillation change as a consequence of the interaction forces (and also dissipative processes, as discussed in the last section).

In order to get a basic understanding of the underlying physics, it is instructive to consider a very simplified case. Assume that the vibration amplitude is small compared to the range of force interaction. Since van der Waals forces range over typical distances of 10 nm, the vibration amplitude should be less than 1 nm. Furthermore, we require that the force gradient $\partial F_{ts}/\partial z$ does not vary significantly over one oscillation cycle.

We can view the AFM setup as a coupling of two springs (see Fig. 15.1). Whereas the cantilever is represented by a spring with spring constant k, the force interaction between tip and surface can be modeled by

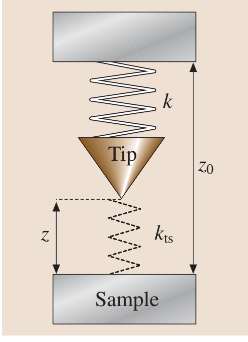

Fig. 15.1 Model of the AFM tip while experiencing tip-sample forces. The tip is attached to a cantilever with spring constant k, and the force interaction is modeled by a spring with a stiffness k_{ts} equal to the force gradient. Note that the force interaction spring is not constant, but depends on the tip-sample distance z

a second spring. The derivative of the force with respect to tip-sample distance is the force gradient and represents the spring constant k_{ts} of the interaction spring. This spring constant k_{ts} is constant only with respect to one oscillation cycle, but varies with the average tip-sample distance as the probe is approached to the sample. The two springs are coupled in series. Therefore, we can write for the total spring constant of the AFM system:

$$k_{total} = k + k_{ts} = k - \frac{\partial F_{ts}}{\partial z} \,. \tag{15.2}$$

From the simple harmonic oscillator (neglecting any damping effects) we find that the resonant frequency ω of the system is shifted by $\Delta\omega$ from the free resonant frequency ω_0 due to the force interaction:

$$\omega^2 = (\omega_0 + \Delta\omega)^2 = k_{total}/m^* = \left(k + \frac{\partial F_{ts}}{\partial z}\right)/m^* \,. \tag{15.3}$$

Here m^* represents the effective mass of the cantilever. A detailed analysis of how m^* is related to the geometry and total mass of the cantilever can be found in the literature [15.3]. In the approximation that $\Delta\omega$ is much smaller than ω_0, we can write:

$$\frac{\Delta\omega}{\omega_0} \cong -\frac{1}{2k}\frac{\partial F_{ts}}{\partial z} \,. \tag{15.4}$$

Therefore, we find that the frequency shift of the cantilever resonance is proportional to the force gradient of the tip-sample interaction.

Although the above consideration is based on a very simplified model, it shows qualitatively that in dynamic force microscopy we will find that the oscillation frequency depends on the force gradient, while static force microscopy measures the force itself. In principle, we can calculate the force curve from the force gradient and vice versa (neglecting a constant offset). It seems, therefore, that the two methods are equivalent, and our choice will depend on whether we can measure the beam deflection or the frequency shift with better precision at the cost of technical effort.

However, we have neglected one important issue for the operation of the AFM thus far: the mechanical stability of the measurement. In static AFM, the tip is slowly approached toward the surface. The force between the tip and the surface will always be counteracted by the restoring force of the cantilever. In Fig. 15.2, you can see a typical force-distance curve. Upon approach of the tip toward the sample, the negative attractive forces, representing, e.g., van der Waals or chemical interaction forces, increase until a maximum is reached. This turnaround point is due to the onset of repulsive forces caused by coulomb repulsion, which will start to dominate upon further approach. The spring constant of the cantilever is represented by the slope of the straight line. The position of the z-transducer (typically a piezo element), which moves the probe, is at the intersection of the line with the horizontal axis. The position of the tip, shifted from the probe's base due to the lever bending, can be found at the intersection of the cantilever line with the force curve. Hence, the total force is zero, i. e., the cantilever is in its equilibrium position (note that the spring constant line here shows attractive forces, although in reality the forces are repulsive, i. e., pulling back the tip from the surface). As soon as the position A in Fig. 15.2 is reached, we find two possible intersection points, and upon further approach there are even three force equilibrium points. However, between point A to B the tip is at a local energy minimum and, therefore, will still follow the force curve. But at

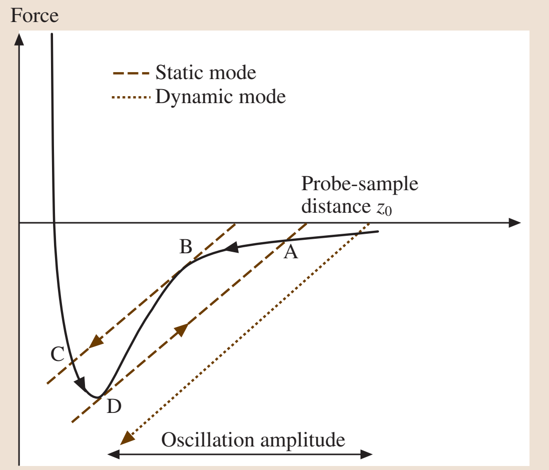

Fig. 15.2 Force-distance curve of a typical tip-sample interaction. In static mode AFM, the tip would follow the force curve until point B is reached. If the slope of the force curve becomes larger than the spring constant of the cantilever (*dashed line*), the tip will suddenly jump to position C. Upon retraction, a different path will be followed along D and A again. In dynamic AFM, the cantilever oscillates with amplitude A. Although the equilibrium position of the oscillation is far from the surface, the tip will experience the maximum attractive force at point D during some parts of the oscillation cycle. However, the total force is always pointing away from the surface, therefore, avoiding an instability

point B, when the adhesion force upon further approach would become larger than the spring restoring force, the tip will suddenly jump to point C. We can then probe the predominantly repulsive force interaction by further reducing the tip-sample distance. Then, while retracting the tip, we will pass point C, because the tip is still in a local energy minimum. At position D the tip will jump suddenly to point A again, since the restoring force now exceeds the adhesion. From Fig. 15.2 we can see that the sudden instability will happen at exactly the point where the slope of the adhesion force exceeds the slope of the spring constant. Therefore, if the negative force gradient of the tip-sample interaction will at any point exceed the spring constant, a mechanical instability occurs. Mathematically speaking, we demand that for a stable measurement:

$$\left.\frac{\partial F_{\text{ts}}}{\partial z}\right|_z > k \quad \text{for all points } z\,. \tag{15.5}$$

The phenomenon of mechanical instability is often referred to as the "jump-to-contact".

Looking at Fig. 15.2, we realize that large parts of the force curve cannot be measured if the jump-to-contact phenomenon occurs. We will not be able to measure the point at which the attractive forces reach their maximum, representing the temporary chemical bonding of the tip and the surface atoms. Secondly, the sudden instability, the jump-to-contact, will often cause the tip to change the very last tip or surface atoms. A smooth, careful approach needed to measure the full force curve does not seem feasible. Our goal of measuring the chemical interaction forces of two single molecules may become impossible.

There are several solutions to the jump-to-contact problem: On the one hand, we can simply choose a sufficiently stiff spring, so that (15.5) is fulfilled at all points of the force curve. On the other hand, we can resort to a trick to enhance the counteracting force of the cantilever: We can oscillate the cantilever with large amplitude, thereby making it virtually stiffer at the point of strong force interaction.

Consider the first solution, which seems simpler at first glance. Chemical bonding forces extend over a distance range of about 0.1 nm. Typical binding energies of a couple of eV will lead to adhesion forces on the order of some nN. Force gradients will, therefore, reach values of some 10 N/m. A spring for stable force measurements will have to be as stiff as 100 N/m to ensure that no instability occurs (a safety factor of ten seems to be a minimum requirement, since usually one cannot be sure a priori that only one atom will dominate the interaction). In order to measure the nN interaction force, a static cantilever deflection of 0.01 nm has to be detected. With standard beam deflection AFM setups this becomes a challenging task.

This problem was solved [15.4, 5] using an in situ optical interferometer measuring the beam deflection at liquid nitrogen temperature in a UHV environment. In order to ensure that the force gradients are smaller than the lever spring constant (50 N/m), the tips were fabricated to terminate in only three atoms, therefore, minimizing the total force interaction. The only tool known to be able to engineer SPM tips down to atomic dimensions is the field ion microscope (FIM). This technique not only allows imaging of the tip apex with atomic precision, but also can be used to manipulate the tip atoms by field evaporation [15.6], as shown in Fig. 15.3. Atomic interaction forces were measured with sub-nanonewton precision, revealing force curves of only a few atoms interacting without mechanical hysteresis. However, the technical effort to achieve this type of measurement is considerable, and most researchers today have resorted to the second solution.

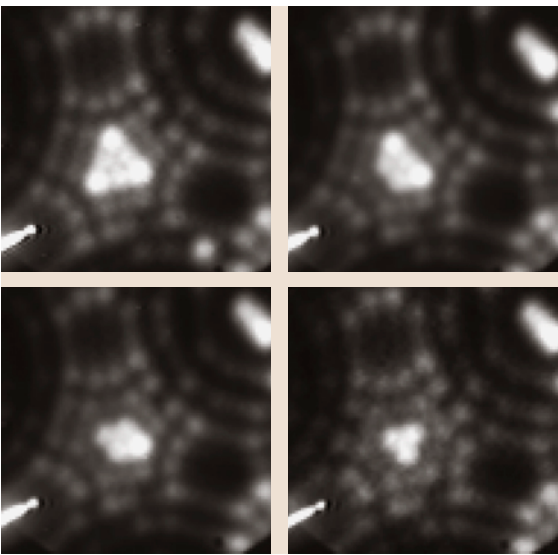

Fig. 15.3 Manipulation of the apex atoms of an AFM tip using field ion microscopy (FIM). Images are obtained at a tip bias of 4.5 kV. The last six atoms of the tip can be inspected in this example. Field evaporation to remove single atoms is performed by increasing the bias voltage for a short time to 5.2 kV. Each of the outer three atoms can be consecutively removed, eventually leaving a trimer tip apex

The alternative solution can be visualized in Fig. 15.2. The straight, dashed line now represents the force values of the oscillating cantilever, with amplitude A assuming Hooke's law is valid. This is the tensile force of the cantilever spring pulling the tip away from the sample. The restoring force of the cantilever is at all points stronger than the adhesion force. For example, the total force at point D is still pointing away from the sample, although the spring has the same stiffness as before. Mathematically speaking, the measurement is stable as long as the cantilever spring force $F_{cb} = kA$ is larger than the attractive tip-sample force F_{ts} [15.7]. In the static mode we would already experience an instability at that point. However, in the dynamic mode, the spring is pre-loaded with a force stronger than the attractive tip-sample force. The equilibrium point of the oscillation is still far away from the point of closest contact of the tip and surface atoms. The total force curve can be probed by varying the equilibrium point of the oscillation, i. e., by adjusting the z-piezo.

The diagram also shows that the oscillation amplitude has to be quite large if fairly soft cantilevers are to be used. With lever spring constants of 10 N/m, the amplitude must be at least 1 nm to ensure forces of 1 nN can be reliably measured. In practical applications, amplitudes of 10–100 nm are used to stay on the safe side. This means that the oscillation amplitude is much larger than the force interaction range. The above simplification, that the force gradient remains constant within one oscillation cycle, does not hold anymore. Measurement stability is gained at the cost of a simple quantitative analysis of the experiments. In fact, dynamic AFM was first used to obtain atomic resolution images of clean surfaces [15.8], and it took another six years [15.1] before quantitative measurements of single bond forces were obtained.

The technical realization of dynamic mode AFMs is based on the same key components as a DC-AFM setup. The most common principle is the method of laser deflection sensing (see, e.g., Fig. 15.4). A laser beam is focused on the back side of a microfabricated cantilever. The reflected laser spot is detected with a positional sensitive diode (PSD). This photodiode is sectioned into two parts that are read-out separately (usually even a four-quadrant diode is used to detect torsional movements of the cantilever for lateral

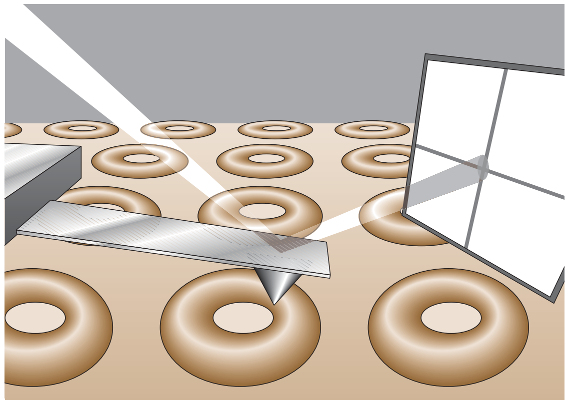

Fig. 15.4 Representation of an AFM setup with the laser beam deflection method. Cantilever and tip are microfabricated from silicon wafers. A laser beam is deflected from the back side of the cantilever and again focused on a photosensitive diode. The diode is segmented into four quadrants, which allows the measurement of vertical and torsional bending of the cantilever (artwork from *Jörg Heimel* rendered with POV-Ray 3.0)

friction measurements). With the cantilever at equilibrium, the spot is adjusted such that the two sections show the same intensity. If the cantilever bends up or down, the spot moves, and the difference signal between the upper and lower sections is a measure of the bending.

In order to enhance sensitivity, several groups have adopted an interferometer system to measure the cantilever deflection. A thorough comparison of different measurement methods with analysis of sensitivity and noise level is given by [15.3].

The cantilever is mounted on a device that allows oscillation of the beam. Often a piezo-element serves this purpose. The reflected laser beam is analyzed for oscillation amplitude, frequency, and phase difference between excitation and vibration. Depending on the mode of operation, a feedback mechanism will adjust oscillation parameters and/or tip-sample distance during the scanning. The setup can be operated in air, UHV, and even in fluids. This allows measurement of a wide range of surface properties from atomic resolution imaging [15.8] up to studying biological processes in liquid [15.9, 10].

15.2 Harmonic Oscillator: A Model System for Dynamic AFM

The oscillating cantilever has three degrees of freedom: the amplitude, the frequency, and the phase difference between excitation and oscillation. Let us consider the damped driven harmonic oscillator. The cantilever is mounted on a piezoelectric element that is oscillating with amplitude A_d at frequency ω:

$$z_d(t) = A_d \cos(\omega t) . \quad (15.6)$$

We assume that the cantilever spring obeys Hooke's law. Secondly, we introduce a friction force that is proportional to the speed of the cantilever motion, whereas α denotes the damping coefficient (Amontons's law). With Newton's first law we find for the oscillating system the following equation of motion for the position $z(t)$ of the cantilever tip (see also Fig. 15.1):

$$m\ddot{z}(t) = -\alpha\dot{z}(t) - kz(t) - kz_d(t) . \quad (15.7)$$

We define $\omega_0^2 = k/m^*$, which turns out to be the resonant frequency of the free (undamped, i.e., $\alpha = 0$) oscillating beam. We further define the dimensionless quality factor $Q = m^*\omega_0/\alpha$, antiproportional to the damping coefficient. The quality factor describes the number of oscillation cycles, after which the damped oscillation amplitude decays to 1/e of the initial amplitude with no external excitation ($A_d = 0$). After some basic math, this results in the following differential equation:

$$\ddot{z}(t) + \frac{\omega_0}{Q}\dot{z}(t) + \omega_0^2 z(t) = A_d\omega_0^2 \cos(\omega t) . \quad (15.8)$$

The solution is a linear combination of two regimes [15.11]. Starting from rest and switching on the piezo-excitation at $t = 0$, the amplitude will increase from zero to the final magnitude and reach a steady state, where amplitude, phase, and frequency of the oscillation stay constant over time. The steady-state solution $z_1(t)$ is reached after $2Q$ oscillation cycles and follows the external excitation with amplitude A_0 and phase difference φ:

$$z_1(t) = A_0 \cos(\omega t + \varphi) . \quad (15.9)$$

The oscillation amplitude in the transient regime during the first $2Q$ cycles follows:

$$z_2(t) = A_t \mathrm{e}^{-\omega_0 t/2Q} \sin(\omega_0 t + \varphi_t) . \quad (15.10)$$

We emphasize the important fact that the exponential term causes $z_2(t)$ to diminish exponentially with time constant τ:

$$\tau = 2Q/\omega_0 . \quad (15.11)$$

In vacuum conditions, only the internal dissipation due to bending of the cantilever is present, and Q reaches values of 10,000 at typical resonant frequencies of 100,000 Hz. This results in a relatively long transient regime of $\tau \cong 30$ ms, which limits the possible operational modes for dynamic AFM (detailed analysis by [15.11]). Changes in the measured amplitude, which reflect a change of atomic forces, will have a time lag of 30 ms, which is very slow considering one wants to scan a 200×200 point image within a few minutes. In air, however, viscous damping due to air friction dominates and Q goes down to less than 1,000, resulting in a time constant below the millisecond level. This response time is fast enough to use the amplitude as a measurement parameter.

If we evaluate the steady state solution $z_1(t)$ in the differential equation, we find the following well-known

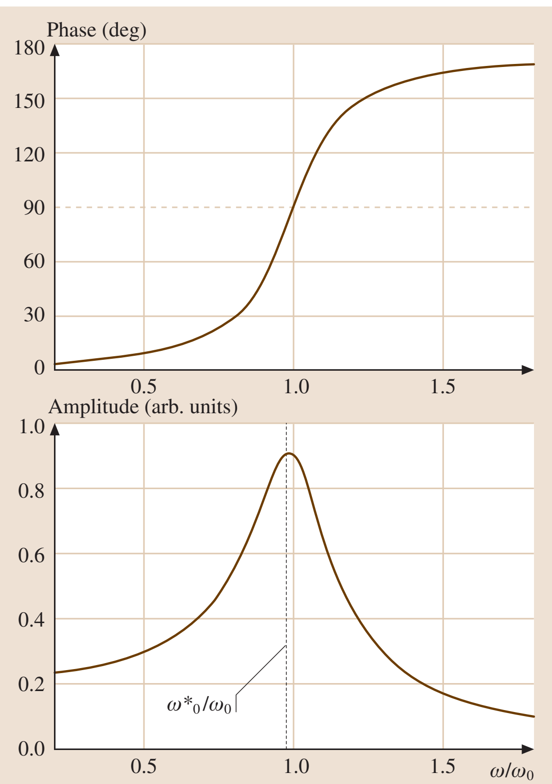

Fig. 15.5 Amplitude and phase versus excitation frequency curves for the damped harmonic oscillator with a quality factor of $Q = 4$

Springer Handbook *of* Nanotechnology
B. Bhushan • © Springer 2004

solution for amplitude and phase of the oscillation as a function of the excitation frequency ω:

$$A_0 = \frac{A_d Q \omega_0^2}{\sqrt{\omega^2\omega_0^2 + Q^2\left(\omega_0^2 - \omega^2\right)^2}} \quad (15.12)$$

$$\varphi = \arctan\left(\frac{\omega\omega_0}{Q\left(\omega_0^2 - \omega^2\right)}\right) . \quad (15.13)$$

Amplitude and phase diagrams are depicted in Fig. 15.5. As can be seen from (15.12), the amplitude will reach its maximum at a frequency different from ω_0, if Q has a finite value. The damping term of the harmonic oscillator causes the resonant frequency to shift from ω_0 to ω_0^*:

$$\omega_0^* = \omega_0\sqrt{1 - \frac{1}{2Q^2}} . \quad (15.14)$$

The shift is negligible for Q-factors of 100 and above, which is the case for most applications in vacuum or air. However, for measurements in liquids, Q can be smaller than 10 and ω_0 differs significantly from ω_0^*. As we will discuss later, it is also possible to enhance Q by using a special excitation method.

In the case that the excitation frequency is equal to the resonant frequency of the undamped cantilever, $\omega = \omega_0$, we find the useful relation:

$$A_0 = QA_d \quad \text{for } \omega = \omega_0 . \quad (15.15)$$

Since $\omega_0^* \approx \omega_0$ for most cases, we find that (15.15) holds true for exciting the cantilever at its resonance. From a similar argument, the phase becomes approximately 90 deg for the resonance case. We also see that in order to reach vibration amplitudes of some 10 nm, the excitation only has to be as small as 1 pm for typical cantilevers operated in vacuum.

So far, we have not considered an additional force term, describing the interaction between the probing tip and the sample. For typical, large vibration amplitudes of 10–100 nm no general solution for this analytical problem has been found yet. The cantilever tip will experience a whole range of force interactions during one single oscillation cycle, rather than one defined tip-sample force. Only in the special case of a self-excited cantilever oscillation has the problem been solved semi-analytically, as we will see later.

15.3 Dynamic AFM Operational Modes

While the quantitative interpretation of force curves in contact AFM is straightforward using (15.1), we explained in the previous paragraphs that its application to assess short-range attractive interatomic forces is rather limited. The dynamic mode of operation seems to open a viable direction toward achieving this task. However interpretation of the measurements generally appears to be more difficult. Different operational modes are employed in dynamic AFM, and the following paragraphs are intended to distinguish these modes and categorize them in a systematic way.

The oscillation trajectory of a dynamically driven cantilever is determined by three parameters: the amplitude, the phase, and the frequency. Tip-sample interactions can influence all three parameters, in the following, termed the internal parameters. The oscillation is driven externally, with excitation amplitude A_d and excitation frequency ω. These variables will be referred to as the external parameters. The external parameters are set by the experimentalist, whereas the internal parameters are measured and contain the crucial information about the force interaction. In scanning probe applications, it is common to control the probe-surface distance z_0 in order to keep an internal parameter constant (i. e., the tunneling current in STM or the beam deflection in contact AFM), which represents a certain tip-sample interaction. In z-spectroscopy mode, the distance is varied in a certain range, and the change of the internal parameters are measured as a fingerprint of the tip-sample interactions.

In dynamic AFM the situation is rather complex. Any of the internal parameters can be used for feedback of the tip-sample distance z_0. However, we already realized that, in general, the tip-sample forces could only be fully assessed by measuring all three parameters. This makes it difficult to obtain images where the distance z_0 is representative of the surface at one force set-point. A solution to this problem is to establish additional feedback loops, which keep the internal parameters constant by adjusting the external variables.

In the simplest setup, the excitation frequency is set to a predefined value, and the excitation amplitude remains constant by a feedback loop. This is called the AM mode (amplitude modulation), or tap-

ping mode (TM). As stated before, in principle, any of the internal parameters can be used for feedback to the tip-sample distance – in AM mode the amplitude signal is used. A certain amplitude (smaller than the free oscillation amplitude) at a frequency close to the resonance of the cantilever is chosen, the tip is approached toward the surface under investigation, and the approach is stopped as soon as the set-point amplitude is reached. The oscillation-phase is usually recorded during the scan, however, the shift of the resonant frequency of the cantilever cannot be directly accessed, since this degree of freedom is blocked by the external excitation at a fixed frequency. It turns out that this mode is simple to operate from a technical perspective, but quantitative information about the tip-sample interaction forces has so far not been reliably extracted from AM-mode AFM. Still, it is one of the most commonly used modes in dynamic AFM operated in air, and even in liquid. The strength of this mode is the qualitative imaging of a large variety of surfaces.

It is interesting to discuss the AM mode in the extreme situation that the external excitation frequency is much lower than the resonant frequency [15.12,13]. This results in a quasi-static measurement, although a dynamic oscillation force is applied, and, therefore, this mode can be viewed as a hybrid between static and dynamic AFM. Unfortunately, it has the drawbacks of the static mode, namely, that stiff spring constants must be used and, therefore, the sensitivity of the deflection measurement must be very good, typically employing a high resolution interferometer. Still, it has the advantage of the static measurement in quantitative interpretation, since in the regime of small amplitudes (< 0.1 nm) a direct interpretation of the experiments is possible. In particular, the force gradient at tip-sample distance z_0 is given by the change of the amplitude A and the phase angle φ:

$$\left.\frac{\partial F_{\mathrm{ts}}}{\partial z}\right|_{z_0} = k\left(1 - \frac{A_0}{A}\cos\varphi\right) . \tag{15.16}$$

In effect, the modulated AFM, in contrast to the purely static AFM, can enhance sensitivity due to the use of lock-in techniques, which allows the measurement of the amplitude and phase of the oscillation signal with high precision.

As stated before, the internal parameters can be fed back to the external excitation variables. One of the most useful applications in this direction is the self-excitation system. Here the resonant frequency of the cantilever is detected and selected again as the excitation frequency. In a typical setup, this is done with a phase shift of 90 deg by feeding back the detector signal to the excitation piezo, i. e., the cantilever is always excited in resonance. Influences of the tip-sample interaction forces on the resonant frequency do not change the two other parameters of the oscillation, i. e., amplitude and phase; only the oscillation frequency is shifted. Therefore, it is sufficient to measure the frequency shift between the free oscillation and the oscillation with tip-sample interaction. Since the phase remains at a fixed value, the oscillating system is much better defined than before, and the degrees of freedom for the oscillation are reduced. To even reduce the last degree of freedom, the oscillation amplitude, another feedback loop can be established to keep the oscillation amplitude A constant by varying the excitation amplitude A_{d}. Now, all internal parameters have a fixed relation to the external excitation variables, the system is well-defined, and all parameters can be assessed during the measurement. As it turns out, this mode is the only dynamic mode in which a quantitative relation between tip-sample forces and the change of the resonant frequency can be established.

In the following section we want to discuss the two most popular operational modes, tapping mode and self-excitation mode, in more detail.

15.3.1 Amplitude-Modulation/ Tapping-Mode AFMs

In tapping mode, or AM-AFM, the cantilever is excited externally at a constant frequency close to its resonance. Oscillation amplitude and phase during approach of tip and sample serve as the experimental observation channels. Figure 15.6 shows a diagram of a typical tapping-mode AFM setup. The oscillation amplitude and the phase (not shown in diagram) detected with the photodiode are analyzed with a lock-in amplifier. The amplitude is compared to the set-point, and the difference or error signal is used to adjust the z-piezo, i. e., the probe-sample distance. The external modulation unit supplies the signal for the excitation piezo, and, at the same time, the oscillation signal serves as the reference for the lock-in amplifier.

During one oscillation cycle with amplitudes of 10–100 nm, the tip-sample interaction will range over a wide distribution of forces, including attractive, as well as repulsive forces. We will, therefore, measure a convolution of the force-distance curve with the oscillation trajectory. This complicates the interpretation of AM-AFM measurements appreciably.

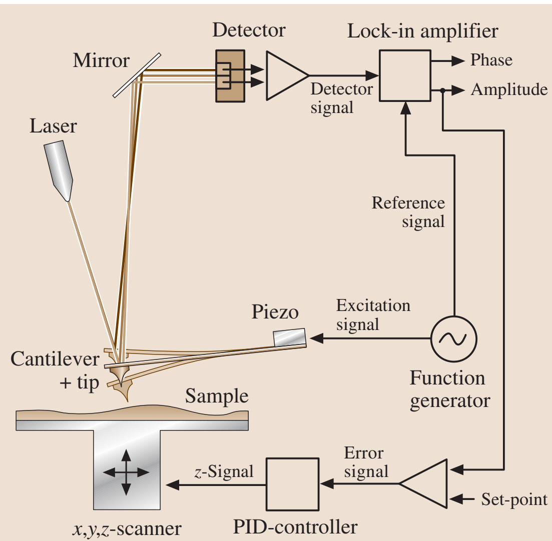

Fig. 15.6 Setup of a dynamic force microscope operated in the AM or tapping mode. A laser beam is deflected by the back side of the cantilever, and the deflection is detected by a split photodiode. The excitation frequency is chosen externally with a modulation unit, which drives the excitation piezo. A lock-in amplifier analyzes phase and amplitude of the cantilever oscillation. The amplitude is used as the feedback signal for the probe-sample distance control

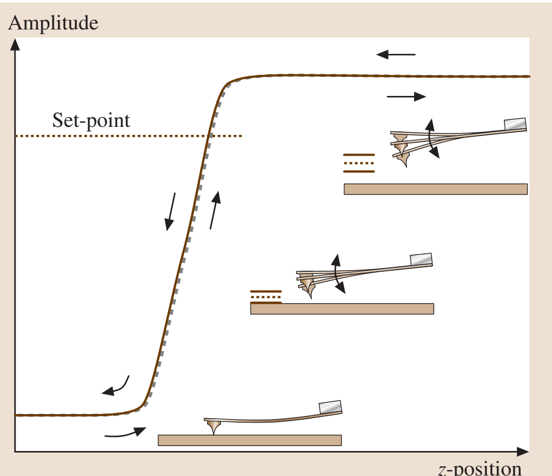

Fig. 15.7 Simplified model showing the oscillation amplitude in tapping-mode AFM for various probe-sample distances

At the same time, the resonant frequency of the cantilever will change due to the appearing force gradients, as could already be seen in the simplified model from (15.4). If the cantilever is excited exactly at its resonant frequency before, it will be excited off-resonance after interaction forces are encountered. This, in turn, changes amplitude and phase (15.12, 15.13), which serve as the measurement signals. Consequently, a different amplitude will cause a change in the encountered effective force. We can see already from this simple *gedanken*-experiment that the interpretation of force curves will be highly complicated. In fact, there is no quantitative theory for AM-AFM available, which allows the experimentalist to unambiguously convert the experimental data to a force-distance relationship.

The qualitative behavior for amplitude versus z_0-position curves is depicted in Fig. 15.7. At large distances, where the forces between tip and sample are negligible, the cantilever oscillates with its free oscillation amplitude. Upon approach of the probe toward the surface the interaction forces cause the amplitude to change, resulting typically in an amplitude getting smaller with continuously decreased tip-sample distance. This is expected, since the force-distance curve will eventually reach the repulsive part and the tip is hindered from indenting further into the sample, resulting in smaller oscillation amplitudes.

However, in order to gain some qualitative insight into the complex relationship between forces and oscillation parameters, we resort to numerical simulations. *Anczykowski* et al. [15.14, 15] have calculated the oscillation trajectory of the cantilever under the influence of a given force model. Van der Waals interactions were considered the only effective, attractive forces, and the total interaction resembled a Lennard-Jones-type potential. Mechanical relaxations of the tip and sample surface were treated in the limits of continuum theory with the numerical MYD/BHW [15.16, 17] approach, which allows the simulations to be compared to corresponding experiments. Figure 15.8 shows the force-distance curves for different tip radii underlying the dynamic AFM simulations.

The cantilever trajectory was analyzed by solving the differential equation (15.7) extended by the force-distance relations from Fig. 15.8 using the numerical Verlet algorithm [15.18, 19]. The results of the simulation for the amplitude and phase of the tip oscillation as a function of z-position of the probe are presented in Fig. 15.9. One has to keep in mind that the z-position

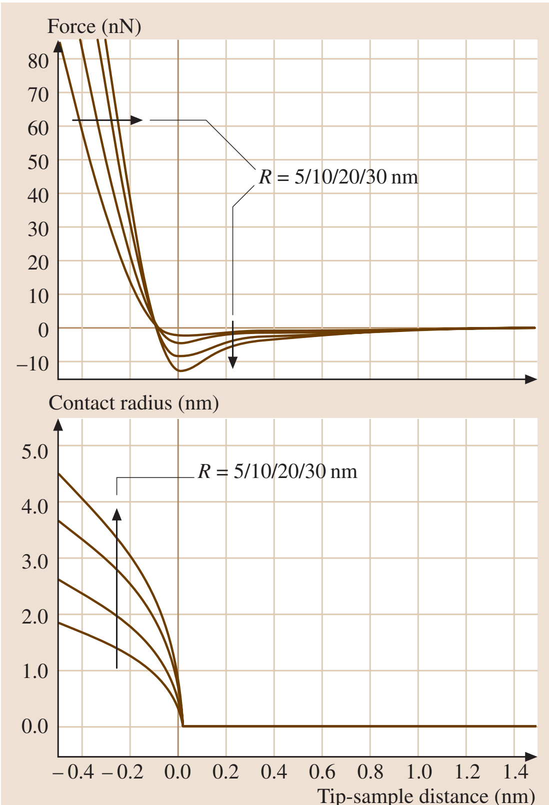

Fig. 15.8 Force curves and corresponding contact radius calculated with the MYD/BHW-model as a function of tip radius for a Si–Si contact. These force curves are used for the tapping-mode AFM simulations

of the probe is not equivalent to the real tip-sample distance at equilibrium position, since the cantilever might bend statically due to the interaction forces. The behavior of the cantilever can be subdivided into three different regimes. We distinguish the cases in which the beam is oscillated below its resonant frequency ω_0, exactly at ω_0, and above ω_0. In the following, we will refer to ω_0 as the resonant frequency, although the correct resonant frequency is ω_0^* if taking into account the finite Q-value.

Clearly, Fig. 15.9 exhibits more features than were anticipated from the initial, simple arguments. Amplitude and phase seem to change rather abruptly at certain points when the z_0-position is decreased. Besides, the amplitude or phase-distance curves don't resemble the force-distance curves from Fig. 15.8 in a simple, direct manner. Additionally, we find a hysteresis between approach and retraction.

As an example, let us start by discussing the discontinuous features in the AFM spectroscopy curves of the first case, where the excitation frequency is smaller than ω_0. Consider the oscillation amplitude as a function of excitation frequency in Fig. 15.5 in conjunction with a typical force curve, as depicted in Fig. 15.8. Upon approach of probe and sample, attractive forces will lower the effective resonant frequency of the oscillator. Therefore, the excitation frequency will now be closer to the resonant frequency, causing the vibration amplitude to increase. This, in turn, reduces the tip-sample distance, which again gives rise to a stronger attractive force. The system becomes unstable until the point $z_0 = d_{app}$ is reached, where repulsive forces stop the self-enhancing instability. This can be clearly observed in Fig. 15.9. Large parts of the force-distance curve cannot be measured due to this instability.

In the second case, where the excitation equals the free resonant frequency, only a small discontinuity is observed upon reduction of the z-position. Here, a shift of the resonant frequency toward smaller values, induced by the attractive force interaction, will reduce the oscillation amplitude. The distance between tip and sample is, therefore, reduced as well, and the self-amplifying effect with the sudden instability does not occur as long as repulsive forces are not encountered. However, at closer tip-sample distances, repulsive forces will cause the resonant frequency to shift again toward higher values, increasing the amplitude with decreasing tip-sample distance. Therefore, a self-enhancing instability will also occur in this case, but at the crossover from purely attractive forces to the regime where repulsive forces occur. Correspondingly, a small kink in the amplitude curve can be observed in Fig. 15.9. An even clearer indication of this effect is manifested by the sudden change in the phase signal at d_{app}.

In the last case, with $\omega > \omega_0$, the effect of amplitude reduction due to the resonant frequency shift is even larger. Again, we find no instability in the amplitude signal during approach in the attractive force regime. However, as soon as the repulsive force regime is reached, the instability occurs due to the induced positive frequency shift. Consequently, a large jump in the phase curve from values smaller than 90 deg to values larger than 90 deg is observed. The small change in the amplitude curve is not resolved in the simulated curves in Fig. 15.9, however, it can be clearly seen in the experimental curves in Fig. 15.10.

Figure 15.10 depicts the corresponding experimental amplitude and phase curves. The measurements were performed in air with a Si cantilever approaching

Additionally, the bottom diagrams show the interaction forces at the point of closest tip–sample distance, i. e., the lower turnaround point of the oscillation

a Si wafer, with a cantilever resonant frequency of 299.95 kHz. Qualitatively, all prominent features of the simulated curves can also be found in the experimental data sets. Hence, the above model seems to capture the important factors necessary for an appropriate description of the experimental situation.

But what is the reason for this unexpected behavior? We have to turn to the numerical simulations again, where we have access to all physical parameters, in order to understand the underlying processes. The lower part of Fig. 15.9 also shows the interaction force between the tip and the sample at the point of closest approach, i. e., the sample-sided turnaround point of the oscillation. We see that exactly at the points of the discontinuities the total interaction force changes from the net-attractive regime to the attractive-repulsive regime, also termed the intermittent contact regime. The term net-attractive is used to emphasize that the total force is attractive, despite the fact that some minor contributions might still originate from repulsive forces. As soon as a minimum distance is reached, the tip also starts to experience repulsive forces, which completely changes the oscillation behavior. In other words, the dynamic system switches between two oscillatory states.

Directly related to this fact is the second phenomenon: the hysteresis effect. We find separate curves for the approach of the probe toward the surface and the retraction. This seems to be somewhat counterintuitive, since the tip is constantly approaching and retracting from the surface, and the average values of amplitude and phase should be independent of the direction of the average tip-sample distance movement. A hysteresis between approach and retraction within one oscillation due to dissipative processes should directly influence amplitude and phase. However, no dissipation models were included in the simulation. In this case, the hysteresis in Fig. 15.9 is due to the fact that the oscillation jumps into different modes, the system exhibits bistability. This effect is often observed

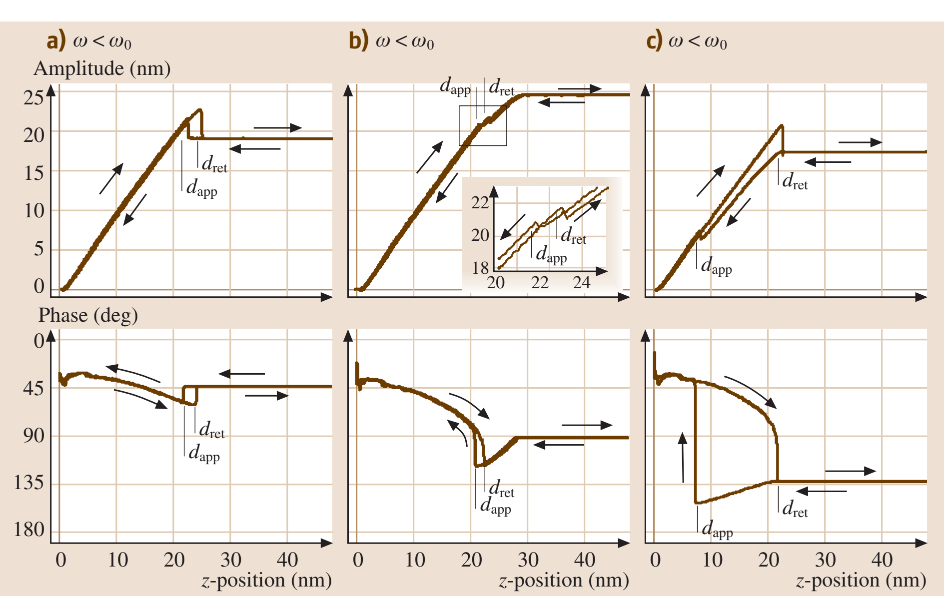

Fig. 15.10a–c Amplitude and phase diagrams with excitation frequency **(a)** below, **(b)** exactly at, and **(c)** above the resonant frequency for tapping-mode AFM from experiments with a Si cantilever on a Si wafer in air

in oscillators under the influence of nonlinear forces [15.20].

For the interpretation of these effects it is helpful to look at Fig. 15.11, which shows the behavior of the simulated tip vibration and force during one oscillation cycle over time. The data is recorded at the same z-position at a point where hysteresis is observed, while a) was taken during the approach and b) during the retraction. Excitation is in resonance, representing case 2, where the amplitude shows a small hysteresis. Also note that the amplitude is almost exactly the same in a) and b). We see that the oscillation at the same z-position exhibits two different modes: While in a) the experienced force is net-attractive, in b) the tip is exposed to attractive and repulsive interactions. Experimental and simulated data show that the change between the net-attractive and intermittent contact mode takes place at different z-positions (d_{app} and d_{ret}) for approach and retraction. Between d_{app} and d_{ret} the system is in a bistable mode. Depending on the history of the measurement, e.g., whether the position d_{app} during the approach (or d_{ret} during retraction) has been reached, the system flips to the other oscillation mode. While the amplitude might not be influenced strongly (case 2), the phase is a clear indicator of the mode switch. On the other hand, if point d_{app} is never reached during the approach, the system will stay in the net-attractive regime and no hysteresis is observed, i. e., the system remains stable.

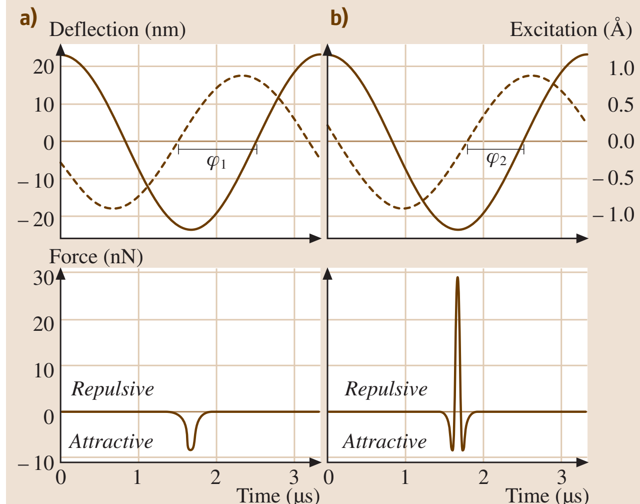

Fig. 15.11a,b Simulation of the tapping-mode cantilever oscillation in the **(a)** net-attractive and **(b)** the intermittent contact regime. The *dashed line* represents the excitation amplitude and the *solid line* is the oscillation amplitude

In conclusion, we find that although a qualitative interpretation of the interaction forces is possible, the AM- nor tapping-mode AFM is not suitable to gain direct quantitative knowledge of tip-sample force interactions. However, it is a very useful tool for imaging nanometer-sized structures in a wide variety of setups, in air or even

in liquid. We find that two distinct modes exist for the externally excited oscillation – the net-attractive and the intermittent contact mode – which describe what kind of forces the tip-sample interaction is governed by. The phase can be used as an indicator of which mode the system is running in.

In particular, it can be easily seen that if the free resonant frequency of the cantilever is higher than the excitation frequency, the system cannot stay in the net-attractive regime due to a self-enhancing instability. Since in many applications involving soft and delicate biological samples strong repulsive forces should be avoided, the tapping-mode AFM should be operated at frequencies equal to or above the free resonant frequency [15.21]. Even then, statistical changes of tip-sample forces during the scan might induce a sudden jump into the intermittent contact mode, and the previously explained hysteresis will tend to keep the system in this mode. It is, therefore, of high importance to tune the oscillation parameters in such a way that the AFM stays in the net-attractive regime [15.22]. A concept that achieves this task is the Q-control system, which will be discussed in some detail in the forthcoming paragraphs.

A last word concerning the overlap of simulation and experimental data: While the qualitative agreement down to the detailed shape of hysteresis and instabilities is rather striking, we still find some quantitative discrepancies between the positions of the instabilities d_{app} and d_{ret}. This is probably due to the simplified force model, which only takes into account van der Waals and repulsive forces. Especially at ambient conditions, an omnipresent water meniscus between tip and sample will give rise to much stronger attractive and also dissipative forces than considered in the model. A very interesting feature is that the simulated phase curves in the intermittent contact regime tend to have a steeper slope in the simulation than in the experiments (see also Fig. 15.12). We will later show that this effect is a fingerprint of an effect that had not been included in the above simulation at all: dissipative processes during the oscillation, giving rise to an additional loss of oscillation energy.

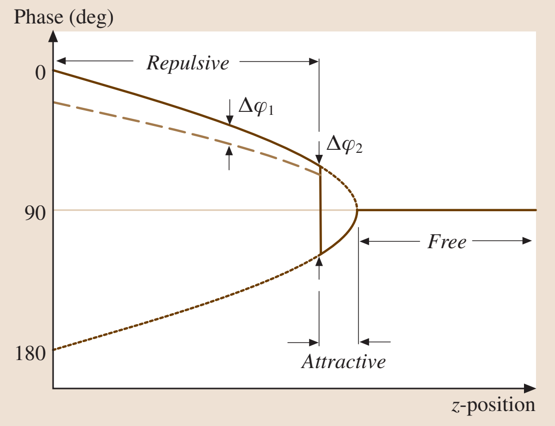

Fig. 15.12 Phase shift in tapping mode as a function of tip-sample distance

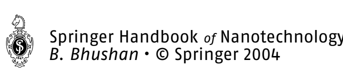
15.3.2 Self-Excitation Modes

Despite the wide range of technical applications of the AM or tapping mode of dynamic AFM, it has been found unsuitable for measurements in an environment extremely useful for scientific research: vacuum or ultrahigh vacuum (UHV) with pressures reaching 1×10^{-10} mbar. The STM has already shown how much insight can be gained from some highly defined experiments under those conditions. Consider (15.11) from the above section. The time constant τ for the amplitude to adjust to a different tip-sample force scales with $1/Q$. In vacuum applications, Q of the cantilever is on the order of 10,000, which means that τ is in the range of some 10 ms. This is clearly too long for a scan of at least (100×100) data points. The temperature-induced drift of the sample will render useful interpretation of images an impossible task. However, the resonant frequency of the system will react instantaneously to tip-sample forces. This has led *Albrecht* et al. [15.11] to use a modified excitation scheme.

The system is always oscillated at its resonant frequency. This is achieved by feeding back the oscillation signal from the cantilever into the excitation piezo-element. Figure 15.13 pictures the method in a block diagram. The signal from the PSD is phase shifted by 90 deg (and, therefore, always exciting in resonance) and used as the excitation signal of the cantilever. An additional feedback loop adjusts the excitation amplitude in such a way that the oscillation amplitude remains constant. This ensures that the tip-sample distance is not influenced by changes in the oscillation amplitude. The only degree of freedom of the oscillation system that can react to the tip-sample forces is the change of the resonant frequency. This shift of the frequency is detected and used as the set-point signal for surface scans. Therefore, this mode is also called the FM (frequency modulated) mode.

Let us take a look at the sensitivity of the dynamic AFM. If electronic noise, laser noise, and thermal drift



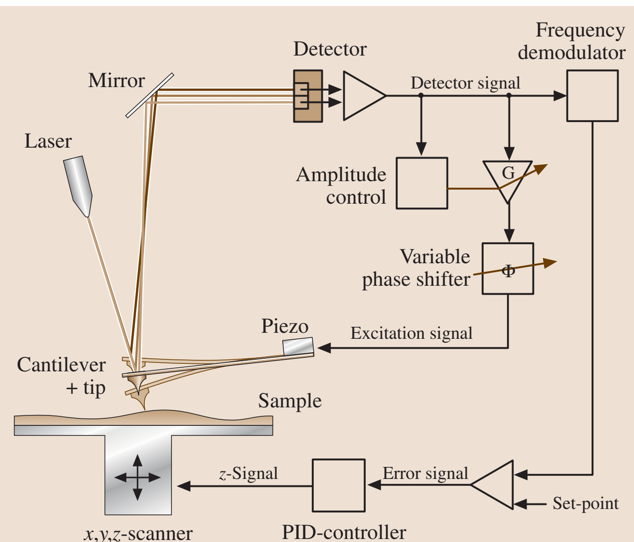


Fig. 15.13 Dynamic AFM operated in the self-excitation mode, where the oscillation signal is directly feedbacked to the excitation piezo. The detector signal is amplified with the variable gain G and phase shifted by phase ϕ. The frequency demodulator detects the frequency shift due to tip-sample interactions, which serves as the control signal for the probe-sample distance

can be neglected, the main noise contribution will come from thermal excitation of the cantilever. A detailed analysis of a dynamic system yields for the minimum detectable force gradient the following relation [15.11]:

$$\left.\frac{\partial F}{\partial z}\right|_{\text{MIN}} = \sqrt{\frac{4k_{\text{B}}TB \cdot k}{\omega_0 Q \langle z_{\text{osc}}^2 \rangle}} \,. \tag{15.17}$$

Here B is the bandwidth of the measurement, T the temperature, and $\langle z_{\text{osc}}^2 \rangle$ is the mean-square amplitude of the oscillation. Please note that this sensitivity limit was deliberately calculated for the FM mode. A similar analysis of the AM mode, however, yields virtually the same result [15.23]. We find that the minimum detectable force gradient, i. e., the measurement sensitivity, is inversely proportional to the square root of the Q-factor of the cantilever. This means that it should be possible to achieve very high-resolution imaging in vacuum conditions. In contrast, AM- or tapping-mode AFM cannot be usefully pursued with large Q. Only the FM mode makes it possible to take practical advantage of (15.17).

A breakthrough in high-resolution AFM application was the atomic resolution imaging of the Si(111)-(7×7) surface reconstruction by Giessibl [15.8] under UHV conditions. Today, atomic resolution imaging has become a standard feature guaranteed by industrially produced dynamic AFM systems. While STM has already proven to be an indispensable tool to gain detailed insight into surface structures of conductors with atomic resolution, the dynamic AFM has opened up the avenue into investigating nonconductive surfaces with equal precision (for example, on aluminium oxide by *Barth* et al. [15.24]).

However, we are concerned with measuring atomic force potentials of a single pair of molecules. Clearly, FM-mode AFM will allow us to identify single atoms, and with sufficient care we will be able to ensure that only one atom from the tip contributes to the total force interaction. Can we, therefore, fill in the last bit of information and find a quantitative relation between the oscillation parameters and the force?

Gotsmann et al. [15.25] investigated this relation by employing a numerical approach. During each oscillation cycle the tip experiences a whole range of forces. For each step during the approach the differential equation for the whole oscillation loop (including also the feedback system) was evaluated and the relation between force and frequency shift revealed. It was possible to determine the quantitative interaction forces of a metallic contact of nanometer dimensions.

However, it was shown that there also exists an analytical relationship if some approximations are accepted [15.7, 26, 27]. Here, we will follow the route indicated by *Dürig* [15.27], although different alternative ways have also proven successful. Consider the tip oscillation trajectory reaching over a large part of the force gradient curve in Fig. 15.2. We model the tip-sample interaction as a spring constant of stiffness $k_{\text{ts}}(z) = \partial F/\partial z|_{z_0}$, as in Fig. 15.1. For small oscillation amplitudes, we already found that the frequency shift is proportional to the force gradient in (15.4). For large amplitudes, we can calculate an effective force gradient k_{eff} as a convolution of the force and the fraction of time the tip spends between the positions x and $x + \mathrm{d}x$:

$$k_{\text{eff}}(z) = \frac{2}{\pi A^2} \int_{z}^{z+2A} F(x) g\left(\frac{x-z}{A} - 1\right) \mathrm{d}x$$
$$\text{with } g(u) = -\frac{u}{\sqrt{1-u^2}} \,. \tag{15.18}$$

In the approximation that the vibration amplitude is much larger than the range of the tip-sample forces,

the above equation can be simplified to:

$$k_{\text{eff}}(z) = \frac{\sqrt{2}}{\pi} A^{3/2} \int_z^\infty \frac{F(x)}{\sqrt{x-z}} \, dx \,. \quad (15.19)$$

This effective force gradient can now be used in (15.4), the relation between frequency shift and force gradient. We find:

$$\Delta f = \frac{f_0}{\sqrt{2}\pi k A^{3/2}} \int_z^\infty \frac{F(x)}{\sqrt{x-z}} \, dx \,. \quad (15.20)$$

If we separate the integral from other parameters, we can define:

$$\Delta f = \frac{f_0}{kA^{3/2}} \gamma(z)$$

$$\text{with } \gamma(z) = \frac{1}{\sqrt{2}\pi} \int_z^\infty \frac{F(x)}{\sqrt{x-z}} \, dx \,. \quad (15.21)$$

This means we can define $\gamma(z)$, which is only dependent on the shape of the force curve $F(z)$ but independent of the external parameters of the oscillation. The function $\gamma(z)$ is also referred to as the "normalized frequency shift" [15.7], a very useful parameter, which allows us to compare measurements independent of resonant frequency, amplitude and spring constant of the cantilever.

The dependence of the frequency shift on the vibration amplitude is an especially useful relation, since this parameter can be easily varied during one experiment. A nice example is depicted in Fig. 15.14, where frequency shift curves for different amplitudes were found to coincide very well in the $\gamma(z)$ diagrams [15.28].

This relationship has been nicely exploited for the calibration of the vibration amplitude by *Guggisberg* [15.29], which is a problem often encountered in dynamic AFM operation and worthwhile discussing. One approaches tip and sample and takes frequency shift curves versus distance, which show a reproducible shape. Then, the z-feedback is permanently turned off, and several curves with different amplitudes are taken. The amplitudes are typically chosen by adjusting the amplitude set-point in volts. One has to take care that drift in the z-direction is negligible. An analysis of the corresponding $\gamma(z)$-curves will show the same curves (as in Fig. 15.14), but the curves will be shifted in the horizontal axis. These shifts correspond to the change in amplitude, allowing one to correlate the voltage values with the z-distances.

For the oft-encountered force contributions from electrostatic, van der Waals, and chemical binding forces the frequency shift has been calculated from the force laws. In the approximation that the tip radius R is larger than the tip-sample distance z, an electrostatic potential V will yield a normalized frequency shift of (adapted from [15.30]):

$$\gamma(z) = \frac{\pi \varepsilon_0 R V^2}{\sqrt{2}} z^{-1/2} \,. \quad (15.22)$$

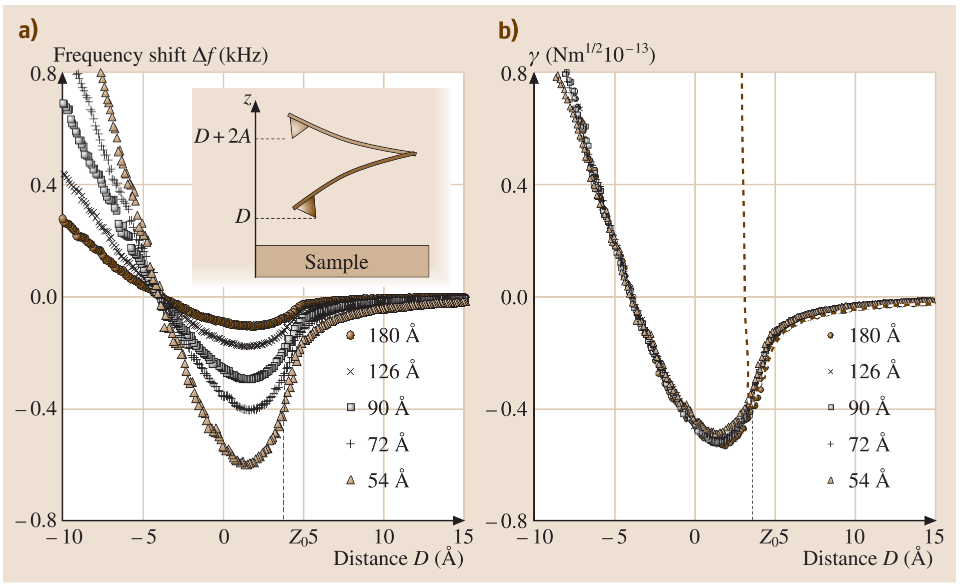

Fig. 15.14 **(a)** Frequency-shift curves for different oscillation amplitudes for a silicon tip on a graphite surface in UHV, **(b)** γ-curves calculated from the Δf-curves in **(a)**. (After [15.28] with permission, Copyright (2000) by The American Physical Society)

For van der Waals forces with Hamaker constant H and with R larger than z, we find accordingly:

$$\gamma(z) = \frac{HR}{12\sqrt{2}} z^{-3/2} . \tag{15.23}$$

Finally, short-range chemical forces represented by the well-known Morse potential (with the parameters binding energy U_0, decay length λ, and equilibrium distance z_{equ}) yield:

$$\gamma(z) = \frac{U_0\sqrt{2}}{\sqrt{\pi\lambda}} \exp\left(-\frac{(z - z_{\text{equ}})}{\lambda}\right) . \tag{15.24}$$

These equations allow the experimentalist to directly interpret the spectroscopic measurements. For example, the contributions of the electrostatic and van der Waals forces can be easily distinguished by their slope in a log-log plot (for an example, see [15.30]).

Alternatively, if the force law is not known beforehand, the experimentalist wants to analyze the experimental frequency-shift data curves and extract the force or energy potential curves. We, therefore, have to invert the integral in (15.21) to find the tip-sample interaction potential V_{ts} from the $\gamma(z)$-curves [15.27]:

$$V_{\text{ts}}(z) = \sqrt{2} \int_z^\infty \frac{\gamma(x)}{\sqrt{x - z}} \, \mathrm{d}x . \tag{15.25}$$

Using this method, quantitative force curves were extracted from Δf-spectroscopy measurements on different, atomically resolved sites of the Si(111)-(7×7) reconstruction [15.1]. Comparison to theoretical MD simulations showed good quantitative agreement with theory and confirmed the assumption that force interactions were governed by a single atom at the tip apex. Our initially formulated goal seems to be achieved: With FM-AFM we have found a powerful method that allows us to measure the chemical bond formation of single molecules. The last uncertainty, the exact shape and identity of the tip apex atom, can possibly be resolved by employing the FIM technique to characterize the tip surface in combination with FM-AFM.

All the above equations are strictly valid only in the approximation that the oscillation amplitudes are much larger than the distance range of the encountered forces. For amplitudes of 10 nm and long-range forces like electrostatic interactions this approximation may not be valid. An iterative approach has been presented by *Dürig* [15.31] to overcome this problem. The interaction force is calculated from the frequency shift curves [gradient of (15.25)]. This force curve again is used to calculate the frequency shift with the exact relation from (15.18). The difference between the experimental Δf-curve and the reconstructed Δf-curve can now be used to calculate a first-order correction term to the interaction force. This procedure can be iteratively followed until sufficient agreement is found.

In this context it is worthwhile to point out a slightly different dynamic AFM method. While in the typical FM-AFM setup the oscillation amplitude is controlled to stay constant by a dedicated feedback circuit, one could simply keep the excitation amplitude constant (this has been termed *CA = constant amplitude*, as opposed to the *CE = constant excitation* mode). It is expected that this mode is more gentle to the surface, because any dissipative interaction will reduce the amplitude and therefore increase the tip-sample distance. The tip is prevented from deeply indenting the surface. This mode has been employed to image soft biological molecules like DNA or thiols in UHV [15.32]. However, quantitative interpretation of the obtained frequency spectra is more complicated, since the amplitude and tip-sample distance are altered during the measurement. Until now, we have always associated the self-excitation scheme with vacuum applications. Although it is difficult to operate the FM-AFM in constant amplitude mode in air, since large dissipative effects make it difficult to ensure a constant amplitude, it is indeed possible to use the constant-excitation FM-AFM in air or even in liquid. Still, only a few applications of FM-AFM under ambient or liquid conditions have been reported so far. In fact, a low budget construction set (employing a tuning-fork force sensor) for a CE-mode dynamic AFM setup has been published on the Internet (*http://www.sxm4.uni-muenster.de*).

15.4 *Q*-Control

We have already discussed the virtues of a high Q value for high sensitivity measurements: The minimum detectable force gradient was inversely proportional to the square root of Q. In vacuum, Q mainly represents the internal dissipation of the cantilever during oscillation, an internal damping factor. Little damping is obtained by

using high quality cantilevers, which are cut (or etched) from defect-free, single-crystal silicon wafers. Under ambient or liquid conditions, the quality factor is dominated by dissipative interactions between the cantilever and the surrounding medium, and Q values can be as low as 100 for air or even 5 in liquid. Still, we ask if it is somehow possible to compensate for the damping effect by exciting the cantilever in a sophisticated way?

It turns out that the shape of the resonance curves in Fig. 15.15 can be influenced toward higher (or lower) Q values by an amplitude feedback loop. In principle, there are several mechanisms to couple the amplitude signal back to the cantilever, by the photothermal effect [15.33] or capacitive forces [15.34]. Figure 15.16 shows a method in which the amplitude feedback is mediated directly by the excitation piezo [15.35]. This has the advantage that no additional mechanical setups are necessary.

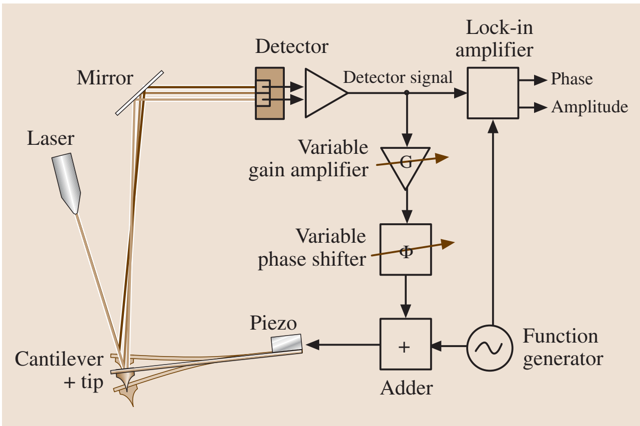

Fig. 15.16 Schematic diagram of operating a Q-Control feedback circuit with an externally driven dynamic AFM. The tapping mode setup is in effect extended by an additional feedback loop

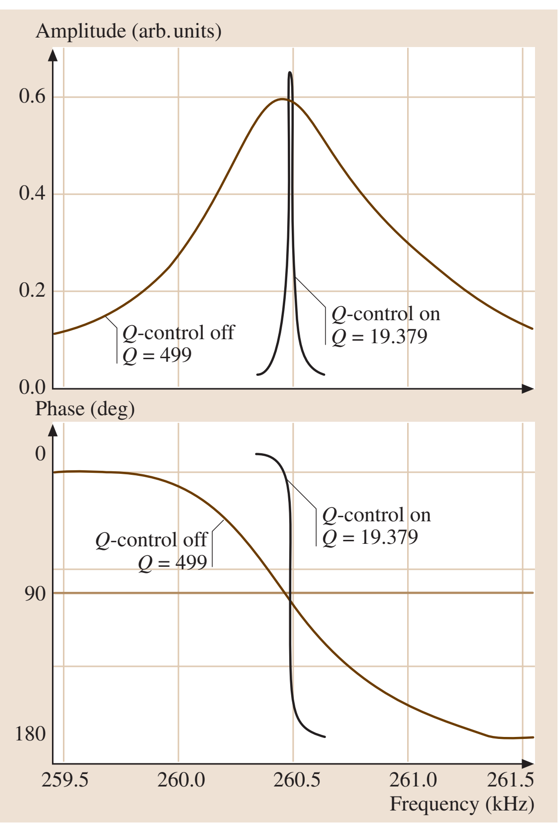

Fig. 15.15 Amplitude and phase diagrams measured in air with a Si cantilever far away from the sample. The quality factor can be increased from 450 to 20,000 by using the Q-Control feedback method

The working principle of the feedback loop can be understood by analyzing the equation of motion of the modified dynamic system:

$$m^*\ddot{z}(t)+\alpha\dot{z}(t)+kz(t)-F_{ts}\left(z_0+z(t)\right) = F_{ext}\cos(\omega t)+G\,e^{i\phi}z(t)\,. \quad (15.26)$$

This ansatz takes into account the feedback of the detector signal through a phase shifter, amplifier, and adder as an additional force, which is linked to the cantilever deflection $z(t)$ through the gain G and the phase shift $e^{i\phi}$. To a good approximation, we assume that the oscillation can be described by a harmonic trajectory. With a phase

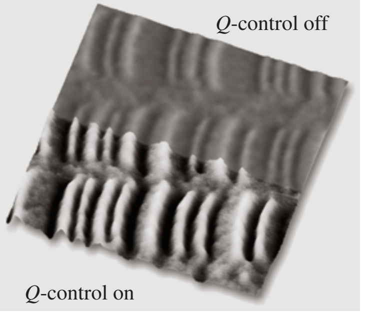

Fig. 15.17 Enhancement of the contrast in the phase channel due to Q-Control on a magnetic hard disk measured with a magnetic tip in tapping-mode AFM in air. Scan size $5\times5\,\mu$m, phase range 10 deg (www.nanoanalytics.com)

shift of $\phi = \pm\pi/2$ we find:

$$e^{\pm i\pi/2} z(t) = \pm\frac{1}{\omega}\dot{z}(t)\ . \qquad (15.27)$$

This means that the additional feedback force signal $G\,e^{i\phi} z(t)$ is proportional to the velocity of the cantilever, just like the damping term in the equation of motion. We can define an effective damping constant α_{eff}, which combines the two terms:

$$m^*\ddot{z}(t) + \alpha_{\text{eff}}\dot{z}(t) + kz(t) - F_{\text{ts}}(z_0 + z(t)) = F_{\text{ext}}\cos(\omega t)$$
$$\text{with } \alpha_{\text{eff}} = \alpha \mp \frac{1}{\omega}G \quad \text{for } \phi = \pm\frac{\pi}{2}\ . \qquad (15.28)$$

Equation (15.28) shows that the dampening of the oscillator can be enhanced or weakened by the choice of G, $\phi = +\pi/2$ or $\phi = -\pi/2$, respectively. The feedback loop, therefore, allows us to vary the effective quality factor $Q_{\text{eff}} = m\omega_0/\alpha_{\text{eff}}$ of the complete dynamic system. Hence, we term this system Q-Control. Figure 15.15 shows experimental data on the effect of Q-Control on the amplitude and phase as a function of the external excitation frequency [15.35]. While $Q = 449$, without Q-Control the quality factor of the system operated in air is enhanced by a factor of more than 40 by applying the feedback loop.

The effect of improved image contrast is demonstrated in Fig. 15.17. Here, a computer hard disk was analyzed with a magnetic tip in tapping mode, where the magnetic contrast is observed in the phase image. The upper part shows the recorded magnetic data structures in standard mode, whereas in the lower part of the image Q-Control feedback was activated, giving rise to an improved signal, i. e., magnetic contrast. A more detailed analysis of measurements on a magnetic tape shows that the signal amplitude (upper diagrams in Fig. 15.18), i. e.,

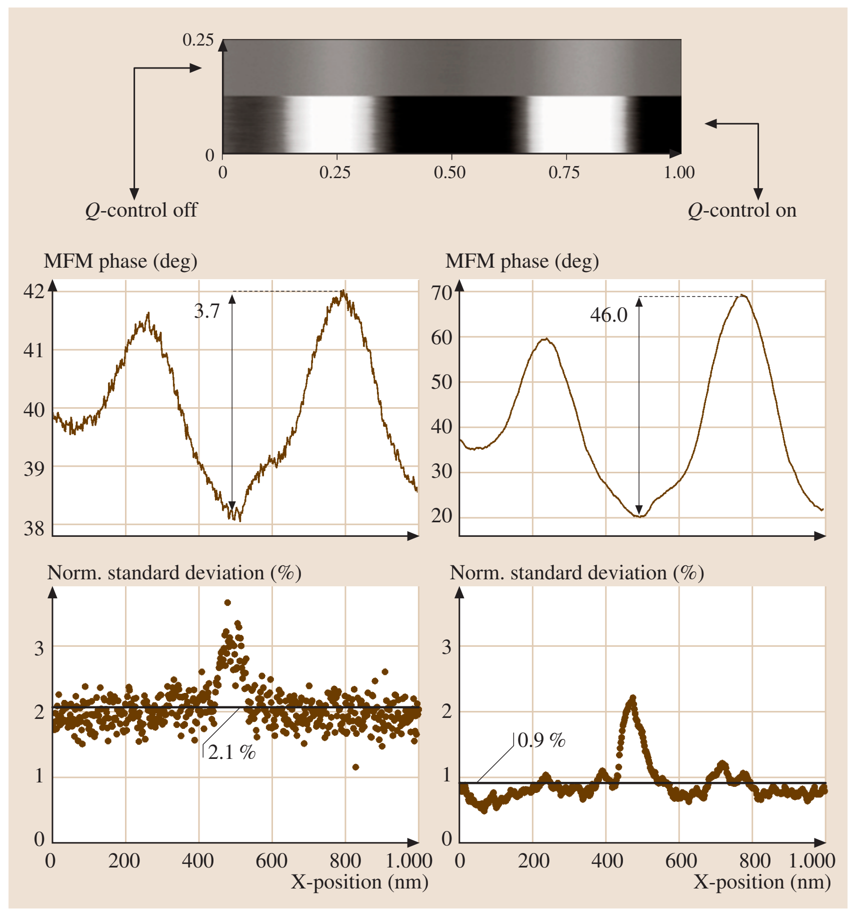

Fig. 15.18 Signal-to-noise analysis with a magnetic tip in tapping-mode AFM on a magnetic tape sample with Q-Control

the image contrast, was increased by a factor of 12.4 by the Q-Control feedback. The lower image shows a noise analysis of the signal, indicating an increase of the signal-to-noise ratio by a factor of 2.3.

Note that the diagrams represent measurements in air with an AFM operated in AM mode. Only then can we make a distinction between excitation and vibration frequency, since in the FM mode these two frequencies are equal by definition. Although the relation between sensitivity and Q-factor in (15.17) is the same for AM and FM mode, it must be critically investigated to see whether the enhanced quality factor by Q-Control can be inserted in the equation for FM-mode AFM. In vacuum applications, Q is already very high, which makes it oblique to operate an additional Q-Control module.

As stated before, we can also use Q-Control to enhance the dampening in the oscillating system. This would decrease the sensitivity of the system. But on the other hand, the response time of the amplitude change is decreased as well. For tapping-mode applications, where high speed scanning is the goal, Q-Control will be able to reduce the relaxation time [15.36].

A large quality factor Q does not only have the virtue of increasing the force sensitivity of the instrument. It also has the advantage of increasing the parameter space of stable AFM operation in tapping- or AM-mode AFM. Consider the resonance curve of Fig. 15.5. When approaching the tip toward the surface there are two competing mechanisms: On the one hand, we bring the tip closer to the sample, which results in an increase in attractive forces (see Fig. 15.2). On the other hand, for the case $\omega > \omega_0$, the resonant frequency of the cantilever is shifted toward smaller values due to the attractive forces, which causes the amplitude to become smaller, preventing a tip-sample contact. This is the desirable regime, where stable operation of the AFM is possible in the net-attractive regime. But as explained before, below a certain tip-sample separation d_{app}, the system switches suddenly into intermittent contact mode, where surface modifications are likely due to the onset of strong repulsive forces. The steeper the amplitude curve the larger the regime of stable, net-attractive AFM operation. Looking at Fig. 15.5 we find that the slope of the amplitude curve is governed by the quality factor Q. A high Q, therefore, facilitates stable operation of the AM-AFM in the net-attractive regime.

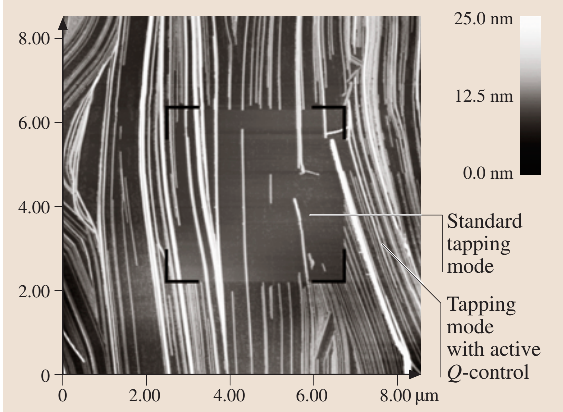

Fig. 15.19 Imaging of a delicate organic surface with Q-Control. Sample was a Langmuir-Blodgett film (ethyl-2,3-dihydroxyoctadecanoate) on a mica substrate. The topographical image clearly shows that the highly sensitive sample surface can only be imaged non-destructively with active Q-Control, whereas the periodic repulsive contact with the probe in standard operation without Q-Control leads to a significant modification or destruction of the surface structure. (Data courtesy of *Lifeng Chi* and coworkers, Westfälische Wilhelms-Universität, Münster, Germany)

An example can be found in Fig. 15.19. Here, a surface scan of an ultrathin organic film is acquired in tapping mode under ambient conditions. First, the inner square is scanned without the Q enhancement, and then a wider surface area was scanned with applied Q-Control. The high quality factor provides a larger parameter space for operating the AFM in the net-attractive regime, allowing good resolution of the delicate organic surface structure. Without the Q-Control the surface structures are deformed and even destroyed due to the strong repulsive tip-sample interactions [15.37–39]. This also allowed imaging of DNA structures without predominantly depressing the soft material during imaging. It was then possible to observe a DNA diameter close to the theoretical value with the Q-Control feedback [15.40].

In conclusion, we have shown that by applying an additional feedback circuit to the dynamic AFM system it is possible to influence the quality factor Q of the oscillator system. High-resolution, high-speed, or low-force scanning is then possible.

15.5 Dissipation Processes Measured with Dynamic AFM

Dynamic AFM methods have proven their great potential for imaging surface structures at the nanoscale, and we have also discussed methods that allow the assessment of forces between distinct single molecules. However, there is another physical mechanism that can be analyzed with the dynamic mode and has been mentioned in some previous paragraphs: energy dissipation. In Fig. 15.12, we have already shown an example, where the phase signal in tapping mode cannot be explained by conservative forces alone; dissipative processes must also play a role. In constant-amplitude FM mode, where the quantitative interpretation of experiments has proven to be less difficult, an intuitive distinction between conservative and dissipative tip-sample interaction is possible. While we have shown the correlation between forces and frequency shifts of the oscillating system, we have neglected one experimental input channel. The excitation amplitude, which is necessary to keep the oscillation amplitude constant, is a direct indication of the energy dissipated during one oscillation cycle. *Dürig* [15.41] has shown that in self-excitation mode (with an excitation-oscillation phase difference of 90 deg), conservative and dissipative interactions can be strictly separated. Part of this energy is dissipated in the cantilever itself, another part is due to external viscous forces in the surrounding medium. But more interestingly, some energy is dissipated at the tip-sample junction. This is the focus of the following paragraphs.

In contrast to conservative forces acting at the tip-sample junction, which at least in vacuum can be understood in terms of van der Waals, electrostatic, and chemical interactions, the dissipative processes are poorly understood. *Stowe* et al. [15.42] have shown that if a voltage potential is applied between tip and sample, charges are induced in the sample surface, which will follow the tip motion (here the oscillation is parallel to the surface). Due to the finite resistance of the sample material, energy will be dissipated during the charge movement. This effect has been exploited to image the doping level of semiconductors. Energy dissipation has also been observed in imaging magnetic materials. *Liu* et al. [15.43] found that energy dissipation due to magnetic interactions was enhanced at the boundaries of magnetic domains, which was attributed to domain wall oscillations. But also in the absence of external electromagnetic fields, energy dissipation was observed in close proximity of tip and sample, within 1 nm. Clearly, mechanical surface relaxations must give rise to energy losses. One could model the AFM tip as a small hammer, hitting the surface at high frequency, possibly resulting in phonon excitations. From a contiuum mechanics point of view, we assume that the mechanical relaxation of the surface is not only governed by elastic responses. Viscoelastic effects of soft surfaces will also render a significant contribution to energy dissipation. The whole area of phase imaging in tapping mode is concerned with those effects [15.44–47].

In the atomistic view, the last tip atom can be envisaged to change position while yielding to the tip-sample force field. A strictly reversible change of position would not result in a loss of energy. Still, it has been pointed out by *Sasaki* et al. [15.48] that a change in atom position would result in a change in the force interaction itself. Therefore, it is possible that the tip atom changes position at different tip-surface distances during approach and retraction, effectively causing an atomic-scale hysteresis to develop. In fact, *Hoffmann* et al. [15.13] have measured short-range energy dissipation for a tungsten tip on silicon in UHV. A theoretical model explaining this effect on the basis of a two-energy-state system was developed. However, a clear understanding of the underlying physical mechanism is still lacking.

Nonetheless, the dissipation channel has been used to image surfaces with atomic resolution [15.49]. Instead of feedbacking the distance on the frequency shift, the excitation amplitude in FM mode has been used as the control signal. The Si(111)-(7×7) reconstruction was successfully imaged in this mode. The step edges of monoatomic NaCl islands on single-crystalline copper have also rendered atomic resolution contrast in the dissipation channel [15.50]. The dissipation processes discussed so far are mostly in the configuration in which the tip is oscillated perpendicular to the surface. Friction is usually referred to as the energy loss due to lateral movement of solid bodies in contact. It is interesting to note in this context that *Israelachivili* [15.51] has pointed out a quantitative relationship between lateral and vertical (with respect to the surface) dissipation. He states that the hysteresis in vertical force-distance curves should equal the energy loss in lateral friction. An experimental confirmation of this conjecture at the molecular level is still missing.

Physical interpretation of energy dissipation processes at the atomic scale seems to be a daunting task at this point. Notwithstanding, we can find a quantitative relation between the energy loss per oscillation cycle and the experimental parameters in dynamic AFM, as will be shown in the following section.

In static AFM it was found that permanent changes of the sample surface by indentations can cause a hysteresis between approach and retraction (e.g., [15.5]). The area between the approach and retraction curves in a force-distance diagram represents the lost or dissipated energy caused by the irreversible change of the surface structure. In dynamic-mode AFM, the oscillation parameters like amplitude, frequency, and phase must contain the information about the dissipated energy per cycle. So far, we have resorted to a treatment of the equation of motion of the cantilever vibration in order to find a quantitative correlation between forces and the experimental parameters. For the dissipation it is useful to treat the system from the energy conservation point of view.

Assuming a dynamic system is in equilibrium, the average energy input must equal the average energy output or dissipation. Applying this rule to an AFM running in a dynamic mode means that the average power fed into the cantilever oscillation by an external driver, denoted $\bar{P}_{\mathrm{in}}$, must equal the average power dissipated by the motion of the cantilever beam $\bar{P}_0$ and by tip-sample interaction $\bar{P}_{\mathrm{tip}}$:

$$\bar{P}_{\mathrm{in}} = \bar{P}_0 + \bar{P}_{\mathrm{tip}} \,. \qquad (15.29)$$

The term $\bar{P}_{\mathrm{tip}}$ is what we are interested in, since it gives us a direct physical quantity to characterize the tip-sample interaction. Therefore, we have first to calculate and then measure the two other terms in (15.29) in order to determine the power dissipated when the tip periodically probes the sample surface. This requires an appropriate rheological model to describe the dynamic system. Although there are investigations in which the complete flexural motion of the cantilever beam has been considered [15.52], a simplified model, comprising a spring and two dashpots (Fig. 15.20), represents a good approximation in this case [15.53].

The spring, characterized by the constant k according to Hooke's law, represents the only channel through which power P_{in} can be delivered to the oscillating tip $z(t)$ by the external driver $z_{\mathrm{d}}(t)$. Therefore, the instantaneous power fed into the dynamic system is equal to the force exerted by the driver times the velocity of the driver (the force that is necessary to move the base side of the dashpot can be neglected, since this power is directly dissipated and, therefore, does not contribute to the power delivered to the oscillating tip):

$$P_{\mathrm{in}}(t) = F_{\mathrm{d}}(t)\dot{z}_{\mathrm{d}}(t) = k\,[z(t) - z_{\mathrm{d}}(t)]\,\dot{z}_{\mathrm{d}}(t) \,. \qquad (15.30)$$

Assuming a sinusoidal steady state response and that the base of the cantilever is driven sinusoidally (see (15.6)) with amplitude A_{d} and frequency ω, the deflection from equilibrium of the end of the cantilever follows (15.9), where A and $0 \le \varphi \le \pi$ are the oscillation amplitude and phase shift, respectively. This allows us to calculate the average power input per oscillation cycle by integrating (15.30) over one period $T = 2\pi/\omega$:

$$\bar{P}_{\mathrm{in}} = \frac{1}{T}\int_0^T P_{\mathrm{in}}(t)\,\mathrm{d}t = \frac{1}{2}k\omega A_{\mathrm{d}} A \sin\varphi \,. \qquad (15.31)$$

This contains the familiar result that the maximum power is delivered to an oscillator when the response is 90 deg out of phase with the drive.

The simplified rheological model, as it is depicted in Fig. 15.20, exhibits two major contributions to the damping term $\bar{P}_0$. Both are related to the motion of the cantilever body and assumed to be well modeled by viscous damping with coefficients α_1 and α_2. The dominant damping mechanism in UHV conditions is intrinsic damping caused by the deflection of the cantilever beam, i. e., the motion of the tip relative to the cantilever base. Therefore, the instantaneous power dissipated by such a mechanism is given by

$$P_{01}(t) = |F_{01}(t)\dot{z}(t)| = |\alpha_1\,[\dot{z}(t) - \dot{z}_{\mathrm{d}}(t)]\,\dot{z}(t)| \,. \qquad (15.32)$$

Note that the absolute value has to be calculated, since all dissipated power is "lost" and, therefore, cannot be returned to the dynamic system.

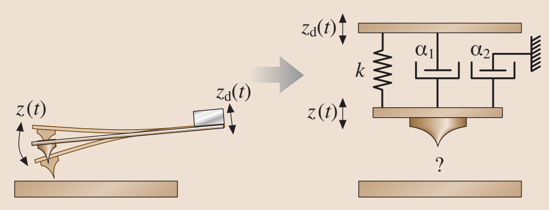

Fig. 15.20 Rheological model applied to describe the dynamic AFM system, comprising the oscillating cantilever and tip interacting with the sample surface. The movement of the cantilever base and the tip is denoted as $z_{\mathrm{d}}(t)$ and $z(t)$, respectively. The cantilever is characterized by the spring constant k and the damping constant α. In a first approach, damping is broken into two pieces, α_1 and α_2. First, intrinsic damping caused by the movement of the cantilever's tip relative to its base. Second, damping related to the movement of the cantilever body in a surrounding medium, e.g., air damping

However, when running an AFM in ambient conditions an additional damping mechanism has to be considered. Damping due to the motion of the cantilever body in the surrounding medium, e.g., air damping, is in most cases the dominant effect. The corresponding instantaneous power dissipation is given by

$$P_{02}(t) = |F_{02}(t)\dot{z}(t)| = \alpha_2 \dot{z}^2(t)\,. \quad (15.33)$$

In order to calculate the average power dissipation, (15.32) and (15.33) have to be integrated over one complete oscillation cycle. This yields

$$\begin{aligned}\bar{P}_{01} &= \frac{1}{T}\int_0^T P_{01}(t)\,\mathrm{d}t \\ &= \frac{1}{\pi}\alpha_1\omega^2 A\Bigg[(A - A_\mathrm{d}\cos\varphi) \\ &\quad\times \arcsin\left(\frac{A - A_\mathrm{d}\cos\varphi}{\sqrt{A^2 + A_\mathrm{d}^2 - 2AA_\mathrm{d}\cos\varphi}}\right) \\ &\quad + A_\mathrm{d}\sin\varphi\Bigg]\,, \end{aligned} \quad (15.34)$$

and

$$P_{02}(t) = \frac{1}{T}\int_0^T P_{02}(t)\,\mathrm{d}t = \frac{1}{2}\alpha_2\omega^2 A^2\,. \quad (15.35)$$

Considering the fact that commonly used cantilevers exhibit a quality factor of at least several hundreds (in UHV several tens of thousands), we can assume that the oscillation amplitude is significantly larger than the drive amplitude when the dynamic system is driven at or near its resonance frequency: $A \gg A_\mathrm{d}$. Therefore, (15.34) can be simplified in first order approximation to an expression similar to (15.35). Combining the two equations yields the total average power dissipated by the oscillating cantilever

$$\bar{P}_0 = \frac{1}{2}\alpha\omega^2 A^2 \quad \text{with } \alpha = \alpha_1 + \alpha_2\,, \quad (15.36)$$

where α denotes the overall effective damping constant.

We can now solve (15.29) for the power dissipation localized to the small interaction volume of the probing tip with the sample surface, represented by the question mark in Fig. 15.20. Furthermore, by expressing the damping constant α in terms of experimentally accessible quantities such as the spring constant k, the quality factor Q, and the natural resonant frequency ω_0 of the free oscillating cantilever, $\alpha = \frac{k}{Q\omega_0}$, we obtain:

$$\begin{aligned}\bar{P}_\mathrm{tip} &= \bar{P}_\mathrm{in} - \bar{P}_0 \\ &= \frac{1}{2}\frac{k\omega}{Q}\left(Q_\mathrm{cant}A_\mathrm{d}A\sin\varphi - A^2\frac{\omega}{\omega_0}\right)\,. \end{aligned} \quad (15.37)$$

Note that so far no assumptions have been made regarding how the AFM is operated, except that the motion of the oscillating cantilever has to remain sinusoidal to a good approximation. Therefore, (15.37) is applicable to a variety of different dynamic AFM modes.

For example, in FM-mode AFM the oscillation frequency ω changes due to tip-sample interaction, while at the same time the oscillation amplitude A is kept constant by adjusting the drive amplitude A_d. By measuring these quantities, one can apply (15.37) to determine the average power dissipation related to tip-sample interaction. In spectroscopy applications, usually $A_\mathrm{d}(d)$ is not measured directly, but a signal $G(d)$ proportional to $A_\mathrm{d}(d)$ is acquired representing the gain factor applied to the excitation piezo. With the help of (15.15) we can write:

$$A_\mathrm{d}(d) = \frac{A_0 G(d)}{QG_0}\,, \quad (15.38)$$

while A_0 and G_0 are the amplitude and gain at large tip-sample distances, where the tip-sample interactions are negligible.

Now let us consider the tapping-mode, or AM-AFM. In this case, the cantilever is driven at a fixed frequency and with constant drive amplitude, while the oscillation amplitude and phase shift may change when the probing tip interacts with the sample surface. Assuming that the oscillation frequency is chosen to be ω_0, (15.37) can be further simplified by again employing (15.15) for the free oscillation amplitude A_0. This yields

$$\bar{P}_\mathrm{tip} = \frac{1}{2}\frac{k\omega_0}{Q}\left(A_0 A\sin\varphi - A^2\right)\,. \quad (15.39)$$

Equation (15.39) implies that if the oscillation amplitude A is kept constant by a feedback loop, like it is commonly done in tapping mode, simultaneously acquired phase data can be interpreted in terms of energy dissipation [15.45, 47, 54, 55]. When analyzing such phase images [15.56–58], one has also to consider the fact that the phase may also change due to the transition from net-attractive ($\varphi > 90°$) to intermittent contact ($\varphi < 90°$) interaction between the tip and the sample [15.15, 35, 59, 60]. For example,

consider the phase shift in tapping mode as a function of z-position, Fig. 15.12. If phase measurements are performed close to the point where the oscillation switches from the net-attractive to the intermittent contact regime, a large contrast in the phase channel is observed. However, this contrast is not due to dissipative processes. Only a variation of the phase signal within the intermittent contact regime will give information of the tip-sample dissipative processes.

An example of a dissipation measurement is depicted in Fig. 15.21. The surface of a polymer blend was imaged in air, simultaneously acquiring the topography and dissipation. The dissipation on the softer polyurethane-matrix is significantly larger than on the embedded, mechanically stiffer polypropylene particles.

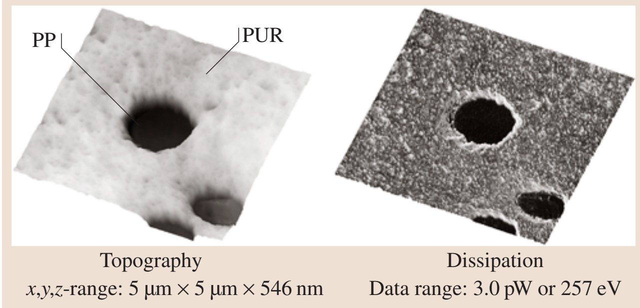

Fig. 15.21 Topography and phase image in tapping-mode AFM of a polymer blend composed of polypropylene (PP) particles embedded in a polyurethane (PUR) matrix. The dissipation image shows a strong contrast between the harder PP (little dissipation, *dark*) to the softer PUR (large dissipation, *bright*) surface

15.6 Conclusion

Dynamic force microscopy is a powerful tool that is capable of imaging surfaces with atomic precision. It also allows us to look at surface dynamics, and it can operate in vacuum, air, or even in liquid. However, the oscillating cantilever system introduces a level of complexity that disallows a straightforward interpretation of acquired images. An exception is the self-excitation mode, where tip-sample forces can be successfully extracted from spectroscopic experiments. However, not only conservative forces can be investigated with dynamic AFM; energy dissipation also influences the cantilever oscillation and can, therefore, serve as a new information channel.

Open questions still exist concerning the exact geometric and chemical identity of the probing tip, which significantly influences the imaging and spectroscopic results. Using predefined tips like single-walled nanotubes or atomic resolution techniques like field ion microscopy to image the tip itself are possible approaches to addressing this issue. Furthermore, little is known about the dissipative processes at the scale where only a few atoms between tip and sample interact. It is also desirable to learn more about the interpretation of images acquired in tapping mode.

16. Molecular Recognition Force Microscopy

Atomic force microscopy (AFM), developed in the late eighties to explore atomic details on hard material surfaces, has evolved to an imaging method capable of achieving fine structural details on biological samples. Its particular advantage in biology is that the measurements can be carried out in aqueous and physiological environment, which opens the possibility to study the dynamics of biological processes in vivo. The additional potential of the AFM to measure ultra-low forces at high lateral resolution has paved the way for measuring inter- and intra-molecular forces of bio-molecules on the single molecule level. Molecular recognition studies using AFM open the possibility to detect specific ligand–receptor interaction forces and to observe molecular recognition of a single ligand–receptor pair. Applications include biotin–avidin, antibody–antigen, NTA nitrilotriacetate–hexahistidine 6, and cellular proteins, either isolated or in cell membranes.

The general strategy is to bind ligands to AFM tips and receptors to probe surfaces (or vice versa), respectively. In a force–distance cycle, the tip is first approached towards the surface whereupon a single receptor–ligand complex is formed, due to the specific ligand receptor recognition. During subsequent tip–surface retraction a temporarily increasing force is exerted to the ligand–receptor connection thus reducing its lifetime until the interaction bond breaks at a critical force (unbinding force). Such experiments allow for estimation of affinity, rate constants, and structural data of the binding pocket. Comparing them with values obtained from ensemble-average techniques and binding energies is of particular interest. The dependences of unbinding force on the rate of load increase exerted to the receptor–ligand bond reveal details of the molecular dynamics of the recognition process and energy landscapes. Similar experimental strategies were also used for studying intra-molecular force properties of polymers and unfolding–refolding kinetics of filamentous proteins. Recognition imaging, developed by combing dynamic force microscopy with force spectroscopy, allows for localization of receptor sites on surfaces with nanometer positional accuracy.

Macromolecular interactions play a key role in cellular regulation and biological function. Molecular recognition is one of the most important regulatory elements, as it is often the initiating step in reaction pathways and cascades. Since the immune system has evolved recognition molecules that are both highly specific and versatile, antibody-antigen interaction is often used as a paradigm for molecular recognition. However, molecular recognition also plays fundamental roles in the regulation of gene expression, cellular metabolism, and drug design.

Molecular recognition studies emphasize specific biological interactions between receptors and their cog-

nitive ligands. Despite a growing literature on the structure and function of receptor-ligand complexes, it is still not possible to predict reaction kinetics or energetics for any given complex formation, even when the structures are known. Additional insights, in particular about the molecular dynamics within the complex during the association and dissociation process, are needed. The high-end strategy is to probe quantitatively the science that underlies a specific biological recognition in which the chemical structures can be defined at atomic resolution, and genetic or chemical means are available to vary the structure of the interacting partners.

Receptor-ligand complexes are usually formed by a few tens of parallel weak interactions of contacting chemical groups in complementary determining regions supported by framework residues providing structurally conserved scaffolding. Both the complementary determining regions and the framework have a considerable amount of plasticity and flexibility resulting in conformational changes upon association and dissociation (induced fit). In addition to what is known about structure, energies, and kinetic constants, information about conformational movements is required for the understanding of the recognition process. It is likely that insight into the temporal and spatial action of the many weak interactions, in particular the cooparativity of bond formation, is the key to understanding receptor-ligand recognition.

For this, experiments on the single-molecule level at time scales typical for receptor-ligand complex formation and dissociation appear to be required. The potential of the atomic force microscope (AFM) [16.1] to measure ultralow forces at high lateral resolution has paved the way for single-molecule recognition force microscopy studies. The particular advantage of AFM in biology is that the measurements can be carried out in aqueous and physiological environments, which opens the possibility for studying biological processes in vivo. The methodology for investigating the molecular dynamics of receptor-ligand interactions described in this chapter, *Molecular Recognition Force Microscopy* (MRFM) [16.2–4], was developed from scanning probe microscopy (SPM) [16.1]. A force is exerted on a receptor-ligand complex, and the dissociation process is followed over time. Dynamic aspects of recognition are addressed in force spectroscopy (FS) experiments, in which distinct force-time profiles are applied to give insight into the changes in conformations and states during receptor-ligand dissociation. It will be shown that MRFM is a versatile tool to explore kinetic and structural details of receptor-ligand recognition.

16.1 Ligand Tip Chemistry

In MRFM experiments, the binding of ligands on AFM tips to surface-bound receptors (or vice versa) is studied by applying a force to the receptor-ligand complex that reduces its lifetime until the bond breaks at a measurable unbinding force. This requires a careful AFM tip sensor design, including tight attachment of the ligands to the tip surface. In the first pioneering demonstrations of single-molecule recognition force measurements [16.2, 3], strong physical adsorption of bovine serum albumin (BSA) was used to directly coat the tip [16.3] or, alternatively, a glass bead glued to it [16.2]. This physisorbed protein layer may then serve as a functional matrix for the biochemical modification with chemically active ligands (Fig. 16.1). In spite of the large number of probe molecules on the tip ($10^3 – 10^4/\mu m^2$), the low fraction of properly oriented molecules, or internal blocks of most reactive sites (see Fig. 16.1), allowed the measurement of single receptor-ligand unbinding forces. Nevertheless, parallel breakage of multiple bonds was predominately observed with this configuration.

For measuring interactions between isolated receptor-ligand pairs, strictly defined conditions need to be fulfilled. Covalently coupling ligands to gold-coated tip surfaces via freely accessible SH-groups guarantees a sufficiently stable attachment, because these bonds are about ten times stronger than typical ligand-receptor interactions [16.5]. This chemistry has been used to detect the forces between complementary DNA strands [16.6] and single nucleotides [16.7]. Self-assembled monolayers of dithio-bis(succinimidylundecanoate) were formed to enable covalent coupling of biomolecules via amines [16.8], and were used to study the binding strength between cell adhesion proteoglycans [16.9] and between biotin-directed IgG antibodies and biotin [16.10]. A vectorial orientation of Fab molecules on gold tips was achieved by a firsthand site-directed chemical binding via their SH-groups [16.11], without the need of additional linkers. For this, antibodies were

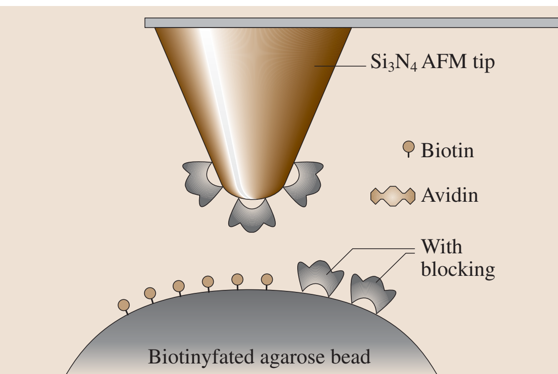

Fig. 16.1 Avidin-functionalized AFM tip. A dense layer of biotinylated BSA was adsorbed to the tip and subsequently saturated with avidin. The biotinylated agarose bead opposing the tip also contained a high surface density of reactive sites, which were, therefore, partly blocked with avidin to achieve single-molecule binding events (after [16.3])

digested with papain and subsequently purified to generate Fab fragments with freely accessible SH-groups in the hinge region.

Gold surfaces provide a unique and selective affinity for thiols, although the adhesion strength of the formed bond is weaker than that of other covalent bonds [16.5]. Since all commercially available AFM tips are etched of silicon nitride or silicon oxide material, deposition of a gold layer onto the tip surface is required prior to using this chemistry. Therefore, designing a sensor with covalent attachments of the biomolecules to the silicon surface may be more straightforward. Amine-functionalization procedures, a strategy widely used in surface bio-chemistry, were applied using ethanolamine [16.4, 12] and various silanization methods [16.13–15] as a first step in thoroughly developed surface anchoring protocols suitable for single molecule experiments. Since the amine density achieved in these procedures often determines the number of ligands on the tip that can specifically bind to the receptors on the surface, it has to be sufficiently low to guarantee single molecule detection [16.4, 12]. One molecule per tip apex ($\sim 5-20$ nm) corresponds to a macroscopic density of about 500 molecules per μm^2. A most striking example of a single ligand molecule tip was realized by gluing a single nanotube to the cantilever, thus minimizing the contact between tip and surface with a chemically well-defined and extremely small tip apex [16.16]. The ligand molecule was reacted to an activated chemical site at the open end of the nanotube.

In a number of laboratories, a distensible and flexible linker was used to space the ligand molecule from the tip surface (e.g., [16.4, 14]) (Fig. 16.2). At a given low number of spacer molecules per tip, the ligand can freely orient and diffuse within a certain volume provided by the length of the tether to achieve unconstrained binding to its receptor. The unbinding process occurs with little torque, and the ligand molecule escapes the danger of being squeezed between the tip and the surface. It also opens the possibility of site-directed coupling for a defined orientation of the ligand relative to the receptor at receptor-ligand unbinding. As a crosslinking element, poly(ethylene glycol) (PEG), a water soluble, nontoxic polymer with a wide range of applications in surface technology and clinical research, was often used [16.17]. PEG is known to prevent surface adsorption of proteins and lipid structures and therefore appears ideally suited for this purpose. Gluteraldehyde [16.13] and DNA [16.6] were also successfully applied in recognition force studies. Crosslinker lengths, ideally arriving at a good compromise between high tip molecule mobility and narrow lateral resolution of the target recognition site, varied from 2 to 100 nm.

For coupling to the tip surface and to the ligands, respectively, the crosslinker is mostly equipped with two different functional ends, e.g., an N-hydroxy-

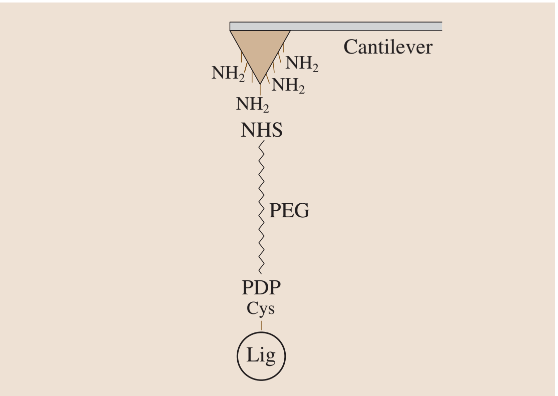

Fig. 16.2 Linkage of ligands to AFM tips. Ligands were covalently coupled to AFM tips via a heterobifunctional polyethylene glycol (PEG) derivative of 8 nm length. Silicon tips were first functionalized with ethanolamine ($NH_2-C_2H_4OH \cdot HCl$). Then, the NHS (N-hydroxy-succinimide) end of the PEG linker was covalently bound to amines on the tip surface before ligands were attached to the PDP (Pyridoyldithiopropionate) end via a free thiol or cysteine

succinimidyl (NHS) residue on the one end is reactive to amines on the tip and a 2-pyridyldithiopropionyl (PDP) [16.18] or a vinyl sulfon [16.19] residue on the other end, can be covalently bound to thiols of ligands (Fig. 16.2). This sulfur chemistry is highly advantageous, since it is very reactive and renders site-directed coupling possible. However, free thiols are hardly available on native ligands and must, therefore, be generated.

Different strategies were used to achieve this goal. Lysins of protein-ligands were derived from the short heterobifunctional linker N-succinnimidyl-3-(S-acethylthio)propionate (SATP) and subsequent deprotection with NH_2OH led to reactive SH groups [16.18]. Since it is very delicate to react distinct lysins with this method, the coupling to the crosslinker is often not specifically site directed. Several protocols are commercially available (Pierce, Rockford, IL) to generate active antibody fragments with free cysteines. Half-antibodies are produced by cleaving the two disulfides in the central region of the heavy chain using 2-mercaptoethylamine HCl [16.20] and Fab fragments are generated from digestion using papain [16.11]. The most elegant methods are to mutate a cysteine into the primary sequence of proteins and to append a thiol to the end of synthesized DNA strands [16.6], because they allow for a defined, sequence-specific coupling of the ligand to the crosslinker.

A nice alternative for a most common, strong but noncovalent site-directed anchor on the spacer has been introduced recently. The binding strength of the NTA (nitrilotriacetate) - His_6 (histidine 6) system, routinely used on chromatographic and biosensor matrices for the binding of recombinant proteins to which a His_6 tag is appended to the primary sequence, was found to be significantly larger than typical values of other ligand-receptor systems [16.21–23]. Therefore, a crosslinker containing an NTA residue is ideally suited for coupling a recombinant ligand carrying a His_6 in its sequence to the AFM tip. This general, site-directed, and oriented coupling strategy also allows rigid and fast control of the specificity of ligand-receptor recognition by using Ni^{++} as a molecular switch of the NTA-His_6 bond.

16.2 Fixation of Receptors to Probe Surfaces

For the recognition by ligands on the AFM tip, receptors should be tightly attached to probe surfaces. Loose receptor fixation could lead to a pull-off of the receptor from the surface by the ligand on the tip, which would consequently block ligand-receptor recognition and obscure the recognition force experiments.

Freshly cleaved muscovite mica is a perfectly pure and atomically flat surface and, therefore, ideally suited for MRFM studies. Moreover, the strong negative charge of mica accomplishes very tight electrostatic binding of certain types of biomolecules. Some receptor proteins such as lysozyme [16.20] or avidin [16.24] strongly adhere to mica due to the strong positive charge of these highly basic proteins at $pH < 8$. In this case, it is safe to purely adsorb the receptors from the solution, since the unspecific attachment to the surface is sufficiently strong for recognition force experiments. Nucleic acids are firmly bound to mica via Zn^{2+}, Ni^{2+}, or Mg^{2+} bridges [16.25]. Electrostatic interaction has also been used to adsorb the strongly acidic sarcoplasmic domain of the Ca^{2+} release channel via Ca^{2+}-bridges to probe the cytoplasmic surface [16.26]. Similarly, protein crystals and bacterial layers have been deposited onto mica in defined orientations with an appropriate choice of buffer conditions [16.27, 28].

In many cases, however, one cannot rely on electrostatic binding toward surfaces. Ideally, water-soluble receptors like globular antigenic proteins or extracellular protein chimeras are then anchored covalently. When glass, silicon, or mica is used as the probe surface, exactly the same surface chemistry described for the silicon AFM tips applies (see above). The number of reactive SiOH groups of the relatively chemically inert mica can be optionally increased by water plasma treatment [16.29]. Frequently, crosslinkers were also used on probe surfaces to provide the receptors with motional freedom, too [16.4]. Protein binding to photocrosslinkers thereby enables rigid temporal control of the reaction [16.30].

A major limitation of the silicon chemistry is the impossibility of reaching a high surface density of functional sites ($< 1{,}000/\mu m^2$). By comparison, a monolayer of streptavidin would consist of 60,000 molecules per μm^2 and a phospholipid monolayer would consist of 1.7×10^6 molecules per μm^2. The latter density is also achieved by chemisorption of alkanethiols to gold. Tightly bound, ordered, self-assembled

monolayers are formed on ultraflat gold surfaces and display excellent probes for AFM [16.10]. Alkanethiols can carry reactive groups at the free end that allow for covalent attachment of biomolecules [16.10, 31] (Fig. 16.3).

A recently developed anchoring strategy to gold uses dithio-phospholipids consisting of a propyldithio group at their hydrophobic end and either a phosphocholine head group (as host lipid) or a phosphethanolamine head group [16.32]. The latter head group is chemically reactive and was derived from a long chain biotin for the molecular recognition of streptavidin molecules in an initial study [16.32]. This phospholipid layer closely mimicks a cell surface and has been optimized by nature to afford little nonspecific adsorption. Additionally, it can be spread as an insoluble monolayer at an air-water interface. Thereby, the ratio of functionalized thio-lipids in host thio-lipids accurately defines the surface density of bio-reactive sites in the monolayer. Subsequent transfer onto gold substrates leads to covalent and, therefore, tight attachment of the monolayer, and thus it is suited for recognition force studies.

Immobilization of cells mainly depends on the type of cell. Cells with adherent growth are readily usable for MRFM, whereas cells that grow in solution without contact to a surface have to be adsorbed. Various protocols for a tight cell anchoring are available. The easiest way is to grow the cells directly on glass or other surfaces in their cell culture medium [16.33]. Various adhesive coatings like Cell-Tak [16.34], gelatin, and poly-lysin increase the strength of adhesion and/or display appropriate surfaces to immobilize spherical cells. Other hydrophic surfaces like gold or carbon are suitable matrices as well [16.35]. Covalent binding of cells to surfaces can be accomplished by using PEG crosslinkers as the one described for the tip chemistry, since they react with free thiols on the cell surface [16.34]. Alternatively, PEG crosslinkers carrying a fatty acid penetrate into the interior of the cell membrane, which guarantees a sufficiently strong fixation without interference with membrane proteins [16.34].

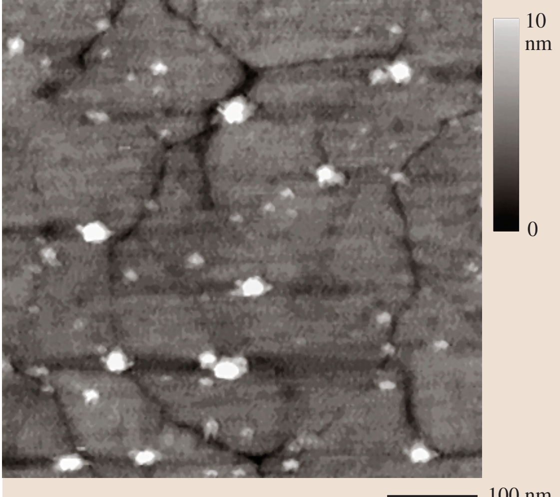

Fig. 16.3 AFM image of hisRNAP molecules specifically bound to nickel-NTA domains on a functionalized gold surface. Alkanethiols terminated with ethylene glycol groups to resist unspecific protein adsorption served as host matrices and were doped with 10% nickel-NTA alkenthiols. The sample was prepared to achieve full monolayer coverage. Ten individual hisRNAP molecules can be clearly seen bound to the surface. The more abundant, smaller, lower features are NTA islands with no bound molecules. The underlying morphology of the gold can also be distinguished (after [16.31])

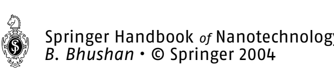
16.3 Single-Molecule Recognition Force Detection

Quantification of recognition forces goes back to ensemble techniques such as shear flow detachment measurements (SFD) [16.36] and the surface force apparatus (SFA) [16.37]. In SFD, receptors are fixed to a surface to which beads or cells containing ligands attach via their specific bonds. A fluid shear stress is applied to the surface-bound particles by a flow of given velocity that disrupts the ligand-receptor-bonds at a critical force. However, the unbinding force per single bond can only be estimated, because the calculation of the net force on the particle is complicated by the stress distribution and the number of bonds per particle is assumed from the geometry of the contact area.

SFA directly measures the vertical forces between two macroscopic surfaces containing receptors and ligands, respectively, using a spring as a force prober and interferometry for detection. Although SFA does not have a great sensitivity in measuring absolute forces and requires assumptions to be made for down-scaling to



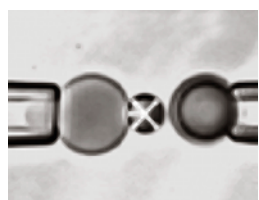


Fig. 16.4 Experimental setup of the biomembrane force probe (BFP). The spring in the BFP is a pressurized membrane capsule. Its spring constant is set by the membrane tension, which is controlled by micropipette suction. The BFP tip, a glass microbead of 1–2 μm diameter, was chemically glued to the membrane. Operated on the stage of an inverted microscope, the BFP (on the *left*) was kept stationary and the microbead test surface (on the *right*) was translated to/from contact with the BFP tip by precision piezo control (after [16.38])

single bonds, its z-resolution is highly accurate (better than 1 Å) over a long range. Adhesion and compression forces, as well as rapid transient effects can be followed in real time.

The bio force probe (BFP) technique (for a recent paper see [16.38]) (Fig. 16.4) uses soft membranes as the force transducer, rather than a mechanical spring. A single cell or giant vesicle is held by suction at the tip of a glass micropipette and its spring constants are adjusted by the aspiration pressure and can be varied over several orders of magnitude. Interaction forces with opposing cells, vesicles, or functionalized beads are obtained from the micromechanical analysis of the deformations of the membranes and/or via interference contrast microscopy. A force range from 0.1 pN to 1 nN is accessible with high force sensitivity down to the single-bond level.
