Dynamic Web Pages

Maristella Matera
Polytechnico di Milano University, Milan, Italy

Definition

They are Web pages that are composed at run-time, by dynamically extracting contents from a data source and composing them into pre-defined page templates.

Key Points

Historically, hypertext navigation was meant as a way to move among “static” documents, i.e., Web pages whose HTML code includes both the content to be presented, as well as the mark-up tags determining content rendition. Real-life Web applications however require the capability of serving to the users pages that dynamically publish content coming from one or more data sources. For example, the content of the home page of a news magazine is refreshed daily, by extracting the latest news from the news repository. This requirement goes beyond the original capabilities of the HTTP protocol, which is designed to exchange requests and resources between the browser and the server, and not to govern the process by which the desired resource is built.

Some server-side technologies have therefore been introduced to overcome these limitations and to enable the construction of Web pages “on the fly.” The most common solution is to adopt server-side scripting technologies (such as JSP or PHP), which enable inserting into an HTML page template some programming instructions that a server-side program execute to compute the contents to be extracted dynamically from the application data source. The result sent back to the client is then a properly formatted HTML page, including the extracted contents.

Other solutions imply the extension of the Web server, through execution engines (for example Java Servlet API) able to serve the requests for the dynamic construction of Web pages.

► Web Characteristics and Evolution

eAccessibility

Constantine Stephanidis[1,2]
[1]Foundation for Research and Technology – Hellas (FORTH), Heraklion, Greece
[2]University of Crete, Heraklion, Greece

Definition

eAccessibility refers to the access of Information and Communication Technologies (ICT) by people with disabilities, with particular emphasis on the World Wide Web. It is the extent to which the use of an application or service is affected by the user's particular functional limitations or abilities (permanent or temporary). eAccessibility can be considered as a fundamental prerequisite of usability.

Historical Background

The percentage of disabled citizens has increased dramatically in the last century due to life condition improvements, higher life expectancy, and population aging. This trend is anticipated to further increase in the next decades.

Traditional efforts to provide eAccessibility for users with disabilities were based on the adaptation of applications and services originally developed for able-bodied users. In the context of the Information Society, this raises the fundamental issue of granting to disabled citizens access to a variety of technologies that become progressively more entangled with all types of everyday activities.

Early technical approaches to eAccessibility mainly focused on two directions. The first treats each application separately, and takes all the necessary implementation steps to arrive at an alternative accessible version (*product-level adaptation*). Practically, product-level adaptation often implies redevelopment from scratch. The second approach "intervenes" at the level of the particular interactive application environment (e.g., MS-Windows) in order to provide appropriate software and hardware technology so as to make that environment accessible through alternative means (*environment-level adaptation*). The latter option extends the scope of eAccessibility to cover potentially all applications running under the same interactive environment, rather than a single application, and is therefore acknowledged as a more promising strategy.

The above approaches have given rise to several methods for addressing eAccessibility, including techniques for the configuration of input/output at the level of the user interface, and the provision of Assistive Technologies. Popular Assistive Technologies supporting eAccessibility include screen readers and Braille displays for blind users, screen magnifiers for users with low vision, alternative input and output devices for motor impaired users (e.g., adapted keyboards, mouse emulators, joystick, binary switches), specialized browsers (e.g., [10]), and text prediction systems (e.g., [4]). Assistive Technologies are legally defined in the US as "Any item, piece of equipment, or system, whether acquired commercially, modified, or customized, that is commonly used to increase, maintain, or improve functional capabilities of individuals with disabilities [15]."

Despite progress, Assistive Technologies and dedicated design approaches have been criticized for their essentially reactive nature [13]. Although the "reactive" approach to eAccessibility may be the only viable solution in many cases, it suffers from potentially serious shortcomings, such as limited and low quality access, as well as difficulties in development, maintenance, and keeping pace with technological evolution.

Therefore, the need for more systematic and proactive approaches to the provision of eAccessibility has emerged, leading to the concepts of Universal Access and Design for All.

Foundations

Universal Access implies the accessibility and usability of Information Society Technologies by anyone, anywhere, anytime, with the aim to enable equitable access and active participation of potentially all citizens in existing and emerging computer-mediated human activities. This can be achieved by developing universally accessible and usable products and services, which are capable of accommodating individual user requirements in different contexts of use and independently of location, target machine, or run-time environment. The discipline of Human-Computer Interaction (HCI) plays a critical role towards ensuring Universal Access to computer-based products and services, as users experience new technologies through contact with their user interfaces.

In the context of Universal Access, eAccessibility refers to the extent to which the use of an application or service is affected by the user's particular functional limitations or abilities (permanent or temporary), as well as by other contextual factors (e.g., characteristics of the environment). This implies that, for each user task of an application or service, and taking into account specific functional limitations and abilities, as well as other relevant contextual factors, there is a sequence of input actions and associated feedback, via accessible input/output devices, which leads to successful task accomplishment.

Universal Access is predominantly an issue of design. Thus, the question arises of how it is possible to design systems that permit systematic and cost-effective approaches to accommodating the requirements of potentially all users. To this effect, the concept of Design for All has been revisited in recent years in the context of HCI [14].

Design for All, or Universal Design, is well known in several engineering disciplines, such as, for example, civil engineering and architecture, with many applications in interior design, building and road construction. In the context of Universal Access, Design for All either subsumes, or is a synonym of, terms such as accessible design, inclusive design, barrier-free design, universal design, etc., each highlighting different aspects of the concept. It has a broad and multidisciplinary connotation, abstracting over different perspectives, such as:

1. Design of interactive products, services and applications, which are suitable for most of the potential users without any modifications. Related efforts mainly aim to formulate eAccessibility guidelines and standards. This is pursued in the context of international collaborative initiatives. A significant example is the effort carried out by the W3C-WAI Initiative in the area of Web accessibility guidelines [16]. Another source of web accessibility guidance is Section 508 of the US Rehabilitation Act [15].
2. Design of products which have standardized interfaces, capable of being accessed by specialized user interaction devices. An example of this approach is the Universal Remote Console, defined as a combination of hardware and software that allows a user to control and view displays of any (compatible) electronic and information technology device or service (or "target") in a way that is accessible and convenient to the user [18].
3. Design of products which are easily adaptable to different users (e.g., by incorporating adaptable or customizable user interfaces). The latter approach fosters a conscious and systematic effort to proactively apply principles and methods, and employ appropriate tools, in order to develop interactive products and services which are accessible and usable by all citizens in the Information Society, thus avoiding the need for a posteriori adaptations, or specialized design. This entails an effort to build access features into a product starting from its conception, throughout the entire development life-cycle [12].

Independently from the approach through which it may be achieved, accessibility aims to make the user experience of people with diverse functional or contextual limitations as near as possible, in terms of task accomplishment, to that of people without such limitations. Under a Universal Access perspective, accessibility has to be "designed into" the system rather than decided upon and implemented a posteriori. This raises several requirements regarding the methods, techniques and tools which can be used to integrate accessibility throughout the development lifecycle of interactive products and services. In this context, eAccessibility implies the concurrent (or adaptation driven) availability of alternative modalities, external devices and interaction styles to accommodate different needs. Therefore, multimodality plays a very important role [3].

Key Applications

eAccessibility is relevant to all interactive applications and services addressing citizens in the Information Society, in a variety of domains of everyday life, including healthcare, access to information, education, entertainment, and public administration. Some significant examples are reported below.

Web Accessibility

Access of disabled users to the World Wide Web involves the accessibility of both web content and browsing applications (web browsers). Web content accessibility is usually addressed through conformance to guidelines [16]. Various tools are available for the automatic or semiautomatic accessibility assessment and repair of web content [17]. More recent approaches go in the direction of automatic web content transformation to more accessible versions (e.g., [8]), as well as server side automatic adaptation [1]. Accessibility of web browsers is addressed through dedicated design for particular target user groups (e.g., blind users, [10]) as well as adaptation based approaches. The universally accessible AVANTI web browser [1] provides an interface to web-based information systems for a range of user categories, including: (i) "able-bodied" people, (ii) blind people, (iii) motor-impaired people with different degrees of difficulty in employing traditional input devices.

Media Accessibility

The term "rich media" indicates a broad range of digital interactive media downloadable or embedded in a web site, including video, animations, images, and sound. This type of content can be viewed or used offline with media players. Media accessibility is usually addressed through the provision of equivalent information perceivable through different senses, e.g., captioning, audio description, subtitling, and sign language translation. This requires the availability of authoring tools which support the appropriate provision of such information (e.g., [11]). Access to rich media by people with disabilities also requires the availability of accessible media players (e.g., [10]).

Accessibility in Education

eLearning systems typically rely on repositories of online materials that are made available to learners and teachers. The accessibility of eLearning content implies more than web or media accessibility, as it requires not only equivalence of information among different modalities, but also its appropriateness for the learning experience of users with diverse abilities. Meta-data classifications are under elaboration, which allow the classification of learning content according to the needs and preferences for alternative presentations of resources, methods of controlling resources, equivalent to the resources themselves and enhancements or support required by the user [9]. Access to educational material by people with disabilities also implies accessible software for the interactive delivery of such material, as well as authoring tools supporting the provision of educational content in an accessible form (e.g., [7]).

Game Accessibility

Computer games are usually quite demanding in terms of motor, sensor and mental skills needed for interaction control, and they often require mastering inflexible, quite complicated, input devices and techniques. These facts often render games inaccessible to a large percentage of people with disabilities. Furthermore, with respect to HCI, computer games have fundamental differences from all the other types of software applications for which accessibility guidelines and solutions are becoming available. Current approaches to game accessibility include the development of mainstream games compatible with the use of assistive technologies, the development of special-purpose games, optimally designed for people with disabilities, like audio-based games for blind people and switch-based games for the motor-impaired, as well as the development of universally accessible games. Examples of the latter approach are the UA-Chess web-based chess game [5] and Access Invaders ([6] – a universally accessible version of the popular classic "Space Invaders" action game), which can be played concurrently by people with different abilities and preferences, including people with disabilities (e.g., low-vision, blind and hand-motor impaired), and Access Invaders [17], a universally accessible version of the popular classic "Space Invaders" action game.

Future Directions

In the years ahead, as a result of the increasing demand for ubiquitous and continuous access to information and services, Information Society Technologies are anticipated to evolve towards a new computing paradigm referred to as Ambient Intelligence. Such an environment will be characterised by invisible (i.e., embedded) computational power in everyday appliances and other surrounding physical objects, and populated by intelligent mobile and wearable devices. Ambient Intelligence will have profound consequences on the type, content and functionality of the emerging products and services, as well as on the way people will interact with them, bringing about multiple new requirements for the development of Information Society Technologies. In such a dynamically evolving technological environment, accessibility and usability of such a complex technological environment by users with different characteristics and requirements can not be addressed through solutions introduced once the main building components of the new environment are in place. In such a context, the concepts of Universal Access and Design for All acquire critical importance towards streamlining accessibility into the new technological environment through generic solutions [2]. However, in the context of Ambient Intelligence, Universal Access will need to evolve in order to address a series of new challenges posed by the evolving technological environment. Such challenges include the distribution of interaction in the physical environment, the optimal degree of automation vs. human control, the identification of concrete human needs and requirements in such an environment, as well as issues related to health and safety, privacy and security, and social implications. In order to support the development of Universal Access solutions for Ambient Intelligence, new methodologies to capture requirements, appropriate development methods and tools, as well as design knowledge in the form of guidelines and standards will have to be provided, thus dramatically altering the current notion and practices of eAccessibility.

ECA Rule Action

Jonas Mellin, Mikael Berndtsson
University of Skövde, Skövde, Sweden

Definition

An ECA rule action is typically arbitrary code invoked if the condition of a triggered rule evaluates to true.

Key Points

The ECA rule actions are executed in response to events triggering rules whose conditions evaluates to true. The action is executed as part of a transaction or as a transaction depending on the coupling mode in the system. One major problem is that several actions can be executed concurrently and these may be in conflict. Another major problem is that executing an action may results in events triggering rules, that is, cascading rule triggering.

► ECA Rule Condition

ECA Rule Condition

Jonas Mellin, Mikael Berndtsson
University of Skövde, Skövde, Sweden

Definition

An ECA rule condition is either a database query, a logical expression or a call to a subprogram (function or method) executing arbitrary code returning true or false. If database queries are employed, then a non-empty set is equivalent to true and an empty set is equivalent to false.

Key Points

A key issue of an ECA rule condition is that it ought to take parameters carried by the event triggering the rule that, in turn, evaluates the condition. The condition either returns a set (as a result of an SQL query) or a boolean value (as a result of evaluation of the logical expression or the execution of the subprogram). An empty set is equal to false, and a non-empty set is equal to true. Another key issue is that results of the condition evaluation can be used to optimize rule action execution in many cases. Thus, there is a need to pass parameters from the condition evaluation to the rule action execution.

ECA Rules

Mikael Berndtsson, Jonas Mellin
University of Skövde, Skövde, Sweden

Synonyms

Triggers; Event-condition-action rules; Reactive rules

Definition

An ECA rule has three parts: an event, a condition, and an action. The semantics of an ECA rule are: when the event has been detected, evaluate the condition, and if the condition is satisfied, execute the action.

Historical Background

ECA rules are used within active databases for supporting reactive behavior and were first proposed in the HiPAC project [2].

Foundations

The semantics of an ECA rule is straightforward: when an event is detected, evaluate the condition, and if the condition is true, then execute the action. There are a number of reasons why the reactive behavior is abstracted to three different parts [1]:

First of all, events, conditions, and actions have different roles. An event specifies when to trigger a rule, a condition specifies what to check, and an action specifies what to execute in response to the event. Thus, the semantics of an ECA rule is clean, and avoids ad hoc mixing of events, conditions, and actions.

Second, the separation into events, conditions, and actions is also necessary if the application requires flexible execution semantics, i.e., coupling modes.

Third, the distinct roles facilitates optimization. The event part is a prerequisite for evaluating the condition, thus conditions are evaluated when the event occurs, and not always. If the active database only allows specification of rule conditions as query statements against the database, then the condition part is a pure question on the database state and the active database can thereby utilize well known query optimization techniques.

Finally, conceptual modeling of reactive applications is made simpler if there is a corresponding notion of events both within the application domain and within the active database.

e-Commerce Transactions

Jari Veijalainen
University of Jyvaskyla, Jyvaskyla, Finland

Synonyms

Electronic commerce transactions; EC transactions

Definition

"An electronic transaction is the sale or purchase of goods or services, whether between businesses, households, individuals, governments, and other public or private organizations, conducted over computer mediated networks. The goods and services are ordered over those networks, but the payment and the ultimate delivery of the good or service may be conducted on or off-line." [1]

A mobile e-Commerce transaction is an e-Commerce transaction that is initiated and performed using a *mobile device*, such as a mobile phone or a laptop, over a *wireless access network* or a *short-range wireless link*.

Key Points

E-commerce transaction was defined by OECD [1] from business and statistical perspective. The parties above can be individual customers (C), companies (B), or governments (A). One speaks accordingly about B2C, B2A, B2B, C2C e-Commerce and e-Commerce transactions. Historically, Electronic Data Interchange (EDI) was the first technology used in B2B and B2A e-commerce since 1970's. EDI is based on a number of agreed-upon (EDIFACT) message types whose instances are exchanged by the parties. Notice that B2C, B2A, B2B and C2C e-Commerce are usually governed by different laws. HTTP, HTML, and WWW server and browser technology matured during 1990's and E-commerce for individual customers (B2C, C2C) became possible. Physical (tangible) goods need to be delivered through a separate logistics channel, whereas digital information ("intangible goods") can be delivered through the same digital network as the order. Especially the global digital network ("Internet"), simultaneous emergence of suitable digital contents (software, music, videos, maps, etc.), and global payment infrastructure (credit cards, international banking) have made global digital B2C and other e-Commerce to explode since mid 1990's. Perceived as a distributed application one can require that a typical (B2C) e-Commerce transaction, during which a customer buys a good or goods, must satisfy *money atomicity, goods atomicity, and certified delivery* [2]. A more technical view is that an e-Commerce transaction is in general implemented as a distributed, hierarchical *workflow* crossing organizational borders. While performed, it must satisfy semantically defined atomicity constraints at each level [3]. Money atomicity and other desired properties follow from the constraints and thus the system implementation must enforce them. The challenges are that the steps must be performed by autonomous organizations, the workflow can last days or weeks (order book from USA to Europe) and that the originating entity (customer's terminal) cannot directly control the emerging execution or its duration, because it cannot decide or even know the emerging structure of the workflow. Rather, the latter is dynamically decided by the seller and its subcontractors (suppliers). A further challenge is that the customer can later optionally cancel the order and return the received goods to the seller. The time window typically varies from 7 to 30 days depending on the local consumer protection legislation. Conceptually, this possible phase belongs to the E-commerce transaction, but in practice this is taken care of by a distinct exception handling transaction that is often semi-automatically or manually performed.

Relevance evaluation of IR systems

Definition

In information retrieval (IR), effectiveness is defined as the relevance of retrieved information to a given query. System effectiveness evaluation typically focuses on the problem of document retrieval: retrieving a ranked list of documents for each input query. Effectiveness is then measured with respect to an environment of interest consisting of the populations of documents, queries, and relevance judgments defining which of these documents are relevant to which queries. Sampling methodologies are employed for each of these populations to estimate a relevance metric, typically a function of precision (the ratio of relevant documents retrieved to the total number of documents retrieved) and recall (the ratio of relevant documents retrieved to the total number of relevant documents for that query). Conclusions about which systems outperform others are drawn from common experimental design, typically focusing on a random sample of queries, each with a corresponding value of the relevance metric. These individual measurements for each query must be aggregated across a sufficiently large sample of queries to draw conclusions with confidence.

Historical Background

Effectiveness evaluation can be divided into user-centered evaluation, where users are given access to an information retrieval system and observed while attempting a task, and system (ad hoc) evaluation where the retrieval process is evaluated over multiple queries without user interaction. The Cranfield experiments defined information retrieval experimentation in terms of a document collection, a set of queries, and a corresponding set of relevance judgments for each of those queries [3]. However, they assumed that the relevance of every document in the collection would be judged for each query. The Text REtrieval Conference (TREC) extended this methodology to construct reusable test collections without judging every document in the collection. They achieve this by holding constant the test collection and query set, pooling the top X results (typically 100) from each system and manually judging each document in the pool as relevant or irrelevant. It has been shown that if X (the judgment depth) is sufficiently large, these collections are reusable, in that the relative effectiveness of runs from new systems over the same documents and queries can be evaluated simply by applying the existing judgments and assuming documents that are not judged are irrelevant [1]. Recent work examines how to scale evaluation to collections the size of the World Wide Web [2].

Foundations

Evaluation paradigms based on Cranfield (including TREC) make several common assumptions:

- Documents are either relevant or irrelevant (relevance is binary).
- Relevance of a given document is independent of any others (relevance is independent).
- The information need for which the query was derived does not change (static users).

Although these assumptions are obviously untrue in practice, they continue to be the basis for simplifying the evaluation problem. Various tracks at TREC have investigated search tasks where these assumptions are particularly broken. For example, navigational search, where users are looking for a particular destination as opposed to all of the information about a given topic was studied for several years [4].

The majority of published work in information retrieval leverages the TREC methodology and its reusable test collections. This is due not only to the scientific virtue of repeatable experiments, but also to the extraordinary effort required to evaluate the effectiveness of information retrieval systems. Judging more and more documents as new retrieval algorithms are evaluated is often prohibitive. However, the growth of very large document collections such as the Web has called into question the reusability of test collections developed in this manner. Rather, some results indicate that simply judging each of the top ranked results to a shallow depth for a larger number of queries may be more efficient for achieving reproducibility on such large collections [6]. Most recently, methods of incorporating automatic evaluations (such as click through evidence or known results from taxonomies) with manual ones have been developed to reach reproducible conclusions with less manual effort [5].

There are many specific metrics available for combined measurement of precision and recall, and for aggregating these measurements across queries. The F-measure is often used to combine point-wise precision and recall in tasks where only a single measurement of each is available. Evaluating ranked lists, however, provides an inherent threshold mechanism for taking many such measurements, each at a different depth into that list. Average precision combines these measurements at varying depths, and is aggregated across multiple queries by either the arithmetic mean (MAP – Mean Average Precision) or geometric one (GMAP – Geometric Mean Average Precision). Let AP_n represents the Average Precision value for a query from a set of n queries, then MAP and GMAP can be computed as follows:

$$MAP = \frac{1}{n} \sum_{n} AP_n$$

$$GMAP = \sqrt[n]{\prod_{n} AP_n}$$

R-precision takes the precision and recall measurements at depth R where R is the number of relevant documents for that query, which averages well across queries with varying numbers of relevant documents. The arithmetic mean of the R-precision values for an information retrieval system over a set of n queries is called the Average R-precision.

Other information retrieval tasks, such as navigational searches focusing on one correct answer, do not involve a recall component. These are often evaluated by the reciprocal rank of the correct result in the list. Specifically, the Reciprocal Rank value of a query is the reciprocal of the rank at which the first relevant result was retrieved for the query. When the Reciprocal Rank values are averaged across multiple queries, the measure is called the Mean Reciprocal Rank (MRR).

Key Applications

As in any field, improvements in information retrieval depend on the ability to evaluate. Researchers continue to leverage these techniques to refine retrieval algorithms. Search is also one of the most used features on the web, making evaluating its effectiveness critical.

Ehrenfeucht-Fraïssé Games

Nicole Schweikardt
Johann Wolfgang Goethe-University Frankfurt am Main, Frankfurt, Germany

Synonyms

Ehrenfeucht games; EF-games

Definition

The Ehrenfeucht-Fraïssé game (EF-game, for short) is played by two players, usually called the *spoiler* and the *duplicator* (in the literature, the two players are sometimes also called *Samson* and *Delilah* or, simply, *player I* and *player II*). The board of the game consists of two structures $\mathcal{A}$ and $\mathcal{B}$ of the same vocabulary. The spoiler's intention is to show a difference between the two structures, while the duplicator tries to make them look alike.

The rules of the classical EF-game are as follows: The players play a certain number r of rounds. Each round i consists of two steps. First, the spoiler chooses either an element a_i in the universe of $\mathcal{A}$ or an element b_i in the universe of $\mathcal{B}$. Afterwards, the duplicator chooses an element in the other structure, i.e., she chooses an element b_i in the universe of $\mathcal{B}$ if the spoiler's move was in $\mathcal{A}$, respectively, an element a_i in the universe of $\mathcal{A}$ if the spoiler's move was in $\mathcal{B}$.

After r rounds, the game finishes with elements $a_1,\ldots,a_r$ chosen in $\mathcal{A}$ and $b_1,\ldots,b_r$ chosen in $\mathcal{B}$, and exactly one of the two players has won the game. Roughly speaking, the duplicator has won if and only if the structures $\mathcal{A}$ and $\mathcal{B}$, restricted to the elements chosen during the rounds of the game, are indistinguishable. To give a precise description of the winning condition let us assume, for simplicity, that the vocabulary of the structures $\mathcal{A}$ and $\mathcal{B}$ only contains relation symbols. Precisely, the duplicator has won the game if and only if the following two conditions are met: (i) for all $i,j \in \{1,...,r\}$, $a_i = a_j$ iff $b_i = b_j$, and (ii) for each arity k, each relation symbol R of arity k in the vocabulary, and all $i_1,...,i_k \in \{1,...,r\}$, the tuple $(a_{i_1},...,a_{i_k})$ belongs to the interpretation of R in the structure $\mathcal{A}$ if and only if the tuple $(b_{i_1},...,b_{i_k})$ belongs to the interpretation of R in the structure $\mathcal{B}$.

Since the game is finite, one of the two players must have a *winning strategy*, i.e., he or she can always win the game, no matter how the other player plays.

Key Points

EF-games are a tool for proving expressivity bounds for query languages. They were introduced by Ehrenfeucht [1] and Fraïssé [3]. The fundamental use of the game comes from the fact that it characterizes first-order logic as follows: The duplicator has a winning strategy in the r-round EF-game on two structures $\mathcal{A}$ and $\mathcal{B}$ of the same vocabulary if, and only if, $\mathcal{A}$ and $\mathcal{B}$ satisfy the same first-order sentences of quantifier rank at most r (recall that the quantifier rank of a first-order formula is the maximum nesting depth of quantifiers occurring in the formula). This is known as the *Ehrenfeucht-Fraïssé Theorem*, and it gives rise to the following methodology for proving inexpressibility results, i.e., for proving that certain Boolean queries cannot be expressed in first-oder logic: To show that a Boolean query Q is *not* definable in first-order logic, it suffices to find, for each positive integer r, two structures $\mathcal{A}_r$ and $\mathcal{B}_r$ such that (i) $\mathcal{A}_r$ satisfies query Q, (ii) $\mathcal{B}_r$ does not satisfy query Q, and (iii) the duplicator has a winning strategy in the r-round EF-game on $\mathcal{A}_r$ and $\mathcal{B}_r$.

Using this methodology, one can prove, for example, that none of the following queries is definable in first-order logic: “Does the given structure’s universe have even cardinality?”, “Is the given graph connected?”, “Is the given graph a tree?” (cf., e.g., the textbook [4]).

In fact, the described methodology is the major tool available for proving inexpressibility results when restricting attention to *finite* structures. Applying it, however, requires finding a winning strategy for the duplicator in the EF-game, and this often is a non-trivial task that involves complicated combinatorial arguments. Fortunately, techniques are known that simplify this task, among them a number of sufficient conditions (e.g., *Hanf-locality* and *Gaifman-locality*) that guarantee the existence of a winning strategy for the duplicator (see e.g., the survey [2] and the textbook [4]).

Variants of EF-games exist also for other logics than first-order logic, e.g., for finite variable logics and for monadic second-order logic (details can be found in the textbook [4]).

Synonyms

eDictionary; Machine-readable dictionary (MRD); Terminological database

Definition

An electronic dictionary contains lexicographic information that is stored and accessed via a computer. The term "electronic dictionary" may refer to the data alone (e.g., a machine-readable dictionary), but more typically refers to a software or software/hardware system that provides access to dictionary data. Although a dictionary may include encyclopedic entries, it is typically distinct from an electronic encyclopedia. Terminological databases are special-purpose dictionaries that are used primarily to distinguish domain-specific terminology and choose appropriate terms when translating technical documents. Thesauri are special-purpose word books organized by relationships between words. They may contain definitions, but most famously, Roget's Thesaurus (available in electronic form from Project Gutenberg) does not.

Historical Background

The first widely available electronic data from print dictionaries were produced in 1966–1968 by John Olney at System Development Corporation. At that time, compositor tapes were created by commercial printers solely for their use in printing books under contract with publishers. Printers encoded typesetting information in proprietary formats. Even dictionary publishers had no access to the electronic form of the data. Therefore, to create an early electronic dictionary, Olney supervised the transcription of the contents of the Merriam-Webster New Pocket Dictionary (MPD) and the Merriam-Webster Seventh Collegiate Dictionary (W7) into punch-card images, which he subsequently distributed under license as multi-reel magnetic tape data sets.

As publishers began to realize the value of retaining the content of their dictionaries in electronic form, they began requesting printers to provide a digital copy of the typesetting data along with the print copies of the dictionary. The version of the Collins English Dictionary distributed by the Oxford Text Archive illustrates non-standard print formatting codes as used by commercial print houses.

Subsequently, publishers embraced text encoding standards, such as SGML. They teamed up with computer scientists to convert many of their books, including dictionaries, to use such standard formatting, and requested printers to typeset their dictionaries from these standard formats. The largest project to convert a legacy print text dictionary into contemporary markup text data was carried out by the Oxford University Press, in conjunction with IBM and the University of Waterloo, to computerize the Oxford English Dictionary [7].

The advent of the personal computer and CD-ROM readers led to the direct sale of CD-ROM versions of print dictionaries with proprietary interfaces and encodings of the text content. The World Wide Web also provided publishers with the opportunity to sell subscription-based access to electronic monolingual and bilingual dictionaries.

In 1978–1980, Amsler [2] directed a project at the Linguistics Research Center of The University of Texas at Austin to produce the first taxonomically structured dictionary from the Olney 1968 MPD. The project employed graduate students to manually "disambiguate" the kernel terms in dictionary definitions, providing the basis for connecting the dictionary entries defined by those terms into a "tangled" hierarchy. Olney had proposed such an enterprise a decade earlier, but had run out of funding before it could be undertaken.

Subsequent to Amsler's work, Roy Byrd [3] at IBM began a comprehensive program of computational lexicology work to use the contents of the W7 for computational linguistics. Using a new parsing algorithm for dictionary definitions, Byrd et al. also created a taxonomically structured version of the W7, but due to copyright restrictions neither the Amsler nor the Byrd taxonomic dictionaries were ever redistributed.

In 1986, George Miller planned the creation of the WordNet electronic dictionary to test psychological theories of semantic memory [4]. WordNet Version 1.0, released in 1991, offered alphabetic and taxonomic access to English definitions. Miller avoided copyright issues by creating his own definition texts, making it possible to widely distribute WordNet for others to use in academic and commercial ventures. WordNet has spawned the creation of other special-purpose electronic dictionaries, including monolingual and bilingual WordNets for languages other than English. It remains the major free electronic dictionary available to the research community.

Foundations

Dictionaries are among the most complex documents, owing to the large number of distinct fields they contain. The structural elements found within electronic dictionaries are typically represented by XML tags or some other form of markup, such as described by the Text Encoding Initiative [6].

A typical entry in a conventional monolingual dictionary begins with a headword, usually divided into syllables, and optionally including a homograph number to distinguish the entry from others with the same headword. This is followed by the pronunciation(s), with high and low stress marks for its syllables, followed by any variant pronunciations. Next there are part-of-speech (POS) labels, other labels that reflect general usage (e.g., whether a word is formal or colloquial, whether its use is geographically restricted, and whether it is used primarily within one discipline), and inflected forms of the headword, if any. An etymology may follow, containing various language designations together with the word forms or affixes from which the headword is believed to have been derived. The etymology might also include dates and names of specific individuals when a headword's origin is reported to come from a specific person or event.

Definitions in a major dictionary are divided into distinct senses, sub-senses, sub-sub-senses, etc., down several levels. The order of the senses in a dictionary is typically either historical, with the earliest senses first, or prioritized from most common to least common senses. Each sense may include labels that document its use as being restricted to a particular region or to a particular discipline, and it may be illustrated by one or more example sentences. In the oldest dictionaries, examples were taken from notable authors, but this practice has given way to artificially constructed examples designed to be simplified illustrations of the meaning and usage of the sense. Definitions may also contain cross-references to specific senses of related headwords.

Following the definitions may be several additional entry features. These include so-called run-on entries, which are morphologically related extended forms of the headword that do not warrant their own entries elsewhere in the dictionary. These will typically have their own syllables, parts of speech and pronunciations listed. There may also be run-on entries for common phrases. Finally, an entry may also contain special treatments of synonyms and antonyms for the headword.

Key Applications

In addition to the use of dictionaries to look up individual words and their meanings (or translations), electronic dictionaries have been used in two major application areas. The first was to better understand the nature of lexical semantics through construction of taxonomies out of dictionary definition texts [2]. The second was to utilize electronic dictionaries for computational linguistic tasks ranging from morphological analysis and speech generation through word sense disambiguation. The former purpose led to WordNet and the growth of ontologies in artificial intelligence. The latter, while initially seen as promising, led to disappointment on the part of many computational linguists when they found print dictionaries inadequate to the tasks of reliably performing all computational linguistic processing tasks. However, the introduction of large electronic dictionaries changed the nature of computational linguistic system development to step away from "toy system" lexicons of a few hundred words to forever establish that systems had to be prepared for electronic dictionary-sized lexicons. Subsequently some computational linguists have embarked on creating specialized computer-based lexical resources [5]: electronic dictionaries that exist independently of the publishing community and contain advanced syntactic and semantic information.

eEncyclopedia

Definition

An electronic encyclopedia, like its print counterpart, provides extensive information covering general knowledge or specific disciplines through a vast collection of small articles, typically arranged alphabetically or indexed by title. Initially, electronic encyclopedias were restricted to ASCII encodings of the text portions of entries in print encyclopedias. Advances in the representation and presentation of universal character sets, images, sound, video, and interactive graphics allow today's electronic encyclopedias to present multimedia articles that are competitive with those found in conventional print encyclopedias.

Key Points

Electronic encyclopedias were initially computer-based delivery systems for their printed counterparts, accessed primarily via optical media or over computer networks. More recently, Wikipedia has demonstrated the effectiveness of collaborative co-authoring to create an electronic encyclopedia that has no print equivalent.

Encyclopedias need to be current: if not continually updated, they become obsolete with each change in geo-politics, scientific advance, or the death of a prominent individual. Furthermore, whereas print encyclopedias have elaborate indexes, taking up one or more volumes of their printed text, they cannot support compound searches. By supporting Boolean search, an electronic encyclopedia offers the ability to combine multiple concepts unanticipated by the encyclopedia editors. For example, it can support searches for entries that mention both (Winston) Churchill and (Albert) Einstein, and reveal that both won Nobel Prizes.

Entries in an electronic encyclopedia are typically multimedia articles, having text encoded with XML. Many articles also contain hyperlinks to other entries (or even to other potential entries that do not yet exist, as in Wikipedia).

Unlike commercial encyclopedias, Wikipedia is a free Web-based encyclopedia that allows readers to create and modify its content. For example, if a Wikipedia reader follows a link to a non-existent entry, the software invites the creation of the entry and will immediately accept any text offered as the body for that entry. Readers are also encouraged to update any entry deemed to be incorrect or out of date. This form of bootstrapping provides for the rapid creation of numerous entries and the editing of information in existing entries. Each editing change becomes a new entry, but can be "reverted" back to the prior entry by a future editor. Entries also have discussion pages on which authors and potential editors can comment on their content or explain their editing changes. Modification of an entry can trigger the sending of email to prior authors if they so choose, which gives authors some control over what happens to their text. In the event there are irreconcilable differences between multiple authors, the Wikipedia core group can lock down the article text and request authors to instead debate the changes in the comments pages.

Due to its large user base and the ability to monitor and revert entries to prior states, Wikipedia has flourished with millions of entries in multiple languages. However critics have questioned how it can achieve and maintain a high level of accuracy in the absence of authoritative controls over its contributors.

As well as including conventional encyclopedic information, Wikipedia has achieved broad coverage of popular culture, much of which has traditionally been regarded as trivia and unsuitable for inclusion in a print encyclopedia. Yet, for decades there have been specialty publications on trivia, crossword puzzle terminology, and special reference works for every conceivable category of information. Thus Wikipedia is more than an alternative to traditional encyclopedias: it is a potential replacement for all reference works.

The Wikipedia software is also freely available and has spawned the growth of numerous additional Wiki-based encyclopedias on the World Wide Web. Wiki software is used behind the scenes in many informational web sites. Modifications to the permissions allow Wiki software to restrict changes in content to select groups and thus permit its use in a variety of circumstances.

Electronic Health Record

Amnon Shabo (Shvo)
IBM Research Lab-Haifa, Haifa, Israel

Synonyms

Virtual health record; Shared health record; Longitudinal health record; EHR

Definition

An electronic health record (EHR) is a standard-based machine-processable information entity consisting of health data pertaining to an individual. It is a result of an exhaustive aggregation of personal health data, which is longitudinal, cross-institutional and multimodal.

Historical Background

The term "medical record" usually refers to any recording/documentation of medical care or services given to a patient. The use of computerized patient records within healthcare enterprises is already a common and well-appreciated practice that has started about four decades ago [8]. It facilitates the documentation process required for medico-legal reasons and administrative procedures [10]. It also increases the availability of clinical data at the point of care which includes medical history, lab results, diagnostic imaging and so forth. The availability of such data at the point of care could help avoiding redundant tests thus saving time and cutting costs. It could also reduce medical errors and increase the overall quality and safety of care [9].

Nevertheless, medical records are typically partial and contain incomplete and inconsistent data due to fragmentation in the healthcare arena [5] where data is created in disparate systems of various healthcare providers, from single-physician offices to expert clinics, hospitals and large HMOs (health managed organizations) to name just a few (Note that the generic term "medical record" is used to refer to records also known by the acronyms Electronic Medical Record (EMR), Computerized Patient Record (CPR), and Electronic Patient Record (EPR)). In addition, the computerization of the traditional paper-based records and charts has been slow thus far and the user interfaces of many clinical information systems have been poorly designed causing time-pressed clinicians to avoid the use of it altogether.

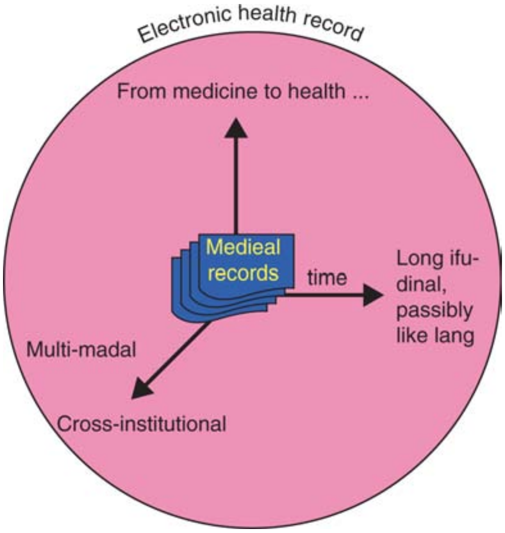
These factors and others made the benefit of computerized patient records quite limited. This situation gave rise to the emerging concept of an electronic health record (EHR). An ISO technical report [11] states that "Previous attempts to develop a definition for the Electronic Health Record have foundered due to the difficulty of encapsulating all of the many and varied facets of the EHR in a single comprehensive definition." The report lists several definitions of EHR which demonstrate the various aspects of EHRs versus medical records such as the focus on sharing data to support integrated care. In an attempt to consolidate the various definitions, the ISO report presents the following combined definition: "A repository of information regarding the health of a subject of care in computer processable form, stored and transmitted securely, and accessible by multiple authorized users. The EHR has a standardized information model which is independent of EHR systems. Its primary purpose is the support of continuing, efficient and quality integrated healthcare and it contains information which is retrospective, concurrent and prospective."

As a result of the above challenges, there have been several attempts in the past decade to realize the emerging EHR concept through national EHR efforts (e.g., in the UK [3]), regional health information exchange efforts (e.g., in the US [1]) as well as through eHealth initiatives (e.g., the Danish national eHealth portal [2]). Most of those attempts are still facing challenges due to several reasons ranging from technical issues in integrating data from dispersed sources, to the semantic differences between various formats used by healthcare providers and to socio-economic and medico-legal issues such as privacy, ownership of the EHR, access rights, governance and business models of organizations undertaking the sustainability of patient-centric EHRs.

Foundations

The term “health record” refers to an information entity which extends the traditional medical record entity described in the previous section. The extension occurs along three dimensions (Fig. 1):

1. Content: A health record contains any health-related information including self documentation, life style, environmental data, personal preferences, etc. and is not limited to medical data as in medical records.
2. Source: While a medical record is created by a healthcare provider in order to record the care or services given to a patient by that provider, a health record is a broader information entity in the sense that it aggregates recordings created by all healthcare providers regarding that patient as well as other sources of data pertaining to the health of the patient.
3. Time: A health record is a longitudinal information entity aggregating data created possibly throughout the lifetime of the individual, while a medical record is typically a recording of medical care or services given to a patient at a specific point in time.



Electronic Health Record. Figure 1. Extending the traditional enterprise medical record information entity to the all-encompassing EHR.

It is important to note that this encyclopedia entry describes the EHR information entity and does not deal with information systems that handle medical and health records. Most of these “EHR Systems” maintain medical records of a single enterprise and cannot cope with the EHR information entity as defined here.

The following sections describe each of the extension dimensions in more detail:

Content

Extending the content of medical records to any health-related data involves the integration of data types that have not been traditionally captured in medical records such as the self documentation of habits and events as experienced by the individual, whether instructed by a healthcare professional or self initiated. Other types of data include environmental and workplace related data that can provide context to clinical data and may support reasoning about possible diagnoses and treatments. A great challenge is the personal genetic data (e.g., personal DNA variations) that can assist in the realization of the personalized medicine vision [4]. While genetic data seems yet another type of lab results, there are many differences that make it distinct and rarely captured in common medical records. In particular, the notion of genomics refer to new tests and assays applied to multiple genes interacting through complex biological pathways where personal changes in the DNA sequence as well in the expression levels of coding DNA and resulting polypeptides have significant impact on the health of that individual. The challenge in this type of data is not only its complexity and rapid changing nature but also the association to phenotypic data, whether observed in the patient or scientifically known as possible interpretations of the genetic/genomic observations. The creation of genotype-phenotype associations relevant to an individual is perhaps the greatest challenge of the emerging health record concept. Only coherent and standard presentation can enable the safe and efficient use of this diverse data set to the benefit of the patient [13].

Source

Extending the typical single-enterprise source of medical records involves sharing data from multiple healthcare providers, expert clinics, community health services, clinical testing laboratories, diagnostic imaging facilities and any other institute that creates data about an individual. Sharing data for providing better care to a patient is challenging both semantically and technically wise.

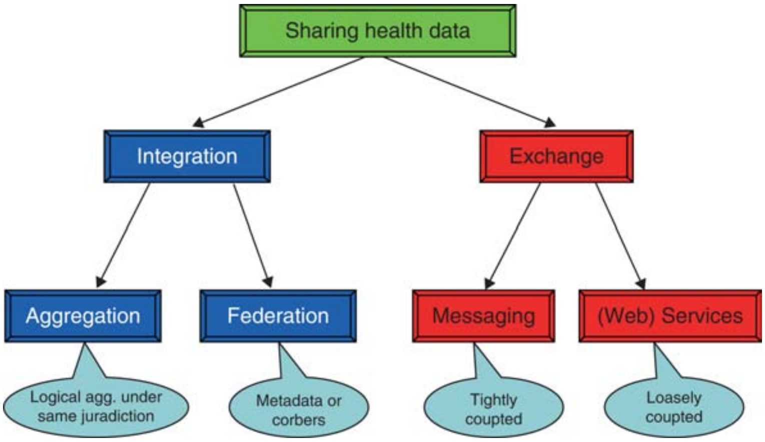
At the semantic level, the challenge is to reconcile the various formats by which the various medical records are created. The format of a medical record includes the structure (e.g., database schema, message definition, etc.) and values assigned to data items in a given structure (numeric value, medical codes, time spec, free text, etc.). To come up with a meaningful longitudinal view of the health record, it is essential to normalize the various proprietary representations of the source data; however, the lack of clear definition of the record structure could seriously hinder such effort.

At the technical level, the challenge is to find the most appropriate approach to fulfilling the requirements of information systems which handle electronic health records. The two main approaches of sharing data are exchange and integration. Data exchange is typically limited to a small number of systems exchanging information (e.g., point-to-point messaging) although the emerging service oriented architecture makes the service-based exchange more flexible.

Data integration is the preferred approach for the creation of EHRs. In principle, integration can be achieved by means of federation or aggregation (Fig. 2). In data federation (also known as "integration on the glass"), the source data is typically maintained by the enterprise where it was created and the EHR is compiled "on demand" by accessing the various sources, retrieving the data and presenting the compilation to the user. Curation and normalization are difficult to achieve at the point of care when interactive response times are expected. Efforts have been made to reach a consensus around federated formats suitable for clinical decision support and these formats are usually called Virtual Medical records (VMR). In contrast, data aggregation can be done in an on-going fashion bringing all source data into the EHR and reconciling each new item with the existing normalized record. At the point of care when the EHR is requested, an information system that aggregated the data can serve a coherent EHR in a timely fashion. The caveats of data aggregation have to do mainly with legal issues such as the release of health data by a healthcare provider and addressing privacy issues appropriately so that the EHR is highly secured and only authorized access is allowed based on proper consent of the patient. Note that the technical issues of data integartion have many governance implications and are influenced by national/regional policies as well as considerations at the socio-economic and medico-legal level [14].

Time

Medical records are typically episodic, describing visits, operations, hospitalizations, consultations and



Electronic Health Record. Figure 2. Major paradigms of data sharing through which an EHR could be created.

other services occurred in specific points in time. An EHR is a longitudinal aggregation of health data that embeds the temporal medical records along with other relevant data in a way that provides the opportunity to computationally create summaries of the data such as (i) non-redundant lists of essential data such as allergies, immunizations, diagnoses, medications etc. and (ii) useful summaries of the data such as a topical view (e.g., all data pertaining to a specific disease of the patient) or an event view (all data pertaining to a trauma the patient has gone through).

Unlike medical records, the EHR is ideally a single information entity per individual and its main value added is that it enables the creation of information layers atop of raw data (Fig. 3).

Key Applications

The main application of an electronic health record is an EHR system – a computerized information system that handles EHR information entities. EHR systems are expected to create, maintain and serve patient-centric EHRs to all authorized parties. Example of such systems are those built within the recent national and regional efforts across the globe aiming at sharing of health information in order to provide better care for the individual. Other emerging systems related to EHR are those handling the so-called Personal Health Records (PHR) – a type of EHR which is typically owned and controlled by the individual with emphases on the personal aspects in EHR such as self documentation, life style, preferences, and the like.

To overcome the diversity of formats used in the various sources integrated by an EHR system it is crucial to use standardized formats, preferably internationally-recognized EHR standards. Indeed, in the recent years, two significant standards have been developed and published by international standards development organizations. Health Level Seven coordinated an intensive international effort to publish a Functional Model Standard for EHR [7] and the European Standardization Body (CEN) has finalized an information model for EHR along with a new constraining formalism [12] to enable the standard representation of common health data sets within the EHR.

A somewhat related standard is the Clinical Document Architecture (CDA) that provides an electronic counterpart of the so common paper-based clinical documents such as operative notes, discharge summaries, referral letters and so forth [6]. These documents are a natural input to the longitudinal EHR as they typically include summary of patient's health conditions. All those standards complement each other and lay the ground for EHR Systems to finally be ready to achieve the ultimate goal of a patient-centric, standard-based, longitudinal and cross-institutional electronic health record.

A key application in the area of sharing and managing clinical documents as a step towards the EHR is an integration profile that has been developed by the IHE (Integrating the Healthcare Enterprise) and is coined XDS (Cross-enterprise Document Sharing [15]). The XDS integration profile is in fact a workflow specification that a clinical affinity domain (CAD) employs in order to share clinical documents created in disparate locations about the same patient. A CAD is established by enterprises that create and maintain

EHR

Electronic Health Record. Figure 3. Layers of temporal and summative data constituting the EHR.

clinical documents and decided to share the documents through the affinity domain. Each CAD has a centralized registry where metadata about each document (e.g., the patient, author, authenticator, encounter, services, etc.) are registered by "document sources" so that queries can be posed by "document consumers." The retrieved data from the registry includes merely the metadata and once the document consumer selects documents of interest, the registry then approaches the relevant documents repositories residing in the respective premises of the CAD cooperating enterprises. Given proper authorization of the document consumer, the selected documents are then presented to the consumer. These documents could then be further processed to provide summary or analysis content per the user request. Such processes are complex to perform "on-the-fly" but the hope is that simple analyses could show the benefits of EHR to users who then might demand the creation of a coherent patient-centric EHR out of all available clinical documents and other types of medical records.

It is important to note that the XDS architecture doesn't allow for fully querying of the clinical documents stored in the enterprise repositories. The query can be done only against the metadata that was registered by the document sources. Queries by clinical data that is typically held in the body of the documents cannot be queried using the XDS integration profile. Nevertheless, the addition of an EHR data model on the top of an XDS architecture could then make the XDS repositories fully structured according to an EHR data model such as that of the CEN 13606 standard. Systems with such capabilities will also lend themselves to queries which are not patient-specific, e.g., search for data by disease, pathogens, populations and even genetic data.

Electronic Ink Indexing

Walid G. Aref
Purdue University, West Lafayette, IN, USA

Synonyms

Handwritten text; Online handwriting

Definition

With the proliferation of personal digital assistants (PDAs) and pen-based handheld devices, it is important that computers understand handwritten text (or electronic ink). In this pen-based environment, one can have handwritten file contents, handwritten file names, handwritten directory names, handwritten email messages, handwritten signatures, etc. With the large bodies of handwritten content, indexing techniques are essential in order to search for the relevant content. The fact that the data is handwritten makes the problem more difficult than in conventional situations. No two persons handwrite a word in exactly the same way. Even the same person cannot write a word in the same way twice. This makes the indexing and retrieval of handwritten data a hard problem.

Historical Background

Retrieval techniques for handwritten data have to be scalable so that they can handle the continually growing sizes of multimedia data, e.g., scanned documents in digital libraries and handwriting databases. An additional requirement for ink processing in a pen-based and/or a personal digital assistant environment is the need to support online retrieval and fast response time. There are two approaches to dealing with handwritten electronic data, namely, handwriting recognition and ink pattern matching.

Handwriting recognition is a procedure for converting pen strokes into strings of characters (or any other fixed character set). Once converted into characters, strings can be manipulated and searched in conventional ways. One problem with handwriting recognition is that it is prone to errors. Many critics point out that handwriting recognition does not meet the need of users. In fact, it is widely believed that this shortcoming is one of the main causes why the sales of pen-based tablets have fallen short of the expected figures. Moreover, even if handwriting recognition becomes highly accurate, it is clear that it provides a mapping from a highly expressive medium such as ink to a constrained medium, such as character strings. Handwriting recognition is not directly applicable to diagrams, drawings and many special symbols that the user can write.

Because of the drawbacks of handwriting recognition, the notions of *approximate ink matching* (AIM) and *pictograms* have emerged as an interesting alternative to handwriting recognition [11]. Pictograms are simply handwritten pictures, while AIM is the technique that evaluates how well two pictograms match. By using pattern matching techniques, AIM can take an input pictogram and evaluate how well it matches each one of the previously stored pictograms. AIM eliminates the problems of expressiveness, language and alphabet dependency and inaccuracy of handwriting recognition. The procedure simply focuses on finding a pictogram that resembles the input, without trying to "understand" or translate its meaning. AIM algorithms with high matching accuracy have been developed.

The problem with the AIM technique is that it could be computationally expensive. Without any other tool, AIM techniques are forced to sequentially search the entire pictogram repository. As the size of the pictogram repository grows, this process becomes painfully slow and impractical, especially that pattern matching techniques can be computationally expensive. This highlights the need for scalable techniques that provide fast response time for retrieval queries in handwritten databases of larger sizes.

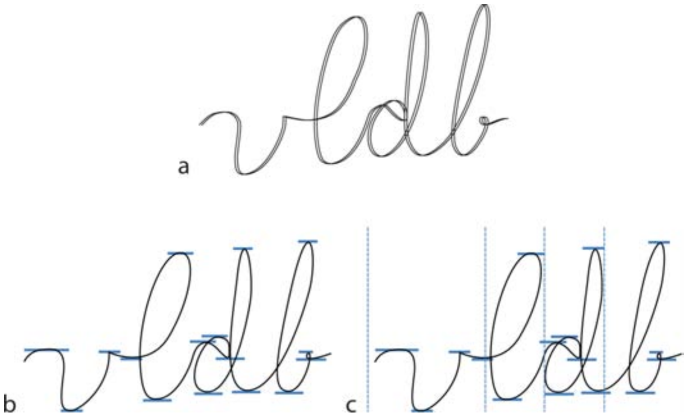
Foundations

Electronic handwritten ink in the form of a pictogram needs to be transformed into a more robust form before being passed to the database for further processing. This transformation needs to take place regardless of whether the pictrogram is to be inserted into the database, or used within a query to search the database. Electronic ink can be expressed as a sequence of time-stamped points in the plane:

$$s = (x_1, y_1, t_1), (x_2, y_2, t_2), \ldots., (X_k, Y_k, t_k),$$

where (x_i, y_i) represents the location of an electronic ink pixel at time t_i, $t_i \leq t_{\,i} + 1$, and k is the number of pixels in the pictogram.

Given a sequence S and a database of sequences S_j $(j = 1, \ldots, M)$ an important operation is to search the database for the sequences that are similar to S. Traditionally, databases use an alphanumeric representation of the data. This representation is ideally unique, precise and stable. Electronic ink data lack these qualities, making its matching a difficult problem. The data are often corrupted with noise. Even ideal ink does not provide an adequate basis for sequence identification, because a pictogram needs to be identified given slightly different variations in its shape. Different people cannot write the same word in the same way. Even for the same person, it is very difficult to generate *exactly* the same pictogram twice (it will almost always be the case that the stroke information varies each time the person writes the same word).

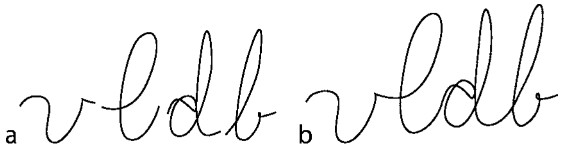


Electronic Ink Indexing. Figure 1. Example illustrating the segmentation of the pictogram in (a) into (b) strokes, and (c) alphabet symbols.

Electronic Ink Representation

In order to allow for approximate matching of handwritten electronic ink, each handwritten pictogram needs to be transformed into a more robust form. The raw electronic ink data that corresponds to points (or pixels) in the two-dimensional space is not robust as a slight shift in the input sequence may change the values of the x and y coordinates of the points representing a word. As a result, other features that are less sensitive to common deformations, e.g., translation, and rotation, are computed. Example features are the bounding box that contains all the points that form a pictogram, the average curvature, the number of points, etc.

These features can be computed at different levels of granularities. In this regard, handwritten electronic ink can be viewed at three levels of abstraction: the stroke level, the alphabet symbol level, and the pictogram level. Figure 1 illustrates a pictogram and its segmentation into pen strokes and handwritten symbols. Pictograms can be represented by any of the three granules in the figure, i.e., as one entity containing the entire pictogram (Fig. 1a), as a sequence of pen strokes (Fig. 1b), or as a sequence of alphabet symbols (Fig. 1c). For instance, in order to select the symbols as granules, a segmentation algorithm is needed to properly separate the symbols. For strokes, a simple segmentation algorithm picks local minimum (or maximum) points and uses them to segment the curve. Segmentation could be a difficult task for some types of pictograms, such as cursive handwritten words (Fig. 2b), or a simpler task as in handprinted words (see Fig. 2a). Some languages, like Japanese, lend themselves easily to symbol segmentation. In Japanese, Kanji symbols are already separated by blank spaces. The choice of granularity has an impact on the type of indexes to be built.



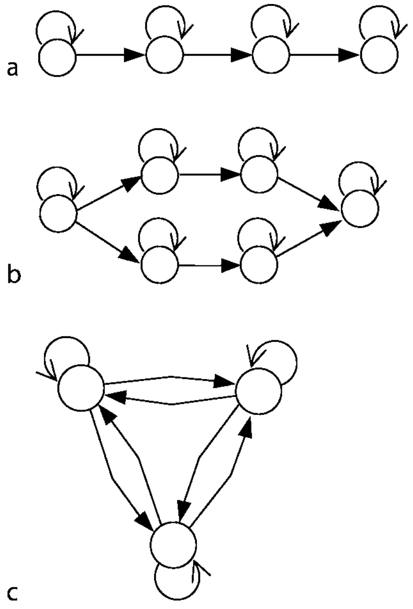
Electronic Ink Indexing. Figure 2. A handprinted word, (b) a cursive handwritten word.

The second issue is that, for matching purposes, it is better to talk about pictogram (symbols or strokes) classes instead of individual pictograms (symbols or strokes). A pictogram class is the set of pictograms that have the same semantics, according to the user. Of course, it would be impractical to store a pictogram class by storing the list of pictograms that belong to it. Alternatively, a *representative* of the class and a *distance metric* needs to be adopted. Inputs are matched against the representative (after the necessary preprocessing) and the distance metric ranks the matches. The representative is not a pictogram, but rather a model that captures the essential qualities of the pictogram class. In the next section, a sample model is presented that can be used to represent pictograms.

Hidden Markov Models (HMM)

HMMs are already used in the field of speech and handwriting recognition as a powerful tool for speech and handwritten document matching (see e.g., [11–13,15]). Each pictogram in the database can be modeled by an HMM. The HMM is constructed so that it accepts the specific pictogram with high probability (relative to the other pictograms in the database). In order to recognize a given input pictogram, each HMM in the database is executed and the one that generates the input sequence with the highest probability is selected. Each HMM in the underlying sequence database has to be tested, which results in a linear process, and the speed of execution becomes the primary difficulty.

An HMM is a doubly stochastic process, where there is a probability distribution that governs the transitions between states and an output probability distribution that identifies the distribution of output symbols for each state. An excellent coverage of HMMs can be found in [12,13]. For demonstration purposes, one type of HMM structures, termed *left-to-right HMM* [5] is illustrated in Fig. 3a. Left-to-right HMMs are useful for modeling temporal signals as in sound (see e.g., [13]) and cursive handwritten text (see e.g., [11]) because the underlying state sequence associated with the model has the property that, as time increases, the state index increases (or stays the same) – that is, the system states proceed from left to right.



Electronic Ink Indexing. Figure 3. (a) a left-to-right HMM model with four states, (b) a parallel path left-to-right HMM model with six states, and (c) the ergodic model with three states.

A left-to-right HMM can be constructed to model a handwritten word or an alphabet symbol. The HMM is constructed so that it accepts the word (or the symbol) with high probability (relative to the other words in the database). Training techniques may be applicable in the case where multiple instances of the word are available (e.g., a word can be handwritten multiple times, resulting in more than one sample). These samples can be used to train the HMM so that it can match similar words with higher probabilities (see e.g., [1,10]). The probability given by the HMM is the distance metric used for ranking purposes.

Given an HMM that models a word (or symbol), an input symbol can be run against the HMM to obtain as output a matching probability. Given a set of stored words (or symbols) with their associated HMMs, an input word (or symbol) can be searched by running each one of the corresponding HMMs against the input and choosing those with the best matching probability. In fact, the size of the answer set can be set as a parameter to choose the k best matches. To train HMMs and to use them to match a word or a symbol, a more robust form of ink representation needs to be used.

Representation Granularity

Features can be computed at the stroke level, pictogram level, symbol level, or through a collection of local features. For example, in the case of a stroke, a pictogram is segmented into a set of strokes, where each stroke is carefully described with a set of features. Thus, a pictogram can be represented by a collection of points in the feature space, one point per stroke. In contrast, at the pictogram level, a set of global features can be computed for the entire handwritten pictogram. Thus, each pictogram is described with a vector of feature values and is represented as one point in a multi-dimensional space.

Another simple, but efficient way of representing a pictogram is to pick some sample points from the pictogram (or symbol, or stroke) and compute some local features, ones that depend on a sample point and possibly the one (or two) surrounding points from each side. Depending on the application, some of these features may be more relevant than others, and hence not all of the features need be computed at a given point in the sequence. Common features are: direction, velocity, change in direction, change in velocity, accumulative angle (with respect to the initial point), accumulative length and angle of bounding box diagonal (also with respect to the initial point), and accumulative sequence length [14]. As an example of computing local features, the speed f_s at point p can be computed by: $f_s = sqrt(\Delta x_p^2 + \Delta y_p^2)/\Delta t_p$, *where* $\Delta x_p = x_{p+1} - x_p$, $\Delta y_p = y_p + 1 - y_p$, and $\Delta t_p = t_p + 1$ $t_p + 1 - t_p$. After computing the local features, the pictogram can be represented by a sequence of feature vectors (v_1, t_1), (v_2, t_2),... The dimensionality of v_i corresponds to the number of local features at each point.

Indexing Techniques

Sequential search does not scale well. The process becomes unacceptably slow as the number of pictograms stored in the database grows. Therefore, indexing techniques that help prune the choices are called for. However, indexing techniques for handwritten pictograms must exhibit two characteristics that make them different from traditional indexing techniques:

1. The structures must incorporate the underlying model that is chosen to represent ink. The model must play an active part of the index.
2. Due to the high variability of the ink data, the indices must provide approximate matching.

The following sections overview two sample indexing techniques that exhibit both of the characteristics stated above.

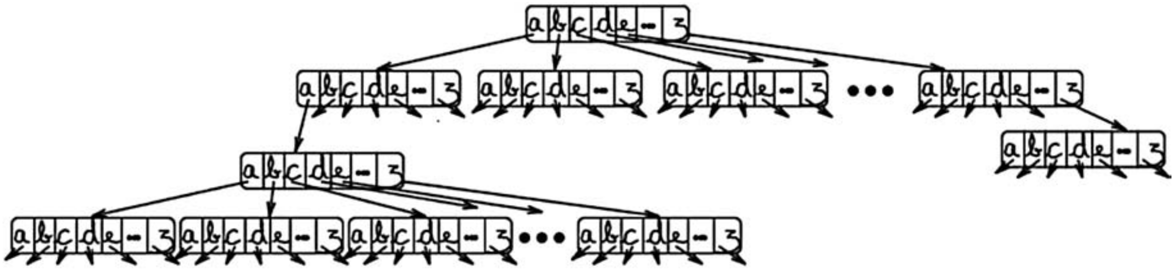
Alphabet-Level Indexing The handwritten trie [2] (Fig. 4) models ink at the alphabet symbol level and represents each of the symbol classes by using HMMs. The traditional trie data structure [4] is an *M*-ary tree whose nodes have *M* entries, and each entry corresponds to a digit or a character of the alphabet. Each node on level *l* of the trie represents the set of all keys that begin with a certain sequence of l characters; the node specifies an *M*-way branch, depending on the *(l + 1)*th character.

As pointed out in [6], the memory space of the trie structure can be significantly reduced (at the expense of running time) by using a linked list for each node, since most of the entries in the nodes tend to be empty. This results in what is termed the *forest trie.*

The handwritten trie uses a variant of the forest trie where nodes of the forest trie are packed into disk pages (a disk-based trie). Alphabet symbols of the trie are all handwritten. Since each symbol can be written differently each time, a separate HMM model per alphabet symbol is used in order to model that symbol. Given a handwritten query word, say w, a preprocessing step takes place to breakdown or segment *w* into a sequence of handwritten strokes or segments w_s. Various segmentation techniques can be used, e.g., [3]. Next, the handwritten trie is searched for an instance of w_s. Each of the HMMs at the root of the handwritten trie is executed against the first symbol in w_s and the search branches to the child node that has the best match. Mismatchings between w_s and items in handwritten trie are dealt with by backtracking and exploring different paths based on best matches between items of w_s and the corresponding items in the trie. An adapted version of the A* algorithm is used in order to prioritize which nodes of the trie to visit next.

In the case of the handwritten trie, matching is performed by using Hidden Markov Models (HMMs) [12]. The handwritten trie uses one type of HMMs, namely the *left-to-right HMM* [1] (see e.g., Fig. 3a), which is useful for modeling temporal signals as in sound (see e.g., [13]) and cursive handwritten text (see e.g., [11]).

The backtracking search mechanism in the handwritten trie takes care of 1-1 substitution errors, i.e.,



Electronic Ink Indexing. Figure 4. An example Handwritten Trie.

when a letter is mal-written, and hence is classified as another letter. However, there are other types of errors that are common in handwriting that needs to be dealt with. For example, if one of the symbols or letters in the query word is omitted (i.e., a *deletion* error), then an entire level of the handwritten trie is skipped and a node's grandchildren instead of its children are checked. Similarly, when an extraneous letter is introduced, e.g., due to an error in the cursive writing segmentation procedure (i.e., an *insertion* error), then the corresponding symbol of the input query word needs to be consumed without probing a node's children. To summarize, when deciding on how to match a symbol from the input query word against a node in the handwritten trie, all three types of error scenarios (1-1 substitution, deletion, and insertion errors) need to be investigated and prioritized using the A* search algorithm. Details of this procedure can be found in [4].

Stroke-Level Indexing

Indexing of handwritten text can be performed at the stroke level. A pictogram is segmented into a set of strokes. Each stroke is carefully described with a set of features, and, thus, can be stored as points in the feature space. Subsequently, any multi-dimensional access method, such as the R-tree, can be used. Similarity-based retrieval can be performed by executing a few range queries and then applying a voting algorithm to the output to select the handwritten words in the database that are most similar to the query [8]. The main advantage of this approach is that it is able to handle substring matching efficiently. Also, in contrast to the handwritten trie, stroke-level indexes are not order-dependent. For example, in scenarios where the order of handwriting a word may differ, the difference in the order of writing the strokes that compose Chinese characters does not adversely affect the search process. The reason is that regardless of the order, each stroke is mapped to a point into the multi-dimensional space and the neighborhood of each point is search for a best match, or best-k matches. Some rank aggregation needs to take place in order to merge all the returned best-k matches and return the best matched handwritten word in the database. Several techniques can be adopted to insure that the index is resilient to the kind of errors that result from the segmentation process, namely, stroke insertion/deletion and substitution errors [9].

Pictogram-Level Indexing

At the pictogram level, a set of global features can be computed for the entire handwritten pictogram. Thus, each pictogram is described with a vector of feature values and is represented as a point in a multi-dimensional space. In contrast to indexes that are based on stroke-level representations, no voting algorithms are needed as each pictogram is represented by only one point [9]. However, in order to increase the robustness and the matching rate of this approach, a multistage retrieval algorithm is adopted. At the first stage, the index is used to reduce the search space to a small set of candidate words that are similar to the handwritten query pictogram. The candidate set is then subjected to a pipeline of two sequential search algorithms that use a different set of extracted features and a distance ranking function to extract the most similar pictogram to the handwritten query pictogram.

Handwritten Ink as a Special Form of Time-Sequence Data

It is to be observed that handwritten text is one form of time-sequence data. As a result, all the indexing techniques applicable to handwritten text can also be applicable to the more general case of sequence data. For example, modeling sequence data using HMMs and similarity search and approximate matching techniques are also applicable to general sequence data and are not limited to only handwritten text. However, the converse is not true. The techniques used for indexing and similarity-based retrieval of time sequence data need to be adapted to make use of the special nature and features of electronic ink.

Electronic Newspapers

Robert B. Allen
Drexel University, Philadelphia, PA, USA

Definition

Newspapers collect, organize, and periodically disseminate information to a community in the form of news articles and other features. They are complex information resources which generally must also be economically viable. Electronic newspapers can provide many of the same types of services as traditional newspapers but they have many additional advantages for the readers. The electronic newspaper can be updated with the latest bulletins, tailored to the reader's interest, and take advantage of multimedia. However, increasingly, news and related services are being disaggregated and provided by separate suppliers so that in some cases, the electronic newspaper can sometimes be just a personalized web portal.

Historical Background

Newspapers arose in the seventeenth century in mercantile cities in Germany and the Netherlands. From the eighteenth to the twentieth centuries, newspapers were often the primary source of citizen's knowledge of the world beyond his immediate experience. Gradual changes in news communication technologies such as the telegraph, production technologies such as printing, delivery technologies such as trucking, increased the circulation and impact of newspapers throughout the nineteenth and early twentieth centuries. Early electronic media such as radio and television provided competition but newspapers still thrived. However, at the end of the twentieth century cable television began 24 h news coverage. The 24-h news cycle means that there is a greater need for newspapers to provide background and analysis and in many cases newspapers seem to be becoming more partisan. Interactive electronic media have amplified these trends and dramatically lowered the barriers to entry for news services. Among the notable effects has been the rise of blogging and citizen journalism. Although some electronic editions are very similar to their paper editions, in many cases it is better to consider electronic newspapers as a set of relatively loosely connected services rather than monolithic entities.

These technological upheavals have led to uncertainty as to how to maintain viable business models for newspaper publishing. As a result of digital convergence and shift to Web distribution most news content is supported by Web advertising. Web development and management also allows the multi-purposing of news content across delivery platforms. However, the Web has lowered the barriers to entry and allowed non-traditional news sources such as blogs and citizen journalism to flourish. Thus, the emerging news sources are broader but do support the depth of news gathering that has existed in the past.

While the focus of this review is on articles, electronic newspapers incorporate many other types of content such as classifieds, financial data, editorials, movie reviews, weather, sports, cartoons, and other advertising. Indeed, the distinction between news and entertainment is becoming blurred. Moreover, because of the ease of electronic publication, many sources of news are emerging such as blogs and citizen journalism. Indeed, these many be seen broadening newspapers' role in developing an informed citizenry. While dissemination of newspapers and journalism can broaden freedom of information there remains the possibility that information technology may ultimately facilitate censorship.

Foundations

An electronic newspaper is not just the presentation of a static newspaper page on a screen. Many electronic services contribute to its production, dissemination, and access and while news articles are the defining characteristic of newspapers, there are many other components which are coordinated to make up the content.

Managing Content

Metadata A comprehensive set of metadata descriptions for news articles would include date, rights, genre, and topic. An extensive set of XML-based descriptive metadata for news has been developed by the International Press and Telecommunications Council (IPTC). Beyond the general genre and topic descriptors for individual articles there are also content tags (e.g., for named entities) and structural descriptions for tabular material such as sports scores and financial data. The IPTC descriptive systems also include metadata for news images such as metadata describing the nature of the shot. For broader applications such as long term preservation and composite news objects, a multilayer metadata description framework such as the Multimedia Encoding and Transmission System (METS) can be used.

Digital Asset Management Systems Repositories extend standard Web servers by supporting content management services. The repositories used by electronic newspapers may be best characterized as digital asset management systems. Different types of digital asset management systems typically support different types of activities. Content developers such as journalists, editors, and layout designers would use a library-like service to access stored digital resources. This could provide access to stored content in a way similar to traditional photo "morgues" used by newspapers. That is they would share aspects of library services and production management services. A second major area of application for digital asset management systems in electronic newspapers could be to organize and push content to a web site. In other words, they would provide digital supply chain services.

Automated Text Processing of News Resources

To support complex activities such as composing news stories and allowing readers to interact with them, digital asset management systems need to support intermediate-level services such as summarization, search, rights management, and preservation.

Information Extraction and Text Data Mining While some news articles are now developed and disseminated with rich metadata and semantic annotation embedded, there is still a lot of untagged text. Extracting that text from unstructured news information would allow better text processing. The primary approach is based on the extraction of named-entities. There are also other extraction techniques such as template matching. Taken together, such information extraction techniques are examples of text data mining. Eventually, such text mining might extract facts in the news articles and allow them to be used in a question-answering system. In addition, it could be used to track opinions expressed on the Web in editorials, movie reviews, and blogs.

Event Detection and Tracking Of course, the main purpose of news articles is to report events so extracting, those events will be critical to any attempt to process the news articles. Topic Detection and Tracking (TDT) uses statistical approaches similar to those from information retrieval (IR). In this approach a topic is defined as a set of related stories. TDT is composed of several tasks such as new topic identification and topic tracking across a set of articles. The main technique is statistical clustering. However, this is a challenging task and the similarity is usually based on the entire description, not just the primary event. In order to improve accuracy, recent approaches have examined events at a finer-grained level. These approaches typically employ rule-based linguistic methods. For instance, they may attempt to determine the verb frames which are employed.

Commercial News Aggregators, News Summarization, and Searching Commercial news content aggregators collect articles from various news sources. In order to present them the aggregator generally clusters them. The most effective of these techniques perform the clustering on named-entities. The articles in each cluster are then ranked by attributes of their source, estimates of their scope and impact, and popularity and then presented to users.

Although they are not yet common in commercial news aggregation systems, summaries may be automatically synthesized for the clusters. Because this is done across news articles it is a type of multi-document summarization. Like most complex text, news text is composed of high-level rhetorical units. Identifying those units turns out to be helpful for generating summaries.

Individual articles and clusters of articles which are collected by news aggregators may also be indexed and searched. In addition to the usual parameters for weighting index terms such as term frequency and document frequency, terms in news articles can also be ranked on factors such as the frequencies and authority of the articles.

Additional Services and Issues

Preservation Services News has been called the "first draft of history" and, more generally, newspapers can be a significant cultural record. For instance, local libraries generally like to keep records of their local newspapers. This is an instance of keeping the record of the community. Unlike paper, electronic copies are ephemeral. However, with the decreasing cost of storage, it is now possible to collect and save almost all local news (with the possible exception of video). Challenges remain in collecting the materials. In addition to the preservation of electronic news materials, there is also now considerable interest in processing digitized historical newspapers. However, automatically extracting and processing the OCRd images has proven difficult because of variable quality.

Rights Management As with many types of commercially produced digital media, it remains unclear what is the best business model for the producers to recoup their expenses. Many publishers believe in maintaining tight control over their resources. This is certainly an issue for publishers with respect to the news aggregators. A related contentious rights issue concerns permission to store archival copies of the new items collected. With traditional newspapers, libraries could legally collect sets of old newspapers. At least in the U.S., libraries and archives are not currently allowed to made copies of digital objects for preservation.

Managing Multimedia News Content

Of course, a lot of news is on television and radio broadcasts and, increasingly, Web-based electronic newspapers include multimedia. The PRX and PBCore metadata standards have been developed for public broadcast radio and video. In addition, there are general multimedia metadata standard such as MPEG-7 and PRISM which can be applied productively to multimedia news objects.

As with data mining of text-based news articles, there could be great value in mining multimedia news objects. There has been considerable work on information extraction and summarization from television and radio news broadcasts. However, this is very challenging because it may involve combinations of different and complex processes including speech processing (unless closed captions are available), image recognition, and video segmentation. These processes tend to be error-prone leading to inaccuracies in named-entity extraction and this, in turn, affects the quality of services such as summarization and searching which use those named entities.

Presentation and Access Services

Personalized Interaction While traditional newspapers aim to provide news which is suitable for a wide range of readers, potentially news articles could be filtered to match a profile of personal preferences. These personalized articles could be combined into an entire personalized newspaper. Indeed, this sort of news interface could already be constructed from articles provided by Really Simple Syndication (RSS) services.

Recommendations Beyond personalization based on an individual's own profile, there are several ways news-related behaviors can be used to increase personalization. One technique is collaborative filtering in which suggestions are made from friends and coworkers. The ubiquity of email forwarding associated with electronic news papers shows the popularity of this type of sharing.

Automated techniques for generating recommendations are based on the pattern of news article accesses by individuals who have no particular connection to the reader. Such recommendations, which are also used for movies and music, are often calculated correlations between the user's choices and those of other individuals. When massive amounts of data are available, variations of singular-valued decomposition (SVD) have proven effective. Another way to simplify the data is by not using correlation but using simple counts such as those provided by "co-visitation." In any event, there are still substantial difficulties in generating effective recommendations such as the stability of people's interests ensuring unobtrusiveness and privacy ensuring in the collection of those interests, and the cold-start problem which occurs when there are no previous observations.

Eleven Point Precision-recall Curve

Ethan Zhang[1,2], Yi Zhang[1]

[1]University of California, Santa Cruz, CA, USA

[2]Yahoo! Inc., Santa Clara, CA, USA

Definition

The *11-point precision-recall curve* is a graph plotting the interpolated precision of an information retrieval (IR) system at 11 standard recall levels, that is, {0.0,0.1,0.2,...,1.0}. The method for interpolation is detailed below. The graph is widely used to evaluate IR systems that return ranked documents, which are common in modern search systems.

Key Points

In a precision-recall graph, precision is plotted as a function of recall. Assume a search system has retrieved n documents. Then for each $k \in [0,n]$, examine the set of top k retrieved documents and calculate the precision and recall for the set. These values are then plotted on a graph of precision versus recall. Figure 1 shows a typical precision-recall curve. It has a saw-toothed shape because the recall remains the same as k while the precision drops when the $(k + 1)$th retrieved document is not relevant.

With the original precision-recall graph, averaging the curve over different queries is not straightforward. A standard approach is to plot interpolated precisions at 11 recall levels, namely, 0.0,0.1,...,1.0. The interpolated precision p_{interp} at recall level r is defined as the highest precision for any recall level $r' \geq r$:

$$p_{interp}(r) = \max_{r' \geq r} p(r')$$

Figure 2 shows the interpolated 11-point precision-recall curve for a good system in TREC 8.

Emergent Semantics

Philippe Cudré-Mauroux
Massachusetts Institute of Technology, Cambridge,
MA, USA

Synonyms

Bottom-up semantics; Evolutionary semantics

Definition

Emergent semantics refers to a set of principles and techniques analyzing the evolution of decentralized semantic structures in large scale distributed information systems. Emergent semantics approaches model the semantics of a distributed system as an ensemble of relationships between syntactic structures. They consider both the representation of semantics and the discovery of the proper interpretation of symbols as the result of a self-organizing process performed by distributed agents exchanging symbols and having utilities dependent on the proper interpretation of the symbols. This is a complex systems perspective on the problem of dealing with semantics.

Historical Background

Syntax is classically considered as the study of the rules of symbol formation and manipulation [8]. Despite its wide usage in many contexts, the notion of *semantics* often lacks a precise definition. As a least common denominator, it can be characterized as a relationship or mapping established between a syntactic structure and some domain. The syntactic structure is a set of symbols that can be combined following syntactic rules. The possible domains that are related to the symbols may vary. In linguistics, such domains are typically considered as domains of conceptual interpretations. In mathematical logic, a semantic interpretation for a formal language is specified by defining mappings from the syntactic constructs of the language to an appropriate mathematical model. Denotational semantics applies this idea to programming languages. Natural language semantics classically concerns a triadic structure comprising a *symbol* (how some idea is expressed), an *idea* (what is abstracted from reality) and a *referent* (the particular object in reality) [9].

Emergent semantics expresses semantics through purely syntactic, recursive domains. The notions underlying emergent semantics are rooted in computational linguistics works relating semantics to the analysis of syntactic constructs. In his seminal work on syntactic semantics [10,11], William J. Rapaport defines semantic understanding as the process of understanding one domain in terms of another – antecedently understood – domain. This further raises the question of how the antecedently domain is itself understood. In the same vein, the antecedently understood domain has to be understood in terms of yet another domain, and so on and so forth recursively. To avoid to ground the recursion to a hypothetical base domain, Rapaport suggest the notions of *semantics as correspondence*, and lets the semantic interpretation function recursively map symbols to themselves or to other symbols. By considering the union of the syntactic and semantic domains, Rapaport regards semantics as syntax, i.e., turns semantics into the study of relations within a single domain of symbols and their interrelations. A dictionary is a simple example of a construct based on that paradigm, where the interpretations of symbols (i.e., words) are given by means of the same symbols, creating a closed correspondence continuum. Emergent semantics applies the conception of a closed correspondence continuum to the analysis of semantics in distributed information systems, by promoting recursive analyses of syntactic constructs – such as schemas, ontologies or mappings – in order to capture semantics.

Foundations

Beyond its implication in linguistics – where it is conjectured that human beings inevitably understand meaning in terms of syntactic domains – emergent semantics is considered as being mostly relevant to computer science. Programs, database schemas, models, or ontologies have no capacity (yet) to refer to reality. However, they have various mechanisms at their disposal for establishing relationships between internal symbols and external artifacts. In the settings where humans provide semantics, relationships among symbols – such as constraints in relational databases – are means to express semantics. In order to rectify some of the problems related to the implicit representation of semantics relying on human cognition, some have proposed the use of an explicit reference system for relating sets of symbols in a software system. Ontologies serve this purpose: an ontology vocabulary consists of formal, explicit but partial definitions of the intended meaning of a domain of discourse. In addition, formal constraints (e.g., on the mandatoriness or cardinality of relationships between concepts) are added to reduce the fuzziness of the informal definitions. Specific formal languages (such as OWL) allow to define complex notions and support inference capabilities. In that way, explicitly represented semantics of syntactic structures in an information system consist of relationships between those syntactic structures and some generally agreed-upon syntactic structure. Thus, the semantics is itself represented by a syntactic structure.

In a large scale distributed environment of information agents, such as in the Semantic Web or Peer-to-Peer systems, the aim is to have the agents interoperate irrespective of their initial vocabularies. To that aim, an agent has to map its vocabulary (carrying the meaning as initially defined in its *base* schema or ontology) to the vocabulary of other agents with which it wants to interoperate. Hence, a relationship between local and distant symbols is established. This relationship may be considered as another form of semantics, independent of the initial semantics of the symbols. Assuming that autonomous agents acquire vocabulary terms through relationships to other agents and that agents interact without human intervention, the original *human assigned* semantics would loose its relevance; from an agent's perspective, *new* semantics would then result from the relationships to its environment. This is a novel way of providing semantics to symbols of agents relative to the symbols of other agents with which they interact. Typically, this type of semantic representation is distributed such that no agent holds a complete representation of a generally agreed-upon semantics.

From a global perspective, considering a society of autonomous agents as one system, one can observe that the agents form a complex, self-referential and dynamic system. It is well-accepted that such systems often result in global states, which cannot be properly characterized at the level of local components. This phenomenon is frequently characterized by the notion of *self-organization*. Thus, emergent semantics is not only a local phenomenon, where agents obtain interpretations locally through adaptive interactions with other agents, but also a global phenomenon, where global semantics emerge from the society of agents and represent the common, current *semantic agreement* in the system. This view of semantics as the emergence of a distributed structure from a set of dynamic processes – or more specifically as some equilibrium state of such processes – is in-line with the generally accepted definitions of emergence and emergent structures in the complex systems literature [2]. In that respect, emergent semantics can be related to dynamic systems disciplines such as evolutionary game theory, semiotic dynamics [13], or graph evolution.

Key Applications

Multimedia Systems: Distributed multimedia applications were the first information systems to take advantage of emergent semantics principles in order to capture the semantics of shared objects. In this context, Santini et al. [12] argue that images do not have an intrinsic meaning, but that they are endowed with a meaning by placing them in the context of other images. From this observation, they propose a system where users are able to manipulate relations between images, and where the semantics of an image is emergent, in the sense that it is a product of the dual activities of users manipulating sets of images and of the database system. Along the same lines, Grosky et al. [5] focus on the role of context for giving meaning to a work of art. In their work, document semantics emerge through the analysis of users' browsing paths through a multimedia collection. They categorize the semantics of each item based on the collection of browsing paths.

Tagging Portals: Emergent semantics can be seen as a natural paradigm to analyze the distributed, user-driven process of giving semantics to items through the use of tags. Extreme Tagging [14] is a technique promoting the tagging of tags and the analysis of the relations between tags. Yeung et al. [15] discuss how shared documents acquire meaning through their associations with other elements. In particular, they demonstrate how different meanings of ambiguous tags can be discovered through the analysis of a tripartite graph involving users, tags, and resources. Herschel et al. [6] discuss query expansion techniques by aggregating users opinions as tags and discuss the role of pragmatics in collaboratively creating semantics.

Heterogeneous Information Systems: Emergent semantics has been suggested as a way to capture semantics in decentralized and heterogeneous information systems [4]. In contrast to mediated integration architectures, recent decentralized integration architectures – such as Peer Data Management Systems – do not require the definition of any global schema or ontology. Thus, the global semantics of such systems can only be captured by considering the collection of conceptualizations as defined by the local databases, along with their interrelations. Semantic Gossiping [1] analyzes transitive closures of schema mappings in that context in order to infer semantic agreement. Related techniques suggest the use of graph theory or probabilistic networks [3] in order to capture global semantics in similar environments. More broadly speaking, emergent semantics techniques are increasingly being seen as a way to minimize manual input and maintenance when dealing with complex and heterogeneous information systems [7].

Emerging Pattern Based Classification

Guozhu Dong[1], Jinyan Li[2]

[2]Nanyang Technological University, Singapore, Singapore

Synonyms

Contrast pattern based classification

Definition

The term “emerging-pattern based classification” refers to any classification algorithm that uses emerging patterns to directly build classifiers or to help build/improve other classifiers.

Key Points

The first approach to consider emerging-pattern based classification is CAEP (classification by aggregating emerging patterns) [2]. The main idea is to aggregate (sum) the discriminating power of many of the emerging patterns contained in a case to be classified. The discriminating power of an emerging pattern is often reflected in the support difference of the pattern in the opposing classes. For each class, the emerging patterns of that class contained in the case are aggregated to form a score; the class with the highest score is deemed to be the class of the case. Score normalization can be used to deal with data/battern imbalance between classes. This classification method can lead to high quality classifiers, comparable or better than other classifiers.

A second major direction in emerging-pattern based classification is the DeEPs method [2], which is an instance-based classification method using emerging patterns. After a case to be classified is given, DeEPs will compute the jumping emerging patterns contained in this case from the training data, and use the training data (that contain some of the discovered jumping emerging patterns) to compute the aggregated scores for the case and the classes. The DeEPs method avoids a deficiency of getting duplicate discriminating power contribution from near equivalent emerging patterns.

Recently, many other emerging-pattern based classification methods have been introduced (e.g., [1]), and several papers study the noise tolerance of emerging pattern based classifiers. More references can be found at www.cs.wright.edu/∼gdong/EPC.html.

Emerging Patterns

Guozhu Dong[1], Jinyan Li[2]
[1]Wright State University, Dayton, OH, USA
[2]Nanyang Technological University, Singapore, Singapore

Synonyms

Contrast pattern; Group difference

Definition

Roughly speaking, emerging patterns [3] are patterns whose support changes significantly from one dataset to another. The definition below captures significant change in terms of big growth rate.

Formally, let $\mathcal{D}_1$ and $\mathcal{D}_2$ be two datasets, and let X be an itemset. For each integer $i \in \{1, 2\}$, let $supp_i(X)$ denote the support of X in $\mathcal{D}_i$. The *growth rate* of X's support from $\mathcal{D}_1$ to $\mathcal{D}_2$ is defined as

$$\text{GrowthRate}(X) = \begin{cases} 0 & \text{if } supp_1(\mathrm{X}) = 0 \text{ and} \\ & \quad supp_2(\mathrm{X}) = 0 \\ \infty & \text{if } supp_1(\mathrm{X}) = 0 \text{ and} \\ & \quad supp_2(\mathrm{X}) \neq 0 \\ \frac{supp_2(X)}{supp_1(X)} & \text{otherwise} \end{cases}$$

Observe that growth rates can also be defined in terms of counts instead of supports. One can also adjust the definition to avoid division by zero, by letting $\text{GrowthRate}(X) = \frac{supp_2(X)}{supp_1(X)+\epsilon}$ for some fixed $\epsilon > 0$.

Given a growth-rate threshold $\rho > 1$, an itemset X is called a *ρ-emerging pattern* (or simply *emerging pattern*, or *EP*) from $\mathcal{D}_1$ to $\mathcal{D}_2$ if $\text{GrowthRate}(X) \geq \rho$; the dataset $\mathcal{D}_1$ is called the *background* dataset, and $\mathcal{D}_2$ the *target* dataset, of X. Emerging patterns whose growth rate is ∞ are called *jumping emerging patterns* (JEPs).

As with frequent itemsets, the number of emerging patterns can be large. One common approach to overcome this problem is to focus on the minimal emerging patterns with respect to the set containment relation.

Historical Background

The concept of emerging patterns was motivated to capture emerging trends or change patterns over time, or significant differences/contrasts between datasets or data classes. The mining of emerging patterns can be viewed as a special case of comparative data mining, where one compares several datasets against each other in order to discover similarities and contrasts, etc. among the datasets. Emerging patterns were initially defined over relational or transactional data [3] and were recently generalized to sequences [6] and graphs [13], etc. In addition to emerging patterns, other patterns on change/difference, together with their mining, were also considered in many other studies [2,3,11,14,16].

Several algorithms have been proposed to mine emerging patterns, including the border-differential algorithm [3], a constraint-based bounding algorithm, a tree-based algorithm, a minimal hypergraph transversal based algorithm [1], a ZBDD based algorithm [12], and an incremental maintenance algorithm [9]. A theoretical analysis on the complexity of emerging pattern mining was reported in [16], and a study on the relationship between emerging patterns and rough set reducts was reported in [14]. Reference [10] proves that the space of jumping emerging patterns is convex and linked that space to version spaces. Reference [8] gives an efficient algorithm for mining minimal (with respect to set containment) emerging patterns, and linked the mining of emerging patterns to the mining of minimal generators and closed patterns. The mining of emerging patterns was also studied in several papers whose focus are on classification using emerging patterns (cf www.cs.wright.edu/∼gdong/EPC.html).

The study of emerging patterns led to two main directions of extensive and fruitful research, namely the use of emerging patterns in classification, and the application of emerging patterns for microarray gene expression data analysis.

Foundations

The border-differential algorithm [3] computes the border of certain sets of emerging patterns, by performing border differential. Borders [3] represent, in a concise manner, large convex collections of itemsets, including certain collections of emerging patterns. A border contains two boundary collections of itemsets, namely a *minB* and a *maxB*; it represents the convex set $\{z \mid \exists x \in minB, \exists y \in maxB \text{ such that } x \subseteq z \subseteq y\}$ of itemsets. For example, $<\{\{2\}, \{3, 4\}\}, \{\{2, 3, 4\}\}>$ is a border, where $\{\{2\}, \{3, 4\}\} = minB$ (containing two itemsets) and $\{\{2, 3, 4\}\} = maxB$ (containing one itemset), representing $\{\{2\}, \{2, 3\}, \{2, 4\}, \{3, 4\}, \{2, 3, 4\}\}$. The main steps of the border-differential algorithm are some iterative expansion–minimization steps used to find the minimal itemsets which are contained in a given positive transaction but which are not contained in any of given negative transactions. The border-differential algorithm can directly compute the set of all jumping emerging patterns, and the set of all emerging patterns whose support in one dataset is lower than a threshold and whose support in the other dataset is higher than another threshold. Experiments show that the algorithm was fairly fast and can handle datasets of up to 75 attributes.

Reference [9] studies how to incrementally modify and maintain the concise border descriptions of the collection of all jumping emerging patterns when small changes to the original data occur. It introduces algorithms to handle four types of changes: insertion of new data, deletion of old data, addition of new attributes, and deletion of old attributes. Similar to the border-differential algorithm, the incremental algorithms obtain the new borders by manipulating the old borders. Experiments show that the incremental algorithms are much faster than the computing-from-scratch method.

Reference [1] shows that computing minimal jumping emerging patterns is equivalent to the well known problem of enumerating the minimal transversals of a hypergraph. It proposes a bottom up approach for computing minimal hypergraph transversals that is particularly suited to the types of hypergraphs arising in jumping emerging pattern mining. Earlier, the three authors of [1] also proposed a tree based algorithm to mine emerging patterns; the tree stores two (or more) counts for each node, one for each dataset; two item orderings, one based on frequency ratio and one based on frequency, are used; it was found that the algorithm was faster than earlier ones and that minimizing tree size may not lead to the shortest computation time.

Reference [12] introduces an efficient algorithm for mining emerging patterns (and generalizations). The algorithm is based on the so-called zero suppressed binary decision diagrams (ZBDDs). Binary decision diagrams (BDDs) are directed acyclic graphs which are efficient representations of boolean formulae. A ZBDD is a special type of BDD, originally introduced for set-manipulation in combinatorial problems. In [12], ZBDD is used to compress sparse high dimensional itemsets/data, and to allow the reuse of past computations. This algorithm can be hundreds of times faster than the tree-based algorithm, and can successfully mine emerging patterns from data with several hundreds (or even thousands) of attributes.

Key Applications

Emerging patterns are useful for capturing multi-dimensional contrasts between datasets/classes. They have been extensively used in classification, and for microarray gene expression data analysis (especially for cancers). Emerging patterns can also be used (i) to discover emerging trends in temporal databases by comparing datasets collected from two time intervals, (ii) to identify rare events, and (iii) to detect network intrusion. References on these can be found at www.cs.wright.edu/~gdong/EPC.html.

Ensemble

Zhi-Hua Zhou
Nanjing University, Nanjing, China

Synonyms

Committee-based learning; Multiple classifier system; Classifier combination

Definition

Ensemble is a machine learning paradigm where multiple learners are trained to solve the same problem. In contrast to ordinary machine learning approaches which try to learn *one* hypothesis from training data, ensemble methods try to construct a *set* of hypotheses and combine them.

Historical Background

It is difficult to trace the starting point of the history of ensemble methods since the basic idea of deploying multiple models has been in use for a long time. However, it is clear that the hot wave of research on ensemble methods since the 1990s owes much to two works. The first is an applied research conducted by Hansen and Salamon at the end of 1980s [5], where they found that predictions made by the combination of a set of neural networks are often more accurate than predictions made by the best single neural network. The second is a theoretical research conducted in 1989, where Schapire proved that *weak learners* which are slightly better than random guess can be boosted to *strong learners* that are able to make very accurate predictions, and the proof resulted in Boosting, one of the most influential ensemble methods [10].

Foundations

Terminologies

Learners composing an ensemble are usually called *base learners*. Many ensemble methods are able to boost *weak learners* which are slightly better than random guess to *strong learners* which can make very accurate predictions. So, "base learners" are also referred as "weak learners". However, it is noteworthy that although most theoretical analyses work on weak learners, base learners used in practice are not necessarily weak since using not-so-weak base learners often results in better performance.

Base learners are usually generated from training data by a *base learning algorithm* which can be decision tree, neural network or other kinds of machine learning algorithms. Most ensemble methods use a single base learning algorithm to produce *homogeneous* base learners, but there are also some methods which use multiple learning algorithms to produce *heterogeneous* learners. In the latter case there is no single base learning algorithm and thus, some people prefer calling the learners *individual learners* or *component learners* to "base learners", while the names "individual learners" and "component learners" can also be used for homogeneous base learners.

Methods

Typically, an ensemble is constructed in two steps. In the first step, a number of base learners are produced. Here the base learners can be generated in a *parallel* style, or in a *sequential* style where the generation of a base learner has influence on the generation of subsequent learners. In the second step, the base learners are combined to use. The most popular combination scheme for classification is *majority voting*, while the most popular combination scheme for regression is *weighted averaging*. The employment of different base learner generation processes and/or different combination schemes leads to different ensemble methods.

The following three paragraphs briefly describe the working routines of three representative ensemble methods, *Boosting* [10], *Bagging* [2] and *Stacking* [13], respectively. Here, binary classification is considered for simplicity. That is, let $\mathcal{X}$ and $\mathcal{Y}$ denote the instance space and the set of class labels, respectively, assuming $\mathcal{Y} = \{-1, +1\}$. A training set $\mathcal{D} = \{(x_1, y_1), (x_2, y_2),\ldots,(x_m, y_m)\}$ is given, where $x_i \in \mathcal{X}$ and $y_i \in \mathcal{Y}$ ($i = 1,\ldots,m$).

For Boosting, let us consider the most famous algorithm, AdaBoost, as an example. In the first step, a number of base learners are produced by emphasizing each learner on the training examples that are wrongly predicted by preceding learners. Here, a weight distribution is maintained over the training examples, which is initialized by equal weights. In the tth learning round, a base learner $h_t : \mathcal{X} \to \mathcal{Y}$ is generated from the training set by using the current weight distribution, D_t. Then, h_t is evaluated on the training set and let ε_t denote the error. The weight distribution for the next learning round, D_{t+1}, is generated in the way that for the training example (x_i, y_i), $D_{t+1}(i) = \frac{D_t(i)}{Z_t} exp\left(\frac{1}{2} ln\left(\frac{1-\epsilon_t}{\epsilon_t}\right) y_i h_t(x_i)\right)$ where Z_t is a normalization factor which enables D_{t+1} to be a distribution. In the second step, the base learners h_t's ($t = 1,\ldots,T$) are combined by $H(x) = sign\left(\sum_{t=1}^{T} \alpha_t h_t(x)\right)$.

For Bagging, in the first step a number of base learners are trained from *bootstrap samples*. A bootstrap sample is obtained by subsampling the training set with replacement, where the size of a sample is as the same as that of the training set. Thus, for a bootstrap sample, some training examples may appear but some may not, where the probability that an example appears at least once is about 0.632. On each sample a base learner $h_t : \mathcal{X} \to \mathcal{Y}$ is produced by calling a base learning algorithm. In the second step, Bagging combines the learners h_t's ($t = 1,\ldots,T$) by majority voting, i.e., $H(x) = argmax_{y \in \mathcal{Y}} \sum_{t=1}^{T} 1(y = h_t(x))$ where the value of $1(a)$ is 1 if a is *true* and 0 otherwise.

For a typical implementation of Stacking, in the first step, a number of individual learners, $h_t : \mathcal{X} \to \mathcal{Y}$ ($t = 1,\ldots,T$), are generated from the training set by employing different learning algorithms. In the second step, the individual learners are combined by using another learner. Here, for the training example (x_i, y_i), a corresponding example (z_i, y_i) is produced, where $z_i = (h_1\ (x_i),\ldots,h_T\ (x_i))$. Then, from $\{(z_i, y_i)\}$ ($i = 1,\ldots,m$) a learner $F : h_t^T \to \mathcal{Y}$ is generated by calling a learning algorithm, which is used to combine the individual learners by $H(x) = F\ (h_1\ (x),\ldots,h_T\ (x))$.

The above methods have many variants. For example, *Random Forests* [3], which has been deemed as one of the most powerful ensemble methods, is a variant of Bagging.

There are many other established ensemble methods, e.g., *Random Subspace* [6]. This method generates a number of base learners from different *subspaces* of the training set in the first step, and then combines these base learners via majority voting in the second step. Here, a subspace is actually a subset of the original attribute set.

It is worth mentioning that in addition to classification and regression, ensemble methods have also been designed for clustering [11] and other kinds of machine learning tasks.

It was thought that using more base learners will lead to a better performance, yet Zhou et al. [15] proved the "many could be better than all" theorem which indicates that this may not be the fact. It was shown that after generating a set of base learners, selecting some base learners instead of using all of them to compose an ensemble is a better choice. Such ensembles are called *selective ensembles*.

Note that usually the computational cost for building an ensemble comprising T base learners is roughly T times the cost of training a single learner. So, from the view of computational complexity, training an ensemble is almost as efficient as training a single learner.

Why Useful?

The generalization ability of an ensemble is usually much stronger than that of a single learner, which makes ensemble methods very attractive. An important question is, why can the ensembles be superior to single learners? For this, Dietterich [4] gave three reasons by viewing the nature of machine learning as searching a hypothesis space for the most accurate hypothesis. The first reason is that, the training data might not provide sufficient information for choosing a single best learner. For example, there may be many learners performing equally well on the training set. Thus, combining these learners may be a better choice. The second reason is that, the search processes of the learning algorithms might be imperfect. For example, even if there exists a unique best hypothesis, it might be difficult to achieve since running the algorithms results in sub-optimal hypotheses. Thus, ensembles can compensate for such imperfect search processes. The third reason is that, the hypothesis space being searched might not contain the true target function, while ensembles can give some good approximation. For example, it is well-known that the classification boundaries of decision trees are linear segments parallel to coordinate axes. If the target classification boundary is a smooth diagonal line, using a single decision tree cannot lead to a good result but a good approximation can be achieved by combining a set of decision trees. Although these intuitive explanations are reasonable, they lack rigorous theoretical analyses.

The *bias-variance decomposition* is often used in studying the performance of ensemble methods [1,15]. It is known that Bagging can significantly reduce the variance, and therefore it is better to be applied to learners suffered from large variance, e.g., unstable learners such as decision trees or neural networks. Boosting can significantly reduce the bias in addition to reducing the variance, and therefore, on weak learners such as decision stumps, Boosting is usually more effective.

There are many theoretical studies on famous ensemble methods such as Boosting and Bagging, yet it is far from a clear understanding of the underlying mechanism of these methods. For example, empirical observations show that Boosting often does *not* overfit even after a large number of rounds, and sometimes it is even able to reduce the generalization error after the training error has already reached zero. Although many people have studied this phenomenon, theoretical explanations are still in arguing.

Accuracy and Diversity

Generally, in order to construct a good ensemble, the base learners should be as more accurate as possible, and as more diverse as possible. This has been formally shown by Krogh and Vedelsby [7], and emphasized by many other people.

The definition of *accuracy* is clear, and there are many effective processes for estimating the accuracy of learners, such as cross-validation, hold-out test, etc. However, there is no rigorous definition on what is intuitively perceived as *diversity*. Although a number of diversity measures have been designed, Kuncheva and Whitaker [8] revealed that the usefulness of existing diversity measures in building ensembles is suspectable.

In practice, the diversity of the base learners can be introduced from different channels, such as subsampling the training examples, manipulating the attributes, manipulating the outputs, injecting randomness into learning algorithms, or even using multiple mechanisms simultaneously.

Key Applications

Ensemble methods have already been used in diverse applications such as optical character recognition, text categorization, face recognition, medical diagnosis, gene expression analysis, etc. Actually, ensemble methods can be used wherever machine learning techniques can be used.

Future Directions

A serious deficiency of ensemble methods is the lack of comprehensibility, i.e., the knowledge learned by ensembles is not understandable to the user. Improving the comprehensibility of ensembles [14] is an important yet largely understudied direction.

Diversity plays an important role in ensembles, yet currently no diversity measures is satisfying [8]. Exploring the relation between the performance of ensembles and the properties of base learners to design useful diversity measures is an interesting direction, which may lead to the development of more powerful ensemble methods.

Although there are much theoretical analyses on ensemble methods, many underlying mechanisms of successful ensemble methods are not clear. So, more theoretical studies are needed. Another ambitious attempt is to establish a general theoretical framework for ensemble methods.

Experimental Results

Empirical studies on popular ensemble methods have been reported in many papers, such as [1,9,12].

Enterprise Application Integration

Janette Wong
IBM Canada Ltd, ON, Canada

Synonyms

EAI; Application-to-application integration; Application-centric interfacing

Definition

Enterprise Application Integration (EAI) is concerned with making applications work together seamlessly, by sharing data and functions among data sources and applications across heterogeneous platforms, facilitated by the use of common middleware. The applications can be a mixture of in-house developed, commercially packaged, and open-source applications; some are contemporary applications, some are legacy systems. Some of the applications were not designed to work together originally. The majority of the definitions set the boundary of EAI for integration within an enterprise. Integration across enterprises involves additional and sometimes different considerations that are covered by solutions that fall under the category of business-to-business (B2B) integration [10]. Variations of the definition of EAI can be found in existing literature. Some of the definitions include the idea that the ultimate goal of EAI is to enable the creation of new business solutions.

Historical Background

Integration of applications started with the sharing of data using files. An application outputs data to a file with specific file naming and placement conventions so that other applications can retrieve the contents of the file. Important decisions include deciding on the file format and how frequently to produce and consume the file. A common issue is that applications can get out of synchronization. When an application uses obsolete data, resulting consequences can be severe.

The next step in the evolution of integration came when client-server architectures became popular and gave rise to the notion of Application Programming Interfaces (APIs) through which a client can invoke the services provided by a remote server. The underlying remote invocation is handled by Remote Procedure Calls (RPC). The main disadvantage is that the API that is being invoked must be in a language and platform compatible with the calling application, which implies multiple APIs are needed to expose an application to other applications on different platforms and languages.

With the advent of object-oriented programming, distributed components in the form of objects allow applications to interact irrespective of their locations and platforms. Common Object Request Broker Architecture (CORBA) took the RPC ideas further by applying them to an object-oriented environment. Although the status of CORBA being the standard distributed object platform has been replaced by more recent platforms such as Java 2 Platform Enterprise Edition (J2EE) and .NET, the ideas from CORBA are still being used today.

When using RPC and distributed objects, applications invoke the APIs of each other directly. This is known as *point-to-point* integration and it has some drawbacks which are aggravated as the number of applications to be integrated increases. Point-to-point integration results in tightly coupled applications and is not a scalable approach.

In the 1990s, ERP (Enterprise Resource Planning) systems became popular, providing a variety of business functions such as accounting and inventory management. Enterprises want to leverage existing functions and data in the ERP systems, but it was difficult to integrate them with other applications. Vendors responded by providing *connectors* (also called *adapters*) to the ERP systems. As the number of applications to be integrated increased, it became clear that a common infrastructure which provides services to allow the applications to interact and manages those interactions would be useful. Such an infrastructure would also minimize the dependencies and assumptions applications make about each other. Industry analysts created the term EAI to represent the software in this infrastructure which enables and facilitates integration.

The success of the Internet provides new opportunities to develop strategic business solutions that bring competitive advantages and fuel the need for integration even further. Standards such as Extensible Markup Language (XML) and industry-specific business protocols provide more common basis for integration. The shift to service-oriented integration, supported by technologies such as Web Services, SOA (Service Oriented Architecture), and SCA (Service Component Architecture) have now taken integration into a new generation.

Foundations

Integrating a diverse set of applications is a big challenge. Following are typical business and technological issues involved in EAI:

- The mindset and policies of organizations need to adapt to an integrated environment. Traditionally, an IT department has almost full control over the applications for which it is responsible. In an integrated environment, an application is only one part of a bigger system. Successful integration requires the cooperation between business units and organizations in addition to cooperation between applications.
- Considerable pressure and expectation are placed on integrated systems to operate seamlessly and optimally, even under adverse and unexpected conditions. This is the result of many integrated systems providing vital business functions where impact, such as cost and reputation, to the business when a failure occurs can be severe.
- The number of applications to be integrated can range from tens to hundreds, or even thousands in a large enterprise.
- Applications to be integrated comprise of legacy systems running on mainframes (e.g., CICS and MVS applications), Commercial-Off the Shelf (COTS) applications such as SAP R/3 and PeopleSoft, in-house developed applications, database management systems, corporate directories, and open-source applications. Such a diverse set of applications often use different technologies and run on different platforms; use different architectural styles: monolithic, 2-tiers, and 3-tiers. Data format and semantics among the applications are usually different. This is known as *semantic dissonance*. Qualities of services among the applications may also be different and need reconciliation.
- Applications, particularly the older ones, were not originally designed to be integrated with.
- Applications are often autonomous: they have different owners and will continue to evolve independently.
- Applications are often geographically distributed which requires remote communication. Networks can be slow, unreliable, and insecure. The applications themselves may also be unavailable at times.
- Applications cannot be changed for the purpose of integration due to organizational and technical reasons. If changes are needed, they must be minimized.
- The breadth of business knowledge and technologies involved require a broad set of skills that is difficult to find in a small number of individuals or in a single organization.

To overcome the technical issues, EAI solutions employ a number of techniques:

- Use the design principle of *loose coupling* to minimize assumptions and dependencies applications have on each other. This will allow applications to evolve independently and if one application changes or an exception occurs, impact to other applications is minimal.
- Use connectors to adapt applications to the target integrated environment. Connectors provide a variety of services including mapping interfaces, transforming data, and exception handling. Performance and reusability are two important aspects in the design of connectors. Many reusable and configurable connectors for a variety of applications and legacy systems are available from vendors.
- Use a middleware integration layer to manage interactions among the applications. This middleware layer runs on a distributed object technology platform and uses a hub and spoke or a Message Bus [1] (also known as Enterprise Service Bus (ESB)) architecture. These architectural styles are highly scalable. Applications only need to be connected to this middleware integration layer, point-to-point integration is no longer needed.
- The middleware layer supports synchronous interactions and *asynchronous messaging*, provides message transformation and routing services, supports distributed transactions and provides security services.
- Asynchronous messaging is one of the techniques to achieve loose coupling. With asynchronous messaging, an application sends a message to a message queue or a Message Channel [1] and the application continues its own processing. There is no need for the sending application to stop and wait for the receiving application to receive the message and respond. This is known as *non-blocking* communication. The message is persisted by the Message Channel which is responsible for forwarding the message to the receiving application. The messaging system also provides transactional support for messages and handles recovery in the case of failure.
- Message transformation is another technique to achieve loose coupling. Transformation allows the format of data and messages between interacting applications to be different.
- Routing allows for the dynamic determination of the target application that is to be invoked. The source application which initiates the interaction can still have some control over which target application it interacts with, but it no longer has to bear the full responsibility of determining the address of the target application, a process known as *binding*. The middleware supports *dynamic binding* which allows the actual address of a target application to be determined based on factors such as load balancing and availability. Dynamic binding is yet another technique to achieve loose coupling.
- The middleware layer may also include sophisticated servers such as:
  - Process servers with embedded workflow engines to orchestrate or choreograph applications to carry out higher level business processes. Process servers automate the execution of tasks within a business process expressed using a standard language such as Business Process Execution Language (BPEL). Process servers often provide the capability to use business rules to control the execution of business tasks.
  - Database and directory integration servers which federates multiple databases and directory servers.
  - Portal servers which aggregate data from multiple applications to create a unified view and interaction experience for end users.

Although the middleware integration layer provides a great deal of assistance in creating an integration solution, even before using the middleware, integration architects still have much to reconcile between business and technical requirements. One important area of focus is on quality of service. Even when a participating application meets all of the functional and data requirements for integration into a target environment, that application may lack quality of service. Quality of service attributes of an application can include:

- Availability
- Reliability
- Performance
- Whether an application idempotent (i.e., no negative effects if invoked multiple times)
- Whether multiple instances of the application can be invoked concurrently
- Whether an application can participate in a transaction

Approaches to Application Integration

With such a variety of technologies, considerations that are technical and business in nature and span inter and intra enterprises, patterns are good ways of acquiring a high level understanding of application integration, its key concepts, the recurring problems, and recommended solutions. Over the years, approaches such as the ones captured by Adams [2], Trowbridge et al. [3] and Ruh et al. [4] have been documented as a set of application integration patterns.

- *Presentation integration* connects applications to give end users a unified view of the data. Among the three approaches to integration, this is the least complicated. Trowbridge [3] referred to this approach as Portal Integration and elaborated upon the different levels of sophistication, ranging from simple display of data from multiple applications to *cross-pane interactivity* where user actions in one portion of the display can affect another portion of the display. Adams [2] provided a broader coverage of presentation issues by considering access from different types of devices such as voice-enabled devices, personalized delivery of information according to user preferences, and security considerations such as single sign-on.
- *Data integration* connects multiple data stores to give applications a unified view of the data. It is responsible for resolving semantic dissonance among the data stores. The two major approaches to data integration are either physically replicating data from the multiple data stores into a central data store, or combining data from multiple data stores in real time presenting an aggregated but virtual view of the data. Sauter [5,6,7,9] identified a several patterns for data integration including Data Consolidation, Data Federation, and Data Cleansing.
- *Process integration* orchestrates interactions among multiple applications, using the services or subprocesses provided by the applications to perform a higher level business process often involving business rules. As part of process integration, business performance of processes and activities can be monitored to provide data that are vital for day to day business decisions.

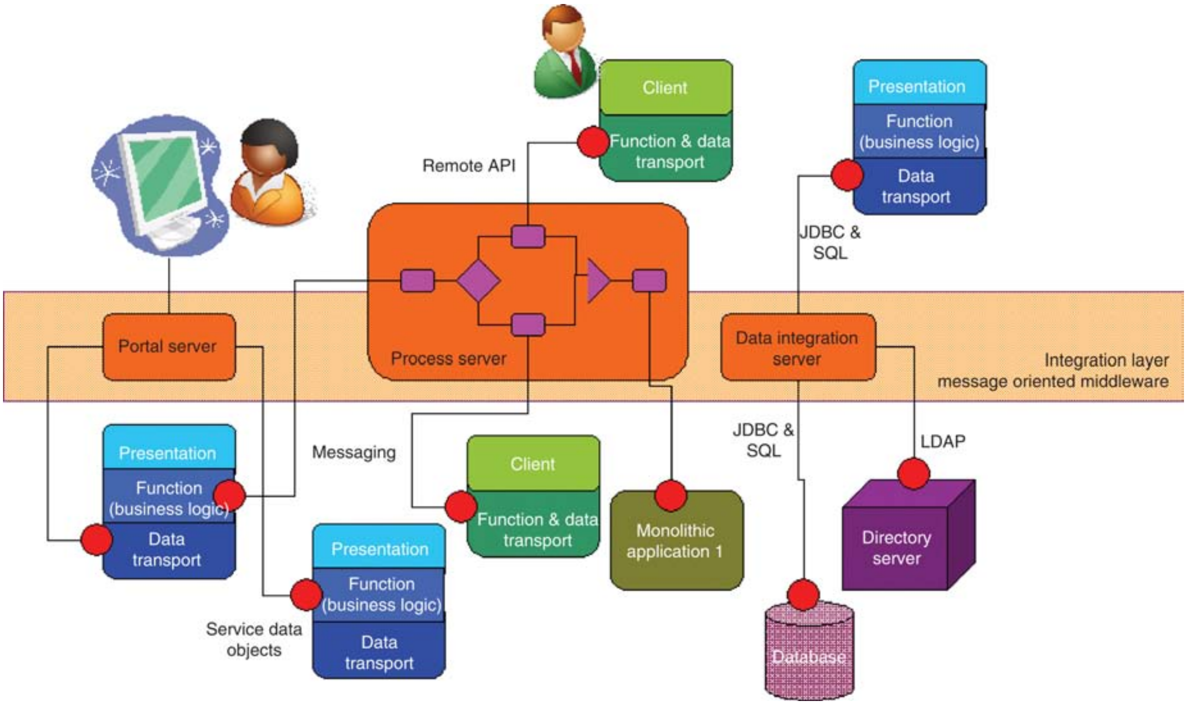
In an integration solution, it is not uncommon to see a combination of the different approaches. Adams [2] additionally provided business patterns to consider the business drivers and requirements before considering the integration approaches.

Figure 1 depicts the different approaches to integration being used together.

Connecting to Applications

Once the overall business purpose of an integration effort is clear and a logical high level understanding of the integration solution has been achieved, another important consideration is how to connect the participating applications to the middleware layer. Many contemporary business applications follow a three-tiered architecture with one layer for presentation, one layer for business logic, and a third layer for handling data. This three-tiered architecture gives rise to three common ways of connecting to an application:

- Connect an application to the middleware layer through the presentation tier of an application. This is the most limiting way of connecting to an application because it is restricted to the data and functions that an application exposes to its end users. It usually is slow in performance and is tightly coupled with the presentation tier of the application and therefore has limited potential for reuse. *Screen scraping* is a common technique to integrate an application through its presentation tier. The integration is achieved by capturing data displayed by the application and extracting relevant information from it.
- Connect an application to the middleware layer through the business logic tier of the application. Connections can be achieved by invoking APIs provided by the application, for instance, by using distributed object technologies, or by invoking the web services interfaces of the application. Asynchronous messaging is used in many cases. Hohpe and Woolf [1] provide an extensive set of asynchronous messaging patterns used for application integration.
- Connect an application to the middleware layer through the data tier of an application. This type of connection mechanism is more flexible and provides access to more data than connecting to the presentation tier. The main disadvantage is that the business logic that resides in the application that processes and manages the data is bypassed, which can lead to data integrity problems. Another disadvantage is that the integration is tied to the data



Enterprise Application Integration. Figure 1. The middleware integration layer connecting various applications (monolithic, 2-tier, 3-tier) and data sources (database, directory server). Different types of integration are supported by the integration layer.

model of the application. Some applications do not consider their data model to be part of their public interface. Directly accessing a "private" data model is a fragile approach. If the data model changes, the integration code has to change accordingly. Connecting to the data tier is more suitable if separate logic, independent of the ones in the existing applications, is intended for processing the aggregated data. A data warehouse is a typical example where logic resides to analyze the aggregated data for the purposes of creating reports and making decisions. The data warehouse typically connects to various data sources through their data tier.

- A variety of tools and data access middleware can be used to connect to an application through the data tier. Such tools and middleware connect to the databases using standard APIs such as Open Database Connectivity (ODBC) or Java Database Connectivity (JDBC). Often, the tools and middleware provide data transformation as well.

Among the three ways of connecting to an application, connecting to the business logic tier is the most flexible and solves the widest range of integration problems, and has the greatest reuse potential. When new business logic and in particular, workflow and transactional integrity, are involved, connecting to the business logic tier is the most appropriate. However, connecting to the business logic tier is also the most complicated and requires the greatest set of skills. Connecting to the data tier directly will always be useful where the situations call for direct connection to data sources and bypassing existing business logic is not an issue.

It should not be surprising that the three major approaches to integration have affinity to the different ways of connecting to an application. The presentation integration approach is typically combined with connecting to an application via its data or presentation tier. The data integration approach is most often associated with connecting to an application via its data tier. Finally, the process integration approach is typically achieved by connecting to an application via its business logic tier.

Standards for Application Integration

While EAI is often interpreted as application integration within an enterprise, with the need for application integration outside of an enterprise, with supply chain, business partners, and regulatory agencies, many organizations want a consistent strategy and approach to integration, irrespective of whether the integration is for inter or intra enterprise. Vendors support this by having their offerings designed to support both types of integration, using the same set of tools and concepts, maximizing reuse while avoiding duplication. Many tools support standards that are applicable to integration. Chari and Seshadri [8] proposed a framework for organizing and navigating the standards according to three orthogonal dimensions. Each dimension is divided into multiple categories.

- *Application architecture*: This dimension classifies a standard according to the architectural layer of an application to which the standard applies. Three architectural layers comprise this dimension: presentation logic, business logic, and data logic.
- *Integration level*: This dimension classifies a standard according to the level of integration to which the standard applies. Three levels of integration comprise this dimension: transport, data format, and process.
- *Industry domain specificity*: This dimension classifies a standard according to whether the standard is applicable to a variety of industries or to a particular industry.

Some standards are sufficiently broad in scope that they belong to multiple categories within a dimension.

Key Applications

When EAI is employed effectively, an enterprise can leverage its existing assets:

- To provide new products and services. An example is the provisioning of an online travel reservation application to employees so that by interacting with a single application, an employee can obtain approval for a business trip, book flights, and make reservations for hotel and car rental.
- To improve its relationships with customers, suppliers, and other stakeholders. An example is when an enterprise wants to obtain a consolidated view of all its business relationships with a customer.
- To streamline and improve its operations, for example, by reducing data redundancy and overlapping functions. An example is when mergers, acquisitions, or spin-offs happen. With these business activities come duplicated and fragmented operations such as multiple payroll systems, corporate directories, and so on, which can be streamlined.
- To simplify interactions among its applications by adopting a standard approach to integration. Once an integration strategy has been created and supported by an appropriate technical infrastructure, adding new participating applications or developing new applications with integration as a key consideration will no longer be as difficult.

Enterprise Content Management

Frank Wm. Tompa
University of Waterloo, Waterloo, ON, Canada

Synonyms

ECM; Office automation; Records management; Document management

Definition

Enterprise content refers to the collections of records and documents that are used in support of business processes. Much of this data is unstructured or semi-structured text created by word processors and other productivity software as part of an enterprises' standard operating procedure. Enterprise content management applies database principles to collect, organize, index, and preserve such data, and ECM systems provide facilities for search, browsing, update, workflow management, web content management, collaboration support, version control, access control, record retention and destruction, legal compliance, and quality control.

Office automation typically refers to the components that create individual documents and manage the workflow. Records management refers to the components that protect and preserve the data and ensure that it is eventually archived or destroyed according to the enterprises' policies.

Key Points

Until recently, unstructured data was usually stored on the individual workstations of the office personnel who created them. This made the data inaccessible to those who wished to apply business intelligence procedures. Enterprise content management systems provide centralized mechanisms to access and manipulate the data, sometimes requiring that the data itself be centralized but often supporting distributed (federated) data management.

In essence, enterprise content management applies database principles and practices to the diverse forms of data that were traditionally outside the purview of relational database management systems.

Enterprise Service Bus

Greg Flurry
IBM SOA Advanced Technology, Armonk, NY, USA

Synonyms

ESB; Service bus

Definition

The enterprise service bus (ESB) is a key architectural pattern in the larger architectural pattern called service-oriented architecture (SOA). The ESB supplies loosely coupled connectivity between service requesters and service providers in service-oriented solutions. Loose coupling permits a clean separation of concerns (temporal, technological, and organizational) between the parts in a solution, enabling flexibility and agility in both business processes and IT systems.

Historical Background

SOA is perhaps the latest stage in the continuing evolution of distributed computing. SOA inherits many principles form earlier stages of distributed computing. Client/server introduced the notion of less monolithic application architectures. Distributed objects focused on smaller-grained function and introduced encapsulated behavior and well-defined interfaces. Web services focused on the use of standards to enhance interoperability. SOA brings a strong focus on the principles of service definition according to business value instead of IT value, service composition via business processes using choreography, and separation of concerns to promote reuse, flexibility and agility.

The ESB contributes greatly to the principle of separation of concerns in SOA. Similar to SOA, the ESB is perhaps just the latest stage in the continuing evolution of the connectivity used in distributed computing and inherits principles from earlier stages. Various messaging systems (sometimes called message-oriented middleware) enabled direct point-to-point interaction. Enterprise application integration introduced centralized management of indirect connectivity and the ability to adapt disparate applications or data sources. Web services emphasized the notion of well-defined interfaces, the use of standards and a service registry to facilitate dynamic behavior. The ESB, in the context of SOA, strengthens the focus on providing loosely-coupled, highly dynamic interactions between service requesters and service providers, whether they adhere to standards or not.

Foundations

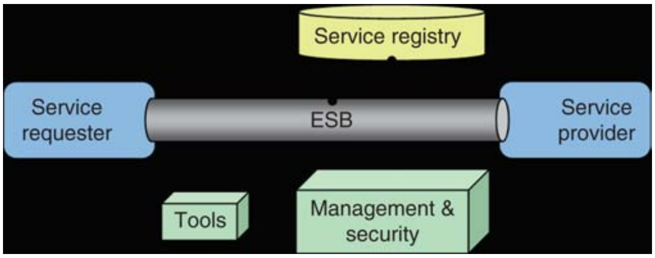
The architectural pattern called the ESB provides the connectivity that enables service interaction in SOA. As illustrated in Fig. 1, in any service interaction there are two roles, the service provider which offers a business function and the service requester that needs the business function. Service requesters and providers interact by exchanging messages. So more precisely, the ESB architectural pattern provides connectivity between service requesters and service providers. The ESB acts as a logical intermediary in the interactions; it intercepts messages from the requester, performs processing, often called mediation, on those messages, and sends the processed messages to the provider. Thus the ESB enables loosely-coupled service interactions. Loose coupling permits a clean separation of concerns (temporal, technological and organizational) between application services to enable flexibility and agility desired from SOA.

The ESB can be physically realized in different ways. The ESB appears like a centralized hub in Fig. 1, and the physical realization of the architectural pattern in many solutions in fact is a hub. The ESB, however, can be distributed so that mediation can physically take place in the service requester's environment, the service provider's environment, in one or more hub environments, or in any combination, allowing for optimization based on the requirements of the solution.

The ESB and Connectivity

Service requesters and service providers implement the application or business logic in a solution, targeted at achieving domain-specific business goals. The ESB implements the connectivity logic in a solution, targeted at achieving loosely-coupled, flexible, and on-demand interactions between service requesters and providers. In an ideal service oriented solution, separation of business logic and connectivity logic is clean, meaning that the services implement no connectivity logic, and that the ESB implements no business logic. Only by architecting this clean separation can an enterprise achieve the flexibility, agility and reuse sought from SOA.

It is sometimes difficult to distinguish between business logic and connectivity logic. There are guidelines, but the distinction may depend on the nature of the organization, or even a particular situation within the organization. One guideline leverages the distinction between semantics and syntax. A service provider performs actions which depend on the semantics, or meaning, of a service request, and so has to understand the meaning of the request; e.g., it creates, reads, updates or deletes business related



Enterprise Service Bus. Figure 1. Enterprise Service Bus.

entities. The ESB compensates for any mismatches in the syntax, or form, of the request between the service requester and provider, and has no need to understand the meaning of the request and does nothing to implement the semantics implied by the request. A related guideline emphasizes the distinction between achieving business objectives versus simply enabling interaction; since the ESB is an intermediary, removing the ESB should have no impact on logically achieving the business objectives; in other words, it adds no semantic value to a service interaction; put another way, the ESB never provides services, it always simply connects services.

Part of the difficulty distinguishing business logic and connectivity logic comes from the reality that the connectivity logic may itself be defined or driven by business considerations. For example, the ESB may route service requests to one of several candidate providers based on factors important to the proper functioning of the business, such as priority attributed to the requester or the time of day.

ESB Core Principles

Support for various forms of mediation allows the ESB to fulfill two core principles in support of separation of concerns. The first principle is service virtualization. The term refers to the ability of the ESB to compensate during service interactions for syntactic differences in:

- Protocol & pattern – Interacting services need not use the same communication protocol or interaction pattern. For example, a requester may require a single monolithic interaction via HTTP, but the provider may require interaction via some message-oriented protocol, using two correlated interactions. The ESB provides the conversion capability needed to mask the protocol and pattern switch.
- Interface – Service requesters and providers need not agree on the interface for an interaction. For example, the requester may use one form of message to retrieve customer information, and the provider may use another form. The ESB provides the transformation capability needed to reconcile the differences.
- Identity – A service requester need not know the identity (e.g., address) of the service provider, or vice versa. For example, service requesters need not be aware that a request could be serviced by any of several candidate providers at different physical locations. The actual provider is known only to, and is chosen by the ESB, and in fact, may change without impact to the requester. The ESB provides the routing capability needed to mask identity.

The second core principle is aspect-oriented connectivity. Service oriented solutions include multiple cross-cutting concerns like management and security. The ESB can implement or enforce such cross-cutting concerns on behalf of service requesters and providers, removing such concerns from of environment of the requesters and providers.

The application of these core principles allows the ESB to affect the qualities of service in interactions. Some aspects of an interaction can be abstracted away from the participants. Consider auditing, for example; if a solution requires auditing, the ESB can "add" it to interactions with no impact on the services. Similarly, the ESB can "add" or perhaps "enhance" qualities of service by retrying failed interactions, or in more sophisticated situations matching requester requirements with provider capabilities.

The ESB in an SOA Context

Figure 1 shows that the ESB performs its role in the larger context of SOA working with other parts of the architecture. The service registry (sometimes called a service repository or service registry/repository) contains and manages the metadata present in a service oriented solution; examples include interface descriptions, endpoint address and policies covering service level agreements, security relationships and so on. This service metadata contained in the registry, and thus the registry itself, have a broad scope in service oriented solutions, spanning governance, development and administration as well as runtime. The ESB can provide value using only static metadata provided during development, but realization of fully dynamic service virtualization and aspect-oriented connectivity requires the ESB to access a service registry at runtime to implement the dynamic connectivity required in a solution. Thus, the service registry can be considered the preferred way to configure the ESB, i.e., the service registry is a policy administration point for the ESB, and the ESB can be considered a policy enforcement point for the registry. As a result, the service registry, while not part of the ESB due to it broader role in SOA, is characterized as tightly coupled to the ESB.

Note that some important capabilities of any service oriented solution, specifically those related to management, are shown independent of, but accessible by the ESB. Management capabilities such as security and IT monitoring and management have a solution-wide scope, and require the coordination and cooperation of parts of a solution beyond the scope of the ESB. The ESB does not provide connectivity between services and management capabilities, and it is possible to secure and manage a solution without participation of the ESB. It is also possible, and frequently desirable, for the ESB to take an explicit, active role in helping secure and manage a solution as part of aspect-oriented connectivity. In this situation, the security and management policies are set by the policy administration points outside the ESB, and one can consider the ESB as a policy enforcement point and sometimes a policy decision point for such policies. Thus policy is set using management and security services that have no direct relationship to the ESB, but the ESB helps enforce the policy. As a result management capabilities are characterized as loosely coupled to the ESB.

An ESB requires tools for development and administration of the ESB. Developers use tools to develop the connectivity logic, or mediations, running in the ESB. Similarly, administrators use tools to deploy mediation and administer the ESB post-deployment. Ideally such tools leverage the service registry. For example, development tooling might allow the mediation developer to find the service providers required for an interaction using the registry; administration tooling might allow addition, deletion or modification of service metadata intended to impact the dynamic behavior of a solution.

Key Applications

An enterprise service bus provides the loose coupling necessary to allow service oriented applications to achieve the desired degree of separation of concerns.

Enterprise Terminology Services

Lawrence Gerstley
PSMI Consulting, San Francisco, CA, USA

Definition

Enterprise Terminology Services refers to the complete lifecycle of vocabulary creation, publication, and supporting processes for the entire electronic medical record system. The supporting processes may include quality assurance, search and retrieval supporting other systems, and mapping for interoperability. Supporting systems, such as managing workflow and regular publication, are also discussed.

Historical Background

One repeatedly encounters the same missing processes and system components required to enable a production level terminology system. In many cases, almost all of the focus is put onto the terminology and storage system, and terminology workflow, publication control, QA, and other sub-systems are added on as afterthoughts. The terminology system itself should have supporting structures, including historical data, metadata, publishing data, and workflow data to support a system that can be fully maintained and utilized by diverse groups.

Tooling in Terminology systems may be minimal or non-existent; existing enterprise-owned applications (such as an office suite of word processing, spreadsheets, etc.) are used to fill the voids. This often results in the author, editor, and user workflows being "shoe-horned" into the tools, rather than the tools being adapted to enable maximum data quality, efficiency, and clarity. The core terminology system and system tooling should be thought of together as the entire Enterprise Terminology System, and should evolve together to fit the needs of the users with the users' direct input.

Import and export of data to other internal enterprise systems, as well as importing and mapping to and from industry standards and vendors (such as SNOMED-CT, LOINC, ICD-9/10, CPT, First Databank/Medispan, etc.) needs to also be considered as a fundamental part of a complete system. Regular maintenance of supporting data, its impact on the enterprise terminology, and required quality assurance to approve changes can range from a few hours to months of effort. Planning and system tuning can pay back any planning and expenditures many times over.

Foundations

System Architecture

1. Core terminology database. Core data model itself may use established models, or be custom developed.
2. Supporting metadata to indicate individual row authorship, last changes, metadata commentary, Dublin Core, and other institution-specific information.
3. Human Workflow, providing complete terminology lifecycle tracking for terminology requests, overall system requests, ad hoc projects, and other project tasks that require tracking.
4. QA/Metrics Reporting layer, providing insights into overall current status, historical throughput, publishing status, and other system metrics.
5. Data interchange layer, providing services for import and export of data to the system, ideally supporting HL7 messaging as a subset of interchange.
6. Centralized knowledgebase for sharing of information throughout the authoring group and end-users.

Key Applications

Case Studies and Experiences

Experience with multiple organizations shows a surprising overlap in system issues and organizational challenges, despite different company work styles, authoring teams, and end-users. In most cases, the problems were due to expediency of getting a working system in place, a philosophy of "add it later" when missing systems were suggested during design phases or identified in the normal course of work. One interesting note is that in a majority of cases, users and managers turn immediately to a spreadsheet application to fill system functionality gaps, often with disastrous consequences.

Users employ spreadsheets to manage small projects, stage data before loading into the authoring system, and other ad hoc tasks. While spreadsheets provide wide flexibility in usage, their use often has unexpected side effects. For example, groups using spreadsheet exhibit internal codes and foreign keys changing through the dropping of leading and trailing zeroes and rounding of decimal places. Intended to aid in the creation of financial information, which was the foundation of spreadsheets, these transformations have serious effects to ICD-9 codes, foreign key mapping, and other scenarios where keys must be treated as immutable. When such functional deficiencies are discovered by authoring groups, attempts are often made to make the spreadsheet application more rigid by setting software options to be standard in the group (disabling automatic formatting), developing internal templates that users should not deviate from, and potentially even developing programmatic control (such as scripting languages like VBA) behind the spreadsheet's GUI.

This is a natural outcome of finding procedural weaknesses; however, the investment of effort is wrongly placed, creating an organic system that is created one piece and a time, creating a fragile and overly complex system. The problem stems from not using the correct technology for the task. If the task is to stage data for loading into the system, experience shows that the creation of a flexible staging model and authoring tools to create terminology in the same system that will ultimately store the verified and validated data centralizes the information so multiple individuals may collaborate. Additionally, the actual tasks of verification and validation are performed instantly making the data available in the production environment.

When spreadsheets are used to perform project management, problems arise when multiple versions of spreadsheets are distributed, updated by multiple individuals, passed in emails, and propagated through a variety of other means, confusion as to which spreadsheet acts as the source of "truth" reigns. Again, this results from employing the wrong tool for the task. Groups often employ project management tools, but such tools focus on the project manager, resulting in a single user overseeing a set of tasks. Terminology authoring groups often need to see overall progress of the active project. Additionally, work may need to be performed piecemeal by team members who can self-assign individual items to themselves from a centralized pool of outstanding work. These challenges are ideally suited to a human workflow engine, such as Serena Software's TeamTrack or K2's workflow products. Such systems provide the ability to create centralized, automated workflow entry, tracking, and reporting with workflows that can be modeled to accurately represent the way that group's work. Additionally, using such systems focuses the group's attention on methods of improving workflow, gaining efficiencies and accuracy, obtaining approvals, and recording those approvals from requesters and other interested parties.

In general, turning to open-source software products to help fill in the process gaps. Firstly, it permits selection of a software tool actually geared towards the problem in question. Too often software is chosen because it is already part of a group's inventory. As with spreadsheets, its use *can* be adapted to solve the problem at hand, but results in changing the group's workflow, de-scoping the desired functionality, and other short cuts. The effects of these ostensibly expedient decisions will be encountered later, and as noted earlier will lead to subsequent additional processes, short cuts, and errors. Using open-source not only allows finding close match between requirements and desired functionality, but also permits tight integration between systems by altering or extending the code base. Such a solution is often more palatable to IT and other engineering groups, and begins to develop a completely integrated work environment. The normal purchasing process is removed from the start-up time, and approvals usually become only technical approvals.

Standardizing and expressing editorial policies formally in a computationally leverageable manner yields many benefits. Using a very simple example, expressing the standards for term string display may include capitalization rules, maximum string length for a particular string, and spaces after different punctuation marks can be expressed as part of a centralized system parameter file. Using an XML format to express such rules delivers many benefits:

1. Such a file is human-readable, providing more transparency into the systems operation.
2. It is technology-agnostic, which means that any future application can process the file for use through standard libraries, regardless of language or platform.
3. Changes may be made easily through any number of tools, ranging from the simplest of text editors (potentially dangerous) to XML editors.
4. As an XML file, it may be versioned with any in-house versioning tool already employed for software control (e.g., CVS, Subversion, SourceSafe, ClearCase).
5. Through open-source technologies like XSLT and FO, the file can be self-documenting, generating formal PDF, Word, RTF, and other test formats for system documentation.

Terminology data models often serve as the focus of development, but often this model is developed to represent the universe of active terminology in a production-ready state. Consequently, it may have little in it supporting developing terminology that must go through a verification and validation process before it is released to outside users. Metadata supporting authoring, publication control, and quality assurance is often missing from the data model, which creates the need for supplemental systems to represent and alter such information.

To illustrate, consider the need to create a new diagnosis in the system, which must be mapped to the appropriate ICD-9/10 code(s) for that diagnosis. Until such a time as a certified coder has looked at the display string, potential synonyms, and the code itself, and certified that code as accurate, such a diagnosis should not be published for outside use. However, putting the data into the authoring system itself means that either the publication process knows not to include the record until it has been verified, or the entire publication of updated terminology must be held until all records are in a satisfactory, verified state (the "all-or-nothing" method of publishing). Sometimes, groups get around this by staging data outside of the authoring system until it is ready for loading, but this brings about additional issues, including all of the previously mentioned issues surrounding use of spreadsheets and other non-authoring applications. Additionally, staging data may lead to a situation where multiple updates to the same record may be prepared outside of the system, and such work will overwrite one another. This scenario often arises during coding updates, or quality assurance and auditing tasks.

These issues necessitate an authoring model that can support records in various stages of completion. Also, it should support different levels of record locking, so that others may see a record in a "dirty" status and be able (or unable) to alter it depending upon their system role. Such a model should include metadata about the terminology records themselves, including:

1. Which user created (initiated) the record?
2. When the record was created?
3. Which user last updated the record?
4. When the last update occured?
5. Commentary about the row itself.
6. Record status (dirty, draft, awaiting publication, propagated).
7. Record publication date/time.

Once an effective set of controlling metadata is in place tracking terminology flow and validation, maintenance routines may begin updating coding and other integrated data, such as pharmaceutical information. Too often such maintenance routines grow without any control over languages used, processes requiring automation, or even documentation for completing updates and handling diverse use-cases. This is the result of different individuals creating processes as time permits, with the tools that they are already familiar with, accomplishing what needs to be done at that point in time. The same maintenance process may contain a potpourri of technologies, each employed at a different point in the process. In general, a small set of tools should be selected and standardized for maintenance, and full documentation should be an absolute requirement for system maintenance. For scripting languages, Perl, Python, and Ruby will all do the job and usually fit within any group's existing IT environment.

Defined metrics reporting should be designed on top of the terminology model, and accessible to those within the team as well as management. Effective reporting systems have been assembled from purchased packages, such as Crystal Reports, as well as open-source packages, such as BIRT, PHP and Apache Cocoon. Cocoon is intriguing in that it uses data "pipelines" which defines how the data is created, transformed, and finally delivered to the requester. Pipelines work with XML structures, so the output at any stage can be brought into other systems. Cocoon also provides a separation between the generation and presentation of data, so that the same pipeline can generate PDF, XML, Doc, HTML, and a number of other formats.

Terminology systems are often the result of evolutionary development, and can benefit greatly from redesign and standardization. Although groups often balk at the time or investment that such a redesign would take, often improvement in just one of the aforementioned areas will pay back such an investment several fold. Additionally, the system will have improvements of all other areas. Internal standardization of the terminology system also prepares it for eventual integration with outside systems, which is an industry goal.

Entity Relationship Model

Il-Yeol Song[1], Peter P. Chen[2]
[1]Drexel University, Philadelphia, PA, USA
[2]Louisiana State University, Baton Rouge, LA, USA

Synonyms

ER Model; ERM; Entity-Relationship Model

Definition

The entity relationship model (ERM) is a conceptual model that represents the information structure of a problem domain in terms of entities and relationships. The result of modeling using the ERM is graphically represented as an entity relationship diagram (ERD). Thus, an ERD represents the conceptual structure of a problem domain being modeled. ERDs are widely used in database design and systems analysis to capture requirements of a system or a problem domain. In particular, when used for data modeling, the ERD assists the database designer in identifying both the data and the rules that are represented and used in a database. ERDs are readily translated into relational database schemas.

Historical Background

The ERM was introduced by Peter Chen in 1976 [2]. The ERM and its variations have been widely used in database modeling and design, systems analysis and design methodologies, computer-aided software engineering (CASE) tools, and repository systems. The popularity of the ER approach led to many extended ER and semantic data models as well as to its variations in notations of ERDs [9]. The ER model and its related research work have also laid the foundation for object-oriented analysis and design methodologies, which led to the development of the Unified Modeling Language (UML). Chen [4] presents historical events related to the ERM up to the early 2000s and roles of the ERM on the development of CASE tools.

Foundations

The three basic modeling components of the ERM are entities, relationships, and attributes.

Entities, Entity Types, and Attributes

An *entity* is a primary object of a problem domain about which users need to capture information. An entity or an *entity instance* (or *entity occurrence*) is an object in the real world with an independent existence. An entity is characterized by its properties called *attributes*. Thus, an entity can be differentiated from other objects when it has at least one property different from the others. An *entity type E* defines a collection of entities that have the same attributes. For example, "John Smith" can be an entity instance of the entity type called *Employee*. Attributes of the *Employee* entity type could include *first name*, *last name*, *social security number*, *date of birth*, *address*, and *salary*. Attributes of a *Customer* entity type could include *customer number*, *first name*, *last name*, *address*, and *customer rating*. Thus, the *Employee* entity type is distinguished from the *Customer* entity type because they have different attributes. In the original ERM, all the attributes are assumed to be simple atomic values, representing numbers, character strings, and dates, not multi-valued attributes such as sets or structures.

Typical entity types usually belong to certain entity categories such as roles of people, locations, tangible things with values, organizations, events, transactions, etc. Thus, *Employee*, *Store*, *Product*, *Company*, *Reservation*, and *Sale* are all examples of entity types. In the literature, an entity and its entity type are not frequently distinguished from each other because the distinction between them is usually clear in the context.

An entity type has two types of properties: identifying attributes and descriptive attributes. An identifying attribute uniquely determines each instance of an entity type. An identifying attribute is called an entity identifier or a *key attribute*. For every entity type, there must be a designated key. For example, the attribute *social security number* would uniquely identify each instance of the entity type *Employee*. Hence, *social security number* is called the entity identifier or the primary key of the *Employee* entity type. A descriptive attribute describes a non-unique property of an entity type. Descriptive attributes of the *Employee* could include *first name*, *last name*, *date of birth*, *address*, and *salary*. Only those attributes that are meaningful in the problem under consideration are included in the ERD. For example, *eye color* would not be included in the *Employee* entity unless one needed to use *eye color* in a meaningful way, e.g., using it in an eye-color activated security system.

An attribute of an entity instance has a *value*. For example, "John" is one value of the attribute *first name*. The *domain* of an attribute is the collection of all possible values an attribute can have. For example, the domain of *first name* is a character string and that of *salary* is a number.

Figure 1 summarizes the notation used in ERDs. An entity type is depicted as a *rectangle* containing the name of the entity type. The name of an attribute is enclosed in an *oval* connected to the rectangle of the entity type they describe. An entity identifier or a key is underlined.

Relationships and Relationship Types

A relationship is an association between or among entities. A relationship in the ERM describes a meaningful association that needs to be remembered between or among entities. A relationship type between entity types *E* and *F* meaningfully relates some entities in *E* to some entities in *F*. Formally, a *relationship R* is a Cartesian product of $n \geq 2$ entities$\{R\ (e_1, e_2,...,e_n) \mid e_1 \in E_1, e_2 \in E_2,...,e_n \in E_n\}$, where e_i is an entity instance, E_i is an entity type, and $R\ (e_1, e_2,...,e_n)$ is a relationship. Here, n is called the *degree* of a relationship *R*, indicating how many entity types are participating in *R*. When $n = 2$, *R* is called a binary relationship; and when $n = 3$, *R* is called a ternary relationship. That is, a binary relationship is a meaningful association between two entity types, and a ternary relationship is a meaningful association among three entity types. In typical modeling, binary relationships are the most common and relationships with $n > 3$ are very rare. In a special binary relationship in which *E1* = *E2*, the relationship is called a recursive relationship because an entity is related to another entity of the same type. That is, a recursive relationship is a meaningful association between entity instances of the same entity type. As shown in Fig. 1, relationships are depicted by *diamonds* between or among entities in the ERD.

Cardinality and Participation Constraints

Cardinality is a constraint on a relationship between two entities. Specifically, the cardinality constraint expresses the maximum number of entities that can be associated with another entity via a relationship type. The values of cardinality are either "one" or "many". They are usually represented by either "1" or "N" in an ERD. A binary relationship can have three possible cardinalities: one-to-one (1:1), one-to-many (1:N), or many-to-many (M:N). Figure 2 shows the three cardinality constraints between two entity types *Customer* and *Account*. One-to-one cardinality states that one *customer* can have at most one *account* and one *account* can be owned by at most one *customer*. One-to-many cardinality says that one *customer* can have many *accounts*, but one *account* cannot be owned by more than one *customer*. Many-to-many cardinality says that one *customer* can have many *accounts* and one *account* may be owned by many *customers*. Figure 3 shows examples of a recursive relationship, binary relationships, and a ternary relationship as well as various cardinality constraints.

Participation is also a relationship constraint. Participation expresses the minimum number of entities that can be associated with another entity via a relationship type. There are two values for participation: *total* (also known as *mandatory*) participation and *partial* (also known as *optional*) participation. If every instance of an entity must participate in a given relationship, then that entity has total participation in the relationship. But if every instance need not participate in a given relationship, then the participation of that entity in the relationship is partial. In an ERD, the total participation of Entity type *E* to relationship type *R* is indicated by a double line from *E* to *R* [6], as shown in Fig. 1. For example, in Fig. 3, the participation of the *Department* entity type in the *Works_for* relationship is total, while that of the *Employee* entity type in the relationship is partial. This implies that a *Department* instance must

have at least one *Employee*, while an *Employee* instance can exist without working for a *Department*.

Cardinality and participation constraints are business rules in the problem domain being modeled. They represent the way one entity type is associated with another entity type. They are also integrity constraints because they help ensure the accuracy of the database. These constraints limit the ways in which data from different parts of the database can be associated. For example, say the cardinality of the relationship between *Customer* and *Account* is one-to-one, as in Fig. 2. If customer C1 is associated with account A3, then C1 cannot be associated with any other accounts and A3 cannot be associated with any other customers.

Attributes of a Relationship

A relationship sometimes has attributes. A relationship attribute represents a property of the relationship, but not of any participating entity type. For example, in Fig. 3, attribute *#Hours* is a property of the relationship *Works-on*, not of *Employee* or *Project*. Another example is the *Quantity* attribute of the ternary relationship *Supplies* in Fig. 3, where *Quantity* is a property created by the interaction of three participating entity types *Supplier*, *Project*, and *Part*. Relationship attributes are most common in many-to-many relationships or ternary relationships.

Roles

The meaning of a relationship type is usually clear between two associated entity types. However, the meaning of a relationship type is not clear if there are multiple relationship types between the participating entity types. In these cases, roles are used to indicate the meaning of an entity to the associated relationship type. Roles are indicated in ERDs by labeling the relationship lines that connect diamonds to rectangles. For example, a recursive relationship always has two lines between an entity type and the recursive relationship. In Fig. 3, *Manages* is a recursive relationship; *Manager* and *Subordinate* are roles of *Employee* entity instances. Thus, the relationship can be read as "an employee with the role of a manager can manage many subordinate employees, and an employee with the role of subordinate can be managed by one manager employee." Thus, in recursive relationships, it is customary to add roles to clarify the meaning of each relationship line. In other occasions, role labels are optional.

Ternary Relationships

A ternary relationship is a meaningful association among three entity types. An important requirement of a ternary relationship is that the three entity types must always occur at the same time in the relationship. For example, in Fig. 3, *Supplies* is a ternary relationship among the *Supplier*, *Project*, and *Part* entity types. The semantics of *Supplies* can be read as follows [7,12]:

- For a given pair of Supplier and Project instance, there are many Part instances.
- For a given pair of Part and Supplier instance, there are many Project instances.
- For a given pair of Part and Project instance, there are many Supplier instances.

Weak Entity Types

An entity type that does not have its own unique identifier is referred to as a weak entity type. A weak entity type has one or more *owner* (or *strong*) entity types connected through one or more one-to-many relationships (called *weak relationships*). Therefore, the primary key of a weak entity type is always composite. The key consists of the primary keys of all the owner entity types and a *discriminator (or partial key)* of a weak entity set, where the discriminator is the set of attributes that distinguishes among all the entities of a weak entity.

As shown in Fig. 1, a weak entity type is depicted by double rectangles, a weak relationship by double diamonds, and a discriminator is underlined with a dashed line. For example, in Fig. 3, *Dependent* is a weak entity, *Dependent_of* is a weak relationship, *Employee* is the owner entity type of *Dependent*, and *Dep_Name* is the discriminator of *Dependent*. Thus, the primary key of *Dependent* is a composite of *Employee.SSN* and *Dependent.Dep_Name*.

Two important properties of a weak entity type are the *identifier dependency* (ID-dependency) and the *existence dependency*. The ID-dependency means that the primary key of the owner entity type is included in that of the weak entity type. Therefore, a weak entity always has total participation in its weak relationship, as shown in Fig. 3. Due to this property, the weak relationship is also called the identifying relationship. The existence dependency means the existence of a weak entity instance is dependent on the existence of its related owner entity instance. For example, in Fig. 3, if an *Employee* entity instance is deleted, then all of its associated *Dependent* entity instances must also be deleted.

ER Modeling Techniques

Developing a syntactically and semantically correct ER model for a domain requires both effective modeling techniques and experience. Techniques for developing a correct and complete ERD are beyond the scope of this article. An excellent starting point for understanding techniques of constructing ERDs from a problem statement is presented by Chen [3]. Chen presents a fundamental framework for developing an ERD from English sentence structure by showing the similarity between English grammar and ER modeling components. Batini et al. [1] present conceptual modeling using ERMs. Song et al. [9] present a comparison of popular ERD notations as well as a comparison between *n*-ary models and binary models. Ling [8] presents a notion of a normalized ER diagrams. Dullea et al. [5] discuss validity and redundancy in ER diagrams. Teorey et al. [10] cover in detail the database modeling and design using the ERM.

Translation of ERDs into a Relational Schema

This section briefly presents how to translate ERDs into relational schemas. There are several different methods for creating relational schemas from an ERD. See [6,10,11] for more detailed treatments of the subject. The one described here is the most popular technique [6,10]. The rules are:

1. Every entity type becomes a table.
   a. All the attributes of the entity become the attributes of the table.
2. Each 1:N relationship type is mapped into the associated N-side entity type as follows:
   a. For each N-side entity type:
      (a) Add the primary key (PK) of the 1-side entity type. This added PK becomes a foreign key.
      (b) Also add any descriptive attributes of the relationship.
   b. When this rule is applied to recursive relationships:
      (a) The PK of the 1-side entity type is annotated with its role name.
3. Each M:N relationship type becomes a separate table.
   a. Add PKs of the participating entity types to the table. They become foreign keys.
   b. Add all the descriptive attributes of the relationship type to the table.
   c. The PK of the table consists of the PKs of the two participating entity types.
   d. When this rule is applied to M:N recursive relationship type:
      (a) The two foreign keys are annotated with their role names.
4. Each 1:1 relationship type can be combined with either side of the entity type or can be treated like a 1:N relationship type.
5. A weak entity type becomes a table that includes the primary key of the identifying owner entity type.
   a. The PK of the table consists of the foreign key and the discriminator.
6. Each relationship type becomes a separate table.
   a. Add PKs of the participating entity types to the table. They become foreign keys.
   b. Add all the descriptive attributes of the relationship type to the table.
   c. The PK of the table consists of the foreign keys of the three participating entity types when the cardinality is many-many-many. When the cardinality is not many-many-many, the PK of the table consists of at least two foreign keys, where all the foreign keys coming from many-side entity types must be included in the PK of the table.

Applying the above translation rules to the ERD shown in Fig. 3 yields the following relational schema:

1. Employee (SSN, Name, D#, Manager_SSN).
2. Dependent (SSN, Dep_Name, Sex).
3. Department (D#, DName).
4. Project (P#, PName, D#).
5. Works_on (SSN, P#, #Hours).
6. Supplier (S#, SName).
7. Part (Pt#, PtName).
8. Supplies (P#, S#, Pt#, Quantity).

Key Applications

The ER model is widely used in database modeling and design and in conceptual modeling of information systems. Most commercial CASE tools support an ERM or some of its variations. The ER approach has been applied to design of object-oriented databases, data warehouses, temporal databases, spatial databases, and meta models. The ER model also laid the foundation for class modeling techniques of object-oriented analysis and design.

URL to Code

An international conference that focuses on entity-relationship approaches and conceptual modeling has been held regularly since 1979. The conference is now known as International Conferences on Conceptual Modeling and is cataloged in http://conceptualmodeling.org [7].

Equality-Generating Dependencies

Ronald Fagin
IBM Almaden Research Center, San Jose, CA, USA

Synonyms

egd

Definition

Equality-generating dependencies, or *egds*, are one of the two major types of *database dependencies* (the other major type consists of *tuple-generating dependencies*, or *tgds*).

To define egds, it is necessary to begin with the notion of an *atomic formula*, where an example is the formula $P(x_1,...,x_k)$, where P is a k-ary relational symbol, and $x_1,...,x_k$ are variables, not necessarily distinct.

Then egds are formulas of the form $\forall \mathbf{x}(\varphi(\mathbf{x}) \rightarrow (x_1 = x_2))$, where

1. $\varphi(\mathbf{x})$ is a conjunction of atomic formulas, all with variables among the variables in **x**.
2. Every variable in **x** appears in $\varphi(\mathbf{x})$.
3. x_1 and x_2 are distinct variables in **x**.

Conditions (1) and (2) together are sometimes replaced by the weaker condition that $\varphi(\mathbf{x})$ be an arbitrary first-order formula with free variables exactly those in **x**.

Key Points

The most important example of an egd is a *functional dependency*, where an example is the formula

$$\forall x_1 \ldots \forall x_k \forall x_i'(P(x_1,\ldots,x_k) \\ \wedge P(x_1,\ldots,x_{i-1}, x_i', x_{i+1},\ldots,x_k) \rightarrow (x_i = x_i')),$$

where P is a k-ary relation symbol.

Historically, functional dependencies were the first database dependencies. They were introduced by Codd [2] for the purpose of database normalization and design. Fagin [3] defined the class of *embedded implicational dependencies*, which includes both tgds and egds, but he focused on the case where they are (i) unirelational (so that all atomic formulas involve the same relation symbol) and (ii) typed (so that no variable can appear in both the ith and jth position of an atomic formula if $i \neq j$). Beeri and Vardi [1] defined and named tgds and egds.

Escrow Transactions

Patrick O'Neil
University of Massachusetts, Boston, MA, USA

Synonyms

Escrow transactions

Definition

Escrow transactions [3] permit non-blocking concurrency for the most common high volume transactions, those that perform updates of hotspot data only by incrementing and decrementing aggregate data items. An example of such a transaction is one that increments dollar sale total of a customer for each purchase that decrements the quantity on hand of a product. A *hotspot* of a database under a high volume transactional workload consists of the set of data items, each one of which frequently needs to be updated by multiple concurrent transactions in order to maintain needed throughput. While this is impossible using read-write locking, since write operations do not commute, high-volume OLTP applications of this kind can be performed without blocking by a transactional system that performs increments and decrements with the appropriate protocols. Increment-decrement updates have been used for years in the IMS Fast Path product [1,2], supporting commuting high volume short-term transactions on data items in a centralized DBMS. Escrow transactions generalized this approach to support commuting long-lived transactions performing increment-decrement updates of aggregate data items, possibly in a distributed database.

Key Points

The term "escrow" is from banking: a large company entering into a business transaction in a remote location would not want to "lock" it's main bank account for this purpose, but would elect an *escrow agent*, to hold the money in trust pending fulfillment of the transaction; if the transaction succeeds, the escrow agent would transfer the money, but otherwise the money would be returned to the company. Note that this is a long-lived transaction in the sense that a business transaction using escrow might take days or weeks to complete. In the same way the Escrow transactions perform quick increments and decrements to an account, then hold no locks on what quantity remains, and so lock only the portion of an aggregate quantity needed for the business purpose of the transaction.

Escrow transactions can be illustrated with an example of a product table *Prod* with a primary key *prid* and rows containing data about warehouse storage of a product, e.g., storage_capacity, price, etc. Updates to columns of Prod are infrequent and take part in short-term update transactions, but orders changing Quantity on Hand of the product are held long-term in an Escrow data item qoh, as explained below. The qoh item can be thought of as a *composite* column for each row of the Prod table, having the appropriate prid and a number of int fields, as follows:

(qoh, prid, val, inf, sup)

The qoh item must be exempted from standard transactional recovery using before images and after images, since Escrow recover is special-purpose as described below. Note that an increment operation Inc(qoh, prid, tid, delta) by transaction tid can represent either an increment (with a positive value of delta) or a decrement (with a negative value of delta). It is assumed that product orders such as this can be held pending for an extended length of time (weeks), and either committed or aborted at the end of that time, with a fee paid by the customer for this flexibility; thus each Inc operation can be thought of as an *Option to Buy (Return)* if delta is negative (positive).

The field val represents the value of the balance if all outstanding transactions that have incremented this quantity should abort, while the field inf(sup) represent the lowest (highest) values val could attain if all transactions that have performed Inc operations with positive-valued (negative-valued) delta increments were to abort, while all increments with deltas of the opposite sign commit. Thus as new Inc operations are submitted, negative-valued deltas will lower the inf value and positive valued deltas will increase the sup value, while val will remain unchanged until one of the transactions commits. In addition, as each Inc operation causes qoh items to change, an Escrow log (Elog) is created and both the Elog and the qoh are made durable (written to mirrored disk for example), to guarantee that the Elog will be recovered in event of a system crash. Recovery from a system crash will therefore result in recovery of qoh and all Elogs, so each Escrow update is brought back to a state where it can be either committed or aborted. There are also Max and Min field values in the descriptor of the qoh data item to provide a constraint on the maximum and minimum attainable values for val. The seller will disallow an Inc(delta) with negative delta which brings inf below Min (usually zero since this would mean that some purchase order will fail if no items are returned, while there will also be a limit on how many positive delta increments can be accepted for a given product (sup will be constrained to be less than Max), since there is a limited amount of storage. Back-orders for purchase or return can be provided when circumstances permit.

Note that while Inc operations commute, they do not commute with Reads or Writes. One cannot Read or Write an Escrow item that has indeterminate value (between inf and sup), although a Read function call to return this range of possible values could be provided.

Escrow Commits and Aborts

The commutative property of Escrow transactions is based on the fact that updates by multiple concurrent transactions on any single Escrow data item can be committed or aborted in any order. This is motivated with a short example. Assume the qoh data item on a product with prid = 1234 begins with val = 1000, and that Max = 2000 and Min = 0. A sequence of transactions T_i updates this qoh creating Escrow logs, and then all T_i Commit (C_i) or Abort (A_i).

To start: (qoh, prid: 1234, val: 1000, inf: 1000, sup:1000)
Inc_1: Inc(qoh, prid: 1234, tid: 1, delta: −500)
Result: (qoh, prid: 1234, val: 1000, inf: 500, sup:1000), Elog: (tid: 1, delta:−500, qoh[1234])
Inc_2: Inc(qoh, prid: 1234, tid: 2, delta: + 500)

Result: (qoh, prid: 1234, val: 1000, inf: 500, sup:1500), Elog: (tid: 2, delta: + 500, qoh[1234]) C_2: (qoh, prid: 1234, val: 1500, inf: 1000, sup:1500), Elog for tid = 2 was used and is now invalidated.
A_1: (qoh, prid: 1234, val: 1500, inf: 1500, sup:1000), Elog for tid = 1 was used and is now invalidated.

Recall that a positive increment such as Inc_2: Inc (qoh, prid: 1234, tid: 2, delta: + 500) causes the sup value to increase by delta. Then an Abort A_2, reading off the Escrow log for Inc_2, causes the sup value to be decremented by delta again, with no other field changed, while a Commit C_2 causes the inf, and val values to be incremented by the same amount (if no other transactions remain active, the val, inf and sup must end with the same values). Similarly a negative increment Inc_1: Inc(qoh, prid: 1234, tid: 1, delta: −500) causes the inf value to be decremented by the negative delta; an Abort A_2, reading off the Escrow log for Inc_1, will cause the inf value to be incremented by delta (a positive value), while a Commit will cause the val and sup values to be decremented as well.

It should be clear from this that the minimum value possible for val at the end of a sequence of Commits and Aborts will be inf, and the maximum value will be sup. Any combination of a specific set of Aborts and Commits in any order will result in the same val value.

Distributed Escrow Transactions

A classical definition of distributed transactions has a Transactional Coordinator on one host performing updates on its own host and coordinating updates on several foreign hosts to provide ACID properties for a global transaction. The updates lock records on all hosts in the classical situation, often leading to difficulties in terms of blocking, especially if one of the non-coordinating hosts should crash at an inopportune moment during concluding Two-Phase Commit. Escrow transactions are perfect for situations like this, since they lock only the (usually small) portion of an aggregate quantity needed for the business purpose of the transaction, while original Escrow update automatically requests Phase 1 of a Two-Phase Commit. The upshot of all this is that there is no particular rush about completing Phase 2 of a Two-Phase Commit, and indeed even if the Coordinator host crashes after the final commit has started, one can afford to wait for recovery without blocking all the data items involved against further Escrow updates.

European Law in Databases

Michael Carroll
Villanova University, Villanova, PA, USA

Synonyms

Intellectual Property; License

Definition

European law provides three types of legal rights to database owners to control copying: (i) copyright law, (ii) the right to impose contracts or licenses on users, and (iii) a unique statutory right applicable to the non-copyrightable information – such as factual data – in European databases. This entry discusses only the third of these rights. This stand-alone or "sui generis" database right gives a database owner a claim against one who extracts or reuses the whole or a substantial part of the database contents, where "substantial part" is evaluated qualitatively or quantitatively.

Historical Background

Prior to 1996, the legal treatment of databases in Europe varied in the requirements for copyright protection. In 1992, the European Commission proposed that EU copyright law be harmonized with US law by requiring originality for copyright protection to apply. However, the European Commission also proposed that a separate legal right should be granted for unoriginal databases that require substantial investment to create or update. After further revision to ensure certain user rights, the proposal was adopted as Directive 96/9/EC of the European Parliament and of the Council on the legal protection of databases. The Directive required Member States to harmonize their copyright treatment of databases with US law and to further enact national legislation providing database owners with a new stand-alone legal right to control certain copying of non-copyrightable information in databases. All 25 countries subject to the Directive have complied with this requirement.

An analysis of the effect of the Directive conducted by the European Commission in 2005 concluded that "[w]ith respect to 'non-original' databases, the assumption that more and more layers of IP protection means more innovation and growth appears not to hold up." The report offered policymakers four options: (i) Repeal the whole Database Directive; (ii) Withdraw the sui generis right while leaving protection for creative databases unchanged; (iii) Amend the sui generis provisions in order to clarify their scope; (iv) Maintain the status quo. Comments were solicited from specific stakeholders. There was support for each option and as of January 2008 no legislation was pending.

Foundations

Article 7 of the Directive requires that: "Member States shall provide for a right for the maker of a database which shows that there has been qualitatively and/or quantitatively a substantial investment in either the obtaining, verification or presentation of the contents to prevent extraction and/or reutilization of the whole or of a substantial part, evaluated qualitatively and/or quantitatively, of the contents of that database."

This provision can be broken down into (i) the eligibility criteria and (ii) the scope of the rights granted to those deemed eligible.

Eligibility

Under the Directive, a database is "a collection of independent works, data or other materials arranged in a systematic or methodical way and individually accessible by electronic or other means." To qualify for this database right, the creator, which, unlike in European copyright law, can be a corporation, must have made qualitatively or quantitatively a substantial investment in either the obtaining, verification or presentation of the contents."

Notice that the eligibility criteria allow for multiple rightsholders in the same data. For example, Company *A* may make a substantial investment in collecting data. Company *A* may then sell the data to Company *B*, which makes a substantial investment in verifying the data. Company *B* may then sell the data to Company *C*, which makes a substantial investment in presenting the data.

This database right is initially held by the person or corporation which made the substantial investment, so long as (i) the person is a national or domiciliary of a Member State or (ii) the corporation is formed according to the laws of a Member State and has its registered office or principal place of business within the European Union. The database right lasts for 15 years from the date of publication or, in the case of unpublished databases, from the year of creation.

Scope of Rights – Extraction or Reutilization

Under the Directive, a rightsholder may bring a claim for unauthorized "extraction" or "reutilization" of a "substantial part" of a database.

Extraction is defined broadly to mean "the permanent or temporary transfer of all or a substantial part of the contents of a database to another medium by any means or in any form."

Reutilization is also defined broadly to mean "any form of making available to the public all or a substantial part of the contents of a database by the distribution of copies, by renting, by on-line or other forms of transmission."

A substantial part of the database is to be evaluated quantitatively or qualitatively, which means that even extraction or reuse of a small amount of data may infringe the right if that data has economic value to the rightholder.

Somewhat in conflict with the express language defining the right as covering only substantial parts of the database, Article 7(5) also provides that "repeated and systematic extraction and/or reutilization of insubstantial parts of the contents of the database implying acts which conflict with a normal exploitation of that database or which unreasonably prejudice the legitimate interests of the maker of the database shall not be permitted."

Exceptions and Limitations

The broad rights granted under the Directive are subject to specific exceptions and limitations.

Where copies of the database are sold in material form, such as on a CD ROM, the rightholder's reutilization right is exhausted after the first sale. This means one may resell or otherwise redistribute one's copy of the database without liability. Public lending of such a copy also is not an infringement of the reutilization right.

In addition, the Directive provides three specific exceptions under which a substantial part of a database may be extracted or reutilized without permission:

1. In the case of extraction for private purposes of the contents of a non-electronic database;
2. In the case of extraction for the purposes of illustration for teaching or scientific research, as long as the source is indicated and to the extent justified by the non-commercial purpose to be achieved; and
3. In the case of extraction and/or reutilization for the purposes of public security or an administrative or judicial procedure.

Importantly, under the Directive, the rightsholder may not supplement the protection of the database right with a contractual license that restricts the user's right to use insubstantial parts of the database without authorization.

Key Applications

At the national level, court judgments reflect a range of databases considered eligible for the sui generis right. These include listings of telephone subscribers; databases compiling case-law and legislation; websites containing classified advertisements; catalogs of various sorts; lists of headings of newspaper articles. The European Court of Justice also has accepted a broad reading of what collections of information qualify as a database under the Directive.

The eligibility requirement of "substantial investment" in the database has received varied, and arguably conflicting, interpretations in the courts. Examples of databases that courts have satisfied the criterion include a compilation of several thousand real estate listings (Belgium) and the effort to collect and verify the data for the weekly "Top 10" hit chart of music titles (Germany). Examples of databases that have failed to show substantial investment include a website containing information on building construction (Germany) and a listing of newspaper headlines that were deemed to be a "spin-off" of the primary database of news articles (Netherlands). A related area of divergent judgments concerns copying from on-line databases and Internet-related activities such as "hyper linking" or "deep-linking" using search engines.

Related differences of opinion have emerged with respect to what constitutes an extraction or reutilization of a "substantial part" of the database, particularly with regard to indexing of on-line resources such as news sites by search engines.

Disputes over sports-related data were referred to the European Court of Justice in 2004 to clarify the scope of the Directive. The ECJ rejected claims by sports bodies that organize contests to ownership over the scores or results and other data related to these contests.

Evaluation Metrics for Structured Text Retrieval

Jovan Pehcevski[1], Benjamin Piwowarski[2]
[1]INRIA Paris-Rocquencourt, Le Chesnay Cedex, France
[2]University of Glasgow, Glasgow, UK

Synonyms

Performance metrics; Evaluation of XML retrieval effectiveness

Definition

An *evaluation metric* is used to evaluate the effectiveness of information retrieval systems and to justify theoretical and/or pragmatic developments of these systems. It consists of a set of measures that follow a common underlying evaluation methodology.

There are many metrics that can be used to evaluate the effectiveness of structured text retrieval systems. These metrics are based on different evaluation assumptions, incorporate different hypotheses of the expected user behavior, and implement their own evaluation methodologies to handle the level of overlap among the units of retrieval.

Historical Background

Over the past 5 years, the initiative for the evaluation of XML retrieval (INEX) has investigated various aspects of structured text retrieval, by particularly focusing on XML retrieval. Major advances, both in terms of approaches to XML retrieval and evaluation of XML retrieval, have been made in the context of INEX. The focus of this entry is on evaluation metrics for XML retrieval, as evaluation metrics for structured text retrieval have thus far been proposed in the context of XML retrieval.

Compared to traditional information retrieval, where whole documents are the retrievable units, information retrieval from XML documents creates additional evaluation challenges. By exploiting the logical document structure, XML allows for more focused retrieval by identifying information units (or XML elements) as answers to user queries. Due to the underlying XML hierarchy, in addition to finding the most specific elements that at the same time exhaustively cover the user's information need, an XML retrieval system needs to also determine the appropriate level of answer granularity to return to the user. The *overlap problem* of having multiple nested elements, each containing identical textual information, can have a huge impact on XML retrieval evaluation [6].

Traditional information retrieval evaluation measures (such as recall and precision) mostly assume that the relevance of an information unit (e.g., a document) is binary and independent of the relevance of other information units, and that the user has access to only one information unit at a time. Furthermore, they also assume that the information units are approximately equally sized.

These two assumptions do not hold in XML retrieval, where the information units are nested elements of very different sizes. As nested elements share parts of the same information, an evaluation metric for XML retrieval can no longer assume than the relevance of elements is independent. Moreover, since users can access different parts of an XML document, it also can no longer be assumed that they will have access to only one element at a time. Each of the evaluation metrics for XML retrieval supports the above assumptions to a different extent.

Another limitation of the traditional information retrieval metrics is that they are not adapted to the evaluation of specific retrieval tasks, which could use more advanced ways of presenting results that arise naturally when dealing with XML documents. For example, one task in XML retrieval is to present the retrieved elements by their containing documents, allowing for an easier identification of the relevant information within each document.

INEX has been used as an arena to investigate the behavior of a variety of evaluation metrics for XML retrieval. Most of them are extensions of traditional information retrieval metrics, namely precision-recall and cumulated gain. Precision-recall is a bi-dimensional metric that captures the concentration and the number of relevant documents retrieved by an information retrieval system. An alternative definition of this metric calculates precision at a given recall level ℓ (between 0 and 100%) as the probability that a retrieved document is relevant, provided that a user wants to see ℓ percent of the relevant documents that exist for the topic of interest [12]. The precision-recall metric was the first one extended for the purposes of XML retrieval evaluation.

The cumulated gain (CG) metric [2] relies on the idea that each retrieved document corresponds to a gain for the user, where the gain is a value between 0 and 1. The metric then simply computes the CG at a given rank k as a sum of the gains for the documents retrieved between the first rank and rank k. When normalized, the CG value is somewhat similar to recall, and it is also possible to construct an equivalent of precision for CG. The importance of extending this metric for XML retrieval lies in the fact that it allows for non-binary relevance, which means it can capture elements of varying sizes and granularity.

Foundations

A common notation is used throughout this document to describe the formulae of the different evaluation metrics for XML retrieval. The notation is presented in Table 1. It is also assumed that any XML element can be represented as a textual segment that spans the text corresponding to that XML element. This conceptual representation is practical, as it is possible to define the intersection, the union, the inclusion, and the size of any two segments.

Evaluation Metrics for Structured Text Retrieval. Table 1. Common notations used to describe formulae of XML retrieval metrics

Notation	Short description
e	An XML element
e_i	The *i*th XML element in the list
$spe(e)$	The (normalized) specificity
$exh(e)$	The (normalized) exhaustivity
$q(e)$	A quantization function
$\mathfrak{I}$	The set of ideal elements
$\mathcal{L}$	The ideal ranked list of elements
ℓ	Arbitrary recall level
size(e)	The size of element *e*, usually in number of characters
overlap(i)	The level of overlap between the *i*th element of the list and the previously returned elements

Evaluation Concepts

In XML retrieval, the commonly used ad hoc retrieval task simulates how a digital library is typically used, where information residing in a static set of XML documents is retrieved using a new set of topics. Different sub-tasks can be distinguished within the broad ad hoc retrieval task.

XML Retrieval Tasks

The main XML retrieval tasks, considered to be subtasks of the main INEX ad hoc retrieval task, are:

- Thorough, where XML retrieval systems are required to estimate the relevance of a retrieved element and return a ranked list of all the overlapping relevant elements.
- Focused, where the returned ranked list consists of non-overlapping relevant elements.
- Relevant in context (RiC), where systems are required to return a ranked list of relevant articles, where for each article a set of non-overlapping relevant elements needs to be correctly identified.
- Best in context (BiC), where the systems are required to return a ranked list of relevant articles, where for each article the best entry point for starting to read the relevant information within the article needs to be correctly identified.

User Behavior

The evaluation metrics typically model a sequential user browsing behavior: given a ranked list of answer elements, users start from the beginning of the list and inspect one element at a time, until either all the elements in the list have been inspected, or users had stopped inspecting the list since their information needs were fully satisfied. However, while inspecting a ranked list of elements, users of an XML retrieval system could also have access to other structurally related elements, or indeed could be able to inspect the *context* where the answer elements reside (which may be supported by features such as browsing, scrolling, or table of contents).

Accordingly, in addition to modeling the sequential user model, the evaluation metrics should also be able to model various user browsing behaviors.

Relevance Dimensions

The *relevance* of a retrieved XML element to a query can be described in many ways. It is therefore necessary to define a relevance scale that can be used by the evaluation metrics. Traditional information retrieval usually uses a binary relevance scale, while in XML retrieval there is a multi-graded (or continuous) relevance scale that uses the following two relevance dimensions:

- Exhaustivity (denoted exh), which shows the extent to which an XML element covers aspects of the information need.
- Specificity (denoted spe), which shows the extent to which an XML element is focused on the information need.

The two relevance dimensions have evolved over the years (readers are referred to the *relevance* definitional entry for more details). For simplicity, it will be assumed that each relevance dimension uses a continuous relevance scale with values between 0 and 1. For example, the four-graded relevance scale used by the two dimensions in INEX from 2002 until 2004 can be mapped onto the values 0, $\frac{1}{3}$, $\frac{2}{3}$ and 1.

The normalized exhaustivity and *specificity* of an XML element e are respectively denoted as $exh(e)$ and $spe(e)$. They can take values between 0 and 1.

Quantization

Quantization is the process of transforming the values obtained from the two relevance dimensions into a single normalized relevance score (which again takes values between 0 and 1). It is used to represent the extent to which the retrieved element is relevant.

For example, the strict quantization function can be used to measure the XML retrieval performance when only highly relevant elements are targets of retrieval, while the generalized quantization function can be used to measure the performance when elements with multiple degrees of relevance are targets of retrieval:

$$q_{\text{strict}}(e) = \begin{cases} 1 & \text{if } exh(e) = spe(e) = 1 \\ 0 & \text{otherwise} \end{cases}$$

$$q_{\text{gen}}(e) = exh(e) \times spe(e)$$

The strict quantization can therefore be used to reward systems that only retrieve elements that are fully exhaustive and specific, while the generalized quantization rewards systems that retrieve elements with multiple relevance degrees.

Ideality

The concept of ideality emerged in XML retrieval as a concept that is used to distinguish those among all judged relevant elements that users would prefer to see as answers. For example, in order to distinguish between the intrinsic relevance of a paragraph from the inherited relevance of its containing section, it could be said that, even though both elements are relevant, only the paragraph is *ideal*. By definition, an ideal element is always relevant but the reverse is true only in traditional information retrieval.

Ideal elements, unlike relevant elements, can be assumed to be independent. Note that this assumption is similar to the independence of document relevance in traditional information retrieval; that is, ideal elements, as documents, can overlap *conceptually* (they can contain same answers to the underlying information need) as long as they do not overlap *physically*. In XML retrieval, this assumption implies that ideal elements cannot be nested. Note that ideality can be extended to more general units than elements, namely the passages.

Construction of Ideal Sets and Lists

To construct a set $\mathfrak{I}$ of ideal elements, one has to make hypotheses about the underlying retrieval task and the expected user behavior [5].

One example of methodology for identifying the ideal elements is as follows [3]: given any two elements on a relevant path, the element with the higher quantized score is first selected. A *relevant path* is a path in the document tree that starts from the document element and ends with a relevant element that either does not contain other elements, or contains only irrelevant elements. If the two element scores are equal, the one deeper in the tree is chosen. The procedure is applied recursively to all overlapping pairs of elements along a relevant path until only one element remains. It is important that the methodology for identifying ideal elements closely reflects the expected user behavior, since it has been shown that the choice of methodology can have a dramatic impact on XML retrieval evaluation [3].

Given a set of ideal elements, and an evaluation metric that uses that set, it is then possible to construct an ideal list $\mathcal{L}$ of retrieved elements that maximises the metric score at each rank cutoff.

Near Misses and Overlap

Support of near misses is an important aspect that needs to be considered by the evaluation metrics for XML retrieval. *Near misses* are elements close to an ideal element, which act as entry points leading to one or more ideal elements. It is generally admitted that systems that retrieve near misses should be rewarded by the evaluation metrics, but to a lesser extent than when ideal elements are retrieved [4].

Early attempts that extended the traditional information retrieval metrics to support XML retrieval rewarded near misses by assigning partial scores to the elements nearby an ideal one [1,6]. However, this implies that systems that return only ideal elements will never achieve a 100% recall, since both ideal elements and near misses have to be returned to achieve this level of recall [10].

Moreover, these metric extensions are commonly considered to be “overlap positive” [14], which means that they reward systems for retrieving twice the same ideal element, either directly or indirectly, and that the total reward for retrieving that ideal element increases with the number of times it is retrieved. To cater for this problem, overlap neutral and/or negative evaluation metrics have since been developed [1,5].

It is therefore important to be able to compute the degree of overlap between an element e_i and other elements previously retrieved in the ranked list $(e_1,\ldots,e_i)$. A commonly adopted measure is the percentage of text in common between the element and the other previously retrieved elements:

$$\mathrm{overlap}(i) = \frac{\mathrm{size}\left(e_i \cap \bigcup_{j=1}^{i-1} e_j\right)}{\mathrm{size}(e_{\mathrm{i}})} \qquad (1)$$

The overlap function equals 0 when there is no overlap between the element e_i and any of the previously retrieved elements e_j, and equals 1 when there is full overlap (i.e., either all its descendants or one of its ancestors have been retrieved). A value between 0 and 1 denotes intermediate possibilities.

Metric Properties

An evaluation metric for XML retrieval should provide a support for the following properties.

- *Faithfulness*. The metric should measure what it is supposed to measure (*fidelity*) and it should be *reliable* enough so that its evaluation results can be trusted.
- *Interpretation*. The outcome of the evaluation metric should be easy to interpret.

- *Recall/precision*. The metric should capture both *recall* and *precision*, as they are complementary dimensions whose importance have been recognized in traditional information retrieval (some retrieval tasks put more focus on recall while others prefer precision).
- *Ideality*. The metric should support the notion of ideal elements.
- *Near misses*. The metric should be able to properly handle near misses.
- *Overlap*. The metric should properly handle the overlap among retrieved and judged elements.
- *Ideality graded scale*. The metric should be able to support multi-graded or continuous scales, in order to distinguish the ideality of two elements.
- *User models and retrieval tasks*. The metric should be able to model different *user behaviors* and support different *retrieval tasks*, since XML retrieval systems support a variety of features that allow information access.

Table 2 summarizes the above metric properties and provides an overview of the extent to which each of the evaluation metrics for XML retrieval (described in the next section) provides a support for them.

Evaluation Metrics

This section presents the different evaluation metrics that were proposed so far in XML retrieval.

The inex_eval Metric

For 3 years from 2002, the `inex_eval` metric [1] was used as the official INEX metric to evaluate the effectiveness of XML retrieval systems. This metric supports *weak ordering* of elements in the answer list [12], where one or more elements are assigned identical retrieval status values by an XML retrieval system. For simplicity, the discussion is restricted to the case where elements are fully ordered.

The `inex_eval` metric assumes that the degree (or probability) of relevance of an element e is directly given by the quantization function $q(e)$. Its degree

Evaluation Metrics for Structured Text Retrieval. Table 2. Metric properties, and the extent to which each of the XML retrieval metrics supports them. In the table, "y" stands for yes, "n" for no, "i" for indirect, "+" for overlap positive, "–" for overlap negative, and "=" for overlap neutral. The question mark "?" signifies unclear or not demonstrated property

Metric Property	inex_eval	inex_eval_ng	nXCG	ep/gr	T2I	GR	PRUM	EPRUM	HiXEval
Research publication	[1]	[1]	[5]	[5]	[13]	[10]	[11]	[9]	[7]
INEX metric (years)	02–04	03	05–06	05–06				06	07
Faithfulness	?	?	y	y	?	y	y	y	y
Interpretation	n[a]	n[a]	y[b]	y[b]	y	y	y	y	y[b]
Recall	y	y	y	y	y	y	y	y	y
Precision	y	y	n	y	y	y	y	y	y
Near misses	i	i	y	y	y	y	y	y	y
Overlap	+	-	=	=	=	=	=	=	=
Ideality	n	n	y	y	y	y	y	y	y[c]
Ideality graded scale	n/a	n/a	y	y	n	y	n	y	y[d]
Explicit user model	n	n	n	n	y	y	y	y	n
XML Retrieval Tasks									
Thorough	y	y	y	y	?	y	y	y	y
Focused	?	?	y	y	y	y	y	y	y
RiC	i	i	i	i	i	y	y	y	i
BiC	i	i	i	i	i	y	y	y	i

[a] But for some special cases.

[b] With parameter α set to 0 or 1.

[c] Highlighted passages are the ideal units in the case of HiXEval.

[d] The ideality of an element is fixed and directly proportional to the amount of highlighted text.

of non-relevance can be symmetrically defined as $(1 - q(e_i))$. At a given rank k, it is then possible to define the expected number of relevant (resp. non-relevant) $R(k)$ (resp. $I(k)$) elements as follows:

$$R(k) = \sum_{i \le k} q(e_i) \quad I(k) = \sum_{i \le k} (1 - q(e_i))$$

For a given recall level ℓ, the *Precall* [12] metric estimates the probability that a retrieved element is relevant to a topic (assuming that a user wants to find ℓ% of the relevant elements in the collection, or equivalently $\ell \cdot N$ relevant elements). If k_ℓ is the smallest rank k for which $R(k)$ is greater or equal to $\ell \cdot N$, then precision is defined as follows:

$$\text{Precision}(\ell) = \frac{\text{number of seen relevant units}}{\text{expected search length}} = \frac{\ell \cdot N}{k_\ell} \tag{2}$$

where N is assumed to be the expectation of the total number of relevant elements that can be found for an INEX topic, i.e., $N = \sum_e q(e)$ across all the elements of the collection.

Beyond the lack of support for various XML retrieval tasks, the main weakness of the `inex_eval` metric is that one has to choose (with the quantization function) whether the metric should allow near misses or should be overlap neutral – both are not possible. To support overlap, it is possible to compute a set of ideal elements by setting the normalized quantization scores of non-ideal elements to 0, thus not rewarding near misses. To reward near misses, the quantization function should give a non-zero values for elements nearby the ideal elements, but then the system will get fully rewarded only if it returns both the ideal and the other relevant elements. Another problematic issue is the use of non-binary relevance values inside the `inex_eval` formula shown in (2), which makes the metric ill-defined from a theoretical point of view.

The inex_eval_ng Metric

The `inex_eval_ng` metric was proposed as an alternative evaluation metric at INEX 2003 [1]. Here, the two relevance dimensions, *exhaustivity* and *specificity*, are interpreted within an *ideal concept space*, and each of the two dimensions is considered separately while calculating recall and precision scores. There are two variants of this metric, which differ depending on whether overlap among retrieved elements is penalized or not: `inex_eval_ng(o)`, which penalises overlap among retrieved elements; and `inex_eval_ng(s)`, which allows overlap among retrieved elements. Unlike the `inex_eval` metric, this metric directly incorporates element sizes in their relevance definitions.

With `inex_eval_ng(o)`, precision and recall at rank k are calculated as follows:

$$\text{Precision}(k) = \frac{\sum_{i=1}^{k} spe(e_i) \cdot \text{size}(e_i) \cdot (1 - \text{overlap}(i))}{\sum_{i=1}^{k} \text{size}(e_i) \cdot (1 - \text{overlap}(i))}$$

$$\text{Recall}(k) = \frac{\sum_{i=1}^{k} exh(e_i) \cdot (1 - \text{overlap}(i))}{\sum_{i=1}^{\text{N}} exh(e_i)}$$

With `inex_eval_ng(s)`, recall and precision are calculated in the same way as above, except that here the overlap function is replaced by the constant 0 (by which overlap among the retrieved elements is not penalized).

The `inex_eval_ng` metric has an advantage over `inex_eval`, namely the fact that it is possible to penalise overlap. However, due to the fact that it ignores the ideality concept, the metric has been shown to be very unstable if one changes the order of elements in the list, in particular the order of two nested elements [11]. Moreover, `inex_eval_ng` treats the two relevance dimensions in isolation by producing separate evaluation scores, which is of particular concern in evaluation scenarios where combinations of values from the two relevance dimensions are needed to reliably determine the preferable retrieval elements.

The XCG Metrics

In 2005 and 2006, the eXtended cumulated gain (XCG) metrics [5] were adopted as official INEX metrics. The XCG metrics are extensions of the cumulated gain metrics initially used in document retrieval [2].

Gain and Overlap

When the cumulated gain (CG) based metrics are applied to XML retrieval, they follow the assumption that the user will read the whole retrieved element, and not any of its preceding or following elements. An element is partially seen if one or more of its descendants have already been retrieved ($0 < \text{overlap}(i) < 1$), while it is completely seen if any of its ancestors have been retrieved ($\text{overlap}(i) = 1$).

To consider the level of overlap among judged relevant elements, the XCG metrics make use of an ideal set of elements, also known as the *ideal recall base*. To consider the level of overlap among the retrieved elements in the answer list, the XCG metrics implement the following result-list dependent relevance value (or gain) function:

$$\text{gain}(i) = \begin{cases} q(e_i) & \text{if overlap}(i) = 0 \\ (1-\alpha)\cdot q(e_i) & \text{if overlap}(i) = 1 \\ \alpha \cdot \dfrac{\sum_{j/e_j \subseteq e_i} \text{gain}(j)\cdot \text{size}(e_j)}{\text{size}(e_i)} & \text{otherwise} \\ \quad +(1-\alpha)\cdot q(e_i) & \end{cases} \tag{3}$$

The parameter α influences the extent to which the level of overlap among the retrieved elements is considered. For example, with α set to 1 (focused task), the gain function returns 0 for a previously fully seen element, reflecting the fact that an overlapping (and thus redundant) element does not bring any retrieval value in evaluation. Conversely, the level of overlap among the retrieved elements is ignored with α set to 0 (thorough task).

The gain formula cannot guarantee that the sum of the gain values obtained for descendants of an ideal element are smaller than the ideal element gain, and so it is necessary to "normalize" the gain value by forcing an upper gain bound [5].

XCG Metrics

Given a ranked list of elements for an INEX topic, the cumulated gain at rank k, denoted as $XCG(k)$, is computed as the sum of the normalized element gain values up to and including that rank:

$$XCG(k) = \sum_{i=1}^{k} \text{gain}(i) \tag{4}$$

Two XCG metrics used as official XML retrieval metrics at INEX in 2005 and 2006 are nXCG and ep/gr. The nXCG metric is a normalized version of $XCG(k)$, defined as the ratio between the gain values obtained for the evaluated list to the gain values obtained for the ideal list.

The ep/gr metric was defined as an extension of nXCG in order to average performances over runs and to define an equivalent of precision. It consists of two measures: effort-precision *ep*, and gain-recall *gr*.

The gain-recall *gr*, calculated at the rank *k*, is defined as:

$$gr[k] = \frac{XCG[k]}{\sum_{x \in \mathfrak{I}} gain(x)} \tag{5}$$

The effort-precision *ep* is defined as the amount of relative effort (measured as the number of visited ranks) a user is required to spend compared to the effort they could have spent while inspecting an optimal ranking. It is calculated at a cumulated gain level achieved at rank *k* and is defined as:

$$ep[k] = \frac{\min\{i | XCG_{\mathcal{L}}(i) \geq XCG(k)\}}{k} \tag{6}$$

where the indice $\mathcal{L}$ means that the score is evaluated with respect to an ideal list of relevant elements. An *ep* score of 1 reflects an ideal performance, in which case the user made the minimum necessary effort (computed in number of ranks) to reach that particular cumulated gain. An ep/gr curve can then be computed by taking pairs $(gr[k], ep[k])$ for varying rank *k* values.

The XCG metrics have advantages over inex_eval and inex_eval_ng, since its use of an ideal list ensures that the metric is overlap neutral. It also properly handles near misses by the use of an appropriate quantization function. However, the construction of the ideal set of elements relies on heuristics [3]. Other problems of the metric is that the gain is difficult to interpret for values of α other than 0 or 1, which also makes the outcome of the metric somewhat difficult to interpret.

The T2I metric

The tolerance to irrelevance (T2I) metric [13] relies on the same evaluation assumptions as inex_eval, but includes a different user model more suited to XML documents. The underlying user model is based on the intuition that a user processes the retrieved list of elements until their tolerance to irrelevance have been reached (or until they found a relevant element), at which point the user proceeds to the next system result. The T2I metric has only been theoretically proposed, and is yet to be implemented and evaluated.

The (E)PRUM and GR Metrics

The expected precision recall with user modeling (EPRUM) metric [9], which was used as an alternative evaluation metric at INEX in 2005 and as one of the official ones in 2006, extends the traditional definitions of precision and recall to model a variety of user behaviors. EPRUM is unique among all the INEX metrics in that it stochastically defines the user browsing behavior. It is the last defined within a set of three metrics, the previous one being GR (generalized recall) and PRUM (precision recall with user modeling).

The User Model

From a retrieved element, the user can navigate using the corpus structure. The *context* of a list item is defined as the set of elements that can be reached through navigation from it. This includes the pointed elements but also the context of the pointed elements (siblings, ancestors, etc.). To model the user behavior inside the context, the three metrics rely on a set of probabilities on simple events of the form "navigating from a list item to an element in the corpus". The probabilities of navigating from rank j in the list to an element x can be set to values estimated by any adequate method and is denoted $\mathrm{P}(j \rightsquigarrow x)$. When a user is over with this exploration, they *consult* the next entry of the list and repeat the process until their information needs are satisfied. Note that this user model is general enough so as to cope with all INEX tasks, since there is no constraint on how a rank is defined.

Users *see* an element when they navigate to it from another element or from the list, and they *discover* an element if they see it for the first time. The distinction between "seen" and "discovered" is important because the system is rewarded only when elements are discovered. The probability that the user discovers f ideal elements when consulting ranks between 1 and k included is then given by:

$$\mathrm{P}(F_k = f) = \sum_{\substack{A \subseteq \mathfrak{I} \\ |A| = f}} \prod_{x \in A} \mathrm{P}(x \in S_k) \prod_{x \in \mathfrak{I} \setminus A} \mathrm{P}(x \notin S_k) \quad (7)$$

where S_k is the set of all elements seen by the user who has consulted ranks 1 to k. The probability that an element was seen is computed with $P(x \in S_k) = 1 - \prod_{j=1}^{k}(1 - P(j \rightsquigarrow x))$.

GR, PRUM and EPRUM

The GR metric is a generalization of recall with the above specified user model. It simply estimates the expected number of discovered elements at a given rank k, and divides it by the expected number of ideal elements in the database in order to get a normalized value. PRUM is defined as the probability that a consulted list item leads the user to discover an ideal element. Its most important limitation is that it does not handle well non-binary assessments.

EPRUM defines precision based on the comparison of two minimum values: the minimum rank that achieves the specified recall over *all* the possible lists and over the *evaluated* list. For a given recall level ℓ, precision is thus defined as the percentage of effort (in minimum number of consulted ranks) a user would have to make when consulting an ideal list with respect to the effort when consulting the evaluated list:

$$\begin{aligned}&\mathrm{Precision}(\ell)\\&= \mathbb{E}\left[\frac{\begin{array}{c}\text{Minimum number of consulted}\\ \text{list items for achieving a recall } \ell \text{ over all lists}\end{array}}{\begin{array}{c}\text{Minimum number of consulted list items}\\ \text{for achieving a recall } \ell \text{ over the evaluated list}\end{array}}\right]\end{aligned}$$

where the assumption is that when the user cannot achieve recall ℓ in the evaluated list, then the minimum number of consulted list items for the evaluated list is infinite (this assumption is the same as in traditional information retrieval). This measure is an extension of the standard precision-recall metric.

It is similarly possible to extend the traditional definition of precision at a given rank k. If the expected recall of the evaluated list at rank k is r_k, then precision at rank k is defined as the ratio of the minimum number of consulted list items over all possible lists to achieve recall r_k to the number of consulted ranks k.

The EPRUM metric solves some problems of PRUM and substantially reduces its complexity. It also allows proper handling of graded ideality. The advantages of EPRUM metric are the fact that it handles all the INEX tasks through its user model parameters, that the user model is very flexible (for example allowing to reward near misses that are not direct ancestors or descendant of an ideal element), and that the outcome of the metric can easily be interpreted. However, like the XCG metrics, it assumes that the ideal set of elements and the ideal list of retrieved elements can easily be determined, which is shown to be not as straightforward in XML retrieval [3].

The HiXEval Metric

Since 2005, a highlighting assessment procedure is used at INEX to gather relevance assessments for the XML retrieval topics. In this procedure, assessors from the participating groups are asked to highlight sentences representing the relevant information in a pooled set of retrieved documents. To measure the extent to which an XML retrieval system returns relevant information, INEX started to employ evaluation metrics based on the `HiXEval` metric [7,8]. This is motivated by the need to directly exploit the INEX highlighting assessment procedure, and it also leads to evaluation metrics that are natural extensions of the well-established metrics used in traditional information retrieval.

`HiXEval` only considers the specificity relevance dimension, and it credits systems for retrieving elements that contain as much highlighted (relevant) text as possible, without also containing a substantial amount of non-relevant text. So, instead of counting the number of relevant elements retrieved, `HiXEval` measures the amount of relevant text retrieved. Like the XCG metrics, it makes the assumption that the user will read the whole retrieved element, and not any of its preceding or following elements. An element is partially seen by the user if one or more of its descendants have already been retrieved, while it is completely seen if any of its ancestors have been retrieved.

Let rsize(e_i) be the amount of highlighted (relevant) text contained by an element e retrieved at rank i, so that if there is no highlighted text in the element, rsize(e_i) = 0. (Note that rsize(e_i) can also be represented as: rsize(e_i) = $spe(e_i)\cdot$ size(e_i).) To measure the value of retrieving relevant text from e_i, the relevance value function rval(i) is defined as follows:

$$\mathrm{rval}(i) = \begin{cases} \mathrm{rsize}(e_i) & \text{if overlap}(i) = 0 \\ (1-\alpha)\cdot \mathrm{rsize}(e_i) & \text{if overlap}(i) = 1 \\ \mathrm{rsize}(e_i) - \alpha . \sum\limits_{j/e_j \subseteq e_i} \mathrm{rval}(j) & \text{otherwise} \end{cases} \tag{8}$$

As with the XCG metrics, the parameter α is a weighting factor that represents the importance of retrieving non-overlapping elements in the ranked list.

Precision and recall at a rank k are defined as follows:

$$\mathrm{Precision}(k) = \frac{\sum\limits_{i=1}^{k} \mathrm{rval}(i)}{\sum\limits_{i=1}^{k} \mathrm{size}(e_i)}$$

$$\mathrm{Recall}(k) = \frac{1}{Trel} \cdot \sum_{i=1}^{k} \mathrm{rval}(i)$$

In the above equation, *Trel* represents the total amount of highlighted relevant text for an INEX topic. Depending on the XML retrieval task, different *Trel* values are used by the metric. For example, for the focused task *Trel* is the total number of highlighted characters across all *documents*. This means that the total amount of highlighted relevant text for the topic represents the sum of the sizes of the (non-overlapping) highlighted passages contained by all the relevant documents. Conversely, for the thorough task *Trel* is the total number of highlighted characters across all *elements*. For this task, the total amount of highlighted relevant text for the topic represents the sum of the sizes of the (overlapping) highlighted passages contained by all the relevant elements.

The precision and recall scores can be combined in a single score using the standard F-measure (their harmonic mean). By comparing the F-measure scores obtained from different XML retrieval systems, it would be possible to see which system is more capable of retrieving as much relevant information as possible, without also retrieving a substantial amount of non-relevant information.

HiXEval has the advantage of using a naturally defined ideal unit, namely a highlighted passage, and thus overcomes the problem of defining a set of ideal elements in an arbitrary way. One shortcoming of this metric is that it makes the assumption that the degree of ideality of a passage is directly proportional to the passage size. It also shares the same issue identified with the XCG metrics that, with α values different from 0 or 1, the interpretation of the output of the rval (i) function is not very straightforward.

Key Applications

Web Search

Due to the increasing adoption of XML on the World Wide Web, information retrieval from XML document collections has the potential to be used in many Web application scenarios. Accurate and reliable evaluation of XML retrieval effectiveness is very important for improving the usability of Web search, especially if the evaluation captures the extent to which XML retrieval can be adapted to a particular retrieval task or a user model. This could certainly justify the increasing usage of XML in the ever-growing number of interactive Web search systems.

Digital Libraries

Reliable evaluation of XML retrieval effectiveness is also important for improving information retrieval from digital libraries, especially since there is a large amount of structured (XML) information that is increasingly stored in modern digital libraries.

Evaluation of Relational Operators

Jingren Zhou
Microsoft Research, Redmond, WA, USA

Synonyms

Query evaluation; Query processing

Definition

A query usually consists of several relational operators. The corresponding physical query plan is composed of several physical operators. Generally speaking, a physical operator is an implementation of a relational operator. For each relational operator, there are several alternative algorithms (physical operators) for its implementation and there is no universally superior one. So choosing physical operators wisely is crucial for query performance. Which physical operator is the best depends on several factors, such as the sizes of the input relations, the existing sorting orders of the input relations, the existing indexes/materialized views, the buffer replacement policy, and the size of the available buffer pool, etc.

Historical Background

The relational operators serve as the building blocks for query processing. Their implementation techniques have been extensively studied ever since the first relational DBMS was built.

Foundations

Efficient evaluation of relational operators is required to provide good query performance. There are usually different evaluation algorithms for a given relational operator. Each evaluation algorithm is implemented by a physical operator. There can be more than one physical query plan for a query. The query optimizer considers various physical query plans and chooses the cheapest plan in a cost-based fashion.

Pipelined Query Execution

Database systems usually employ a demand-pull query execution model. Each query plan consists of a pipeline of physical operators. In this model, each operator supports a group of three functions that allows a parent operator to get the result *one* tuple at a time.

1. *Open*. The open() function initializes the state of the iterator by allocating buffers for its inputs and output, and is also used to pass in arguments such as selection predicates that modify the behavior of the operator.
2. *Next*. The next() function calls the next() function on each input node recursively and processes the input tuples until one output tuple is generated. The state of the operator is updated to keep track of how much input has been consumed.
3. *Close*. When all output tuples have been produced through repeated calls to the next() function, the close() function deallocates the state information and performs final housekeeping.

The iterator interface supports pipelining of results naturally. The decision to pipeline or materialize input tuples is encapsulated in the operator-specific code that processes input tuples. Pipelining requires much less space for intermediate results during execution. The demand-pull pipelined query execution model can be executed by a single process or thread. This approach has several advantages such as avoiding inter-process communication between operators, avoiding process synchronization and scheduling, minimizing data copies, keeping only the current data items in memory, and performing lazy operator evaluation.

Selection

Given a selection of the form $\sigma_{R.a\ \theta\ c}(R)$, the algorithms for selection use either scanning or indexing. The condition $R.a\ \theta\ c$ is also called the selection predicate. See Fig. 1.

Selection Based on Scanning

If there is no secondary index on $R.a$ and the relation R is not sorted on $R.a$, the only choice of evaluation is to scan the entire relation. For each tuple, the predicate is evaluated and the tuple is added to the result if the predicate is satisfied.

Selection Based on Indexing

If there is no secondary index on $R.a$ but relation R is sorted on $R.a$, relation R is said to be clustered on $R.a$ and can be viewed as a clustered index itself. A binary search can be used to locate the first tuple that satisfies the selection predicate. If the predicate is a range predicate, for example, $R.a > 1$, the rest of the tuples can be retrieved by scanning R from this location until the predicate is no longer satisfied.

If there is a secondary index (usually a B^+ tree) on $R.a$, an index lookup can be performed to locate the first index entry pointing to a qualifying tuple. Then the leaf pages of the index are scanned to retrieve all entries with the key value satisfying the predicate. Following each of these entries, the corresponding R tuple is then retrieved and added to the result.

If an index contains all the columns that are required by the query, the final R tuple retrieval can be skipped. In this scenario, the selection is done by an index only operation.

In summary, which strategy is the best depends on the index availability, whether the index is clustered or nonclustered, and the selectivity of the selection predicate.

Projection

In general, the projection is of the form $\pi_{a,\ b,\ c}(R)$. Some projected columns may be computed from attributes in R, for example, $\pi_{R.a\ +\ R.\ b,\ R.\ c}(R)$. See Fig. 2. To implement projection, unwanted attributes (i.e.,

```
SELECT *
FROM R
WHERE R.a > 1
```

Evaluation of Relational Operators. Figure 1. Selection query.

those not specified in the projection) are removed and expressions, if any, are computed on the fly.

Joins

The join operation, $R \bowtie_{R.\ r\ \theta\ S.\ s} S$, is one of the most useful relational operations and is the primary means of combining information from more than one relation. The condition $R.r\theta S.s$ is called the join predicate.

A join operation can always be implemented as a cross-product followed by selections and projections. See Fig. 3. However, a cross-product generates much larger results and thus can be quite inefficient. It is very important to recognize joins and implement them without materialized the underlying cross-product.

Join operations have received extensive research over years. There are several alternative techniques for implementing joins. Choosing the right join operation and the correct join order plays a major role in finding an optimal physical plan. The decision depends on various factors, such as the size of input relations, the amount of available memory, and available alternative access methods, etc.

Nested Loops Join

Nested loops join is the simplest join algorithm. The algorithm starts with reading the *outer* relation R, and for each tuple $\mathcal{R} \in R$, the *inner* relation S is checked and matching tuples are added to the result.

```
Algorithm 1: Nested Loops Join: $R \bowtie_{pred\ (r,s)} S$
foreach $\mathcal{R} \in R$ do
    foreach $S \in S$ do
        if pred ($\mathcal{R}$.r, S.s) then
            add {$\mathcal{R}$, S} to result
        end
    end
end
```

```
SELECT R.a + R.b, R.c
FROM R
```

Evaluation of Relational Operators. Figure 2. Projection query.

```
SELECT *
FROM R, S
WHERE R.r = S.s
```

Evaluation of Relational Operators. Figure 3. Join query.

One advantage of nested loops join is that it can handle any kind of join predicate, unlike sort-merge join and hash join which mainly deal with an equality join predicate. In order to effectively utilize buffer pages and available indexes, there are two variations of nested loops join.

Block Nested Loops Join Suppose that the memory can hold B buffer pages. If there is enough memory to hold the smaller relation, say R, with at least two extra buffer pages left, the optimal approach is to read in the smaller relation R and to use one extra page as an input buffer to read in the larger relation S and one extra buffer page as an output buffer.

If there is not enough memory to hold the smaller relation, the best approach is to break the outer relation R into *blocks* of $B - 2$ pages each and scan the whole inner relation S for each block of R. As described before, one extra page is used as an input buffer and the other as an output buffer. In this case, the outer relation R is scanned only once while the inner relation S is scanned multiple times.

Index Nested Loops Join If one of the two relations has an index on the join attribute, an index nested loops join can be used to take advantage of the index. Suppose the relation S has a suitable index on the join attribute $S.s$. For each tuple $\mathcal{R} \in R$, the index can be used to retrieve all matching tuples of S. If the number of matching S tuples for each R tuple is small, index lookup is much more efficient than scanning the whole S relation. However, index lookup usually involves random I/Os. If the number of matching S tuples is large, it might be worthwhile considering block nested loops join.

Sort-Merge Join

If the join predicate is an equality predicate, sort-merge join can be used. The basic idea of the sort-merge join algorithm is to *sort* both relations on the join attribute and to then *merge* the sorted relations by scanning them sequentially and looking for qualifying tuples.

The sorting step groups all tuples with the same value in the join attribute together. Such groups are sorted based on the value in the join attribute so that it is easy to locate groups from the two relations with the same attribute value. Sorting operation can be fairly expensive. If the size of the relation is larger than the available memory, external sorting algorithm

```
Algorithm 2: Sort-Merge Join: $R \bowtie_{R.r=S.s} S$
// sorting step
Sort the relation R on the attribute r;
Sort the relation S on the attribute s;
// merging step
$\mathcal{R}$ = first tuple in R;
S = first tuple in S;
S' = first tuple in S;
while $\mathcal{R} \neq eof$ and $S' \neq eof$ do
    while $\mathcal{R}.r < S'.s$ do
        $\mathcal{R}$ = next tuple in R after $\mathcal{R}$
    end
    while $\mathcal{R}.r > S'.s$ do
        S' = next tuple in S after S'
    end
    S = S';
    while $\mathcal{R}$.r == S'.s do
        S = S'
        while $\mathcal{R}$.r == S.s do
            add {$\mathcal{R}$,S} to result;
            S = next tuple in S after S;
        end
        $\mathcal{R}$ = next tuple in R after $\mathcal{R}$;
    end
    S' = S;
end
```

is required. However, if one input relation is already clustered (sorted) on the join attribute, sorting can be completely avoided. That is why sort-merge join looks even more attractive if any of the input relations is sorted on the join attribute.

The merging step starts with scanning the relations *R* and *S* and looking for matching groups from the two relations with the same attribute value. The two scans start at the first tuple in each relation. The algorithm advances the scan of *R* as long as the current *R* tuple has an attribute value which is less than that of the current *S* tuple. Similarly, the algorithm advances the scan of *S* as long as the current *S* tuple has an attribute value which is less than that of the current *R* tuple. The algorithm alternates between such advances until an *R* tuple $\mathcal{R}$ and an *S* tuple $\mathcal{S}$ with $\mathcal{R}.r = \mathcal{S}.s$. The join tuple $\{\mathcal{R}, \mathcal{S}\}$ is added to result.

In fact, there could be several *R* tuples and several *S* tuples with the same attribute value as the current tuples $\mathcal{R}$ and $\mathcal{S}$. That is, several *R* tuples may belong to the current $\mathcal{R}$ group since they all have the same attribute value. The same applies to the current $\mathcal{S}$ group. Every tuple in the current $\mathcal{R}$ group joins with every tuple in the current $\mathcal{S}$ group. The algorithm then resumes scanning *R* and *S*, beginning with the first tuples that follow the group of tuples that are just processed.

When the two relations are too large to be held in available memory, one improvement is to combine the merging step of external sorting with the merging step of the join if the number of buffers available is larger than the total number of sorted runs for both *R* and *S*. The idea is to allocate one buffer page for each run of *R* and one for each run of *S*. The algorithm merges the runs of *R*, merges the runs of *S*, and joins (merges) the resulting *R* and *S* streams as they are generated.

If any of the two relations has an index on the join attribute, another improvement is to merge join the index instead of the relation. Sorting, in this case, can be avoided. After the join, it may be necessary to retrieve other attributes from the relation following qualifying index entries.

Hash Join

The hash join algorithm is commonly used in database systems to implement equijoins efficiently. In its simplest form, the algorithm consists of two phases: the "build" phase and the "probe" phase. In the "build" phase, the algorithm builds a hash table on the smaller relation, say *R*. In the "probe" phase, the algorithm probes the hash table using tuples of the larger relation, say *S*, to find matches.

The algorithm is simple, but it requires that the smaller join relation fits into memory. If there is not enough memory to hold all the tuples in *R*, an additional "partition" phase is required. There are several variants of the basic hash join algorithm. They differ in terms of utilizing memory and handling overflow.

Grace Hash Join The idea behind grace hash join is to hash partition both relations on the join attribute, using the *same* hash function. As the result, each relation is hashed into *k* partitions, and these partitions are written to disk. The key observation is that *R* tuples in partition *i* can join only with *S* tuples in the same partition *i*. If any given partition of *R* can be held in memory, the algorithm can read in and build a hash table on the partition of *R*, and then probe the hash table using tuples of the corresponding partition of *S* for matches.

If one or more of the partitions still does not fit into the available memory (for instance, due to data skewness), the algorithm is recursively applied. An additional orthogonal hash function is chosen to hash the large partition into sub-partitions, which are then processed as before.

Hybrid Hash Join The hybrid hash join algorithm is a refinement of the grace hash join algorithm which takes advantage of more available memory. To partition R (S) into k partitions, the grace hash join uses one input buffer for reading in the relation and k output buffers, one for each partitions.

Suppose there is sufficient memory to hold an in-memory hash table for one partition, say the first partition, of R, the hybrid hash join does not write the partition to disk. Instead, it builds an in-memory hash table for the first partition of R during the "partition" phase. Similarly, when partitioning S, for the tuples in the first partition of S, the algorithm directly probes the in-memory hash table and writes out the results. At the end of the "partition" phase, the algorithm completes the join between the first partitions of R and S while partitioning the two relations. The algorithm then joins the remaining partitions as the grace hash join algorithm.

Compared with the grace hash join algorithm, the hybrid hash join algorithm avoids writing the first partitions of R and S to disk during the "partition" phase and reading them in again during the "build" and the "probe" phases.

```
Algorithm 3: Grace Hash Join: $R \bowtie_{r=s} S$
//partition R into k partitions
foreach $\mathcal{R} \in R$ do
    read $\mathcal{R}$ and add it to buffer page $h_1(\mathcal{R})$;
    flush the page to disk it full;
end
//partition S into k partitions
foreach $S \in S$ do
    read $S$ and add it to buffer page $h_1(S)$;
    flush the page to disk it full;
end
//"build" and "probe" phases
for $i \leftarrow 1$ to $k$ do
    foreach $\mathcal{R} \in$ partition $R_i$ do
        read $\mathcal{R}$ and insert into the hash table using $h_2(\mathcal{R})$;
    end
    foreach $S \in$ partition $S_i$ do
        read $S$ and probe the hash table using $h_2(S)$;
        for matching $\mathcal{R}$ tuples, add $\{\mathcal{R}, S\}$ to result;
    end
    clear the hash table and release the memory;
end
```

Aggregation

Simple aggregation operations include MIN, MAX, SUM, COUNT, and AVG. Aggregation operations can also be used in combination with a GROUP BY clause. See Fig. 4. DISTINCT clause that removes duplicate values can be viewed as a special aggregation operation too, which groups the input by values and outputs one row per group.

For aggregation queries without a GROUP BY clause, the algorithm is straightforward: scan the entire relation and update some state information for each scanned tuple. The state information varies for different aggregation functions. For SUM, the algorithm keeps track of the sum of the values retrieved so far. For AVG, the algorithm keeps track of the sum of the values and the total count of rows retrieved so far. For COUNT, the algorithm keeps track of the total count of values retrieved so far. For MAX (MIN), the algorithm keeps track of the largest (smallest) value retrieved so far.

For aggregation queries with a GROUP BY clause, the aggregation algorithms use either sorting or hashing.

Aggregation Based on Sorting

The sorting algorithm starts with sorting the relation on the grouping attributes and then scanning it again to compute the aggregations functions for each group. By sorting, the algorithm groups together all tuples with the same grouping attributes (therefore belong to the same group). The computation of the aggregation functions is similar to the way of aggregation computation without grouping, except that here the algorithm has to watch for group boundaries. When the algorithm sees a tuple with different grouping attributes, the current group finishes and a new group starts.

Aggregation Based on Hashing

The hashing algorithm first builds an in-memory hash table on the grouping attributes as it scans the relation. Each hash entry corresponds to a group and contains the

```
SELECT SUM (R. x)          SELECT SUM (R. x)
FROM R                     FROM R
                           GROUP NY R.r

       (1)                        (2)
```

Evaluation of Relational Operators. Figure 4. Aggregation queries.

state information required by each aggregation function for the group. For each tuple, the algorithm probes the hash table to find the entry for the group to which this tuple belongs and update the state information. If such entry does not exist, the algorithm creates a new hash entry and initiates the state information.

If the relation is so large that the hash table does not fit in memory, the algorithm hash partitions the relation on the grouping attributes. Since all tuples in a given group are in the same partition, the algorithm can then scan each partition independently and compute aggregation functions as described before.

It is also possible and sometimes preferable to compute aggregation using an index as long as the index covers all the attributes required by the aggregation query. The advantage is to read in a much smaller index compared to the entire relation. If the grouping attributes form a prefix of the indexed keys, the algorithm can avoid the sorting step and scan the index entries sequentially.

Key Applications

Each database query is composed of a few relational operators. The final query plan may implement each relation operator in different ways to achieve an optimal performance. All the implementation techniques are widely used in database systems.

Event and Pattern Detection over Streams

MINGSHENG HONG, ALAN DEMERS, JOHANNES GEHRKE, MIREK RIEDEWALD
Cornell University, Ithaca, NY, USA

Synonyms

Complex event processing (CEP); Event stream processing (ESP)

Definition

An event is a basic unit of information in streaming data. An event pattern is a combination of events correlated over time. Event pattern detection is an important activity in complex event processing. In this setting, the matches to the event patterns are referred to as complex events.

Historical Background

In the early 1990s, a set of pioneering work in *event systems*, such as SNOOP [3] and ODE [8], set out to define query languages for expressing event patterns. In these proposals, the data model for expressing events is not fixed. More recently, the approaches proposed by Cayuga [1,5,6] and SASE [14] for event pattern detection align more closely to relational query processing, in that each event is modeled by a relational schema, and some of the operators for expressing event pattern queries are drawn from relational algebra. Regardless of the data model for events, these systems all use some variant of NFA (Nondeterministic Finite state Automaton) as the processing model.

With the advent of internet-scale message brokering systems, *content based publish-subscribe systems* such as [7] emerged. They are characterized by very limited query languages, allowing simple selection predicates applied to individual events in a data stream. Such systems trade expressiveness for performance – when well engineered, they exhibit very high scalability in both the number of queries and the stream rate. However, their inability to express queries that span multiple input events makes them unsuitable for event pattern detection.

Another category of systems closely related to event pattern detection is *stream databases*, such as Aurora [2], STREAM [10], and TelegraphCQ [4]. Unlike content based publish-subscribe systems, they focus on expressiveness. Such systems have very powerful query languages, typically including a rich functionality and extending SQL with provisions for sliding window and grouping features. Though powerful, stream databases are not designed for detecting event patterns, and their query languages can be awkward for expressing event pattern queries. Moreover, there is little work on scaling up stream database engines with the number of concurrent queries that are reasonably sophisticated.

Foundations

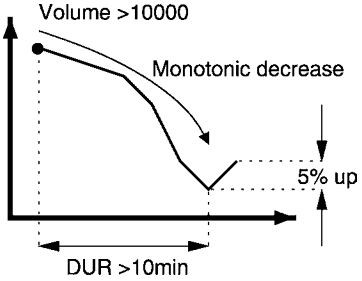
Event Pattern Query Model

An event stream is a potentially infinite sequence of events. Each event has a timestamp value, and its payload content is encoded by a relational tuple. Events are processed in timestamp order by an event processing system. They can be filtered, transformed, and correlated to form event patterns.

The computational model of matching event patterns over event streams naturally extends that of matching regular expression patterns over character streams in the following aspects. First, each stream event can contain multiple attribute-value pairs conforming to a relational schema, where the value domains are potentially infinite. In comparison, each character in a character stream provides for the same single attribute a value drawn from a finite alphabet. Second, given the multiple attributes for each stream event, event patterns can perform relational operations on the events, including filtering, projection and renaming of attributes. This provides expressive power especially to event correlation based on sequencing, where the attribute values of multiple stream events can be compared. Finally, event pattern detection involves a temporal aspect, in that stream events have timestamps, which event patterns reason about. In comparison, regular expression processing only involves character orderings in the streams, which can be viewed as a weaker notion of time.

Event patterns are usually expressed in an event algebra. Many such algebras have been proposed. One representative is the Cayuga algebra [5]. The Cayuga algebra is specifically designed for large-scale event pattern detection. In addition to unary operators for selection predicates and aggregates, the expressive power of this algebra comes from two binary operators. The first binary operator, *sequence*, can correlate two input events based on a join predicate. This join predicate involves timestamps, and can optionally involve other attributes in the stream schema. The second operator, *iteration*, is a generalization of the sequence operator. It is able to produce an event pattern involving arbitrarily many input events by iteratively concatenating input events with the pattern built so far. To allow users to interact with the system in a user-friendly way, a SQL-style query language, referred to as Cayuga Event Language (CEL) [6], has been developed. Figure 1 shows an event pattern query expressed in CEL. This event pattern query

```
SELECT Name, MaxPrice, MinPrice, Price AS FinalPrice
FROM
  FILTER{DUR > 10min}(
    (SELECT Name, Price_1 AS MaxPrice, Price AS MinPrice
    FROM FILTER{Volume > 10000}(Stock))
      FOLD{$2.Name = $.Name, $2.Price < $.Price}
    Stock)
    NEXT{$2.Name = $1.Name AND $2.Price > 1.05*$1.MinPrice}
  Stock
```



Event and Pattern Detection over Streams. Figure 1. Event pattern query to find stock price pattern.

corresponds to a particular trend in stock prices. Intuitively, this query searches for the given price pattern for any company. The pattern starts with a large trade (`Volume > 10,000`), followed by a monotonic decrease in price (`FOLD` clause), which lasts for at least 10 min (`DUR > 10min`). Then the price rebounds with a sudden increase by 5% (`NEXT` clause). The `NEXT` and `FOLD` constructs respectively correspond to the two binary operators in the Cayuga algebra introduced above. `NEXT` matches the next event in the stream that satisfies a given condition (same company name and 5% higher price in the example). `FOLD` is the iterated version of `NEXT`, i.e., it continues matching the next event that satisfies a certain property until a stopping condition is satisfied.

SASE [14] uses a query algebra similar to the Cayuga algebra, where sequence and iteration are the key primitives. SASE also supports *negation*-style event patterns, where a pattern is matched by the absence of an input event, rather than the presence. In addition to online event stream processing supported by Cayuga and SASE, work on sequence database systems has focused on matching event patterns offline over archived data [11,12,13]. Sequence is again the key primitive for expressing event patterns in the SEQ query algebra [13] and the SQL-TS query language [12].

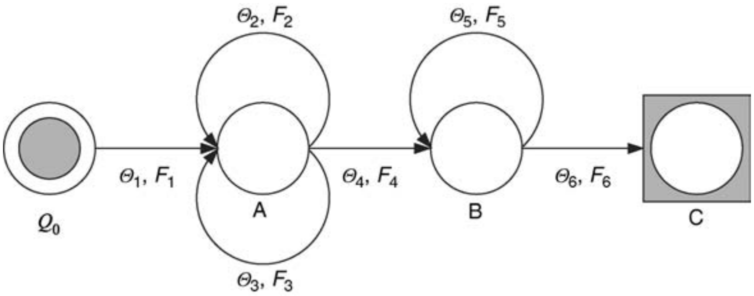
Event Pattern Query Processing

As is mentioned earlier, an event pattern query is typically implemented by a state machine. Continuing the above query example, this approach is described in the context of Cayuga. Each Cayuga automaton is an extension to the classical non-deterministic finite automaton [9] in the following aspects. First, each automaton edge is associated with a predicate, and for an incoming event, this edge is traversed if and only if the predicate is satisfied by this event. This mechanism implements the selection predicates in the event patterns. Second, when patterns are matched, to be able to generate witness events with concrete content instead of boolean answers, each automaton instance needs to store the attributes and values of those events that have contributed to the pattern instance.

Figure 2 shows the automaton for the example query in Fig. 1. The two middle states correspond to the `FOLD` and `NEXT` operators, respectively. The predicates θ_i associated with automaton edges originate either from `FILTER` conditions (θ_1, θ_6 in the example) or from join conditions of the `FOLD` and `NEXT` operators. Specifically, θ_1 implements the filter predicate `vol` $>$ 10,000. When an input stock event *e* satisfying θ_1 occurs, a new automaton instance *I* is created under state *A*, remembering the content of *e*.

Each automaton instance encodes a particular event pattern built from the prefix of the event stream that has been processed so far. When an automaton instance reaches the final state *C*, a match to the entire event pattern specified in the query has been found, and will be output by this automaton.

To continue the explanation of the example Cayuga automaton in Fig. 2, θ_2 and θ_3 respectively implement the two join predicates associated with `FOLD` in the query shown in Fig. 1. These two predicates on the two self-loop edges associated with state *A* together build a monotonically decreasing sequence in the prices of a particular stock. Specifically, after the occurrence of event *e*, when a later stock event e' together with *I* satisfies θ_2; i.e., e' and *I* have the same stock name *s* (say), θ_3 is evaluated to check whether this event pattern built so far can be extended. For this reason, θ_2 serves as a criterion which, when satisfied, concatenates the next input event from `Stock` to the event pattern built up so far, and θ_3 serves as a criterion



Event and Pattern Detection over Streams. Figure 2. Cayuga automaton example (source: [6]).

which, when satisfied, continues the extension of the event pattern being built. The event building process proceeds similarly to state *B* and *C*. The functions F_i are responsible for transforming event stream schemas and automaton state schemas.

Event pattern queries expressed in SASE and SQL-TS are processed in a similar way. In SASE, NFA is one of the run-time operators. Operator re-ordering is performed as part of the query optimization to produce efficient query plans. For example, a selection predicate above an NFA operator can be pushed inside the NFA operator to discard irrelevant input events earlier, thus improving system throughput. In SQL-TS, to optimize pattern search, the query engine exploits the inter-dependencies between the elements of a sequential pattern.

Evaluating one event pattern query efficiently is relatively easy. However, it is challenging to efficiently evaluate a large number of concurrent event patterns. Multi-Query Optimization (MQO) techniques have been developed to share the computation among concurrent event patterns. For example, in Cayuga, the event processing engine achieves this goal by exploiting the relationship of the query algebra to the automata-based query execution, and the commonality among queries. Specifically, each query is first translated into a set of automata. These automata are then "merged" with existing ones in the engine. During the merging process, two optimization techniques are used. First, two automata with the same prefix of states can merge these states, thus sharing computation and storage. This is similar to the technique of finding common subexpressions in relational query processing. Second, some of the filtering predicates on the automaton edges can be managed efficiently by indexes in a way similar to techniques for processing multiple selection operators [7]. These two techniques enable a throughput of thousands of events per second, even for tens of thousands of active event pattern queries.

Key Applications

Event pattern detection targets a large class of both well-established and emerging applications, including supply chain management for RFID (Radio Frequency Identification) tagged products, real-time stock trading, monitoring of large computing systems to detect malfunctioning or attacks, and monitoring of sensor networks, e.g., for surveillance. These *event monitoring applications* need to process massive streams of events in (near) real-time. There is great interest in these applications as indicated by the establishment of sites like http://www.complexevents.com, which bring together major industrial players like BEA, IBM, Oracle, and TIBCO.

Future Directions

One important future direction is to integrate event processing systems with stream databases. In the past they have evolved along different paths, and are designed for different query workloads, as is described in the Historical Background section. It would be beneficial to integrate these two categories of stream processing systems, for two reasons. First, there is much overlap in their functionality. For example, both categories support stateless operations such as filtering and projection, and some forms of stream join. Second, there is a class of stream applications that demand functionality from both categories. There are two major challenges in the integration. At the logical level, a unified query algebra is needed for expressing queries in both categories. At the physical level, it is desirable to evaluate both categories of queries in the same engine. This is a challenging task since current stream database engines, like relational database engines, are usually based on operator trees, while event engines are based on variants of NFAs.

Event Broker

▶ Request Broker

Event Causality

Guy Sharon
IBM Research Labs-Haifa, Haifa, Israel

Definition

The definition of an event processing network includes a relation to express un-modeled event processing logic between events.

The fact that events of type *eT1* cause events of type *eT2* is denoted by the relation *causes(eT1,eT2)*.

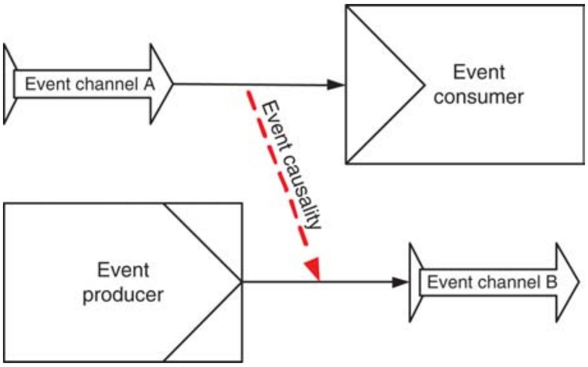
In an EPN where *E* is the set of edges representing event streams, *EC* is the set of Event Channels, *C* is the set of Event Consumers and *P* is the set of Event Producers, the relation is evaluated to be true if events of type *eT1* flow in an event stream *e1(u,v): e1*∈*E, u*∈*EC, v*∈*C* and events of type *eT2* flow in an event stream *e2(m,l): e2*∈*E, m*∈*P, l*∈*EC* and there is some un-modeled event processing logic between events of type *eT1* consumed by *v*∈*e1* and events of type *eT2* produced by *m*∈*e2*.

Key Points

The event processing intent defined by an event processing network may not cover the entire flow of events through systems as there may be cases where an event is handled by an event consumer, such as a software application, and as a result the application publishes, as an event producer, a new event to an event processing network. In essence, there is some un-modeled processing logic performed by the application that results in a new event that may be processed further on. The specifics of this logic are not important for the realization of an event processing network as this logic is implemented and executed by a consumer such as an application, however, having the relation *causes(eT1,eT2)* as part of the model enables to describe the complete event-driven interactions in systems and is used in performing model analysis such as termination analysis [1–3].

In the model, event causality is represented as a red, dashed, and directed edge from the event stream being consumed to the event stream being produced (Fig. 1).

The definition of event causality in an event processing network is meant to be theory neutral and



Event Causality. Figure 1. Event causality.

corresponds to common sense causal interpretation in the physical world. Applying the many theories about causation [4,5] to the cause of an event by another can extend the perception of the event-driven interactions and perhaps most productively enhance analysis capabilities of models, but for the purpose of the realization of an event processing network this is not necessary.

Event Channel

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event connection; Event pathway; Event topic

Definition

An event channel is a routing node in the event processing network that receives events from event sources and event processing agents, and route them to event sinks and event processing agents.

Key Points

An event channel [2] is the main routing vehicle in the event processing network; it is being used to enable loosely coupled architecture, in which the event producer and event consumer does not have any dependency among them [1]. An event channel receives an event (in push or pull) from an event source or from an event processing agent, and makes routing decisions. The routing decision may be of several types:

1. Itinerary based routing: the consumers are explicitly specified within the event content.
2. Subscription based routing: using a "callback" protocol, the consumer subscribes to events on the channel.
3. Intelligent routing: a decision process is activated to decide on the event consumers.
4. Calendar based routing: Routing is controlled by a calendar function.

The routing may be partitioned according to context [3], if context is supported.

Event Cloud

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Definition

Event Cloud is a partially ordered set of events (poset), either bounded or unbounded, where the partial orderings are imposed by the causal, timing and other relationships between the events [2].

Key Points

Event cloud [1] consists of a set of events and one or more partial order relations. The following event relations are being used:

- Causality relation: Each collection of events can be considered as an *event cloud*, the causality relation creates a partial order relation among a collection of events, causality is transitive, anti-symmetric, and non-reflexive.
- Precedes relation: defined as event e1 precedes event e2, if it occurs in e1 occurs in reality before event e2. This is a partially order set – since the relative timing may not be known, or may overlap, if occur during an interval.

Event cloud can be defined over the entire collection of events that flow through some system within a certain bounded or unbounded time[3,4]. A special case of event cloud is all events that are input to a single event processing agent and are ordered as a time-series, in this case the event cloud is a collection of event streams.

Event Detection

JONAS MELLIN, MIKAEL BERNDTSSON
University of Skövde, Skövde, Sweden

Synonyms

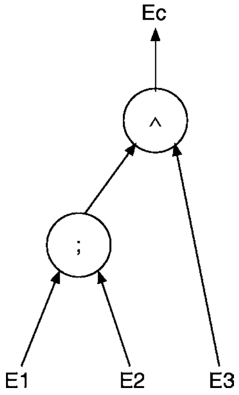
Chronicle recognition; Event trace analysis; Event control; Event composition; Monitoring of real-time logic expressions

Definition

Event detection is the process of analyzing event streams in order to discover sets of events matching patterns of events in an event context. The event patterns and the event contexts define event types. If a set of events matching the pattern of an event type is discovered during the analysis, then subscribers of the event type should be signaled. The analysis typically entails filtering and aggregation of events.

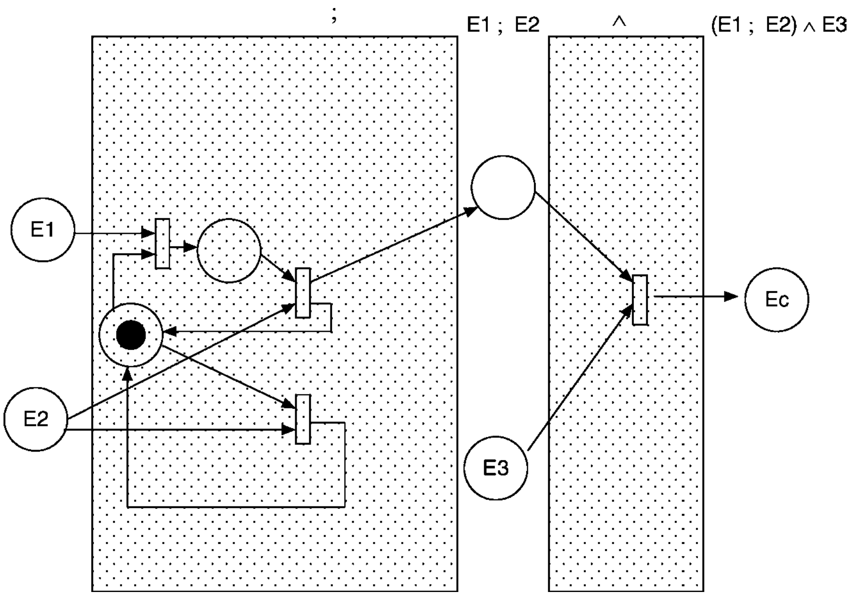
Historical Background

Seminal work on event detection was done in HiPAC [7,11] and Snoop [8,9] as well as in ODE [14] and SAMOS [13]. Essentially, in Snoop, ODE, and SAMOS different methods for realizing the matching of event detection were investigated. In Snoop, implementations of the event operators are structured according to the syntax tree of the event expression, where each node represents an event operator. The event operator in a node is the principal event operator of the event type it corresponds to and each event operator is implemented as a subprogram (e.g., procedure, method). The procedures are invoked during evaluation of the expression. In contrast, in SAMOS [13] operators expressed as Petri-nets are combined; and in ODE [14], finite state automatas built from the event specifications are employed.

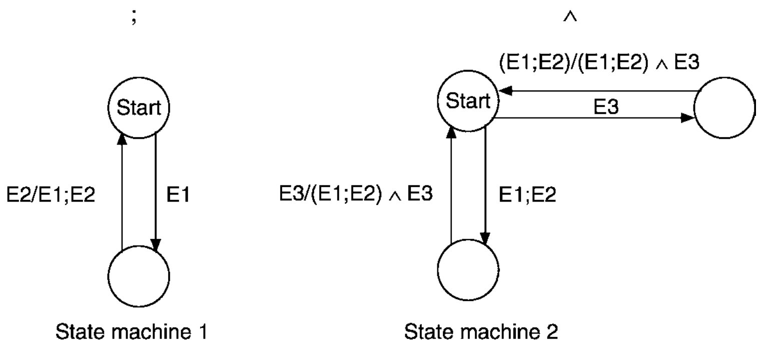


Event Detection. Figure 1. Syntax tree of $(E_1;E_2) \wedge E_3$ [18, Fig. 4.6].

For example, consider the expression E_c **defined by** $(E_1;E_2) \wedge E_3$ that means an E_c occurs if a sequence of E_1 and E_2 and an event of type E_3 occurs. This can be transformed into the syntax tree in Snoop as depicted in Fig. 1, since the conjunction '∧' is the principal event operator of E_c. As in data flow machines, the idea is that the nodes are evaluated according to some policy; for example, a common policy is that as soon as there are data available (events) on the input edges to an event, the operator is evaluated. Thus, the node ';' is evaluated if there are E_1, E_2 or both E_1 and E_2 events available. In colored Petri-nets used in SAMOS, the expression E_c is represented as depicted in Fig. 2. The events are represented as tokens in the places. Further, the event expression can be translated into a finite state automata as in ODE (depicted in Fig. 3), where the transitions are labeled with *Event/Action* where actions denoted E_x means generate a composite event occurrence E_x. A significant difference between the three different representations of event operators is whether they are capable of handling multiple situations in which events are generated concurrently. The approaches in Snoop and SAMOS can handle concurrent situations, whereas finite state automatas must be augmented with processes executing the finite state



Event Detection. Figure 2. Petri-net representation of $(E_1;E_2) \wedge E_3$ [18, Fig. 4.7].



Event Detection. Figure 3. Finite state automata representation of $(E_1;E_2) \wedge E_3$ [18, Fig. 4.8].

automatas to enable this. The rest of the historical background address the following significant issues: *(i)* management of the combinatorial explosion in the analysis of event streams; *(ii)* parameterized event detection, and *(iii)* design issues.

In Snoop [8,9], event contexts or event parameter consumption modes were introduced handle the combinatorial explosion, issue *(i)*, in a systematic way. Each event context represents some semantic or pragmatic knowledge about the situations that are monitored. For example, in recent event context only the most recent event occurrences are allowed to be used to form composite events. This context is meant to be used in, for example, real-time applications. In contrast, in chronicle event context event matching is based on historical order and is meant to be used to monitor, for example, that communication protocols are not violated.

Another way to handle the combinatorial explosion is to limit the size of the past. Essentially, this is a technique from distributed, parallel, and real-time systems, in which time intervals are used to determine the validity of events. For example, in remote procedure calls timeouts are generally used to detect failures such as server node crashes or network packet omissions – timeouts occur if there is no response within a specified time interval. The timeouts can be used to limit the past by removing events that can no longer be part of a composite event in the future. This technique has been suggested in related areas, for example, chronicle recognition [12], monitoring of real-time logic [10], and general monitoring of distributed systems [17]. For example, the technique of using time windows to limit processing has been successfully employed in event detection in real-time control [19].

One significant issue is parameterized event detection (issue *(ii)*), because it is often the case that events in event specifications must carry parameters denoting the situation in which the events were generated. In SAMOS, a limited form of parameterized event detection is allowed by either requiring that events stem from the same transaction or the same user. Bækgaard and Godskesen [2] introduced specification of parameterized events based on TCCS (temporal calculi for communicating systems). However, they have not shown how to transform the specification into code or configuration of event detection. In EPL [20] and XChange^{EQ} [4] parameterized event detection are addressed. Both EPL and XChange^{EQ} stem from databases, for example, an incremental join algorithm for parameterized event detection is proposed by Bry and Eckert [5].

Significant results concerning design issues, issue *(iii)*, are that the following features are among the most important: storage structures for event streams, indexing techniques of event streams, handling of isolation property of transaction with respect to event detection as well as memory management techniques. The BEAST benchmark [15] concluded that indexing techniques and storage structures are more important than, for example, choosing Petri-nets, finite state automata or code to perform the matching. In DeeDS [1], the isolation property is violated in a controlled way by integrating event detection in the transaction processing in such a way that events can violate isolation if explicitly allowed to. The events are cached in a separate filtered event log as well as stored as first class objects in the database. This entails that the problem of doing event detection in the scope of transaction is removed, that is, event objects are not locked as is the case when event detection is performed within transactions.

The drawback is that the filtered event log must be maintained, that is, support recovery processing and the isolation property as well as support pruning of invalid events.

Foundations

There are several issues that are significant. These issues can be categorized into a usage and a development perspective. The use of event detection entails two difficult problems: *(i)* understanding what is actually happening and *(ii)* dealing with event detection in different temporal scopes. The first problem has been considered in, for example, visualization of event detection [3]. It was observed that master's students had difficulty in understanding event detection when the topic was covered in graduate courses. The most likely explanation is that, in contrast to condition evaluation, it is also necessary to know the previous results of event detection to determine the result of the current evaluation. For example, consider Fig. 4 for E_{12} **defined by** $E_1;E_2$ where $\Gamma(E,[t_1,t_2])$ reads that "an event of type E has occurred throughout the interval $[t_1,t_2]$"; in this example, the different results of event detection can be confusing. All variations of E_{12} are discovered in general (unconstrained) event context, and the composite events marked with circles are discovered in the recent event context, whereas the composite events marked with triangles are discovered in chronicle event context. Note that, for example, to understand that $\Gamma(E,[2,4])$ has been discovered require knowledge of that $\Gamma(E[1,3])$ has been discovered and the consequences for future event detection. Thus, there is need for tools to help developing, verifying and validating event specifications. These tools require that the event detection process is instrumented in such a way that internal states can be observed.

The second problem relates to parameterized event detection. This is typically used to enable matching of events with the same temporal scope (e.g., same transaction, same process, accessing the same object). One problem is how these temporal scopes relate to each other, for example, a transaction can encompass multiple processes and these processes can serve several transactions. Sometimes it is necessary to mix temporal scopes, for example, the occurrence of an event outside a temporal scope may negate the occurrence of a composite event within the scope.

From a development perspective of ADBMS and event detection in particular, there are two issues of importance: *(i)* data structures for efficient event detection, and *(ii)* decentralized event detection. In database prototypes simple queue structures has been employed to store events, whereas, for example, some kind of a heap structure may provide better results. In particular, if event detection is explicitly invoked rather than implicitly invoked each time an event occurs, then

Event Detection. Figure 4. Example of event detection in some event contexts [18, Fig. 6.1].

more advanced data structures can improve the performance and time complexity of event detection. Concerning issue *(ii)*, event detection is suitable for decentralized processing, since it follows the data flow machine idea. However, there are a lot of issues that must be considered in such situations. Guiding requirements are, among others, interoperability requirements and the filtering effect of event detection for a particular domain. An example of the latter requirement is network event correlation [16], in which a major part of network events filtered out and the design of event detection should be optimized for pruning events.

In terms of performance, the algorithmic time complexity depends on a number of factors: the type of event context and whether a single signaled event is evaluated (as in implicit invocation of event monitoring) or multiple signaled events are evaluated (as in explicit invocation of event monitoring). In general, the difference in terms of algorithmic time complexity between different event contexts disappears if multiple events are evaluated. Table 1 describes the algorithmic time complexity in situations where all signaled events results in composite events. The meaning of the symbols are as follows: H is the event history (set of buffered events), M is the set of event types, E is an event expression, and P is a the set of parameters carried by each event. The function f depends on how event types are indexed in the system. For example, if the red-black tree technique is employed for indexing then $\mathrm{f}(n) = \log(n)$, whereas $\mathrm{f}(x) = 1$ if hashing is employed instead. Other event contexts (e.g., [6]) may have different algorithmic time complexity characteristics.

The most important factor is the size of the event history and by keeping this as short as possible it is even possible to employ the unconstrained event context in practice (cf. [19]). Event expressions are typically short unless they are automatically generated from some other specifications. For example, if a set of event types is required to occur in a particular order and it is necessary to detect failures to do so as soon as possible, then it is necessary to monitor all permutations of the correct order and in this case the size of event expressions can become uncommonly large. The size of the parameters is typically not a problem in high bandwidth systems and is less significant compared to the event history and the size of the event expressions. Finally, the number of event types in a system is insignificant as long as proper indexing is employed.

Event Detection. Table 1. Algorithmic time complexity of event detection [18].

Event context	Single	Multiple
Recent	$O(\mathrm{f}(\|M\|) + \|E\|\|P\|)$	$O(\|H\|(\mathrm{f}(\|M\|) + \|E\|\|P\|))$
Chronicle		
Continuous	$O(\mathrm{f}(\|M\|) + \|H\|\|E\|\|P\|)$	
Cumulative		
General (unconstrained)	$O(\|H\|^{\|E\|})$	

Key Applications

The key users of this area are the researchers and developers of active functionality in, for example, active databases.

Future Directions

Some future issues in event detection is the following:

1. To develop tools and techniques for developing, understanding, verifying and validating event specifications. As addressed in this entry, the understanding of event detection is more complex than condition evaluation and this is a really crucial issue for successful use of event detection.
2. To investigate relevant data structures to improve event detection, in particular, parameterized event detection as well as decentralized event detection. If large event expressions are prevalent in a system, then this issue becomes critical.
3. To further investigate the performance characteristics in, for example, decentralized event detection. The reported study [18] has been performed for centralized event detection. Further work need to be done in other settings.
4. To investigate fault-tolerant event detection in various settings such as mobile ad-hoc networks.
5. To investigate if fuzzy reasoning inside event detection can be used. For example, in monitoring of real-world situations, it is necessary to handle uncertainties of various kinds.

Event Driven Architecture

K. Mani Chandy
California Institute of Technology, Pasadena, CA, USA

Synonyms

Event driven service-oriented architecture; Event processing systems; Sense and respond systems; Sensor network systems; Active databases; Streaming database systems

Definitions

An event driven architecture is a software architecture for applications that detect and respond to events. An event is a significant change in the state of a system or its environment. The change may occur rapidly or slowly. The occurrence of an event in the past, or its current unfolding, or a prediction of an event in the future is deduced from data. An event-driven architecture includes sensors and other sources of data; processors that fuse data from multiple sensors and detect patterns over time, geographical locations, and other attributes and deduce events that occurred or predict events; responders for initiating actions in response to events; communication links for transferring information between components; and administrative software for monitoring, tailoring and managing the application.

Historical Background

Event driven systems have been used in military command and control systems, and in SCADA (supervisory control and data acquisition) systems for decades. Platforms for event driven applications have been developed by several companies in the last decade; these general-purpose platforms can be tailored to obtain special-purpose event-driven applications. The development of event-driven platforms has evolved from several fields including databases, message-driven middleware, rule-based systems, business intelligence, statistics, and command and control systems.

Foundations

The metrics for evaluating event driven applications are different from those used to evaluate many other information technology systems. A discussion of the metrics helps highlight the goals of event driven systems and clarifies the differences between these systems and more traditional information technologies.

Measures for Evaluating Event Driven Applications

Event-driven applications detect and respond to events. Examples of such applications include those that: take action when earthquakes, tsunamis, or hurricanes are imminent; help manage investment portfolios by sensing risks and opportunities in markets; help disabled or aging people live independently by detecting and responding to potential problems; and prevent crime by identifying and responding to threats.

Measures by which event-driven applications are evaluated include the usual measures of total cost of ownership and measures, called the *REACTS* metrics (after the first letters of the measures), which are more specific to event driven architectures.

- *Relevance*: This measures the relevance of information generated by the system to consumers of the information. A message about a tsunami warning sent to a person's phone is highly relevant while she is on a beach where the tsunami is about to strike but is less relevant while she is hundreds of miles away. Relevance depends on the state of the receiver. Systems that send a great deal of irrelevant information (spam) are likely to be ignored.
- *Effort*: This measures the effort required by operational people to define specifications of events and responses and by IT staff to integrate event applications with existing systems. The time taken by end users, such as stock traders, to tune systems to meet their specific needs, and the time taken by IT staff to integrate event applications with existing infrastructure are major costs.
- *Accuracy*: This measures the costs of inaccurate information, such as false positives. A false tsunami warning gets beaches to be evacuated unnecessarily. High frequencies of inaccurate information result in information being ignored.
- *Completeness*: This measures the costs of incomplete information. For example, the absence of a hurricane warning can results in thousands of deaths. A single false negative has a higher cost than a single false positive in most situations; however, systems are often designed with very high rates of false positives compared to rates of false negatives.
- *Timeliness*: This measures the costs of detecting events too late. The benefit of detecting an event depends on the time available to execute an appropriate response. There is little added benefit in having millisecond responses when responses in minutes will do. There are, however, significant costs in responses initiated too late: a tsunami warning received after a tsunami strikes offers no value.
- *Security*: This measures the costs of reducing and managing intrusions and other attacks. Event driven applications often run for extended periods and manage critical infrastructure. For example, new infrastructure in the electrical power grid enables utilities to control airconditioners and other devices in homes and offices. Attacks that shut off power to homes and factories have severe consequences.

The design of event driven applications is a process of evaluating, comparing, and trading off REACTS measures for different design options.

Components of Event Driven Architectures

An event – a significant state change – is different from the data that describes the event; data that describes an event is often called an *event object*. Event objects may be stored in databases, sent as messages, or used within programs. An action, such as issuing a warning about a possible fraud, is itself an event. Information about the action is captured in an event object or is not captured at all.

Event driven architectures consist of data acquisition components such as sensors; event processors that integrate data from multiple sensors and databases; responders that initiate appropriate actions after events are detected; communication links that transmit information between components and administrative services that help in specifying and managing the operation of event driven applications. Next, each of these components is discussed briefly.

Sensors: Data acquisition components acquire data from the environment and from within the enterprise; this data is analyzed to detect patterns that signify events. Data may be pushed to these components or the components may acquire data by polling services. For example, stock ticker feeds are data acquisition components that push stock ticker information to the application without having the application make an explicit request for each stock price update. Other data acquisition components poll Web sites or other services according to fixed schedules or when requested to do so by event processors. These components send the polled information – or the difference between data obtained on successive polls – to the application, or store the data for later processing. Polling too frequently is onerous for the site being polled, while polling infrequently can increase delays in event detection.

Event Processors: The role of event processors is to integrate data from multiple sensors, add value to event objects by incorporating data from databases and business intelligence repositories, find patterns that signal events, and initiate actions by responders. Event processors may also request sensors to obtain additional data, providing closed-loop coupling between data acquisition and processing. Common functions of event processors include the following:

- Event Filtering: Data may be generated by sensors, such as stock tickers or RFID readers, at rapid rates and only a fraction of this data may be relevant to an application. Event filters are specified by the data that they pass through to later stages of processing. Filters located near sensors, physically or logically, reduce the amount of communication.
- Event Object Enrichment: Enriching an event object by adding relevant data from databases helps in later stages of processing. For example, an event object describing a customer's request for a new service can be enriched by adding data about the customer's history.
- Event Fusion: Sequences of event objects sent by multiple sensors and event processors are integrated, or "fused" by other event processors, to generate new event objects. For example, streams of event objects generated by multiple package-delivery trucks are fused into a single stream dealing with all packages.
- Event Stream Splitting: A stream of event objects can be split into multiple streams each of which deals with a separate set of attributes; processing streams of event objects all of which deal with the same topics is simpler.
- Time Series Analysis: Event processors in many applications carry out time series analyses to detect anomalous behavior or to determine if behaviors have changed significantly over time.
- Complex Event Processing and Event Prediction: The detection of complex patterns requires analytics that spans time, geographical locations, and business functions. Initiating responses in preparation for predicted events reduces reaction delay. The detection of complex patterns in the historical record and the accurate prediction of future events often requires complex processing.

Responders

A typical response is the initiation of a business process. Example responses include updating dashboards that display key performance indicators, sending alerts, setting up temporary task forces to respond to an event, and updating databases and logs for later analysis. The execution of the business process responding to an event may, in turn, generate new events.

Communication Layer

Communication among sensors and event processors, in some applications, is by means of wireless. In some applications, wireless bandwidth may be low because sensors may be required to be inexpensive, power may have to be conserved, or the environment may be noisy. The geographical layout of components communicating by wireless is critical in such applications.

The logical architecture for communication among components in many applications is publish/subscribe. Some components publish event objects, and some components subscribe for specified types of event objects with specified ranges of parameters. The pub/sub network ensures delivery of event objects to appropriate destinations. The logical communication architecture can also be point-to-point, pushing event objects asynchronously from one point in the network to the next, or a broadcast system.

Administration Layer

The administration layer is used for several purposes including the following: initially to tailor a general-purpose event driven architecture to suit a specific application; at run time to monitor an application; and, at redesign time to replay scenarios for forensics and for adapting systems to changing conditions. Since event driven applications are often used to control physical infrastructures over long periods, monitoring sensors and responders is an essential aspect of these applications. Thus, the administrative layer of an event driven application is itself an event driven application.

System Specification

The process of implementing an event driven application is, in essence, an application integration activity: sensors, processors and responders have to be integrated into operations. The specification of an event driven application consists of specifications of the sensing, processing and responding subsystems and their integration. The subsystems are quite different from each other; therefore, the notations used in specifying them are different.

Specifications of sensing subsystems include identification of what data sources and sensors to use, where they should be placed, how they should communicate, activation and polling schedules, and mappings from data models used by the external environment to data models used within the application. Specifications of event processing subsystems deal with functionalities such as fusing, filtering and splitting that also occur in database systems, rule-based systems and business intelligence systems; therefore some notations for specifying event processors use extensions of SQL, or rules, or statistical packages. Specifications of responder subsystems identify activities carried out when an event is detected; these activities are often specified using notations for business process management (BPM) and business application monitoring (BAM).

Key Applications

Many areas of science, commerce and education use event-driven applications. All systems in which data is produced continuously and which require timely response to critical events are candidates for event-driven architectures. Rapid accurate response is a competitive advantage in financial trading of stocks, commodities and foreign exchange. EDA is also used in responding to fraud and non-compliance to regulations.

Cyber infrastructure – the integration of physical infrastructure with information technology – is based on event driven applications. Supply chain applications including airline, railroad and trucking systems use EDA. Energy management in the electrical power transmission system is an increasingly important application of EDA as smart meters and sensors are deployed in homes. Many defense department and homeland security applications, such as interdiction of radiation material, use EDA. Crisis management systems, in public and private sectors, are based on EDA.

Customer relationship management (CRM) requires rapid detection and response to customer interests while customers visit Web sites or call service centers. Event driven applications are used in healthcare to monitor patients and to help an aging population live independently for longer.

Future Directions

Event driven applications will become widespread as sensors become ubiquitous and rates of data production in blogs, news, videos, and other online sources continue to increase. A subdiscipline of event driven systems will be formed by integrating concepts from disciplines such as databases, business intelligence and statistics, distributed systems and control, signal processing and state estimation, decision support and operations research, and collaboration technologies.

Synonyms

Event causality graph

Definition

An event flow is a partially ordered graph that traces event instances and causality relations among them.

Key Points

When an event instance is produced by an event source [1] and transferred to the event processing network, an entry node is created into the “event flow” of the specific application, every event created by an event processing agent is added to the event flow, such that, if the input event instances to the event processing agent are <ei_1,...,ei_n> and the output event instances are <eo_1,...,eo_m> then an edge in the event flow is created for all pairs of the type.

<ei_i, eo_k> where i = 1,...,n and k = 1,...,m. This denotes that there is some causality between the input event-instance and the output event-instance. An event flow may go beyond a single event processing network [3]; an input event to an orchestration node in a sink triggers an action, which in turn, creates more events.

Event flows [2] are being used for purposes of validation for event processing applications, as well as for event lineage.

Event in Active Databases

AnnMarie Ericsson, Mikael Berndtsson,
Jonas Mellin
University of Skövde, Skövde, Sweden

Definition

Events in active databases are typically considered to be atomic and instantaneous, i.e., they either happen or not. Events are either primitive or composite, that is, either they are part of the system (primitive) or they are specified in terms of other events (composite).

Key Points

An event is a happening of interest that can invoke execution of reactive behavior, for example, trigger an ECA rule. Events in active databases are typically considered to be atomic and instantaneous [1,3,4], that is, they either happen or not. However, this leads to problems [2] addressed in the event specification entry.

Events can be classified as primitive or composite events. Primitive events refer to elementary occurrences that are predefined in the system. Primitive events are typically further categorized as database events, time events, transaction events, method events etc. A composite event is a set of events matching an event specification.

Events can have attributes, that is, event parameters. Event parameters are usually passed on to the condition and action part of an ECA rule. In general, event parameters can be broadly classified into: (i) System level information, and (ii) Application level information. System level information is related to parameters such as transaction identity, user identity and time stamp(s). Application level information in an object-oriented environment can, for example, include object identity and parameters of the invoked method.

Events play a key role in active databases, since they specify when an ECA rule is triggered. Whenever an event is defined and used in an ECA rule, one can say that the event is explicitly defined. If the active database allows the event to be implied by the rule definition, then the event is said to be implicit. In this case, the event specification of a rule is optional.

Event in Temporal Databases

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Event relation; Instant relation

Definition

An *event* is an instantaneous fact, i.e., something occurring at an instant of time.

Key Points

Some temporal data models support valid-time relations where tuples represent events and where the tuples are thus timestamped with time values that represent time instants. When granules are used as timestamps, an event timestamped with granule *t* occurs, or is valid, at some instant during *t*.

It may be observed that more general kinds of events have also been considered in the literature, including events with duration and complex and composite events.

Event Lineage

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event pedigree

Definition

An Event lineage is a path in the event processing network that enables the tracing of the consequences of an event, or finding the reasons for a certain action.

Key Points

An event lineage is an audit feature that is determined to answer one of two questions:

1. What were all the implications of event e?
2. What were the events and processing agents that preceded action a?

The event lineage is obtained by maintaining the history of event processing networks using various techniques.

Event Pattern Detection

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event composition (partial overlap)

Definition

Event Pattern detection is a computational process in which a collection of events are evaluated to check whether they satisfy a pre-defined pattern. Formally an event pattern (EP) is defined as:

EP = <C, IE, PT, PRED, Policies, DER>

where:

- C = Context
- IE = List of Input Event types
- PT = Pattern Type
- Pred = Predicate
- Policies = Semantic fine-tuning policies
- Der = Derived Events

- – A context is a collection of semantic dimensions within which the event occurs. These dimensions may include: temporal context, spatial context, state-related context and reference-related context.
- – List of input event types provide the EPN edges (event pipes/event streams) that are potentially input to the pattern. Note that events that open or close contexts are indirectly also input event to the patterns within that context
- – Pattern Types:

A pattern type is a formula with variables substituted by event types, example- and (e1, e2) – where e1, e2 are variables of type event type. There are serial pattern types:

- Basic event oriented patterns, example: and (e1, e2).
- Basic set (stream) oriented patterns, example: (average reading.temperature >35).
- Dimensional patterns – temporal, spatial, spatio-temporal example: moving (e, north).
- Context termination patterns, example: absent (e1).
- Interval-oriented patterns, example: overlap context.

- Predicates: Predicates among various of the input events, example e1.a > e2. b.
- Policies: The policies have been determined to fine-tune the semantics. Example: what should be done if there is synonym events, e.g., the pattern type is and (e1, e2) and there are three instances of e1 followed by five instances of e2 – how many times this pattern will be detected and with which event instances.
- Derived Events: derive one or more events out of the input events that have participated in the pattern detection. The derived event can be a collection of events, or a single event that is derived from the content of other events.

Historical Background

Pattern detection has its roots in several different areas:

1. *Discrete event simulation*: Automatic analysis of event trends to find causality relations among the events in simulation trace has resulted in the need to find "event causality" relations, which has been the motivation for introducing patterns. David Luckham's "complex event processing" has grown up from research in that area
2. *Network and system management*: Network (and later system) management attempt to find the "root cause" of a problem, by taking as an input a collection of symptoms (e.g., device time-outs) and diagnose the core problem that has caused these symptoms. There are relatively simple patterns that belong to this family
3. *Active Databases*: The work on "composite events" in active database is one of the example of event patterns, it features some forms of patterns, and also some policies ("consumption modes")
4. *Middleware*: Publish/subscribe with content selection, and ESB mediations are sources of further (relatively basic) patterns

Event Pattern Detection. Figure 1. User oriented patterns.

Foundations

The notion of pattern has originated from building architecture, as a tool to capture architectural decisions. The area of software design has borrowed this term to document a collection of activities which issue the "best practice" to solve a particular issue (Figure 1). In event processing, the notion of patterns may have several interpretations:

1. Detection of patterns over the event history – as referred to in this entry
2. User-oriented templates that may be developed into more than a single pattern.
3. Best practices pattern of design of use.

Key Applications

Patterns can be related to various types of applications:

1. Real-Time Enterprise application: in which patterns are identified to create actions that are flowing back into the business logic and effecting it. Example: algorithmic trading, active liquidity management, various applications of autonomic computing.
2. Business Activity Management: in which patters are identified to find threats, opportunities and exceptional deviations from the norm or desired behavior measured by constraints and Key Performance Indicators.
3. Diagnostics application: In this application events are symptoms and pattern detection is used in order to determine the problem root cause.
4. Information dissemination: In some cases patterns are used to enable more sophisticated subscription systems, where the user wishes to subscribe not to raw events but to cases in which patterns are satisfied, example: IBM stock has gone up in 2% within 2 h.
5. Prediction: In this case there should be a support in predicted events and the pattern can include predicted events, where the reaction intends to mitigate or eliminate some situation from occurring.

Event Prediction

Segev Wasserkrug
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Prediction regarding future events; Prediction of event occurrence

Definition

Event prediction is the capability to estimate the possibility that some event may occur in the future. Some applications may even be required to advance beyond simply predicting the occurrence of events and need to influence the occurrence of some future event. For example, this may involve either decreasing the chance that a non-desirable event will occur or increasing the chance that a desirable event will occur. To determine whether or not such actions should indeed be carried out requires decision-making capabilities.

Historical Background

The first event-based systems were active databases in which automatic actions were carried out as a result of database queries. This was done using the *ECA* (Event-Condition-Action) paradigm. As such applications evolved, the events to which applications were required to respond evolved beyond single queries (e.g., insertion of deletions of data) and needed to be deterministically inferred from several such queries. As the complexity of such applications continued to grow, and as event-based applications expanded into other application domains, the need to handle explicit uncertainty regarding the occurrence of events needed to be accommodated. Event-based applications needed to handle unreliable sensor readings and reason about the occurrence of events that could not be deterministically inferred.

The next evolutionary step to such event-based capabilities is to enable event-based systems to reason about the possibility that events will occur in the future and provide facilities for reasoning about possibly influencing such occurrences.

Foundations

Events that may or may not occur in the future are inherently uncertain. Therefore, in many cases, event-based applications are required to estimate the likelihood that such events will occur and attempt to influence this likelihood.

As an example, consider an e-trading web site from a commercial bank. Customers interact with this kind of site using banking transaction events, which include queries regarding the account balance, withdrawals, and deposits. Such events may serve as indications of future events. For example, there may be a number of withdrawal actions carried out by a customer, the end result of which is that there is little or no money left in the account. This set of events may be an indication of the customer's intent to close the account.

In such a case, it would be beneficial for the bank to be able to predict the likelihood that the customer will indeed close the account based on the set of withdrawal events. Furthermore, such an application should be able to consider how possible actions could potentially reduce the likelihood of such an event, while taking into account the potential costs and benefits involved.

As the above example illustrates, there are two main components to a solution that addresses event prediction:

- Component enabling prediction regarding future events
- Component that facilitates decisions regarding actions intended to impact the likelihood of future events, while accounting for the implications of these actions

Mechanisms for Event Prediction

A variety of data can be associated with the occurrence of an event (this data is called the event payload). Two examples of such data are the point in time at which an event occurred and the new stock price in an event describing a change in the price of a specific stock. Some data are common to all events (e.g., their time of occurrence), while others are specific only to some events (e.g., data describing stock prices are relevant only for stock-related events). The data items associated with an event are termed *attributes*. Because an event has attributes, the prediction of an event needs to determine the likelihood of the event occurring as well as the possible values of its attributes.

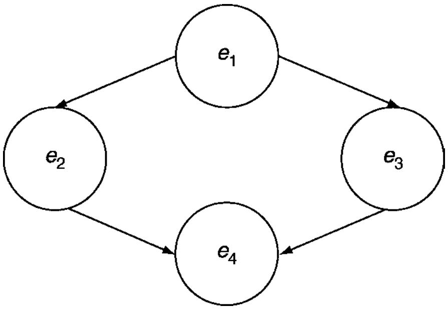
The definition of an event is very broad and may encompass a wide variety of information. Therefore, there are many relevant mechanisms from other domains that can be applied to event prediction. However, when applying these mechanisms, characteristics specific to event-based applications must be taken into account. These characteristics include the need to predict the attribute values of future events and the ability to take into account causal relations between events. This is elaborated below.

Because each event has a set of attributes associated with it, future predictions regarding an event must be able to provide some information about the possible values of the attributes, as well as some information regarding the likelihood that a specific attribute will indeed be assigned a specific value.

The need to take into account causal relations between events stems from the fact that the occurrence of some events may provide information regarding the occurrence of other events. For example, it may be the case that if an event e_1 occurs, event e_2 becomes more likely to occur as well. Such causal relations could be much more complex. For example, consider the relation depicted in Fig. 1, which states the following:

- Event e_1 occurring increases the likelihood of event e_2 occurring, as well as the likelihood of event e_3 occurring.
- Event e_2 occurring increases the likelihood of event e_4 occurring.
- Event e_3 occurring also increases the likelihood of event e_4 occurring.

These relations between events need to be taken into account in the correct manner. For example, if the likelihood of events e_2 and e_3 occurring increase independently of each other, the likelihood of event e_4 occurring may be greater than the case in which the likelihood of events e_2 and e_3 occur increases due only to the fact that event e_1 has occurred.



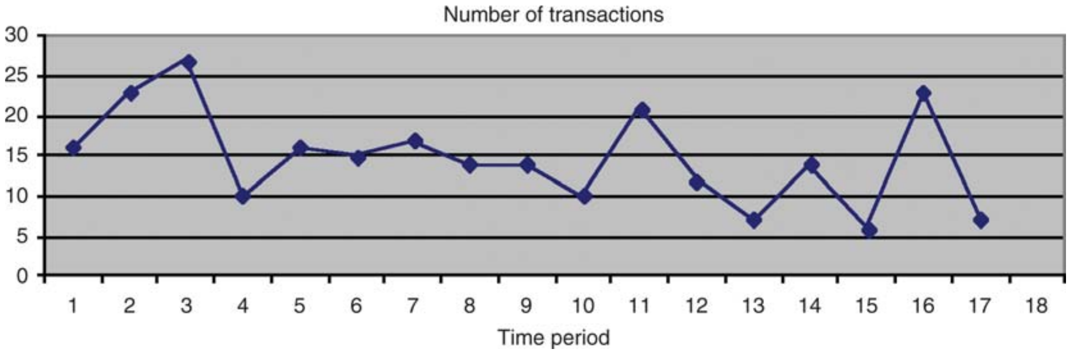
Event Prediction. Figure 1. Example of causal relations between events.

Methods for event prediction can be divided into two general types: explicit modeling methods and implicit modeling methods.

Explicit modeling methods are methods that require the ability to explicitly state the relationship between existing knowledge and events which must be predicted. Usually, such relationships take some known functional form. An example of a well known explicit modeling method is time series analysis, in which some future value is estimated, based on past values, using some function of the past values. The form of the function is defined by the person building the time series model, while the parameters of the function are derived from past data.

Figure 2 shows a plotting of past time series data in which the number of transactions is plotted for 17 time points. Based on this data, the number of transactions at the 18th time point can be predicted using time series analysis methods.

Another explicit modeling method is event composition languages. Event composition languages enable the definition of rules regarding the relationship between events. While most event composition languages are deterministic, there are event composition languages that can take uncertainty into account. Some of these languages are also suitable for defining the relationships required to enable event prediction. For example, a rule could state that if event e_1 is known to have occurred, the probability of event e_2 occurring at some future time t is 0.7. Such languages have the added benefit of naturally enabling the representation of the causal relationships between events. Furthermore, if the language is general enough, it can represent any functional form. Therefore, such languages can be seen as a generalization of all explicit modeling methods.



Event Prediction. Figure 2. Time series plot.

Implicit modeling involves models in which the relationship between the evidence and future events are not explicitly stated, but are directly derived from historical data. An example of such a modeling method is neural networks from the machine learning domain. In the neural network model, a model is constructed which may take many functional forms. The specific functional form is then derived from historical data.

The advantage of explicit models is that they can capture any inherent relationships between existing knowledge and future events, and utilize this knowledge to enable more accurate predictions. The disadvantage is that the person creating the models must possess this knowledge and be able to articulate it in a formal manner. Implicit models remove this burden from the model creator, but require large amounts of historical data. In addition, in implicit models it is more difficult to utilize inherent knowledge to guide the predictions. Consequently, there are also models that attempt to combine the two approaches by enabling the utilization of inherent knowledge when such knowledge is readily available, while deriving other parts of the model from historical data.

Influencing the Occurrence of Future Events

A solution for influencing the occurrence of future events must take into account the following:

- A set of alternative actions A, where each action $a \in A$ is intended to influence the event.
- For each action $a \in A$, the cost c_a of taking the action.
- For each action $a \in A$, the manner in which a will influence the probability of the event.
- For an undesirable event, the benefit b if the event does not occur.
- For a desirable event, the benefit b if the event occurs.
- For an undesirable event, the penalty p if the event occurs.
- For a desirable event, the penalty p if the event does not occur.

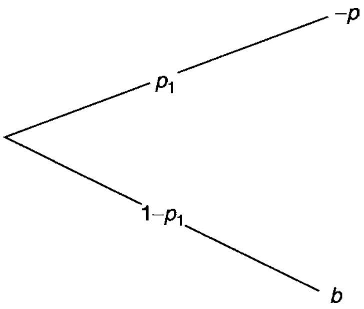
For example, consider the event of a customer closing a banking account. One possible way to prevent a customer from closing the account is to offer better terms, such as higher interest rates on savings. Offering such terms is an action $a \in A$. The loss of income due the higher interest rates is the cost c of taking action a. The benefit of the customer not closing the account is b, while the penalty p is the penalty associated with the customer closing the account.

Several methods exist for taking into account criteria such as the one above. Perhaps the most well known method is utility theory, where decisions are made based on the maximization of some utility function u. The possible decisions in utility theory are often represented by decision trees, such as the one in Fig. 3, which represents the decision tree associated with the event of a customer closing an account.

In Fig. 3, the two branches represent the two possibilities: The customer closing the account (the top branch), and the customer not closing the account (the bottom branch). The quantities at the end of the branches represent the penalties and benefits associated with each action. Therefore, the quantity at the end of the top branch is $-p$, which is the penalty when the customer closes the account, while the benefit of the bottom branch is b, i.e., the benefit when the account remains open. Note that this decision tree represents the case in which no action is taken. In this case, the expected utility can be calculated by $p_1 \cdot (-p) + (1 - p_1) \cdot b$.

Consider the case where it is expected that action a will reduce the probability of the customer closing the account from p_1 to p_2, such that $p_2 < p_1$. For this second case, the expected utility is $p_2 \cdot (-p) + (1 - p_2) \cdot (-c + b)$. In such a case, the decision may be to carry out action a whenever $p_2 \cdot (-p) + (1 - p_2) \cdot (-c + b) > p_1 \cdot (-p) + (1 - p_1) \cdot b$.

Note that the above mechanism for decision making does not explicitly represent an action $a \in A$. Rather, this representation was implicit in the different probability spaces and benefits/costs. Other decision mechanisms, such as Markov Decision Processes (MDPs), do enable an explicit representation of the actions involved, the



Event Prediction. Figure 3. Sample utility decision tree.

manner in which the actions influence the probability of an even occurring, and the associated costs and benefits.

Key Applications

Event-based applications that only react to past events are termed *reactive applications*. Applications that predict, and act upon the prediction of future events, are said to possess *proactive functionality*. Proactive functionality may be required in almost all domains. One such domain is Customer Relationship Management (CRM), in which proactive actions are often required to retain and/or grow market share and benefit. The banking example used throughout this entry is an example of an application in the CRM domain.

Future Directions

While research in event-based applications has been ongoing for several years, research in event prediction is still in its infancy. Therefore, this field is still largely unexplored and is ripe for future research.

Event Processing

▶ Complex Event Processing

Event Processing Agent

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event processing component; Event processing mediator

Definition

A software module and a node in the event processing network that process events [2].

Key Points

An event processing agent [3] is a node in the event processing network that receives one or more events as input, processes them, and creates one or more events as output. There are various types of event processing agents [4]:

1. Filter agent: receives a single event and decides based on a predicate expression whether to route this event further or not (in this case it is a terminal node for this specific event instance).
2. Validation agent: receives a single event and a predicate expression that serves as an integrity constraint for this event. If the integrity constraint is violated may act as a filter (reject the event), may transform the event, or may orchestrate additional actions in an event sink.
3. Transformation agent: receives a single event and transforms this event to another event format.

4. Split agent: receives a single event and creates multiple events, all are functions of the original event (may be either clones or the same events, or distinct overlapping or non-overlapping events).
5. Aggregation agent: receives multiple events and creates a derived event, whose values are aggregated from the values of the input events.
6. Pattern-detection agent: receives multiple events and based on a pre-defined pattern creates a complex event from a collection of events that satisfy the pattern.

Aggregation and pattern detection are statefull agents, and the rest are stateless agents. Aggregation agent has a small state that is incrementally updated, and the input events are not kept; Pattern-detection agent keeps some or the entire input event during the processing period, thus, it may develop large states. Agents may receive events by push or pull [3].

EPN

Definition

An event processing network (EPN) is a graph $G = (V,E)$ where:

1. The set of nodes in an EPN graph G is denoted V such that $V = C \cup P \cup A \cup EC$. V is a set of nodes of four types; C denoting Event Consumer, P denoting Event Producer, A denoting Event Processing Agent and EC denoting Event Channel.
2. The set of edges in an EPN graph G is denoted E such that $E = \{(u,v) \mid (u \in (P \vee A) \rightarrow v \in EC) \wedge (u \in EC \rightarrow v \in (C \vee A))\}$. E is a set of ordered pairs of nodes representing directed edges. These edges are between either an event producer to an event channel, an event channel to an event consumer, an event processing agent to an event channel, or an event channel to an event processing agent.

The EPN model also includes a relationship definition between edges called Event Causality.

An event processing network (EPN) describes how events received from producers are directed to the consumers through agents that process these events by performing transformation, validation or enrichment. Any event flowing from one component to another must flow through a connection component. Therefore, an EPN model consists of four components: Event Producer, Event Consumer, Event Processing Agent, and a connection component called Event Channel.

Historical Background

Event driven computation is not a new concept; it is being used in user interfaces to perform a specific code when a button is pushed and when a mouse button is clicked or released. It is also being used in database systems as triggers to perform specific logic when a record is inserted, deleted or updated. Some existing approaches in configuring and expressing the event processing directives in event-driven systems are through SQL-like languages, script languages, or rule languages and are executed by standalone software, messaging systems or data stream management systems. While event driven processing is not a new concept, there is a need to provide conceptual techniques for definition and modeling of an event driven architecture, making it possible to express event processing intentions independently to the implementation models and executions. This is done through a conceptual model called Event Processing Network [3].

Foundations

As businesses are required to be more agile, to respond to the market rapidly and to be able to adapt quickly and efficiently, there is need for underlying systems and business applications to support such an environment. A sound and cost-effective way to achieve such goals is to introduce an event-driven architecture (EDA).

The producer (source) of the events only knows that the events transpired. The producer has no knowledge of the events' subsequent processing, or the interested parties, leading to entirely decoupled architecture. Such architecture enables flexible definition of the event processing logic: detection of event patterns, derivation of new events, transformation, and routing from producers to consumers based on the business logic required. Thus businesses can react to changes, execute relevant processes as a result, and influence ongoing processes based on the changes. Furthermore, such definition of event processing can be easily modified and quickly deployed in accordance with business needs such as changes to business processes and policies. The Event Processing Network (EPN) concepts model these processing directives.

An EPN model consists of four components: Event Producer, Event Consumer, Event Processing Agent, and a connection component called Event Channel.

Event Channel

An event channel [4] is a mechanism for delivering event streams from event producers and event processing agents to event consumers and event processing agents.

The event channel may receive multiple event streams from different sources and may transfer a combined event stream from all the sources to multiple sinks. It is the responsibility of the event channel to create an ordered and combined event stream from the sources and provide this stream to each target.

Another responsibility of an event channel is to retain the history of the events streaming through for retrospective event processing [6], defined as the discovery of event patterns over the history of events as opposed to online event processing, detecting predefined event patterns as new events become available.

Within a network of nodes and edges an event channel is represented as a node with edges directed to and from the node. Every incoming edge represents an event stream from an event producer or processing agent to publish events on to the channel. Every outgoing edge represents an event stream to an event consumer or processing agent subscribed to the channel. In Fig. 1 a graphical representation of an event channel is presented, where the name of the channel is within the boxed arrow and the event types are given on top of each edge to signify what type of events are provided by the event stream.

An Event Channel is defined as follows:

1. Every node in EC may have event retention policies defined for retrospective processing.
2. The edges connected to a node in EC are defined as $\forall v \in EC,\ \exists e_{in}, e_{out} \in E$: $e_{in} = (u \in (P \vee A), v)$, $e_{out} = (v, u \in (C \vee A))$.

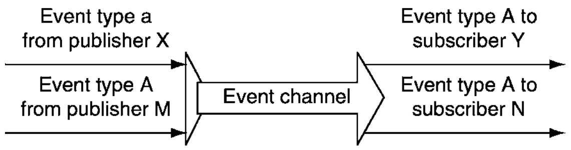
Event Producer and Consumer

An event producer, also known as an event source or event emitter, produces and publishes events through event channels for any party of interest to consume. This could be an event consumer or an event processing agent.

Within a network of nodes and edges an event producer is represented as a source node, i.e., there exist only edges directed from it. The number of edges directed from it is the number of different event channels that the producer publishes to. The edges connected to a node in P are defined as $\forall v \in P, \exists e_{out} \in E$: $e_{out} = (v, u \in EC)$ (Fig. 2).

An event consumer, also known as an event sink, is interested in events to perform its responsibilities. Once the event of interest is known to the consumer it will perform a certain task associated with this event.

Within a network of nodes and edges an event consumer is represented as a sink point, i.e., only edges directed to it. The number of edges directed to



Event Processing Network. Figure 1. Event channel.

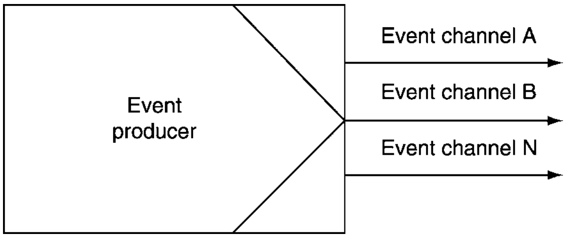
it is the number of different event channels that the consumer subscribes to. The edges connected to a node in C are defined as $\forall v \in C, \exists e_{in} \in E$: $e_{in} = (u \in EC, v)$ (Fig. 3).

Event Processing Agent

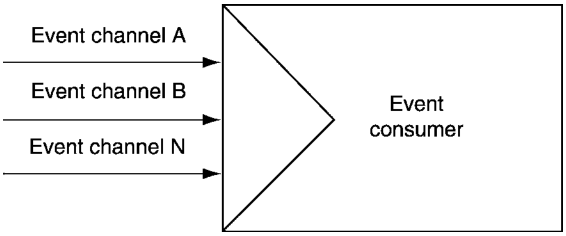
There are cases where there is a gap between the events produced by event producers, and the events required by the event consumers. These events may have different syntax (structure) and/or different semantic meaning than expected. There are also cases where a single event will not trigger an action performed by an event consumer, instead, by a complex composition of events happening at different times and in different contexts [2]. Event processing agents (EPA), also know as event mediators, are needed to detect patterns on 'raw' events, then to process these events through enrichment, transformation and validation, and finally to derive new events and publish them. An event processing agent is responsible in producing these derived events and decides where and how these events should be published.

The event processing agent is made up of three stages:

- Pattern detection – this stage is responsible in selecting events for processing according to a specified pattern.
- Processing – this stage is responsible in applying the processing functions on the selected events satisfying the pattern, resulting in derived events.



Event Processing Network. Figure 2. Event producer.



Event Processing Network. Figure 3. Event consumer.

- Emission – this stage is responsible in deciding where and how to publish the derived events.

An event processing agent subscribes to event channels for its pattern detection and publishes to event channels while emitting events.

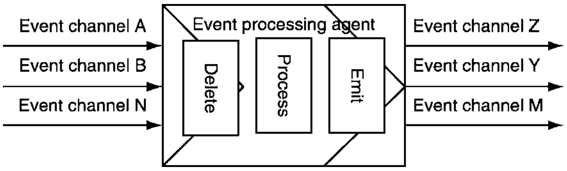
Within a network of nodes and edges an event processing agent is represented as a node with edges directed to and from the node. The number of edges directed to it is the number of different event channels that the agent subscribes to for detecting the pattern. The number of edges directed from it is the number of different event channels that the agent publishes to based on the processing and emission definitions.

The edges connected to a node in A are defined $\forall v \in A$, $\exists e_{in}, e_{out} \in E$: $e_{in} = (u, v)$, $e_{out} = (v, w)$, $u, w \in EC$. e_{in} is an event stream from an event channel the EPA is subscribed to and e_{out} is an event stream of derived events to an event channel the EPA publishes to (Fig. 4).

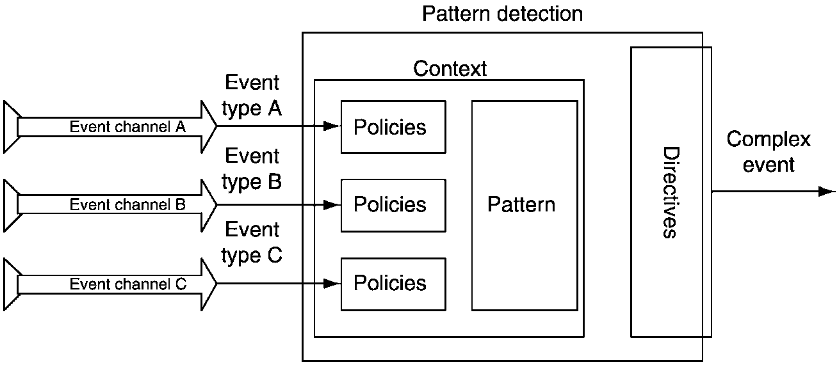
The following sub-sections discuss in detail the different stages within an event processing agent.

Pattern Detection At the pattern stage of an agent, a pattern is defined to be detected at runtime. A single event may match the pattern. In cases where more than one event is needed to detect a pattern, the collection of these events is called a complex event. The single or complex event is passed to the processing stage of an agent. The pattern description consists of four aspects and all are taken from the discipline of complex event processing [1,5] (Fig. 5).

Context – specifies the relevance of the events participating in pattern detection whether it is temporal based, spatial based, or semantic based. Temporal based means that events have to occur within a definable time frame. Spatial based means within a definable space concept such as geographical locations or regions. Semantic based context means that the events participating



Event Processing Network. Figure 4. Event processing agent.



Event Processing Network. Figure 5. Aspects of the pattern detection stage.

in pattern detection have relevance through a mutual object or entity. All types of contexts can be used in the same pattern detection and possibly more than once. Thus, an intersection or union of time frames can be specified as a context, or a context may be defined where events must occur in the same region and within the same time frame for pattern detection. Events occurring within the context defined are denoted as candidates to pattern detection.

Policies – specify how cases in which the semantics need to be fine tuned are handled, discussed in [5] as situation quantifiers. Policies include decisions such as:

- Whether to use the first, last or each of the events in the stream to detect the pattern or any other set operations
- Use only events satisfying a predicate on their attributes
- Whether each event in the stream may override the previous event and remove it from contributing to a pattern detection
- Expiry time, relative or absolute, of an event contributing in detecting the pattern
- Remove an event's contribution, due to the occurrence of a converse event, an event which conditionally implies the expiration of another event, described as contradiction elements in [1]

Choosing each event to contribute to pattern detection may result in multiple pattern detection, resulting in multiple complex events and therefore may result in multiple event publication by the event processing agent as a reaction to a single event consumed by the agent. Events occurring within the context defined and adhere to the defined policies are denoted as candidates to pattern detection.

Pattern – specifies the relationship among events complying with policies within context that is to be detected. Patterns are described in a form of event algebra discussed in [1] as situation operators. Some examples to operation semantics are

- *Any* – any event that occurs within the specified context and for which the policy holds, i.e., candidate, results in pattern detection.
- *Collect* – all events that occur within the specified context and for which the policies hold, i.e., candidates, are collected into one complex event at the end of the detection interval, for example, end of time window and exiting a geographical area.
- *Determine if* – similar to collect, however, the complex event will only include a statement of true if there were events within the detection interval and false otherwise.
- *And {eT1,...,eTn}* – one event from each event type, denoted as *eTi* must occur within the context for this pattern to be detected. There may be multiple pattern detections if there is more than one event of each type. This is determined by policies and whether the occurring events are candidates for pattern detection.

The EPN model does not restrict the set of operations to express patterns nor does it restrict the semantics given to operators.

Directives – specify directives for reporting on pattern detection to the processing stage and what to do with the events that contributed to the pattern detection, discussed in [1] as situation triggering expressions.

- Immediately as the pattern is detected.
- At the end of the detection interval.

- At time-outs associated with event attributes.
- At specifiable periods reporting on all the pattern detections since the last period.
- Allow a single or multiple activation of the processing stage when more than one pattern is detected during the detection interval.
- Consume, maintain always, or maintain an event for certain number of times after pattern detection for further detections, i.e., is the same event allowed to contribute in further pattern detection.
- Include the events that have not contributed to the pattern's detection with the report to the processing stage. When no pattern detection occurred during the reporting time such as at end of detection interval or at time-outs, all events within this period may be passed to the processing stage as well.

Processing Once the pattern detection stage has detected a pattern, it creates either a complex event, in case more than one event contributed to the detection, or passed the original event, in case only it was needed for the detection. This event is further processed based on the processing definition configured for the event processing agent. The result of the processing stage is a derived event ready for emission. There are four possible processing methods that can be performed on the result of the pattern detection stage:

- *Transformation* – specifies a transformation function to be performed on complex events to produce derived events. The transformation can cover a many-to-many relationship. Mapping is in the case of one-to-one where each output of the pattern detection is mapped to a single event structure. Splitting is in the case of one-to-many where each output of the pattern detection is split to several event structures, i.e., multiple derived events from a single complex event. Aggregation is in the case of many-to-one where an aggregation function is performed on the collection of events that are included within the complex event and a single event structure is produced with the function's results. Many-to-many transformation is achieved by applying aggregation and then splitting within the same processing.
- *Derivation* – specifies computations to apply on the collection of events reported by a complex event, which covers more than aggregation transformation. The result can be a single or a set of derived events.
- *Enrichment* – specifies directives in enriching the event with data from external sources such as a database. The result is a new event that is derived from the event received at the processing stage. The additional event data may be used to establish the connection to and retrieval of data from the external source.
- *Validation* – specifies constraints that the event must comply with (assertion) and instructions on how to handle the event in case it does not comply and violates the constraints. The decision on how to handle violation may be conditional and may differ by the repair action.
- Alert and let the processing continue.
- Reject and terminate the processing for this event. The event itself or a derived error event may be published to an event channel for error handling.
- Modify the event for the assertion to hold. When this is not possible, treat it in the same manner as rejecting the event.
- Perform change to external data if used in the assertion to make it hold. Again when this is not possible, treat it in the same manner as rejecting the event.

Emission The emission stage is responsible to emit the derived events to appropriate event channels and is configured with decisions to what event channels to emit and when to emit the events, such as immediately when received from the previous stage, periodically, at specific times or with time offsets. Thus, a single derived event may be emitted to more than one event channel.

Key Applications

Information Dissemination\Situation Awareness

Getting the right information in the right granularity to the right person\target at the right time:

Asset Tracking, Advertising context based content, Command and Control.

Active Diagnostics

Diagnose problems based on symptoms and resolve them:

System Management

Real Time Enterprise Reactions to events as part of business transactions – achieving low latency decisions and quick reaction to threat and opportunities:

Claims processing, Utilities grid management

Business Activity Monitoring

Quick observation into exceptional business behavior and notification to the appropriate people\targets:

Continuous Auditing, Fraud Detection

Predictive Processing

Mitigate or eliminate predicted events:

Epidemic control, Stock Trade

Event Sink

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event consumer

Definition

An entity that receive events from other entities [1].

Key Points

Event sink are nodes in the edge of the event processing network (receiving only) that receive events from the event processing network, event sinks are typically of two types:

1. Orchestration event Sink: receives an event from the event processing network and determines what action should be triggered (e.g., ECA rule) [2]. An action can be – database update, activating a software module, activating/modifying/terminating a workflow instance [3].
2. Notification event sink: receives the event from an event processing network and sends it to a consumer – a person or a dashboard [4].

Note: the action that is triggered by the event sink may be an event source and emit events to the same event processing network or to another event processing network, this will be reflected in the event causality and event lineage.

Event Source

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event producer; Event emitter

Definition

Event source is an entity that provides event for the processing cycle [3].

Key Points

Event sources are typically initial nodes (sending only) in the event processing networks, and provide events to the network for further processing. Event sources can be of various types:

1. Software module – through instrumentation
2. Sensors [1]
3. Clock/Calendar
4. State observers in workflows (BPM).

An event can be obtained from a source in various modes:

1. Push – the source initiates the event emission.
2. Periodic Pull – a calendar service pulls one or more events from the source (e.g., by query the log) [2].
3. On-Demand Pull – an event processing agent pulls the source using request/reply protocol.

Getting events from event sources to processing typically requires adapter to create the event in the desired format.

Event Specification

Jonas Mellin, Mikael Berndtsson
University of Skövde, Skövde, Sweden

Synonyms

Event declaration; Event definition; Composite event query

Definition

Event specifications define event types in terms of patterns of other event types by using event operators (either expressed as operators in an operator grammar or as functions in a functional grammar) and event contexts. Event types are categorized as atomic (or primitive) or composite. An atomic event type is either a system primitive (for example, begin transaction) or it can be any defined atomic change in an activity such as a method, procedure, task etc. (e.g., method has been called). Event types defined in terms of other event types are named composite event types.

Historical Background

Essentially, whenever something has to be defined, it is necessary to have a specification. This can be found in several disciplines of computer science, for example, programming languages, compiler technology etc.

Event specifications became significant with the advent of the HiPAC project [10], in which seminal work on composite event types were done. Prior to HiPAC, mainly primitive event types were addressed in research publications and the event specifications only consisted of single atomic event types (often only system primitives).

Atomic event types in active databases can be categorized according to their sources (e.g., cf. Buchmann [4]): transactional events, temporal events, database manipulation events, and user-defined events. Transactional events are usually system primitives denoting state changes such as "transaction has begun," "transaction has committed," and "transaction has aborted." Temporal events are either absolute (a specified point in time) or relative to some other event and denotes that a time point has passed; further, temporal events can be repetitive and a special case of temporal events are periodic events. The database manipulation events depend on whether the database is relational, object-oriented or object-relational. In relational databases, there is typically only system primitives associated with the state changes corresponding to insertion, update, and deletion of entities (in particular, tuples). In object-oriented databases, system primitive events are typically associated with methods in existing classes associated with the database schema. Finally, in object-relation databases, a mix of system primitive events from both the relational aspect as well as the object-oriented aspect can be found. User-defined atomic events are either associated with methods [4] or composite event queries [3].

There are several event specification languages (either as complete specification languages in their own right or as intrinsic parts of another specification language), usually associated with the active database prototype (e.g., Snoop in Sentinel [8,9], SAMOS [12], ODE [13]), but there are several others that are not explicitly associated with active databases (e.g., GEM [16], monitoring of real-time logic [15]). All of these event specification languages in active databases share a basic set of event operators (e.g., Mellin [17], Carlsson and Lisper [6]): sequence, conjunction, disjunction and non-occurrence. The non-occurrence of events is always enclosed in an half-opened time interval, the question is what event types can be employed to delimit the interval. For example, in Snoop [8,9] and its descendants (e.g., REACH [5]) and SAMOS [12] intervals are delimited by arbitrary event types, whereas in ODE [13] the interval is from when the transaction, in which events occurs, begin. The interval is typically closed by an request to commit transaction or a relative temporal event with respect to the beginning of the interval.

Composite events are specified by event expressions in an operator grammar or in a functional grammar. For example, in Snoop [9] a sequence of events of type E_1 followed by events of type E_2 is expressed as $E_1;E_2$, whereas in EPL [18] it is expressed as $SEQ(E_1,E_2)$. Note that this specification does not dictate how many events of each type that matches the specification and it does not dictate if the events of different event types in the specification are interleaved. Most approaches (e.g., HiPAC [10], Snoop [9,8], SAMOS [12], ODE [13]) employ an operator grammar, whereas, for example, EPL (Event Pattern Language) [18] and XChange^{EQ} [3] are based on a functional grammar. Additionally, XChange^{EQ} is based on XML (e.g., Common Base Events [7]). The advantage of a functional grammar over an operator grammar is threefold:

1. There is no problem with associativity (e.g., the expression SEQ (E_1,E_2,E_3) does not have the ambiguity found in $E_1;E_2;E_3$ that either can mean $E_1;(E_2;E_3)$ or $(E_1;E_2);E_3$)
2. There is no problem with operator priority, a problem that is found in any operator grammar. For example, a conjunction should be prioritized over a disjunction so that $E_1 \& E_2|E_3$ is equivalent to $(E_1 \& E_2)|E_3$ meaning that either an E_3 occurs or a conjunction of E_1 and E_2 occurs, but how should sequences be prioritized with respect to conjunctions and disjunctions?
3. Operators in a functional grammar can be extended to be based on an arbitrary number of event types (e.g., SEQ $(E_1,E_2,...,E_n)$).

There are some pitfalls in event specifications: the definition of disjunctive event operator, and treating all event types as instantaneous. One event operator that have an unintuitive meaning in many event specification languages is disjunction (e.g., Snoop, SAMOS). In logic, disjunction can be inclusive or exclusive, but in many event specification languages it is neither, but a hybrid. Essentially, if an E_1 and an E_2 event occurs concurrently and E **defined by** $E_1|E_2$ is monitored, then the result is two event occurrences of type E with the same end time rather than one event occurrence of type E (inclusive disjunction) or no event occurrence (exclusive disjunction).

Initially, all events, both atomic and composite, were considered to be instantaneous [8,9]. However, as pointed out by Galton and Augusto [11], if all events are considered to be instantaneous, then this will introduce ambiguities in event specifications. For example, it is impossible to distinguish between E_1;(E_2;E_3) and E_2;(E_1;E_3).

Parameterized events carry parameter apart from the system default parameters of events, where the default parameters typically are event type, time stamps, and scope in which the event was generated (e.g., which transaction was the event generated in). Somehow, the event specification needs to enable specification of event parameters as, for example, by Bækgaard et al. [1]. Further, if parameterized event detection is allowed, then it is necessary to specify what parameters are part of the event type specification. Examples of specification of parameterized event detection are found in TCCS [1], XChange^{EQ} [3], and Solicitor [17].

Foundations

As always in formal specifications, there are two main approaches: either to define a minimal specification language that can handle all relevant situations or to define an expressive specification language in which the available expressions and operators are as close as possible to what is needed to express. The latter is prevalent in active database research (cf. Zimmer and Unland [19]), since it is assumed to lead to more comprehensive event specifications (e.g., the work by Liu et al. [15] illustrates the difference between Snoop and real-time logic)

There are four significant research issues that have been pursued within active databases with respect to event specifications: (i) the performance characteristics of event composition, (ii) how to introduce algebraic properties in event specification languages, (iii) how to define event specification languages that enable comprehensive specifications and, in particular, how to specify the orthogonal concepts of patterns and event contexts; and (iv) tools and techniques for understanding event specifications. Issue (i) has been dealt with within a benchmark named BEAST [14] as well as in algorithmic time complexity studies [17, ch. 9]. In the BEAST benchmark study [14] it was concluded that the underlying mechanism (e.g., finite state automatas, Petri-nets, or arbitrary code) of event composition was insignificant compared to typical information maintenance issues such as indexing of event types. It has been shown that the algorithmic time complexity of event composition is mainly based on event contexts, not the event operators per se [17, ch. 9].

The introduction of algebraic properties in event specification languages has been addressed by Carlsson and Lisper [6]. Essentially, they have introduced algebraic properties to an event specification language by defining a new event context: a variety of the recent event context. It is also an attempt to make a minimal language.

A few studies have addressed the specification events (issue (iii)), in particular how to mix event operators and event contexts. There are three approaches: (a) the event operator is locked to one event context as in, for example, ODE [13] or the work by Carlsson et al. [6]; (b) the event operators are explicitly associated with an event context as in, for example, Solicitor [17]; and (c) the different event types in the expressions are decorated with notation (For example, SEQ(*last* : E_1,*first* : E_2) is an example of using the proposed decorators *first* and *last*. This example specification is equivalent to SEQ(E_1,E_2) in recent event context.) that indicate the event context as proposed by Zimmer and Unland [19]. The most comprehensive form is approach (b), but more work is required, in particular on the topic of specifying parameterized event detection. For example, assume that there are concurrent processes accessing a shared variable and it is desirable to check that the processes behave by monitoring that processes enter and exit the critical regions associated with the shared variable within an expected time interval without a "terminate application" event in between. In this case, the matching of events representing entering and exiting the critical regions must be based on that they are generated by the same process, but the "terminate application" event is associated with all existing processes in the application. Further, parameters may express temporal scopes that subsume each other. For example, an event may be generated in a transaction by a particular process executing a specific component and events may carry the identity of transaction, process and component; in some cases, it is only desirable to only match on the transactional level, but in other cases a more precise scope such as the component level is desirable.

Concerning issue (iv), Berndtsson et al. [2] identified, in their investigation of existing visualization techniques of event composition, that event specifications are difficult to understand for M.Sc. level students. The conclusion is that tools to understand event specifications are necessary. Compared to condition evaluation, event composition is far more complicated since, in addition to condition evaluation, it is necessary to check what happened in previous evaluations of event expressions.

Key Applications

Buchmann [4] claims that there are two reasons for separating events from the condition in a rule: (i) to add the semantics of when the rule should be evaluated from what should be evaluated and (ii) efficiency of rule execution. Essentially, event specifications are employed for rule optimization in active databases. Further, if an active database is part of an event based system, then event specifications can be employed to alert other applications outside the active database.

Future Directions

There are three major unresolved threads of research on this topic: (i) specification of parameterized event types for parameterized event detection; (ii) reuse of event specifications; and (iii) usefulness of algebraic properties. The first thread addresses a problem that is similar to join in SQL queries and unification in Prolog programming language. That is, it deals with specifying that the values of certain parameters of an event should match the values of other parameters of another event in an event specification. For example, $E = E_1;E_2$ **where** $E_1.p_1 = E_2.p_2$ could be a notation stating that event occurrences of E only consists of event occurrences of E_1 and E_2 where the values of parameters p_1 and p_2 match. Making this kind of specification comprehensive, precise, unambiguous, and reusable is an open problem. (Note that the notation here is chosen for the likeness of SQL queries, it is not necessarily the best way to specify parameterized event types.)

Reuse of event specifications has not been addressed within active databases, but is a significant topic in software engineering. It would be interesting to, for example, consider if template event specifications can be useful in active databases. For example, in distributed systems call and reply semantics is employed in, among other things, remote procedure calls, that is, something is called and a reply is expected. Assume that C, R and T are template parameters to be instantiated, then a template for detecting a correct (E_c) or incorrect (E_i) sequence of call and reply within a time window could be as follows (where tps(E) and tpe(E) returns the time point of start and end of E):

$$E_c\langle C, R, T\rangle \textbf{ defined by } (C; R) \textbf{ without } E_i \textbf{ within } [\mathrm{tps(C)},\ \mathrm{tps(C)} + \mathrm{T}]$$

$$E_i\langle C, R, T\rangle \textbf{ defined by } \text{non-occurrence of } E_c \textbf{ within } [\mathrm{tps(C)},\ \mathrm{tps(C)} + \mathrm{T}]$$

Given this, a notation such as $E_c\langle A, B, 10s\rangle$ can be used to specify that $C = A$, $R = B$ and $T = 10s$. This specification should also introduce $E_i\langle A, B, 10s\rangle$ implicitly.

With respect to the usefulness of algebraic properties, the question is how useful algebraic properties are? As mentioned, Carlsson et al. [6] has shown that it is possible, but how useful is it compared to existing event contexts. This is still an open issue. For example, basing event composition on historical order, as in the chronicle event context, may become complicated, if not impossible.

Event Stream

Opher Etzion
IBM Research Labs-Haifa, Haifa, Israel

Synonyms

Event pipe; Event network edge

Definition

An Event Stream is a collection of ordered events [4].

Key Points

An event stream is a collection of events, with one or more order relations. The naïve order relation is according to the time that the event arrives to the processing system, but this may not reflect the event order in reality [2], which may define an additional order relation. An event stream may be homogenous (all events have the same structure and type) or heterogeneous (include events that have different types). Homogenous streams are also known as *Data-Type Streams*. For practical usages, typically data-type streams are used. An edge in the event processing network, known as *event pipe* typically is a superset of *event stream* [5].

Sometimes event stream is used as a synonym to event pipe. This term has some relation to "data stream," but it is not identical [1], and does not necessarily correspond to SQL implementation. A typical case of event stream is a time-series, and there are some methods to handle out-of-order arrival in such streams [3].

Event Transformation

Peter Niblett

Event mapping

Definition

In its broadest definition Event Transformation refers to any operation that takes as input a single event message or stream of event messages, and produces a single event message or stream of event messages as its output. As such, this definition encompasses many of the functions provided by an Event Processing Agent in an Event Processing Network, including agents that do complex pattern detection.

There is a somewhat narrower definition in which the operation has to be either a translation, aggregation, split or composition function.

Historical Background

Event translation (transformation of a single input event message into a single output event message) is a special case of message translation – a more general concept where the messages concerned do not necessarily represent events. Message translation has long been used to solve enterprise integration problems where the applications to be integrated have different data models. Enterprise integration sometimes also involves split operations, where input messages are split into multiple outputs. Hohpe and Woolf discuss a number of message translation and splitting patterns in [4].

Event Aggregation and Event Composition operations take streams of event messages as input and are fundamental components of all event stream processing systems. They were included in stream processing systems developed in research departments in the early part of the current century. For more information see the Aurora project [2] and Borealis project [1] from Brandeis, Brown and MIT, or the STREAM project [6] from Stanford. Further material on event processing can be found in [5].

Foundations

Transformations may be classified into the following types, depending on the nature of their input and output:

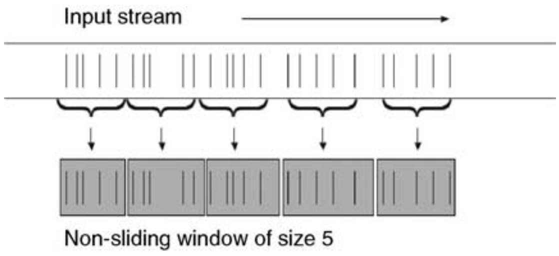
- *Translation.* Gets one event at a time, applies a translation operation and outputs the translated event. A translation operation is sometimes referred to as a *mapping.*
- *Split.* Gets one event at a time and splits the event to N different events, each of which contains a (possibly overlapping) subset of the event attributes.
- *Aggregation.* Takes a stream of events as input, and uses a windowing process to collect events from that stream into windows. The operation then processes each window to produce zero or more "derived" events as output.
- *Composition.* Takes two or more input streams and builds a window for each stream. The operation then takes this set of windows and processes them to produce zero or more derived events as output.

Aggregation and composition both operate against streams of events and since a stream is potentially unbounded they require the concept of a window defined over these input streams. A window is simply a set of event messages that is fetched from the input stream; the operation itself defines how the window is constructed from the stream and the conditions under which it is considered ready for processing. Examples include:

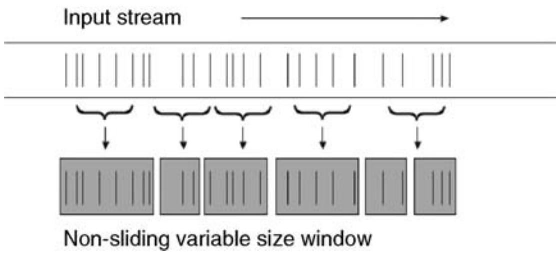
1. Non-sliding window of fixed size N. Events from the input stream are assigned to an "open window." When the specified number of events (N) has been received, the window is closed, ready to be

processed by the operation, and a new window is opened. Each input event is assigned to one and only one window (see Fig. 1).

2. Non-sliding variable size window. This is similar to the fixed-size non-sliding window, except that the closing of the window is triggered by some other condition, for example the detection of a change of type of the incoming event or the detection of a change in the value of a particular attribute on an incoming event (see Fig. 2).
3. Non-sliding time-based window. The operator specifies a time duration and a series of non-overlapping windows is created each of the specified duration. Events are assigned to a window instance based on some timestamp (for example arrival time) associated with the event. Such as if the window is specified to have a length of 2 s, then the window corresponding to time T would contain all events whose timestamp t lies between time T and T-2 seconds (see Fig. 3).
4. Sliding window of fixed size N. A new window is created when each incoming event is encountered. The incoming event and the preceding N-1 events (if any) are assigned to the window, which is then processed by the operation. Unlike the non-sliding examples, each event is assigned to multiple windows (see Fig. 4).
5. Sliding time-based window. A new window is created when each incoming event is encountered, but each window has the same fixed time duration. When a window is created, the incoming event is assigned to the window, along with all preceding events that lie within its time period, and the window is then processed. An alternative, possibly more natural, way of visualizing this is that there is a single window which moves in time; events are added to the window when they are detected, and removed from the window when they have overstayed the time limit. With either definition, if the window is specified to have a length of 2 s, then at time T the window would contain all events whose timestamp t lies between time T and T-2 s. (see Fig. 5).



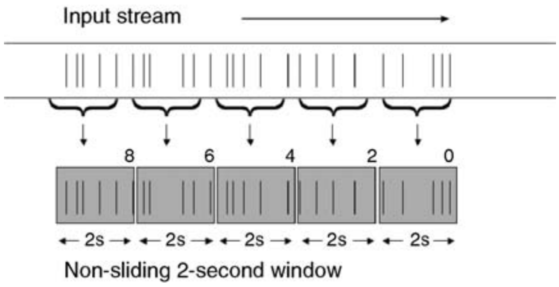
Event Transformation. Figure 1. Non-sliding window of fixed size.



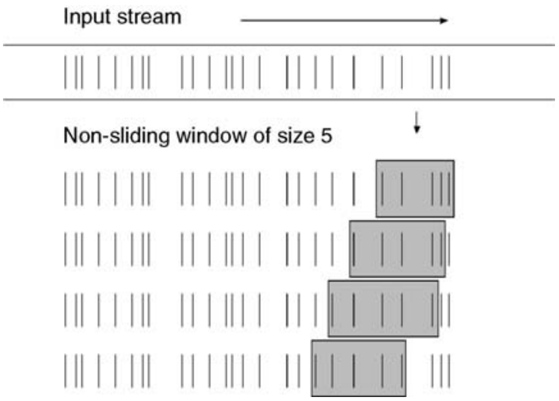
Event Transformation. Figure 2. Non-sliding variable size window.

Non-sliding windows are sometimes referred to as *tumbling* windows.

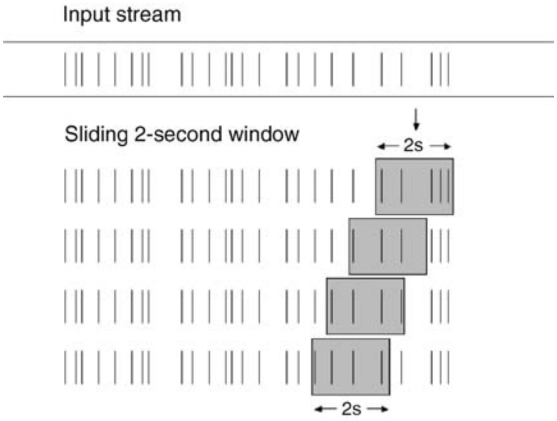
Translate and split style transformations have no requirement for a window, although they could be regarded as operating on a non-sliding window of size 1.



Event Transformation. Figure 3. Non-sliding time-based window.



Event Transformation. Figure 4. Sliding window of fixed size.



Event Transformation. Figure 5. Sliding time-based window.

A transformation where the result of processing a given event is affected by previous events from the input stream is referred to as a Stateful Transformation, whereas transformations where previous events have no effect on the processing of subsequent events are referred to as stateless transformations. Aggregation and composition are stateful by definition, whereas translate (and arguably split) can be either stateful or stateless.

Translation

A translation operation takes one event at a time and transforms it into another. Translation operations can be categorized into a number of different types depending on the amount of change they make to the incoming event.

The least intrusive type of event translation is one that changes the data representation (serialized form) of the event message, without changing its content. For example a translation might be used to convert between an XML and a Comma-Separated Value representation of the event, or to convert between different character sets.

Translation operations are frequently used to make more substantial changes to the content, and even the type, of the event:

- A translation might keep the content of the event unchanged, but modify the types used to represent the attributes of the event. For example it might convert a temperature attribute from Celsius to Fahrenheit, or replace a US state name with a two character code.
- A translation might modify the values of certain attributes of the event. This kind of translation can be used for data cleansing, for example replacing obviously incorrect date values.
- A translation can remove attributes from an event, while preserving the basic type structure of the event. Attributes could be removed if they are not needed by the event consumers, or because they contain sensitive information. A transformation that removes attributes is sometimes called a *projection*.
- Attributes can be added to the event, this is sometimes called *event enrichment*. The values assigned to the additional attributes can be:
  - Fixed values assigned by the translation, for example explicitly filling in default values for attributes omitted from the input event.
  - Values computed from other attributes in the event, for example the translation could assign a severity level to the event.
  - Values computed using an external source of information in addition to data from the event. An example of this would be a translation that uses a customer ID attribute from the input event to retrieve a customer name and address from a database and then adds these as attributes to the output event.

Translations are frequently programmed using visual editing tools, and can be represented using SQL queries, XML Style Sheets [3] that operate on an XML Infoset representation of the event, or other transformation languages.

Splitting

A splitting operation takes a single incoming event as input and produces multiple events as output. It is equivalent to taking a number of copies of the incoming event and applying a different translation to each. Splitting transformations are frequently used in combination with routing operations, with the different output events being routed to different recipients.

Some kinds of splitting transformation are particularly noteworthy:

- Splits that leave the original event untouched, but produce one or more additional events that are projections of the original event.
- Splits that break the original event apart by attribute, and produce a projected for each one of the attributes of the original event.

- Splits that iterate through lists in the original event and produce one projected event for each list item.

A split transformation can be programmed as a set of translations, this is sometimes referred to as a *static split*, since the number of output events is determined by the specification of the split operation. In contrast, in an *iterative split* the number of output events is determined by the data contained in the input event.

Aggregation

An aggregation operation is a function that operates on the events in a window to produce a single output event. The output event summarizes some aspect or aspects of the input events, by either:

- Concatenating the content of the input events, or
- Performing a function on the attributes of the input events; or

Examples of such functions include:

- Maximum, Minimum or "Top-k" values of an attribute.
- Sum or Mean values of an attribute.
- Other forms of average value of an attribute such as median or mode.
- Weighted averages, where one attribute in the event is the value to be averaged and another gives its weight. Weighted attributes are used to compute Volume-Weighted Average Price (VWAP) used in algorithmic trading applications.
- Count of the number of instances of an attribute, or the number of distinct values of an attribute.

An aggregation operation can also carry forwards a value from the previous window. For example when computing a "running maximum" of an attribute, or a VWAP, one may want to consider all events in a given time period (such as the current trading day), rather than just the events in the current window.

The choice of windowing style affects the output of the aggregation. For example an Averaging function with a non-sliding (tumbling) window will give a set of discrete averages, one for each window, whereas the use of sliding window will give a rolling average.

Composition

A composition operation takes windows from two (or more) input streams and performs an operation on them that produces zero, one or more output events. The most common type of composition operation is a *Join*.

Join operations are frequently used with sliding windows, to perform correlation between two streams. Each time an incoming event is detected on one of the streams, it is compared against the events in the window in the other stream using some kind of comparison test, and an event is output if a match is detected. This output event is produced by performing an operation on the attributes of the two matching events. In a two-way join operation both input streams are treated equally, and an incoming event on either stream is compared against the window of events on the other stream.

If the input streams are homogenous, all the events in a window have the same type, then standard relational Join operators can be used, with the two windows being treated as the two tables that are to be joined.

Key Applications

Event transformation of the types described here can be found in most event processing applications, for example in real-time monitoring, algorithmic trading, business activity monitoring.

Event translation has a particular use when integrating event producers and consumers that were not originally intended to work together.

Event aggregation and composition have a particular use in monitoring and simple pattern detection applications.

Event-Driven Business Process Management

Rainer von Ammon
Center for Information Technology Transfer GmbH (CITT), Regensburg, Germany

Synonyms

Workflow management; Business process monitoring

Definition

The term *Event-Driven Business Process Management* is a combination of actually two different disciplines: Business Process Management (BPM) and Complex Event Processing (CEP). The common understanding behind BPM is that each company's unique way of doing business is captured in its business processes. For this reason, business processes are today seen as the most valuable corporate asset. In the context of this entry, BPM means a software platform which provides companies the ability to model, manage, and optimize these processes for significant gain. As an independent system, Complex Event Processing (CEP) is a parallel running platform that analyses and processes events. The BPM- and the CEP-platform correspond via events which are produced by the BPM-workflow engine and by the IT services which are associated with the business process steps.

Historical Background

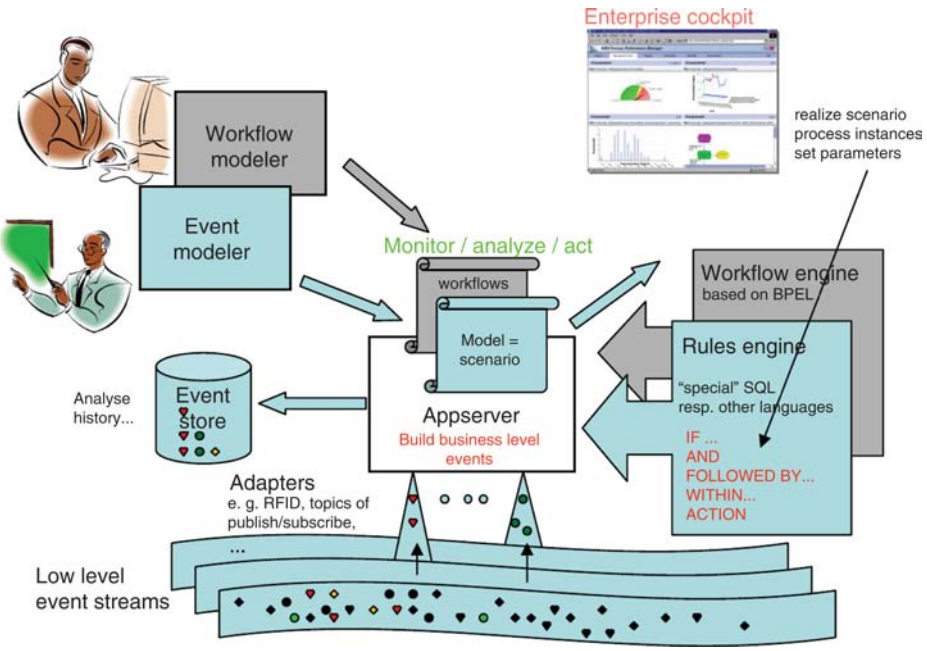
The term "Event Driven Business Process Management" was first used in June 2003 in a white paper of Bruce Silver Associates in connection with the FileNet P8-BPM platform [3]. The term was understood as a synthesis of workflow and Enterprise Application Integration (EAI). Actually, also a concept of event processing and real-time BAM was described in that white paper already, but only as single event processing without knowing anything about CEP which was not a discipline yet. Although the book "The power of events" of David Luckham [7] was already published in 2002, it wasn't well known until 2004 and there was no really working CEP platform so far. In November 2007, the term was explicitly used as a combination of BPM and CEP in an interview with Ruma Sanyal from BEA Systems [4].

Foundations

Figure 1 shows the principle of how a BPM- and BAM/CEP platform work together on the basis of events. The dark shaded components concern workflow respectively BPM, the light shaded components concern the real-time BAM/CEP components. Just started with the availability of commercial CEP platforms, there will be two different kinds of specialists in the future: the workflow modelers or business analysts and the event modelers.

The Business Process Modeler

The workflow modeler identifies business processes, starting from the value chain of an enterprise, he analyses and reengineers or optimizes the business processes by using a Business Process Analyzing-(BPA) tool based on a standard notation like the Business Process Modeling Notation (BPMN), invented 2002 by IBM and now standardized by the Object Management Group (OMG) since 2005, published February 2006 as version 1.0 [8]. A business process model is a graphically designed network based on symbols e.g., for flow objects like activities, gateways and also events. Depending on their position in the network, BPMN categorizes the events as start events, intermediate events and stop events. Each event category has different event types like timer-, message-, exception events etc. In the present release of BPMN 1.1, there are around 25 event types, the new release BPMN 2.0 is announced for Q3/2008. The modeling of business processes is a highly skilled task for a workflow modeler respectively a business analyst, but



Event-Driven Business Process Management. Figure 1. A reference model of the adoption of a CEP/BAM/BPM platform [10].

completely different from the task of an event modeler for real-time BAM/CEP. The event modeler acts with different kinds of events which are produced by the business process instances or from other event sources, like SNMP traps, RFID, log file entries etc.

[The business process models can be transformed into an executable notation of a workflow engine, respectively a BPM platform.] Executable notations are being standardized by OASIS as Business Process Execution Language (BPEL) or as a different standard XPDL by the Workflow Management Coalition (WfMC). To make a business process model really executable, it has to be remodeled more fine grained directly in the BPM platform. From the point of view of the IT department, for example, so called compensations and exceptions have to be modeled, if an IT-service cannot be executed or fails. This task cannot be done by the business analyst who does not know anything about the internals of IT services associated with the process steps. So, in the future as well as with the upcoming BPM platforms and the standards a new procedure for modeling and implementing business processes is needed. Business analysts from the operating departments must closely work with IT specialists, modeling the process and its associated IT services together. This is visualized as BPMN, but directly in an integrated modeling tool of the BPM platform. This is enhanced by a user interface for defining technical information (such as port-types, ports, partnerlinks, peoplelinks etc.), which is needed for the process execution, e.g., by a BPEL-engine. The upcoming BPM platforms are also able to produce events automatically when a service is called or cannot be executed and fails and so on. These are the event types the event modeler has to know for realizing BAM dashboards and enterprise cockpits.

The Event Modeler

By cooperating with the process owners of the operating departments or even with the C-level management of an enterprise, the event modeler has to define which BAM view has to be monitored in a dashboard, which alerts are to send to which roles in the organization and which actions shall be started automatically if a certain event pattern occurs. Derived from such BAM views, the event modeler looks for the needed event types and their instances flowing through the event streams of an enterprise or that are saved in an event store. It requires a high level of skill to define the right event patterns for a real-time BAM view. The event modeler has to know the different event sources like JMS messages realized on the basis of Publish/Subscribe topics etc. He has to install the corresponding event adapters delivered by the

CEP platform as "out of the box" prebuilt features or the event modeler has to care about the development of not yet existing adapters.

Event Processing Languages

The event modeler defines the event patterns for a BAM view on the basis of an Event Processing Language (EPL). At present, there is no standard for an EPL. The CEP community, founded as a discipline at the first CEP symposium in Hawthorne/New York in March 2006, is discussing the right standard for an EPL. It seems that there will be different EPL-approaches for different domains like Algorithmic Trading, BAM etc. At present, the CEP community is gathering use cases and is classifying them according to their corresponding domains [5]. The CEP platforms come with an SQL-like language (e.g., Coral8, Esper, Oracle, StreamBase) or provide a rule-based EPL approach (e.g., AMiT from IBM) or have an abstract user interface that hides any language and generates code like Java (e.g., Tibco, AptSoft).

The models of business processes and event scenarios are deployed into a middleware platform, e.g., into an application server, which is responsible for high availability, limitless scalability, grid computing, failover, transparency of heterogeneous infrastructures and so on.

Relation to the Database Technology

In connection with the term "Event-Driven BPM", there are two major challenges from the point of view of database technologies.

The challenge from the BPM side is storing millions of instances of long running business processes and their status. An enterprise such as a bank or the automotive industry has several thousand business processes like different types of an account opening for a depot, giro account, credit application, project budget confirmation etc. Each business process has several thousand process instances like the credit application of Betty Miller, John Smith etc. For long running processes, the BPM platform has to keep the status of the process instances, e.g., when waiting for the signature of Mrs. Miller or for the confirmation of the credit conditions by the bank. Because that can take days or weeks, there are millions of active business processes in a certain time window at the same time. That is the reason, for example, for overflows of queues in current projects.

The challenge from the BAM/CEP side is processing thousands of events per second generated by business processes and their associated IT-services by in-memory databases, realizing time windows. A memory-centric SQL engine is designed to execute queries without ever writing data to disk. Such an engine also provides a persistence feature for storing the data as "historic events" in an event store for later processing, i.e., for aggregating and correlating them with the current events of the event streams. The basic idea is to route an event through a lot of different in-memory filters, to see what queries it satisfies, rather than executing many queries in sequence against disk-based data. That is a precondition for realizing real-time BAM or the idea of "predictive business" [9].

Examples

If an online credit system receives 50,000 or 100,000 credit applications per day, the bank likes to monitor the application process by typical event patterns that signal, for example, that a credit application could be cancelled within the next moment. In this case, the system shall trigger an action to keep the customer. For this purpose, the event modeler has to identify the corresponding events. If not available from the implemented process, he has to take care of the generation of additional appropriate events. This is a demanding, challenging task.

As another example, BAM/CEP shall send an alert to an employee of the bank, because the loss by cancellations exceeds a certain threshold. However, it wouldn't make sense to send an alert each time a cancellation happens, because too many alerts may result, and the VIRT problem (valuable information at the right time [6]) arises.

Key Applications

Key applications will take place in all domains and first projects on the basis of *Event Driven BPM*-platforms just start 2008:

Logistics applications, e.g., at DHL/Deutsche Post [5].

Finance applications, e.g., Deutsche Bank, Team-Bank [2].

Telco applications, e.g., Deutsche Telekom, T-Mobile.

Current/future research projects, e.g., «Domain specific reference models for event patterns for a faster set-up of BPM/BAM applications» [1].

Eventual Consistency

Marc Shapiro[1], Bettina Kemme[2]
[1]INRIA Paris-Rocquencourt and LIP6, Paris, France
[2]McGill University, Montreal, QC, Canada

Definition

In a replicated database, the consistency level defines whether and how the values of the replicas of a logical object may diverge in the presence of updates. Eventual consistency is the weakest consistency level that guarantees useful properties. Informally, it requires that all replicas of an object will eventually reach the same, correct, final value, assuming that no new updates are submitted to the object.

Key Points

Eventual consistency is an important correctness criterion in systems with a lazy, update-anywhere strategy, also referred to as *optimistic replication* (q.v.). Update operations can be submitted and executed on any node, and the propagation of updates occurs lazily after commit. Conflict resolution and reconciliation must ensure that all replicas (copies) of a logical object eventually converge to the same value. Different objects are considered independent.

In a system where updates are continuously submitted, eventual consistency can be defined by a weak form of schedule equivalence [1]. A schedule S_n^x describes the sequence of update operations node n performs on its replica of object x. An element of the schedule of the form w_i represents the execution of an update to object x, submitted by some user. S_n^x contains an element of the form $\overline{w_i}$, if the update w_i was received by n, but either not executed, or aborted due to conflict resolution.

Typically, two schedules are defined equivalent by restricting how the order of operations in the two schedules may differ. However, for eventual consistency only the convergence of object values matters. Thus, equivalence is defined by comparing the final state of the replicas. Two schedules are said *state equivalent* when, starting from the same initial state, they produce the same final state. For instance: (i) schedules $S = w_1 w_2$ and $S' = w_2 w_1$ are state-equivalent if w_1 and w_2 commute; (ii) schedules $S = w_1 w_2$ and $S' = w_2$ are state-equivalent if w_2 sets the state of the object to a completely new value (e.g., $x := 2$).

Eventual consistency of a replicated object x is defined by the following conditions, which must hold at all times, at any node n with a replica of x [1]. It is assumed that all replicas have the same initial state. There is a prefix of the schedule S_n^x that contains the same operations and is state-equivalent to a prefix of the schedule $S_{n'}^x$ of any other node n' holding a replica of x. Such a prefix is called a *committed prefix* of S_n^x.

- The committed prefix of S_n^x grows monotonically over time, i.e., the extant set of operations and their relative order remains unchanged.
- For every operation w_i submitted by a user, either w_i or $\overline{w_i}$ eventually appears in the committed prefix of S_n^x (but not both, and not more than once).
- An operation of the form w_i in the committed prefix satisfies all its preconditions (e.g., the state of the object immediately before the execution of the operation fulfills certain conditions).

As an example, assume operation w_1 sets x to 2, and w_2 sets it to 5. Operation w_1 is submitted and executed at n_1 while w_2 is first executed at n_2. At this time the local schedules are $S_1 = w_1$ and $S_2 = w_2$ and the committed prefix at both nodes is the empty schedule. Now w_1 is propagated to n_2 and w_2 is propagated to n_1. When n_1 receives w_2, it detects that w_1 and w_2 are concurrent and conflict. Say that conflict reconciliation prioritizes one of the operations, e.g., w_1. Then, w_2 is simply not executed and the new schedule is $S_1^x = w_1\overline{w_2}$. At n_2, when w_1 arrives, the conflict is also detected, w_2 is undone, w_1 is executed and the final schedule is $S_2 = \overline{w_2}w_1$. At this time, S_1 and S_2 are themselves the committed prefixes. Note that further concurrent operations on x might move the schedules further, but the extensions would still be tentative and only become committed once they are reconciled at all replicas.

Evidence Based Medicine

Michael Weiner
Indiana University School of Medicine, Indianapolis, IN, USA

Synonyms

Evidence based practice; Scientific medicine

Definition

Evidence based medicine (EBM) is the "conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients" [1].

Key Points

Although medical practice is historically based on observation and best attempts at scientific method, early medical practices often involved trial and error or observations of one or a few cases. In the last century, advances in research, experience, technology, and communications have moved medicine more towards practice based on established evidence.

Individuals especially responsible for promoting, developing, describing, and discussing EBM have included Archie Cochrane, David Sackett [4], and Gordon Guyatt [2]. The international Cochrane Collaboration [3] has emerged to continue to advance EBM throughout the world. This and several other organizations, such as the US Preventive Services Task Force [1], have assembled, analyzed, and graded collections of medical evidence. Specific evidence reported from such groups often has gradings that indicate the strength of evidence about a topic, based on quality or scope of methods, statistics, reproducibility of findings, etc.

The representation of medical evidence in information systems or databases can assume various forms, especially because the type of evidence is likely to vary substantially from one topic to the next. Nevertheless, the use of standard clinical research methods, such as randomized controlled trials, survival analysis, and meta-analysis, can facilitate knowledge management and representation by limiting the types of information that need to be stored or communicated. Automated extraction of medical knowledge from research reports may benefit from natural language processing when reports are not more structured.

EBM has several positive aspects. It can help to increase adherence to clinical guidelines and minimize variations in medical practice that may be viewed as too large or experimental. It can help to reduce disparities and establish a minimum standard of care for a population. To some degree, EBM seems to hold practitioners and researchers more accountable for their actions and pursuits and also distributes the knowledge among a larger group of professionals and consumers. EBM promotes the development of further research.

Overreliance on EBM may stifle creativity, or it may fail to take into account an individual's preferences or characteristics that may not "fit the mold" or may require special handling not covered by a guideline or established evidence. Thus, practicing EBM requires the ability to find, understand, interpret, and appropriately apply evidence with individual patients or groups. The Internet is increasingly a useful source of EBM knowledge, via databases, literature reviews, and communications.

The rise of EBM has been associated with corresponding local and federal health policies. For example, medical institutions may prohibit certain procedures without adequate evidence of benefit. Not only the practice of medicine, but the reimbursement of modern medical care, often depends on evidence.

Executable Knowledge

Mor Peleg
University of Haifa, Haifa, Israel

Synonyms

Computer-interpretable formalism; Knowledge-based systems

Definition

Executable knowledge is represented in a symbolic formalism that can be understood by human beings and interpreted and executed by a computer program. It allows a computer program to match case data to the knowledge, reason with the knowledge, select recommended actions that are specific to the case data, and deliver them to users. Executed knowledge can be delivered in the form of advice, alerts, and reminders, and can be used in decision-support or process management.

Historical Background

Representing knowledge in a computer-interpretable format and reasoning with it so as to support humans in decision making started to be developed by the artificial intelligence community in the 1970s. According to Newell [6], knowledge is separate from its representation. At the knowledge level, an agent has as parts bodies of knowledge, actions, and goals. An agent processes its knowledge to determine the actions to take. An agent, behaving through the principal of rationality, selects those actions that attain his goals. Representing knowledge in a symbolic way (i.e., data structures and algorithms) allows the expression of knowledge in a way that would be understandable by humans and would allow people and computer programs to reason with the knowledge and select actions in the service of goals. According to Davis et al. [1], knowledge representation serves five roles: (i) a surrogate to enable an entity to determine the consequences of thinking, (ii) a set of ontological commitments about how and what to see in the world, (iii) a fragmentary theory of intelligent reasoning, (iv) a medium for efficient computation, and (v) a medium for human expression.

Research on knowledge representations started to evolve in the 1970s with rule-based systems. One of the most famous rule-based systems is Mycin [11]. This system represented clinical knowledge about diagnosis and treatment of infectious diseases and allowed clinician users to enter patient findings and, through execution of the if-then-else rules, arrive at probable diagnoses and appropriate treatments. In the 1980s decision-theoretic models, such as Bayesian Networks, influence diagrams, and decision trees [7] started to become popular ways of representing and reasoning with decision knowledge in a probabilistic way, under uncertainty.

By the late 1980s, researchers started to realize the importance of integrating knowledge-based systems with databases. In this way, the case data coming from a database could drive the execution of encoded knowledge. An example of an early formalism that addressed data integration is the Arden Syntax for Medical Logic Modules (MLMs) [4], discussed in detail below.

In the 1990, ontologies [3] were developed to formalize a shared understanding of a domain. In knowledge engineering, the term ontology is used to mean definitions of concepts in a domain of interest and the relationships among them ("a specification of a conceptualization of a domain" [3]). An ontology enables software applications and humans to share and reuse the knowledge consistently. Ontologies, as represented in a formal language such as frames or description logic, allow logical inference over the set of concepts and relationships to provide decision support and explanation facilities. Ontologies are much more maintainable than rule-based systems. In rule-based systems, the knowledge is represented as individual rules. It is difficult to foresee the affect of addition, deletion, or modification of a rule on the performance of the rule-based system. This problem is solved by ontologies. Research in the 1990s, led by Musen [5], addressed modeling of domain knowledge and problem-solving methods as ontologies that could be combined together, such that a problem solving method could be applied to several domain ontologies, and decision-support systems in a single domain could utilize several generic problem-solving methods.

In the 1990s, a new generation of executable knowledge-based systems started to be developed by two separate communities: the medical informatics community and the business process community. The common theme to the new developments by both of these communities was that the executable knowledge was no longer representing individual decisions, but rather a process that unfolds over time and includes many activities, and the fact that the knowledge-based process system had to be integrated with other systems in the organization. The process modeling languages in both communities were developed as ontologies.

Foundations

Executable knowledge formalisms were developed by several communities, including the artificial intelligence community, the medical informatics community, and the business process management community. The rest of this article reviews work done by the medical informatics and business process communities.

Following the success of rule-based decision-support systems, and at the same time, recognizing the advantages of linking a knowledge-based system to case data, a standard for encoding individual medical decisions, known as the Arden Syntax for Medical Logic Modules (MLMs) [4], was defined in 1989. Arden Syntax was developed initially under the sponsorship of the American Society for Testing and

Materials and subsequently of Health Level Seven (HL7). Arden Syntax is a published as an American National Standards Institute (ANSI) standard. MLMs, in Arden Syntax, define decision logic via a knowledge category that has data, evoke, logic, and action slots. The event, logic and action slots specify respectively the events that trigger the MLM (e.g., storage of a new serum potassium test result into a database), the logical criterion that is evaluated (e.g., serum potassium value <3.5), and the action that is performed if the logical criterion holds, which is often an alert or reminder (e.g., potassium replacement therapy). The data slot specifies mappings between the specific database records and the MLM's variables. However, only part of this specification is defined by the syntax, as it does not contain standard terminology or a data model for electronic medical records.

In the 1990s, decision-support systems whose knowledge is based on evidence-based clinical guidelines started to be developed. Clinical guidelines are recommendations that are developed by healthcare organizations based on evidence from clinical trials, and are aimed at assisting practitioner and patient decisions about appropriate healthcare for specific clinical circumstances. Unlike individual clinical decisions, such as MLMs, clinical guidelines involve multi-step decisions and actions that unfold over time. Guideline-based decision-support systems help clinicians in the process of patient care, including decision making and task management. These systems are based on process-flow ontologies termed Task-Network Models (TNM) [10] – a hierarchical decomposition of guidelines into networks of component tasks that unfold over time. The task types vary in different TNMs, yet all of them support modeling of medical actions, decisions, and nested tasks. These models contain computer-interpretable specifications of decision criteria and clinical actions that enable an execution engine to interpret the guideline representation and execute it for a given patient case data. Important themes in executable guideline models include the ability of some of them to integrate with electronic databases (e.g., electronic health record systems (EHR)), using standard terminologies to express medical actions (e.g., laboratory tests, drug prescriptions) and patient data items upon which decision criteria are written, using standard expression languages for writing decision criteria, and using messaging standards for exchange of (clinical) data.

In 2003, researchers from six groups that developed TNMs participated in a study that compared their models using two clinical guidelines that served as case studies [10]. The TNMs studied were Asbru, EON, GLIF, Guide, PRODIGY, and PRO*forma*. An example of a guideline model represented in GLIF is shown in Fig. 1. Although these formalisms all depict a guideline as a TNM, they each have their own emphasis. Asbru emphasizes specifying intentions as temporal patterns; EON views the guideline model as the core of an extensible set of models, such as a model for performing temporal abstractions. EON uses a task-based approach to define decision-support services that can be implemented using alternative techniques; GLIF emphasizes the ability to share and integrate guideline specifications among software tools and implementing institutions; GUIDE focuses on integration with organizational workflow using a workflow-based model and linkage to decision-theoretic models, PRODIGY (a project that is no longer active) aimed at producing the simplest, most readily comprehensible model necessary to represent chronic disease management guidelines. It models guidelines as decision maps organized as a collection of clinical contexts; in each context, selection among relevant clinical actions is made; PRO*forma* advocates the support of safe guideline-based decision support and patient management by combining logic programming and object-oriented modeling. Its syntax and semantics are formally defined. One aim of the PRO*forma* project is to explore the expressiveness of a deliberately minimal set of modeling constructs: actions, compound plans, decisions, and inquiries of patient data from a user.

The study compared the TNM models in term of eight components that capture the structure of computerized guidelines: (i) organization of guideline plans, (ii) goals, (iii) model of guideline actions, (iv) decision model, (v) expression language, (vi) data interpretation/abstractions, (vii) medical concept model, and (viii) patient information model.

The purpose of the study was to find consensus among the different formalisms that could be a starting point for creating a standard computerized guideline formalism. Differences between the guideline modeling languages were most apparent in underlying decision models (ranging from simple switching constructs to argumentation rules for and against decision alternatives, and even use of decision-theoretic models such as influence diagrams and decision trees), goal

Executable Knowledge. Figure 1. Part of a GLIF model for a Diabetic Foot guideline, modeled using the Protégé-200 tool. Squares denote actions, diamonds – patient state steps, hexagons – decisions. The bottom part of the figure shows the computable specification of the decision step "Limb-threatening Infection." The decision criterion is based on values of patient data items. Each patient data item is defined using a concept code taken from a controlled medical vocabulary (Unified Medical Language System (UMLS) in this case) and by a patient data model class (e.g., Observation) taken from a data model source, such as Health Level 7's Reference Information Model (RIM).

representation, use of scenarios (as a plan component that defines a particular patient management context that serves as entry points into guidelines), and structured medical actions which could be mapped into controlled vocabulary terms.

Consensus was found in plan organization (plans could be nested and structured as plan components arranged in sequence, in parallel, and in iterative and cyclic structures), expression language for specifying and sharing decision and eligibility criteria, patient state definitions, and preconditions on system actions, conceptual medical record model, medical concept model, and data abstractions (i.e., definitions of abstract terms using mathematical functions of other concepts, temporal abstractions, and concept hierarchies that allow reasoning at different levels of the hierarchy).

The HL7 Clinical Decision Support Technical Committee (CDSTC) has focused on standardization of two of the components for which consensus was found: expression language and conceptual virtual medical record (vMR) model. The object-oriented guideline expression language, GELLO [12], is an extensible guideline expression language that can be used for formally defining decision and eligibility criteria, as well as patient states. It is based on the Object Constraint Language (OCL) (http://www-306.ibm.com/software/rational/uml/resources/documentation.html). In 2004, it was established as a standard of HL7. The CDSTC started the process of standardizing a vMR, based on experiences with the patient information models of PRODIGY, EON and the HL7 RIM, which is also the basis of GLIF's default patient information model. An object oriented vMR would ease the process of mapping guideline patient data items to real EMRs, allowing decision criteria, eligibility criteria and patient states to be defined by in guideline models by reference to the VMR rather than specific EMRs.

The second community that started to develop a new generation of executable knowledge-based systems is the business process management community. Workflow management systems started to be developed based on workflow formalisms that define a model of business processes and a model of the organization, including its individual actors, roles, organizational units, and resources that participate in workflow activities. Several industrial groups defined standards for workflows. The Web Services Business Process Execution Language (BPEL) by the Advanced Open Standards for the Information Society (OASIS), is an executable formalism where the business process behavior is based on Web Services. XML Process Definition Language (XPDL) is a standard that is under development since 1998 by the Workflow Management Coalition – An industry group dedicated to creating software standards for workflow applications. The goal of XPDL is to store and exchange the process diagrams among different workflow tools, including workflow modeling tools (editors) and workflow engines. In 2004 the Workflow Management coalition endorsed the graphical workflow standard called Business Process Modeling Notation (BPMN) developed by Object Management Group, to standardize the way that process definitions are visualized.

The business process management community has developed many tools that enable modeling, analyzing, verifying, simulating, and executing a business process. While the medical informatics community devoted much research to supporting clinical decision making in addition to patient care task management, the business process community made much progress on modeling task management within an organization, where the business process often involves many departmental units and organizational roles. Workflow systems aim to help in resource management, a task that is not addressed by current executable guideline systems.

Key Applications

A generic free and open-source tool for creating ontologies, or knowledge-bases, is Protégé (http://protege.stanford.edu). The Protégé platform supports two main ways of modeling ontologies via the frames and Ontology Web Language (OWL) formalisms. Protégé is implemented in the Java programming language and is extensible. Protégé-frames knowledge bases could be reasoned with several rule-engines, such as Jess and Algernon. Additionally, the Protégé Axiom Language could be used to define first-order-logic constraints and check them for instances in the knowledge base. Several reasoners can be used with Protégé-OWL to classify instances or classes according to class definitions and class hierarchies. They include the commercial product Racer, and the commonly used free reasoners Pellet and Fact + +. The SWRL rule-based engine could also be used to reason with Protege-OWL.

The Arden Syntax for Medical Logic Modules has been applied by universities such as Columbia

University Medical School and by several health information systems vendors, such as Micromedex, Eclypsis Corporation, McKesson Information Solutions, and Siemens Medical Solutions Health Services Corporation to create MLMs that deliver clinical recommendations in the form of alerts and reminders. MLMs are being used by many clinical institutions in the United States (see http://cslxinfmtcs.csmc.edu/hl7/arden/ for a partial list). The Department of BioMedical Informatics at Columbia University developed a knowledgebase of over 240 MLMs that are now available from http://cslxinfmtcs.csmc.edu/hl7/arden/.

Many tools exist to support guideline development, modeling, verification, and execution [2,8]. Asbru modeling tools include Delt/A (http://ieg.ifs.tuwien.ac.at/projects/delta/) and URUZ, both focusing on easing the transition from narrative to formal representations via a mark-up stage, AsbruView (http://www.ifs.tuwien.ac.at/asgaard/asbru/tools.html), which focuses on visualization and user interface for authoring, and CareVis (http://ieg.ifs.tuwien.ac.at/projects/carevis/), which provides multiple simultaneous views to cover different aspects of a complex underlying data structure of treatment plans and patient data. Verification of Asbru guidelines can be done using formal verification methods [13]. Implementations in Asbru were developed for diabetes, artificial ventilation, and breast cancer guidelines.

EON guidelines can be authored in the knowledge-modeling tool Protégé-2000 and executed by an execution engine that uses a temporal data mediator to support queries involving temporal abstractions and temporal relationships. A third component provides explanation services for other components. EON has been used to create hypertension and opiods guidelines that are implemented in various hospitals and clinics of the Veteran Affairs Hospital. Protégé-2000 is also the modeling tool for GLIF guidelines. The GLIF execution engine (GLEE) has been used to implement two guidelines: diabetic foot diagnosis and management and flu vaccinations.

Guide has a new implementation of an authoring tool and an execution engine called NewGuide. Guide has been used to implement guidelines for stroke and for management of patients with heart failure.

A number of software tools have been created for creating, visualizing, and executing PRO*forma* guidelines. They include Arezzo and Tallis. Several PRO*forma* guidelines have been implemented and some have undergone clinical trials to establish their safety and utility. More information on PRO*forma* implementations as well as on implementations of other guideline formalisms can be found at the open clinical web site (www.openclinical.org) – a repository of resources about decision support, clinical workflow and other advanced knowledge management technologies for patient care and clinical research.

Key application for workflow management systems include tools for modeling and executing workflows, such as the open-source workflow tool Bonita (http://bonita.objectweb.org), FLOWer (http://www.workflow-download.com/workflow/flower.html), YAWL (http://www.yawl-system.com/), and Together Workflow Editor andserver(http://www.together.at/together/prod/twe/), and Oracle Workflow (http://www.oracle.com/technology/products/integration/workflow/workflow_fov.html). Other tools exist for verifying [15] workflows (Oracle Worklow). There are business process management engines available from several vendors including Software AG, Savvion, Lombardi, Appian, JBoss, and Tibco.

Future Directions

The challenge of creating executable knowledge that can be shared by multiple implementing institutions and mapped to their information systems started to be addressed by projects such as the Arden Syntax, GLIF, Shareable Active Guideline Environment (SAGE) [14] and Knowledge-Data Ontology Mapper [9], yet more work needs to be done in this area to define how knowledge can be authored in a way that is institution-specific and sharable.

One of the most interesting future directions of executable knowledge concerns synergetic development that draws upon developments made in the medical informatics and the business process communities. Such collaborations are emerging, as manifested by health-care related workshops that are taking place in business-process management and information systems conferences, such as the ProHealth Workshop, which is part of the Business Process Management conference.

Execution Skew

Nikos Hardavellas, Ippokratis Pandis
Carnegie Mellon University, Pittsburgh, PA, USA

Definition

Execution skew is a phenomenon observed during the parallel evaluation of a database query, in which the concurrent operators exhibit disparate execution times.

Key Points

Execution skew is a phenomenon observed in the parallel evaluation of a database query. It arises when there are imbalances in the execution of the operators running in parallel, resulting in some of the operators running for a longer time than others. The differences in execution times may cause some of the processors to remain idle while others still compute a part of the query. Execution skew can be a consequence of other forms of skew within a query, e.g., data skew, or arise because of temporally unavailable resources that affect the execution speed of a unit of work. The database system can minimize execution skew through the careful allocation of processors to operators and the selection of the appropriate parallel query plan. Execution skew arises in both operator-level parallelism as well as intra-operator parallelism. The interested reader is referred to [1] which presents a classification of skew effects in parallel database systems.

Explicit Event

Jonas Mellin, Mikael Berndtsson
University of Skövde, Skövde, Sweden

Definition

In active databases, an explicit event is explicitly specified in the ECA rule definition.

Key Points

ECA rules were developed as an optimization of condition action rules. The performance of rule evaluation was improved by allowing, or even requiring, explicit definition of when rules should be triggered in the form of events. For example, (**ON** *update*$_A$ **followed_by** *update*$_B$ **IF** $A = 5 \wedge B = 3$ **DO** action) is a rule specification that is triggered by the explicit event *update*$_A$ **followed_by** *update*$_B$ (i.e., a sequence of updates).

Exploratory Data Analysis

Hans Hinterberger
ETH Zurich, Zurich, Switzerland

Definition

Exploratory Data Analysis (EDA) is an *approach* to data analysis that employs a number of different techniques to:

1. Look at data to see what it seems to say,
2. Uncover underlying structures,
3. Isolate important variables,
4. Detect outliers and other anomalies,
5. Suggest suitable models for conventional statistics.

Key Points

The term "Exploratory Data Analysis" was introduced by John W. Tukey who in [2] shows how simple graphical and quantitative techniques can be used to open-mindedly explore data.

Typical graphical techniques are

1. Plotting the raw data (e.g., stem-and-leaf diagrams, histograms, scatter plots)
2. Plotting simple statistics (e.g., mean plots, box plots, residual plots)
3. Positioning (multiple) plots to amplify cognition

Typical quantitative techniques are

1. Interval estimation
2. Measures of location or of scale
3. Shapes of distributions

Exploratory data analysis can help to improve the results of statistical hypothesis testing by forcing one to look at data unbiased before formulating hypotheses which are subsequently tested using conventional statistics (confirmatory data analysis). Its techniques allow analysts to better assess assumptions on which statistical inference will be based and support the selection of appropriate statistical tools. EDA can also provide a background for further data collection.

For users of database systems it might be interesting to note that many EDA techniques have been adopted to support the exploration stage of data mining [1]. In particular, they are being used to identify the most relevant variables and to determine the complexity and general nature of models that can be taken into account for the model building and validation stages. Data mining and EDA are complementary in the sense that the former is more oriented towards applications and the later can help understand the basic nature of the underlying phenomena.

Expressive Power of Query Languages

Leonid Libkin
University of Edinburgh, Edinburgh, UK

Definition

The study of expressive power concentrates on comparing classes of queries that can be expressed in different languages, and on proving expressibility – or *in*expressibility – of certain queries in a query language.

Historical Background

Ever since Codd proposed relational calculus (first-order predicate logic) as a basic relational query language, it has been common for database query languages to have limited expressiveness. If a language cannot express everything computable, then it is natural to ask:

1. What queries cannot be expressed in a language $\mathcal{L}$?
2. Which methods are available for proving such results?

Furthermore, if there are two query languages $\mathcal{L}_1$ and $\mathcal{L}_2$, one may want to compare their expressiveness: for example, $\mathcal{L}_1 \subsetneq \mathcal{L}_2$ means that all queries expressible in $\mathcal{L}_1$ are also expressible in $\mathcal{L}_2$, but there are queries expressible in $\mathcal{L}_2$ that are not expressible in $\mathcal{L}_1$.

In 1975, Fagin [4] showed that queries such as the transitive closure of a graph and connectivity test cannot be expressed in relational calculus. The 0-1 law for first-order logic [5] implies that relational calculus furthermore lacks the ability to count, which was confirmed by the design of SQL, that explicitly includes counting primitives (aggregate functions). The field of *finite model theory* [1,9,12] provided many tools for studying the expressiveness of query languages: for example, Ehrenfeucht-Fraïssé games of different kinds, locality, and automata-based techniques for more expressive languages over special classes of structures such as trees.

In the direction of comparing power of languages, one of the most popular lines of work is comparing the power of a language with the class of all queries that have certain data complexity [3]. Classical results along these lines include extensions of relational calculus that describe familiar complexity classes such as PTIME.

Foundations

Relational calculus and algebra have precisely the power of first-order logic (FO) over *finite* relational structures. Many classical tools from logic, however, are inapplicable to finite structures. Investigation of the power of FO that applies to both finite and infinite structures was initiated by Ehrenfeucht and Fraïssé who developed the technique of Ehrenfeucht-Fraïssé games for characterizing the expressiveness of FO. With this technique it is very easy to prove, for example, that the *parity* query (is the number of elements of a set even?) is not expressible in FO. A more complicated application of Ehrenfeucht-Fraïssé games shows that the parity query is not FO-definable even over linear orders.

While parity is a nice and simple example of a query that involves counting, early questions about expressiveness of relational query languages concentrated on queries such as the transitive closure of a graph. For example, if a database represents a management hierarchy, it is natural to ask whether employee x reports to employee y. Such a query, in the absence of a priori bounds on the possible length of a management chain, involves transitive closure computation.

In 1975, Fagin [4] showed that graph connectivity is not definable in FO. In fact he proved a stronger result that it is not even definable in existential monadic second-order logic, whose formulae are of the form $\exists X_1 \ldots \exists X_k\ \varphi$, where the X_i's range over *sets of nodes* and φ is an FO formula. Inexpressibility of graph connectivity implies inexpressibility of transitive closure: had transitive closure E^* of a graph E been expressible, so would be connectivity by $\forall x \forall y E^*(x, y)$.

Early results have been proved using Ehrenfeucht-Fraïssé game techniques. Later easier techniques have been developed, such as *locality* and *zero-one laws*. Locality says that a formula $\varphi(x_1,\ldots,x_n)$ cannot "see" far beyond its free variables. For example, the transitive closure is not local because in a graph with directed edges $(0, 1),(1, 2),(2, 3),\ldots,(n - 1, n)$ a given formula $\varphi(x, y)$ will not see the difference between pairs (j, k) and (k, j) for $j < k$ if the numbers k and j as well as $k - j$ and $n - k$ are sufficiently large.

Zero-one laws say that asymptotically the truth value of a sentence is almost surely false or almost surely true. For example, *parity* violates this property, as the proportion of structures of cardinality n for which the *parity* query is true oscillates between 0 and 1. For surveys of these results, see [1,12].

Since FO cannot do nontrivial counting and cannot express fixed-point computation, database theory research looked in detail into such extensions of FO. The simplest way to add counting is by means of counting quantifiers $\exists ix\varphi(x)$ stating that there are at least i witnesses x of $\varphi(x)$. For example, one can express that the number of witnesses of $\varphi(x)$ is even as $\exists i\exists!ix\ \varphi(x)\ \wedge\exists j\ (j+j=i)$, where $\exists!ix\ \varphi(x)$ says that the number of witnesses is exactly i (it is defined as $\exists ix\ \varphi(x)\ \wedge\exists j(\exists jx\ \varphi(x)\ \wedge\ j>i)$).

One can then prove that such an extension of FO is still local, which means, in particular, that queries such as transitive closure and graph connectivity are not expressible. However, this form of counting is very different from the usual one in SQL, such as aggregate functions together with `GROUPBY` and `HAVING` clauses. These can be modeled by adding more powerful arithmetic and aggregate terms to FO. The idea is that if there are some aggregate functions $\mathcal{F}_1,\ldots,\mathcal{F}_k$ (such as `MIN`, `SUM`, `AVG`), one can have expressions of the form

$$\mathrm{AGGR}_l[i_1:\mathcal{F}_1,\ldots,i_k:\mathcal{F}_k](e)$$

whose semantics is basically that of the following SQL query:

$$\begin{array}{ll}\texttt{SELECT} & \#1,\ldots,\#m,\mathcal{F}_1(\#\texttt{i}_1),\ldots,\mathcal{F}_k(\#\texttt{i}_k)\\ \texttt{FROM} & \texttt{E}\\ \texttt{GROUPBY} & \#1,\ldots,\#\textit{l}\end{array}$$

where `E` is the result of the expression e, which is assumed to produce a relation with m attributes [10,11]. In fact even more general aggregate terms could be permitted, and even with them, the resulting queries that are expressed in such an extension remain local. Hence, even aggregate extensions of FO cannot express fixed-point computations required to compute queries such as the transitive closure [11].

However, for this result it is essential that no operations are permitted on the domain of graph nodes; for example, one cannot compare them and say $a<b$. If an ordering is available, then even with very basic aggregate functions, proving inexpressibility of transitive closure is at least as hard as solving some long-standing open problems related to separation of complexity classes.

Another well-studied extension of FO is that with fixed-point operators. For example, the following Datalog program computes the transitive closure of a graph represented by the edge relation e:

$$\begin{array}{lcl} trcl(x,y) & :- & e(x,y)\\ trcl(x,y) & :- & e(x,z),\wedge trcl(z,y)\end{array}$$

This could also be expressed as a *least fixed-point* formula $\text{LFP}_{R,x,y}\ (E(x,\ y)\ \vee\exists z(E(x,\ z)\ \wedge\ R(z,\ y)))$, which computes the least fixed-point of the operator that sends each binary relation R to the relation $F(R)=E\cup E\circ R$, where $\circ$ is the relational composition.

For such formulae, it is essential that R occur positively (under an even number of negations), but many different flavors of datalog and fixed-point logics are known, which permit more flexible syntax and fewer restrictions (often at the expense of a more complicated semantics).

It was proved that such an extension of FO with least fixed-point still has the zero-one law [2]. In particular, the *parity* query cannot be defined in it. In fact this continues to hold for more powerful fixed-point operators.

But similarly to the case of aggregates, the situation changes dramatically if a linear ordering is allowed on the domain. In that case, the Immerman-Vardi theorem states that the least-fixed-point extension of FO captures precisely the class of queries with PTIME data complexity [8,14]. And various other fixed-point logics have been proposed to capture complexity classes such as DLOGSPACE, NLOGSPACE, PSPACE over ordered structures [9].

This gives rise to a natural question whether it is possible to find a logical query language that captures polynomial-time queries over unordered structures. This question, asked for the first time in [3], remains open, despite multiple attempts to solve it. For example, adding both fixed-point operators and counting still falls short of polynomial time. See Chapts. 1 and 2 in [6] for surveys. There are some positive results when the class of structures is restricted: for example, a different (inflationary) fixed-point operator together with counting captures polynomial time on the class of all unordered planar graphs [7].

Questions related to the expressive power of query languages have been addressed for other data models as well. Results on aggregates are closely related to the expressiveness of relational languages under the bag (multiset) semantics. Many results about expressiveness of languages for nested relations can be derived from the *conservativity* theorem of [15] stating a query from relations to relations, even if it is expressed with the help of the operators of *nested* relational algebra, can be expressed in FO without any such operators. Similar in flavor conservativity results have been proved for constraint databases, and extensions of relational calculus with various constraints, such as polynomial (in) equalities over the reals (see Chapt. 5 of [6]).

Questions related to the expressive power of query languages are also actively studied in the context of XML and query languages for unranked trees (see, e.g., [13] for an overview).

Key Applications

The inability of relational calculus (and more generally its extension with aggregation) to express fixed-point queries was behind the addition of recursive constructs to SQL3. For example, to find all descendants of a node *a* in a graph represented by a relation `Graph(source, destination)`, one can write in SQL3:

```
WITH RECURSIVE TrCl(ancestor,
descendant) AS
    ( (SELECT source as ancestor, desti
      nation as descendant FROM Graph)
   UNION
     (SELECT Graph.source as ancestor,
     TrCl.descendant
     FROM Graph, TrCl
     WHERE Graph.destination = TrCl.
     ancestor)
   )
SELECT descendant FROM TrCl where
ancestor='a'
```

Often it is the understanding of the expressiveness of a language that guides the design of additional features.

Extended Entity-Relationship Model

Bernhard Thalheim
Christian-Albrechts University Kiel, Kiel, Germany

Synonyms

EERM, HERM; Higher-Order Entity-Relationship Model; Hierarchical Entity-Relationship Model

Definition

The extended entity-relationship (EER) model is a language for defining the structure (and functionality) of database or information systems. Its structure is developed inductively. Basic attributes are assigned to base data types. Complex attributes can be constructed by applying constructors such as tuple, list or set constructors to attributes that have already been constructed. Entity types conceptualize structuring of things of reality through attributes. Cluster types generalize types or combine types into singleton types. Relationship types associate types that have already been constructed into an association type. The types may be restricted by integrity constraints and by specification of identification of objects defined for a type. Typical integrity constraints of the extended entity-relationship model are participation, look-across, and general cardinality constraints. Entity, cluster, and relationship classes contain a finite set of objects defined on these types. The types of an EER schema are typically depicted by an EER diagram.

Historical Background

The entity-relationship (ER) model was introduced by P.P. Chen in 1976 [1]. The model conceptualizes and graphically represents the structure of the relational model. It is currently used as the main conceptual model for database and information system development. Due to its extensive usage a large number of extensions to this model were proposed in the 80s and 90s. Cardinality constraints [1,3,4,8] are the most important generalization of relational database constraints [7]. These proposals have been evaluated, integrated or explicitly discarded in an intensive research discussion. The semantic foundations proposed in [2,5,8] and the various generalizations and extensions of the entity-relationship model have led to the introduction of the higher-order or hierarchical entity-relationship model [8] that integrates most of the extensions and also supports conceptualization of functionality, distribution [9], and interactivity [6] for information systems. Class diagrams of the UML standard are a special variant of extended entity-relationship models.

The ER conferences (annually; since 1996: International Conference on Conceptual Modeling, http://www.conceptualmodeling.org/) are the main fora for conceptual models and modeling.

Foundations

The extended entity-relationship model is mainly used as a language for conceptualization of the structure of information systems applications. Conceptualization of database or information systems aims to represent the logical and physical structure of an information system. It should contain all the information required by the user and required for the efficient behavior of the whole information system for all users. Conceptualization may further target the specification of database application processes and the user interaction. Structure descriptions are currently the main use of the extended ER model.

An Example of an EER Diagram

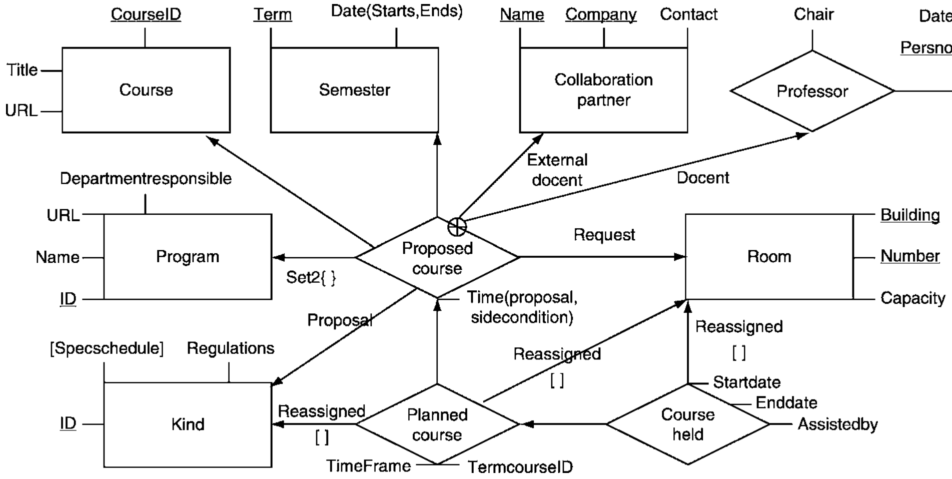
The EER model uses a formal language for schema definition and diagrams for graphical representation of the schema. Let us consider a small university application for management of *Courses*. *Proposed courses* are based on courses and taught by a docent or an external docent within a certain semester and for a set of programs. Proposals typically include a request for a room and for a time and a categorization of the kind of the course. These proposals are the basis for course planning. Planning may change time, room and kind. Planned courses are held at the university. Rooms may be changed. The example is represented by the EER diagram in Fig. 1.

Entity types are represented graphically by rectangles. Attribute types are associated with the corresponding entity or relationship type. Attributes primarily identifying a type are underlined. Relationship types are represented graphically by diamonds and associated by directed arcs to their components. A cluster type is represented by a diamond, is labeled by the disjoint union sign, and has directed arcs from the diamond to its component types. Alternatively, the disjoint union representation $\oplus$ is attached to the relationship type that uses the cluster type. In this case directed arcs associate the $\oplus$ sign with component types. An arc may be annotated with a label.

The Definition Scheme for Structures

The extended entity-relationship model uses a data type system for its attribute types. It allows the construction of entity types $E \triangleq (attr(E), \Sigma_E)$ where E is the entity type defined as a pair – the set $attr(E)$ of attribute types and the set Σ_E of integrity constraints that apply to E. The definition *def* of a type T is denoted by $T \triangleq def$.

The EER model lets users inductively build relationship types $R \triangleq (T_1,...,T_n, attr(R), \Sigma_R)$ of order i $(i \geq 1)$ through a set of (labeled) types of order less than i, a set of attribute types, and a set of integrity constraints that apply to R. The types $T_1,...,T_n$ are the components of the relationship type. Entity types are of order 0.



Extended Entity-Relationship Model. Figure 1. Extended Entity-Relationship Diagram for Course Management.

Relationship types are of order 1 if they have only entity types as component types. Relationship types are of order i if all component types are of order less than i and if one of the component types is of order $i - 1$.

Additionally, cluster types $C \overset{\circ}{=} T_1 \dot{\cup} \ldots \dot{\cup} T_n$ of order i can be defined through a disjoint union $\dot{\cup}$ of relationship types of order less than i or of entity types.

Entity/relationship/cluster classes T^C contain a set of objects of the entity/relationship/cluster type T. The EER model mainly uses set semantics, but (multi-)list or multiset semantics can also be used. Integrity constraints apply to their type and restrict the classes. Only those classes are considered for which the constraints of their types are valid. The notions of a class and of a type are distinguished. Types describe the structure and constraints. Classes contain objects.

The data type system is typically inductively constructed on a base type B by application of constructors such as the tuple or products constructor (..), set constructor {..}, and the list constructor < .. >. Types may be optional component types and are denoted by [..].

The types T can be labeled l : T. The label is used as an alias name for the type. Labels denote roles of the type. Labels must be used if the same type is used several times as a component type in the definition of a relationship or cluster type. In this case they must be unique.

An entity-relationship schema consists of a set of data, attribute, entity, relationship, and cluster types which types are inductively built on the basis of the base types.

Given a base type system B. The types of the ER schema are defined through the type equation: $T = B|(l_1 : T, ..., l_n : T) \;|\{T\}\; | < \mathrm{T} > | \; [\mathrm{T}] \;|\mathrm{T} \dot{\cup} \mathrm{T}|\mathrm{l} : T|N \overset{\circ}{=} T$

Structures in Detail

The classical four-layered approach is used for inductive specification of database structures. The first layer is the data environment, called the basic data type scheme, which is defined by the system or is the assumed set of available basic data types. The second layer is the schema of a database. The third layer is the database itself representing a state of the application's data often called micro-data. The fourth layer consists of the macro-data that are generated from the micro-data by application of view queries to the micro-data.

Attribute Types and Attribute Values The classical ER model uses basic (first normal form) attributes. Complex attributes are inductively constructed by application of type constructors such as the tuple constructor (..), set constructor {..}, and the list constructor < .. >. Typical base types are integers, real numbers, strings, and time. Given a set of names $\mathcal{N}$ and a set of base types B, a basic attribute type $A :: B$ is given by an (attribute) name $A \in \mathcal{N}$ and a base type B. The association between the attribute name and the underlying type is denoted by ::. The base type B is often called the domain of A, i.e., $dom(A) = B$. Complex attributes are constructed on base attributes by application of the type constructors. The notion of a domain is extended to complex attributes, i.e., the domain of the complex attribute A is given by $dom(A)$. Components of complex attributes may be optional, e.g., the *Title* in the attribute *Name*.

Typical examples of complex and basic attributes in Fig. 1 are

Name $\overset{\circ}{=}$ *(FirstNames <FirstName>, FamName, [AcadTitles], [FamilyTitle]),*
PersNo $\overset{\circ}{=}$ *EmplNo* $\dot{\cup}$ *SocSecNo,*
AcadTitles $\overset{\circ}{=}$ *{AcadTitle},*
Contact $\overset{\circ}{=}$ *(Phone({PhoneAtWork}, private), Email, URL, WebContact, [Fax({PhoneAtWork})]),*
PostalAddress $\overset{\circ}{=}$ *(Zip, City, Street, HouseNumber)* for *DateOfBirth :: date, AcadTitle :: acadTitleType, FamilyTitle :: familyTitleAcronym, Zip :: string7, SocSecNo :: string9, EmplNo :: int, City :: varString, Street :: varString, HouseNumber :: smallInt.*

The complex attribute *Name* is structured into a sequence of first names, a family name, an optional complex set-valued attribute for academic titles, and an optional basic attribute for family titles. Academic titles and family titles can be distinguished from each other.

Entity Types and Entity Classes Entity types are characterized by their attributes and their integrity constraints. Entity types have a subset K of the set of attributes which serve to identify the objects of the class of the type. This concept is similar to the concept of key known for relational databases. The key is denoted by ID(K). The set of integrity constraints Σ_E consists of the keys and other integrity constraints. Identifying attributes may be underlined instead of having explicit specification.

Formally, an entity type is given by a name E, a set of attributes $attr(E)$, a subset $id(E)$ of $attr(E)$, and a set Σ_E of integrity constraints, i.e.,

$E \overset{\circ}{=} (attr(E), \Sigma_E)$.

The following types are examples of entity types in Fig. 1:

Person $\overset{\circ}{=}$ *({Name, Login, URL, Address, Contact, DateOfBirth, <u>PersNo</u>})*
Course $\overset{\circ}{=}$ *({CourseID, Title, URL}, {ID({CourseID})}),*
Room $\overset{\circ}{=}$ *({Building, Number, Capacity}, {ID({Building, Number})}),*
Semester $\overset{\circ}{=}$ *({Term, Date(Starts, Ends)}, { ID({ Term })}).*

An ER schema may use the same attribute name with different entity types. For instance, the attribute *URL* in Fig. 1 is used for characterizing additional information for the type *Person* and the type *Course*. If they need to be distinguished, then complex names such as *CourseURL* and *PersonURL* are used.

Objects on type E are tuples with the components specified by a type. For instance, the object (or *entity*) *(HRS3, 408A, 15)* represents data for the *Room* entity type in Fig. 1.

An entity class E^C of type E consists of a finite *set* of objects on type E for which the set Σ_E of integrity constraints is valid.

Cluster Types and Cluster Classes A disjoint union $\dot{\cup}$ of types whose identification type is domain compatible is called a cluster. Types are domain compatible if they are subtypes of a common more general type. The union operation is restricted to disjoint unions since identification must be preserved. Otherwise, objects in a cluster class cannot be related to the component classes of the cluster type. Cluster types can be considered as a generalization of their component types.

A cluster type (or "category") $C \overset{\circ}{=} l_1 : R_1 \dot{\cup} l_2 : R_2 \dot{\cup} \ldots \dot{\cup} l_k : R_k$ is the (labeled) disjoint union of types $R_1, \ldots, R_k$. Labels can be omitted if the types can be distinguished.

The following type is an example of a cluster type:

Teacher $\overset{\circ}{=}$ *ExternalDocent : CollaborationPartner* $\dot{\cup}$ *Docent : Professor.*

The cluster class C^C is the 'disjoint' union of the sets $R_1^C, \ldots, R_k^C$. It is defined if $R_1{}^C, \ldots R_k{}^C$ are disjoint on their identification components. If the sets $R_1^C, \ldots, R_k^C$ are not disjoint then labels are used for differentiating the objects of clusters. In this case, an object uses a pair representation (l_i, o_i) for objects o_i from $R_i{}^C$.

Relationship Types and Relationship Classes First order relationship types are defined as associations between entity types or clusters of entity types. Relationship types can also be defined on the basis of relationship types that are already defined. This construction must be inductive and cannot be cyclic. Therefore, an order is introduced for relationship types. Types can only be defined on the basis of types which have a lower order. For instance, the type *Professor* in Fig. 1 is of order 1. The type *ProposedCourse* is of order 2 since all its component types are either entity types or types of order 1. A relationship type of order i is defined as an association of relationship types of order less than i or of entity types. It is additionally required that at least one of the component types is of order $i - 1$ if $i > 1$. Relationship types can also be characterized by attributes. Relationship types with one component type express a subtype or an Is-A relationship type. For instance, the type *Professor* is a subtype of the type *Person*.

Component types of a relationship type may be labeled. Label names typically provide an understanding of the role of a component type in the relationship type. Labeling uses the definition scheme *Label* : *Type*. For instance, the *Kind* entity type is labeled by *Proposal* for the relationship type *ProposedCourse* in Fig. 1.

Cluster types have the maximal order of their component types. Relationship types also may have cluster type components. The order of cluster type components of a relationship type of order i must be less than i.

Component types that are not used for identification within the relationship type can be optional. For instance, the *Room* component in Fig. 1 is optional for the type *PlannedCourse*. If the relationship object in the *PlannedCourse* class does not have a room then the proposal for rooms in *ProposedCourse* is accepted. A specific extension for translation of optional components may be used. For instance, *Room* in Fig. 1 is inherited to *PlannedCourse* from *ProposedCourse* if the *Room* component for a *PlannedCourse* is missing.

Higher order types allow a convenient description of types that are based on other types. For example, consider the course planning application in Fig. 1. Lectures are courses given by a professor or a collaboration partner within a semester for a number of programs. Proposed courses extend lectures by describing which room is requested and which time proposals and which restrictions are made. Planing of courses assigns a room to a course that has been proposed and assigns a time frame for scheduling. The kind of the course may be changed. Courses that are held are based on courses planned. The room may be changed for a course. The following types specify these assertions.

$$\begin{aligned}
&\mathit{ProposedCourse} \circeq (\underline{\mathit{Teacher}}, \underline{\mathit{Course}}, \mathit{Proposal} : \mathit{Kind}, \\
&\qquad \mathit{Request} : \mathit{Room}, \mathit{Semester}, \mathit{Set2} : \{\mathit{Program}\}, \{\mathit{Time}(\mathit{Proposal}, \mathit{SideCondition})\}, \Sigma_{\mathit{ProposedCourse}}), \\
&\mathit{PlannedCourse} \circeq (\mathit{ProposedCourse}, [\mathit{Reassigned} : \mathit{Kind}], \\
&\qquad [\mathit{Reassigned} : \mathit{Room}], \{\mathit{TimeFrame}, \mathit{TermCourseID}\}, \Sigma_{\mathit{PlannedCourse}}), \\
&\mathit{CourseHeld} \circeq (\mathit{PlannedCourse}, [\mathit{Reassigned} : \mathit{Room}], \\
&\{\mathit{StartDate}, \mathit{EndDate}, \mathit{AssistedBy}\}, \Sigma_{\mathit{CourseHeld}}).
\end{aligned}$$

The second and third types use optional components in case a proposal or a planning of rooms or kinds is changed. Typically, planned courses are identified by their own term-specific identification. Integrity constraints can be omitted until they have been defined.

Formally, a relationship type is given by a name R, a set $\mathit{compon}(R)$ of labeled components, a set of attributes $\mathit{attr}(R)$, and a set Σ_R of integrity constraints that includes the identification of the relationship type by a subset $\mathit{id}(R)$ of $\mathit{compon}(R) \cup \mathit{attr}(R)$, i.e., $R \circeq (\mathit{compon}(R), \mathit{attr}(R), \Sigma_R)$.

It is often assumed that the identification of relationship types is defined exclusively through their component types. Relationship types that have only one component type are unary types. These relationship types define subtypes. If subtypes need to be explicitly represented then binary relationship types named by *IsA* between the subtype and the supertype are used. For instance, the type *Professor* in Fig. 1 is a subtype of the type *Person*.

An object (or a "relationship") on the relationship type $R \overset{\circ}{=} (R_1,\ldots,R_n, \{B_1,\ldots,B_k\}, \mathit{id}(R), \Sigma_R)$ is an element of the Cartesian product $R_1^C \times \ldots \times R_n^C \times \mathit{dom}(B_1) \times \ldots \times \mathit{dom}(B_k)$. A relationship class R^C consists of a finite *set* $R^C \subseteq R_1^C \times \ldots \times R_n^C \times \mathit{dom}(B_1) \times \ldots \times \mathit{dom}(B_k)$ of objects on R for which $\mathit{id}(R)$ is a key of R^C and which obeys the constraints Σ_R.

Integrity Constraints Each database model also uses a set of implicit model-inherent integrity constraints. For instance, relationship types are defined over their component types, and a (relationship) object presumes the existence of corresponding component objects. Typically only finite classes are considered. The EER schema is acyclic. Often names or labels are associated with a minimal semantics that can be derived from the meaning of the words used for names or labels. This minimal semantics allows us to derive synonym, homonym, antonym, toponym, hypernym, and holynym associations among the constructs used.

The most important class of integrity constraints of the EER model is the class of cardinality constraints. Other classes of importance for the EER model are multivalued dependencies, inclusion and exclusion constraints and existence dependencies[5]. Functional dependencies, keys and referential constraints (or key-based inclusion dependencies) can be expressed through cardinality constraints.

Three main kinds of cardinality constraints are distinguished: participation constraints, look-across constraints, and general cardinality constraints. Given a relationship type $R \hat{=} (compon(R), attr(R), \Sigma_R)$, a component R' of R, the remaining substructure $R'' = R \setminus R'$ and the remaining substructure $R''' = R'' \sqcap_R compon(R)$ without attributes of R.

The participation constraint $card(R, R') = (m, n)$ restricts the number of occurrences of R' objects in the relationship class R^C by the lower bound m and the upper bound n. It holds in a relationship class R^C if for any object $o' \in R'^C$ there are at least m and at most n objects $o \in R^C$ with $\pi_{R'}(o) = o'$ for the projection function $\pi_{R'}$ that projects o to its R' components.

Participation constraints relate objects of relationship classes to objects of their component classes. For instance, the constraint *card*(*ProposedCourse*, *SemesterCourse*) = (0, 3) restricts relationship classes for proposals for courses per semester to at least 0 and at most 3, i.e., each course is proposed at most three times in a semester. There are at most three objects o in $ProposedCourse^C$ with the same course and semester objects. The integrity constraint *card*(*ProposedCourse*, *DocentSemester*) = (3, 7) requires that each docent is giving at least 3 courses and at most 7 courses. External docents may be obliged by other restrictions, e.g., *card*(*ProposedCourse*, *ExternalDocentSemester*) = (0,1).

Formally, the integrity constraint $card(R,R') = (m,n)$ is valid in R^C if $m \leq |\{o \in R^C : \pi_{R'}(o) = o'\}| \leq n$ for any $o' \in \pi_{R'}(R^C)$ and the projection $\pi_{R'}(R^C)$ of R^C to R'.

If $card(R, R') = (0, 1)$ then R' forms an identification or a key of R, i.e., $ID(R')$ for R. This identification can also be expressed by a functional dependency $R : R' \rightarrow R''$.

The lookup or look-across constraint $look(R, R') = m..n$ describes how many objects o''' from R'''^C may potentially 'see' an object o' from R'^C. It holds in a relationship class R^C if for any object $o''' \in dom(R''')$ there are at least m and at most n related objects o' with $\pi_{R'}(o) = o'$, i.e., $m \leq |\{o' \in \pi_{R'}(R^C) : o \in R^C \wedge \pi_{R'}(o) = o' \wedge \pi_{R'''}(o) = o'''\}| \leq n$ for any $o''' \in Dom(R''')$. Typically, look-across constraints are used for components consisting of one type. Look-across constraints are not defined for relationship types with one component type.

Look-across constraints are less intuitive for relationship types with more than two component types or with attribute types. For instance, the look-across constraint *look*(*ProposedCourse*, *DocentSemester*) = 0..7 specifies that for any combination of *Teacher*, *Room*, *Kind*, and *Program* objects there are between 0 and 7 *Docent* and *Semester* combinations. The lower bound expresses that there are *Teacher*, *Room*, *Kind*, and *Program* which do not have a *Docent* and *Semester* combination.

Look-across constraints for a binary relationship type whose component types form a key of the relationship type can equivalently be expressed by participation constraints, i.e., $look(R, R_1) = m_1..n_1$ if and only if $card(R, R_2) = (m_1, n_1)$. Similarly, $look(R, R_2) = m_2..n_2$ if and only if $card(R, R_1) = (m_2, n_2)$. This equivalence is neither valid for binary relationship types which cannot by identified by their components nor for relationship types with more than two components.

Participation and look-across constraints can be extended to substructures and intervals and to other types such as entity and cluster types. Given a relationship type R, a substructure R' of R, R'' and R''' as above, and given furthermore an interval $I \subseteq \mathbb{N}_0$ of natural numbers including 0, the (general) cardinality constraint $card(R, R') = I$ holds in a relationship class R^C if for any object $o' \in \pi_{R'}(R^C)$ there are $i \in I$ objects o with $\pi_{R'}(o) = o'$, i.e., $|\{o \in R^C : \pi_{R'}(o) = o'\}| \in I$ for any $o' \in \pi_{R'}(R^C)$.

The following participation, look-across and general cardinality constraints are examples in Fig. 1:

For any $R' \in$ {Semester, Course, Kind} *card*(*ProposedCourse*,R') = (0, n),
card(*ProposedCourse*, *SemesterCourseTeacher*) = (0, 1),
card(*CourseHeld*, *PlannedCourse*) = (1, 1),
card(*PlannedCourse*, *ProposedCourse*[*Semester*]*Room TimeFrame*) = (0, 1),
card(*ProposedCourse*, *DocentSemester*) = {0, 3, 4, 5, 6, 7}.

The first constraint does not restrict the database. The second constraint expresses a key or functional dependency. The types *Semester Course Teacher* identify any of the other types in the type *ProposedCourse*, i.e.,

ProposedCourse: *{Semester, Course, Teacher}* → *{Request, Time, Proposal, Set2}*.

The third constraint requires that any planned course must be given. The fourth constraint requires that rooms are not overbooked. The fifth constraint allows that docents may not teach in a semester, i.e., have a sabbatical. If a docent is teaching in a semester then at least 3 and at most 7 courses are given by the docent.

Look-across constraints were originally introduced by Chen [1] as cardinality constraints. UML uses look-across constraints. Participation and look-across constraints cannot be axiomatized through a Hilbert- or Gentzen-type logical calculus. If only upper bounds are of interest then an axiomatization can be found in [3] and [4]. General cardinality constraints combine equality-generating and object-generating constraints such as keys, functional dependencies and referential integrity constraints into a singleton construct.

Logical operators can be defined for each type. A set of logical formulas using these operators can define the integrity constraints which are valid for each object of the type.

Schemata

The schema is based on a set of base (data) types which are used as value types for attribute types.

A set $\{E_1,...E_n, C_1,...,C_l, R_1,...,R_m\}$ of entity, cluster and (higher-order) relationship types on a data scheme DD is called schema if the relationship and cluster types use only the types from $\{E_1,..., E_n, C_1,...,C_l, R_1,...,R_m\}$ as components and cluster and relationship types are properly layered.

An EER schema is defined by the pair $\mathcal{D} = (\mathcal{S}, \Sigma)$ where $\mathcal{S}$ is a schema and Σ is a set of constraints. A database $\mathcal{D}^C$ on $\mathcal{D}$ consists of classes for each type in $\mathcal{D}$ such that the constraints Σ are valid.

The classes of the extended ER model have been defined through sets of objects on the types. In addition to sets, lists, multi-sets or other collections of objects may be used. In this case, the definitions used above can easily be extended [8].

A number of domain-specific extensions have been introduced to the ER model. One of the most important is the extension of the base types by spatial data types such as: point, line, oriented line, surface, complex surface, oriented surface, line bunch, and surface bunch. These types are supported by a large variety of functions such as: meets, intersects, overlaps, contains, adjacent, planar operations, and a variety of equality predicates.

The translation of the schema to (object-)relational or XML schemata can be based on a profile [4]. Profiles define which translation choice is preferred over other choices, how hierarchies are treated, which redundancy and null-value support must be provided, which kind of constraint enforcement is preferred, which naming conventions are chosen, which alternative for representation of complex attributes is preferred for which types, and whether weak types can be used. The treatment of optional components is also specified through the translation profile of the types of the schema. A profile may require the introduction of identifier types and base the identification on the identifier. Attribute types may be translated into data formats that are supported by the target system.

The EER schema can be used to define views. The generic functions insert, delete, update, projection, union, join, selection and renaming can be defined in a way similarly to the relational model. Additionally, nesting and unnesting functions are used. These functions form the algebra of functions of the schema and are the basis for defining queries. A singleton view is defined by a query that maps the EER schema to new types. Combined views also may be considered which consist of singleton views which together form another EER schema.

A view schema is specified over an EER schema $\mathcal{D}$ by a schema $\mathcal{V} = \{S_1,...,S_m\}$, an auxiliary schema $\mathcal{A}$ and a (complex) query $q : \mathcal{D} \times \mathcal{A} \to \mathcal{V}$ defined on $\mathcal{D}$ and $\mathcal{A}$. Given a database $\mathcal{D}^C$ and the auxiliary database $\mathcal{A}^C$. The view is defined by $q(\mathcal{D}^C \times \mathcal{A}^C)$.

Graphical Representation

The schema in Fig. 1 consists of entity, cluster and relationship types. The style of drawing diagrams is one of many variants that have been considered in the literature. The main difference of representation is the style of drawing unary types. Unary relationship types are often represented by rectangles with rounded corners or by (directed) binary IsA-relationship types which associate by arcs the supertype with the subtype. Tools often do not allow cluster types and relationship types of order higher than one. In this case, those types can be objectified, i.e., represented by a new (abstract) entity type that is associated through binary relationship types to the components of the original type. In this case, identification of objects of the new type is either inherited from the component types or is provided through a new (surrogate) attribute. The first option results in the introduction of so-called weak types. The direct translation of these weak types to object-relational models must be combined with the introduction of rather complex constraint sets. Typically, this complexity can be avoided if the abstract entity type is mapped together with the new relationship types to a singleton object-relational type. This singleton type is also the result of a direct mapping of the original higher-order relationship type.

The diagram can be enhanced by an explicit representation of cardinality and other constraints. If participation constraints $card(R, R') = (m, n)$ are used for component consisting of one type R' then the arc from R to R' is labeled by (m, n). If look-across constraints $look(R, R') = m..n$ are used for binary relationship types then the arc from R to R' is labeled by $m..n$.

Key Applications

The main application area for extended ER models is the conceptualization of database applications.

Database schemata can be translated to relational, XML or other schemata based on transformation profiles that incorporate properties of the target systems.

Future Directions

The ER model has had a deep impact on the development of diagramming techniques in the past and is still influencing extensions of the unified modeling language UML. UML started with binary relationship types with look-across constraints and without relationship type attributes. Class diagrams currently allow n-ary relationship types with attributes. Relationship types may be layered. Cluster types and unary relationship types allow for distinguishing generalization from specialization.

ER models are not supported by native database management systems and are mainly used for modeling of applications at the conceptual or requirements level. ER schemata are translated to logical models such as XML schemata or relational schemata or object-relational schemata. Some of the specifics of the target models are not well supported by ER models and must be added after translating ER schemata to target schemata, e.g., specific type semantics such as list semantics (XML) or as special ordering or aggregation treatment of online analytical processing (OLAP) applications.

The ER model has attracted a lot of research over the last 30 years. Due to novel applications and to evolution of technology old problems and novel problems are challenging the research on this model. Typical old problems that are still not solved in a satisfactory manner are: development of a science of modeling, quality of ER schemata, consistent refinement of schemata, complex constraints, normalization of ER schemata, normalization of schemata in the presence of incomplete constraint sets. Novel topics for ER research are for instance: evolving schema architectures, collaboration of databases based on collaboration schemata, layered information systems and their structuring, schemata with redundant types, ER schemata for OLAP applications.

Structures of database applications are often represented through ER models. Due to the complexity of applications, a large number of extensions have recently been proposed, e.g., temporal data types, spatial data types, OLAP types and stream types. Additionally, database applications must be integrated and cooperate in a consistent form. The harmonization of extensions and the integration of schemata is therefore a never ending task for database research.

ER models are currently extended for support of (web) content management that is based on structuring of data, on aggregation of data, on extending data by concepts and on annotating data sets for simple reference and usage. These applications require novel modeling facilities and separation of syntactic, semantic and pragmatic issues. The ER model can be extended to cope with these applications.

The ER model is mainly used for conceptual specification of database structuring. It can be enhanced by operations and a query algebra. Operations and the queries can also be displayed in a graphical form, e.g., on the basis of VisualSQL. Most tools supporting ER models do not currently use this option. Enhancement of ER models by functionality is necessary if the conceptualization is used for database development. Based on functionality enhancement, view management facilities can easily be incorporated into these tools.

ER models are becoming a basis for workflow systems data. The standards that have been developed for the specification of workflows have not yet been integrated into sophisticated data and application management tools.

Advanced transaction models; Generalization of ACID properties

Definition

Although powerful, the transaction model adopted in traditional database systems is found lacking in functionality and performance when used for applications that involve reactive (endless), open-ended (long-lived) and collaborative (interactive) activities. Hence, various extensions to the traditional model have been proposed, referred to as *extended transactions*. These models are characterized by the structure of their transactions, the commit and abort dependencies and the visibility rules among transactions. *ACTA* is a comprehensive transaction framework that facilitate the specification, analysis and synthesis of extended transaction models. The name *ACTA*, meaning *actions* in Latin, was chosen given the framework’s appropriateness for expressing the properties of actions used to compose a transactional computation.

Key Points

By means of the notion of transactions, database systems offer reliability guarantees concerning the correctness of data in spite of failures and concurrent accesses by multiple users. However, the transaction model as well as the simple data model adopted in traditional database systems have been found lacking in *functionality* and *performance* in their support of the emerging advanced database applications such as design databases, computer publishing, network management, multidatabases and mobile databases. In order to deal with the inherent limitations of the traditional data and atomic transaction model, researchers have proposed semantic and object-oriented data models and extensions to the traditional transaction model. Nested transactions was the first such extension that added a hierarchical structure to the traditional flat atomic transactions. The hierarchical structure allows concurrency within a transaction and fine-grained failure and exception handling since subtransactions can abort independently without causing the abortion of the whole transaction.

The original nested transaction model was subsequently enhanced with new types of subtransactions, relaxed abort and commit dependencies and visibility rules for externalizing partial results among transactions. These extensions led to a variety of open-nested transactions models such as Sagas, Split Transactions, Flex Transactions, ConTracts and S-transactions, and of correctness criteria such as quasi serializability, epsilon-serializability, semantic atomicity, quasi failure-atomicity.

All the above extensions have been introduced with specific applications or with specific transaction properties in mind [2]. Their ad hoc character makes it difficult to identify the properties of transactions that adhere to a particular model and to ascertain in what respects an extended transaction model is similar or different from another. The need for a comprehensive transaction framework that would facilitate the precise specification of the properties of a model, vis a vis visibility, consistency, recovery and permanence, and allow the formal comparison of different models led to the development of *ACTA* [1]. ACTA is a first-order logic based formalism with a precedence relation that allows a transaction modeler to specify both the high level properties (requirements) of a model and the lower level behavioral aspects of the model in terms of axioms. Specifications include the following four components: (i) the set of transaction management events associated with the transaction model, such as *begin, commit, abort, split*, and *join*; (ii) the semantics of these significant events, characterized in terms of their effect on objects (their value and synchronization state) and other transactions (different types of dependencies, such as commit dependency and abort dependency); (iii) the view of each transaction, specifying the state of objects visible to that transaction; and (iv) the conflict set of each transaction, containing those operations with respect to which conflicts need to be considered.

Besides supporting the specification and analysis of existing transaction models, ACTA has the power to specify the requirements of new transactional applications and synthesize models that satisfy these requirements. This was demonstrated by deriving new transaction definitions either by starting from first principles or by modifying and/or combining the specifications of existing transaction models. The exercise of analyzing and synthesizing different transaction models revealed the many advantages of using a simple formalism like ACTA to deal with advanced transactions and has influenced a lot of transaction processing work in industry and academia.

Although ACTA has been developed to characterize extended transaction models, it has been extended to express the various correctness criteria beyond serializability. The use of this formalism resulted in a consolidated notion of correctness in which the different serializability-based criteria, such as predicatewise serializability and cooperative serializability, can been seen as special cases [3].

Extendible Hashing

Definition

Extendible hashing is a dynamically updateable disk-based index structure which implements a hashing scheme utilizing a directory. The index is used to support exact match queries, i.e., find the record with a given key. Compared with the B+-tree index which also supports exact match queries (in logarithmic number of I/Os), Extendible Hashing has better expected query cost O(1) I/O. Compared with linear hashing, extendible hashing does not have any overflow page. Overflows are handled by doubling the directory which logically doubles the number of buckets. Physically, only the overflown bucket is split.

Historical Background

The extendible hashing scheme was introduced by [1]. A hash table is an in-memory data structure that associates keys with values. The primary operation it supports efficiently is a lookup: given a key, find the corresponding value. It works by transforming the key using a hash function into a hash, a number that is used as an index in an array to locate the desired location where the values should be. Multiple keys may be hashed to the same bucket, and all keys in a bucket should be searched upon a query. Hash tables are often used to implement associative arrays, sets and caches. Like arrays, hash tables have O(1) lookup cost on average.

Foundations

Structure

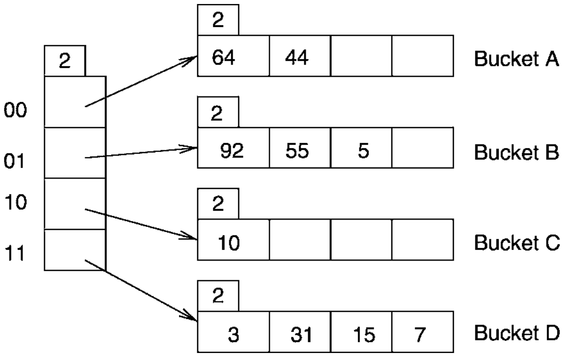
Extendible hashing uses a directory to access its buckets. This directory is usually small enough to be kept in main memory and has the form of an array with 2^d entries, each entry storing a bucket address (pointer to a bucket). The variable d is called the global depth of the directory. To decide where a key k is stored, extendible hashing uses the last d bits of some adopted hash function $h(k)$ to choose the directory entry. Multiple directory entries may point to the same bucket. Every bucket has a local depth *leqd*. The difference between local depth and global depth affects overflow handling.

An example of extendible hashing is shown in Fig. 1. Here there are four directory entries and four buckets. The global depth and all the four local depths are 2. For simplicity assume the adopted hash function is $h(k) = k$. For instance, to search for record 15, one refers to directory entry 15% 4 = 3 (or 11 in binary format), which points to bucket D.

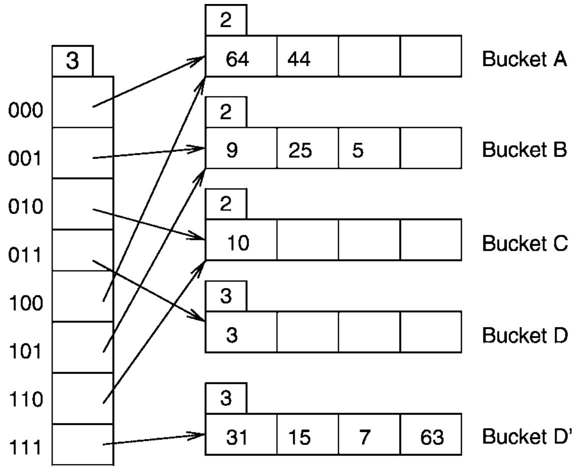
Overflow Handling

If a bucket overflow happens, the bucket is split into two. The directory may or may not double, depending on whether the local depth of the overflown bucket was equal to the global depth before split.

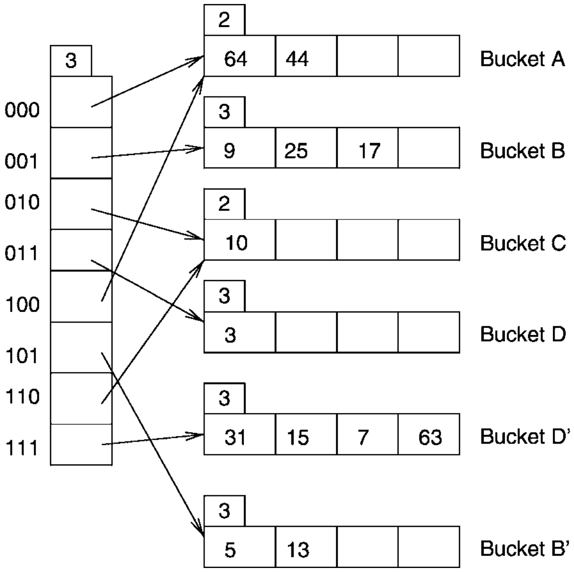
If the local depth was equal to global depth, d bits are not enough to distinguish the search values of the overflown bucket. Thus a directory *doubling* occurs, which effectively uses one more bit from the hash value. The directory size is then doubled (this does not mean that the number of buckets is doubled as buckets will share directory entries). As an example, Fig. 2 illustrates extendible hashing after inserting a new record with key 63 into Fig. 1. Bucket D overflows and the records in it are redistributed between D (where the last three bits of a record's hash value are 011) and D' (where the last three bits of a record's has value are 111). The directory doubles. The global depth is increased by one. The local depth of buckets D and D' are increased



Extendible Hashing. Figure 1. Illustration of the Extendible Hashing.



Extendible Hashing. Figure 2. The directory doubles after inserting 63 into Fig. 1.



Extendible Hashing. Figure 3. The directory does not double after inserting 17 and 13 into Fig. 2.

by one, while the local depth of the other buckets remains to be two. Except 111, which points to the new bucket D', each of the new directory entries points to the existing bucket which shares the last two bits. For instance, directory entry 101 points to the bucket referenced by directory entry 001.

In general, if the local depth of a bucket is d', the number of directory entries pointing to the bucket is $2^{d-d'}$. All these directory entries share the last d' bits.

To split an overflown bucket whose local depth is smaller than the global depth, one does not need to double the size of the directory. Instead, half of the $2^{d-d'}$ directory entries will point to the new bucket, and the local depth of both the overflown bucket and its split image are increased by one. For instance, Fig. 3 illustrates the extendible hashing after inserting 17 and 13 into Fig. 2. Bucket B overflows and a split image, bucket B', is created. There are two directory entries (001 and 101) that pointed to B before the split. Half of them (101) now points to the split image B'. The local depth of both buckets B and B' are increased by one.

Discussion

Deletion may cause a bucket to become empty, in which case it can be merged with its *buddy* bucket. The buddy bucket is referenced by the directory entry which shares the last (local depth − 1) bits. For instance, the buckets referenced by direction entries 1111 and 0111 are buddy buckets. Many deletions can cause the directory to halve its size and thus decrease its global depth. This is triggered by the bucket merging which causes all local depth to be strictly smaller than the global depth.

The fact that extendible hashing does not use any overflow page may significantly increase the directory size, as one insertion may cause the directory to double more than once. Consider the case when global depth is 3, and the bucket referenced by directory entry 001 overflows with five records 1, 17, 33, 49, 65. The directory is doubled. Directory entries 0001 and 1001 points to the overflown bucket and the split image. All the five keys will remain in the original bucket which is again overflowing. Therefore the directory has to be doubled again.

To alleviate this problem, one can allow a certain degree of overflow page links. For instance, whenever the fraction of buckets with overflow pages becomes larger than 1%, double the directory.

Key Applications

Extendible Hashing can be used in applications where exact match query is the most important query such as hash join [2].

Synonyms

ETL; ETL process; ETL tool; Data warehouse back stage; Data warehouse refreshment

Definition

Extraction, transformation, and loading (ETL) processes are responsible for the operations taking place in the background of a data warehouse architecture. In a high level description of an ETL process, first, the data are extracted from the source data stores that can be on-line transaction processing (OLTP) or legacy systems, files under any format, web pages, various kinds of documents (e.g., spreadsheets and text documents) or even data coming in a streaming fashion. Typically, only the data that are different from the previous execution of an ETL process (newly inserted, updated, and deleted information) should be extracted from the sources. Secondly, the extracted data are propagated to a special-purpose area of the warehouse, called the data staging area (DSA), where their transformation, homogenization, and cleansing take place. The most frequently used transformations include filters and checks to ensure that the data propagated to the warehouse respect business rules and integrity constraints, as well as schema transformations that ensure that data fit the target data warehouse schema. Finally, the data are loaded to the central data warehouse (DW) and all its counterparts (e.g., data marts and views). In a traditional data warehouse setting, the ETL process periodically refreshes the data warehouse during idle or low-load, periods of its operation (e.g., every night) and has a specific time-window to complete. Nowadays, business necessities and demands require near real-time data warehouse refreshment and significant attention is drawn to this kind of technological advancement.

Historical Background

Despite the fact that ETL obtained its separate existence during the first decade of the twenty-first century, ETL processes have been a companion to database technology for a longer period of time, in fact, from the beginning of its existence. During that period, ETL software was just silently hidden as a routine programming task without any particular name or individual importance. ETL was born on the first day that a programmer constructed a program that takes records from a certain persistent file and populates or enriches another file with this information. Since then, any kind of data processing software that reshapes or filters records, calculates new values, and populates another data store than the original one is a form of an ETL program.

The earliest form of ETL system goes back to the EXPRESS system [13] that was intended to act as an engine that produces data transformations given some data definition and conversion nonprocedural statements. In later years, during the early days of data integration, the driving force behind data integration were wrapper-mediator schemes; the construction of the wrappers is a primitive form of ETL scripting [12]. In the mid 1990s, data warehousing came in the central stage of database research and still, ETL was there, but hidden behind the lines. Popular books [3] do not mention ETL at all, although the different parts (transformation, cleansing, staging of intermediate data, and loading) are all covered – even if this is done very briefly at times (it is also noteworthy that the third edition of the same book in 2003 mentions ETL, although briefly). At the same time, early research literature treated data warehouses as collections of materialized views since this abstraction was simple and quite convenient for the formulation of research problems.

During the '00s, it became increasingly prevalent that ETL is really important for data integration tasks since it is costly, labor-intensive, and mission-critical – and for all these factors, important for the success of a data warehousing project. The difficulty lies in the combination of data integration and data cleaning tasks: as a typical integration problem, where data are moved and transferred from a certain data store to another, the details of schema and value mappings play a great role. At the same time, the data can be in highly irregular state (both in terms of duplicates, constraint, and business rule violations, and in terms of irregularities in the internal structure of fields – e.g., addresses). Therefore, finding effective ways for taming this nonregularity into a typical relational structure is very hard. Additionally, there are a number of persistent problems: ETL processes are hard to standardize, optimize, and execute in a failure-resilient manner (and thus the problem is hard to solve).

Foundations

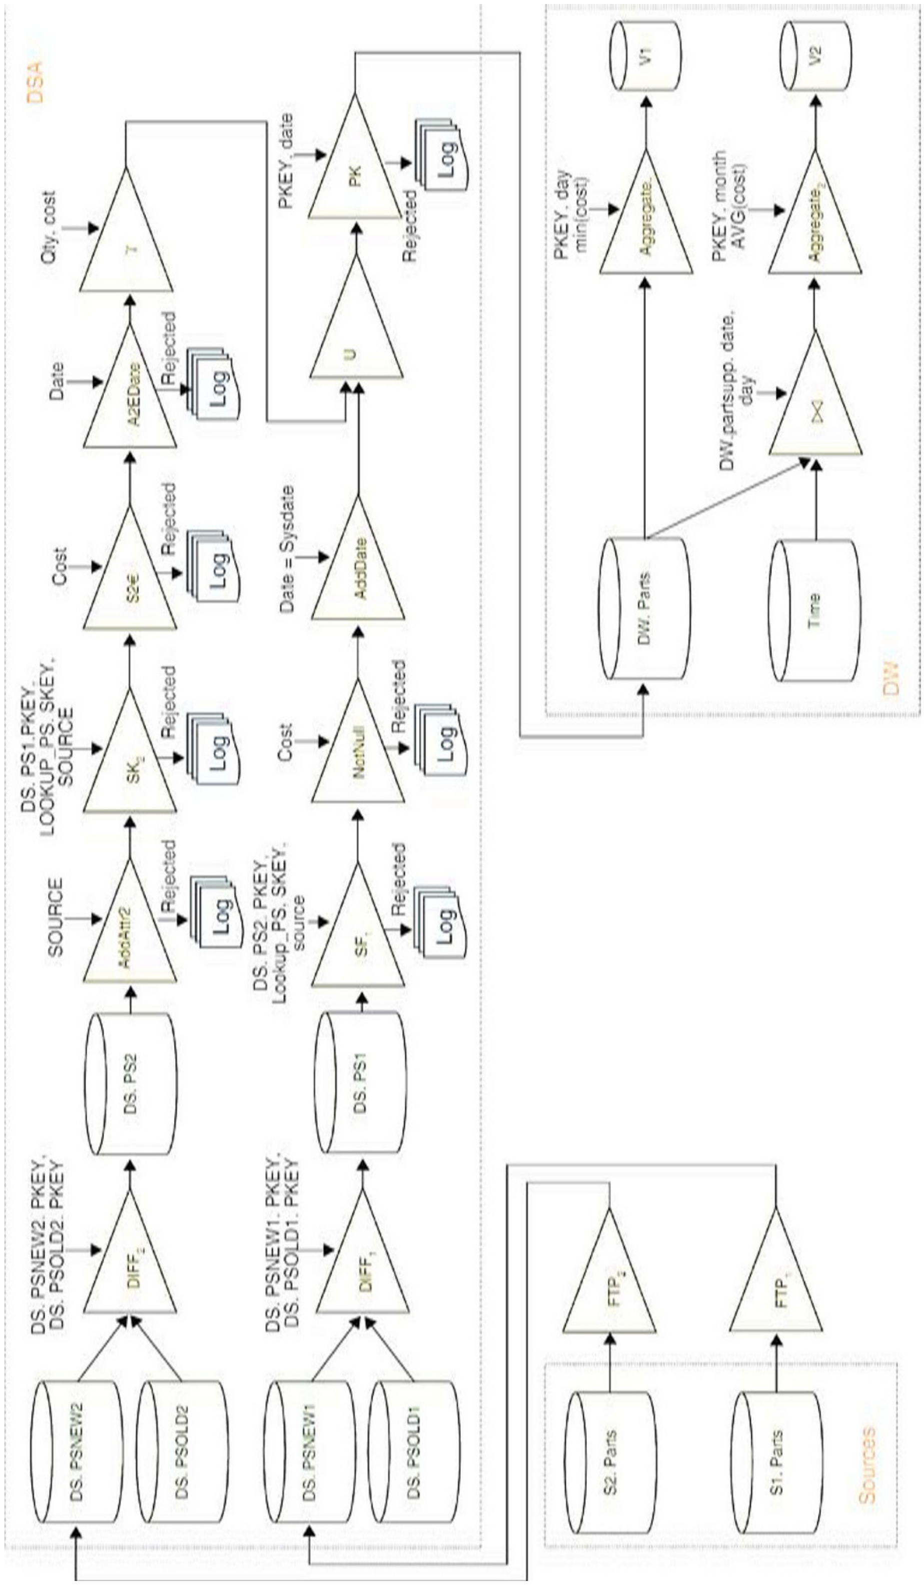
PART I. General description of an ETL process

Intuitively, an ETL process can be thought of as a directed acyclic graph, with activities and record sets forming the nodes of the graph, and input–output relationships between nodes forming its edges. Observe Figure 1, where two sources are depicted in the lower left part of the figure with the names S_1*.PARTS* and S_2*.PARTS*. The data from these sources must be propagated to the target data warehouse fact table *DW.PARTS*, depicted at the bottom right part of the figure. Moreover, the newly inserted records must be further propagated to refresh aggregate views V_1 and V_2. (In fact, the views of the example can be anything among materialized views that are populated by the ETL process, materialized views automatically refreshed by the DBMS, convenient abstractions of data marts, reports, and spreadsheets that are placed in the enterprise portal for the end-users to download, and any other form of aggregated information that is published in some form to the end-users of the warehouse.) The whole process of populating the fact table and any of its views is facilitated by a *workflow of activities* that perform all the appropriate filtering, intermediate data staging, transformations and loadings. The upper part of Figure 1 depicts how the data (which are extracted as snapshots of the sources) are transported to a special purpose intermediate area of the warehouse, called the data staging area (DSA) [4], where the transformation phase takes place. First, the snapshots are compared with their previous versions, so that newly inserted or updated data are discovered. Secondly, these new data are stored in a hard disk so that in the case of a failure, the whole process should not start from scratch. Then, the data pass through several filters or transformations and they are ultimately loaded in the data warehouse. As mentioned, the warehouse fact or dimension tables are not necessarily the end of the journey for the data: at the bottom right of Figure 1, a couple of materialized views (standing as abstractions of reports, spreadsheets, or data marts for the sake of the example) are also refreshed with newly incoming data.

PART II. Individual steps

Extraction. The extraction step is conceptually the simplest task of all, with the goal of identifying the correct subset of source data that has to be submitted to the ETL workflow for further processing. As with the rest of the ETL process, extraction also takes place at idle times of the source system – typically at night. Practically, the task is of considerable difficulty, due to two technical constraints:

- The source should incur minimum overhead during the extraction, since other administrative activities also take place during that period.
- Both for technical and political reasons, administrators are quite reluctant to accept major



Extraction, Transformation, and Loading. Figure 1. An example ETL workflow.

interventions to their system's configuration; therefore, there must be minimum interference with the software configuration at the source side.

Depending on the technological infrastructure and the nature of the source system (relational database, COBOL file, spreadsheet, web site etc.) as well as the volume of the data that has to be processed, different policies can be adopted for the extraction step, which usually is also called "change data capture." The most naïve possibility involves extracting the whole source and processing it as if the original first loading of the warehouse was conducted. A better possibility involves the extraction of a snapshot of data, which is subsequently compared with the previous snapshot of data (either at the source, or the DSA side) and insertions, deletions, and updates are detected. In this case, there is no need to further process the data that remain the same. The work presented in [5] is particularly relevant in this context. Another possibility involves the usage of triggers in the source that are activated whenever a modification takes place in the source database. Obviously, this can be done only if the source database is a relational system; most importantly though, both the interference with the source system and the runtime overhead incurred are deterring factors with respect to this option. An interesting possibility, though, involves "log sniffing," i.e., the appropriate parsing of the log file of the source. In this case, all modifications of committed transactions are detected and they can be "replayed" at the warehouse side.

A final point in the extraction step involves the necessity of encrypting and compressing the data that are transferred from the source to the warehouse, for security and network performance reasons, respectively.

Transformation. Depending on the application and the tool used, ETL processes may contain a plethora of transformations. In general, the transformation and cleaning tasks deal with classes of conflicts and problems that can be distinguished at two levels [7]: the schema and the instance level. In this article, a broader classification of the problems is presented that includes value-level problems, too.

- *Schema-level problems*. The main problems with respect to the schema level are (a) naming conflicts, where the same name is used for different objects (homonyms) or different names are used for the same object (synonyms), and (b) structural conflicts, where one must deal with different representations of the same object in different sources, or converting data types between sources and the warehouse.
- *Record-level problems*. The most typical problems at the record level concern duplicated or contradicting records. Furthermore, consistency problems concerning the granularity or timeliness of data occur, since the designer is faced with the problem of integrating data sets with different aggregation levels (e.g., sales per day vs. sales per year) or reference to different points in time (e.g., current sales as of yesterday for a certain source vs. as of last month for another source).
- *Value-level problems*. Finally, numerous low-level technical problems may be observed in different ETL scenarios. To mention a few, there may exist problems in applying format masks, like for example, different value representations (e.g., for sex: "Male," "M," "1"), or different interpretation of the values (e.g., date formats: American "mm/dd/yy" vs. European "dd/mm/yy"). Other value-level problems include assigning surrogate key management, substituting constants, setting values to NULL or DEFAULT based on a condition, or using frequent SQL operators like UPPER, TRUNC, and SUBSTR.

To deal with such issues, the integration and transformation tasks involve a wide variety of functions, such as normalizing, denormalizing, reformatting, recalculating, summarizing, merging data from multiple sources, modifying key structures, adding an element of time, identifying default values, supplying decision commands to choose between multiple sources, and so forth.

Loading. The end of the source records' journey through the ETL workflow comes with their loading to the appropriate table. A typical dilemma faced by inexperienced developers concerns the choice between bulk loading data through a DBMS-specific utility or inserting data as a sequence of rows. Clear performance reasons strongly suggest the former solution, due to the overheads of the parsing of the insert statements, the maintenance of logs and rollback-segments (or, the risks of their deactivation in the case of failures). A second issue has to do with the possibility of efficiently discriminating records that are to be inserted for the first time, from records that act as updates to previously loaded data. DBMSs typically support some declarative way to deal with this problem (e.g., Oracle's MERGE command [9]). In addition, simple SQL commands are not sufficient since the "open-loop-fetch" technique, where records are inserted one by one, is extremely slow for the vast volume of data to be loaded in the warehouse. A third performance issue that has to be taken into consideration has to do with the existence of indexes, materialized views, or both, defined over the warehouse relations. Every update to these relations automatically incurs the overhead of maintaining the indexes and the materialized views.

PART III. Global picture revisited

Design and Modeling. After the above analysis, one can understand that the design of ETL processes is crucial and complex at the same time. There exist several difficulties underlying the physical procedures already described.

At the beginning of a data warehousing project, the design team in cooperation with the business managers have to clarify the requirements, identify the sources and the target, and determine the appropriate transformations for that specific project; i.e., the first goal is to construct a *conceptual design of the ETL process* [8,18,20]. The most important part of this task is to identify the schema mappings between the source and the target schemata. This procedure is usually done through analysis of the structure and content of the existing data sources and their intentional mapping to the common data warehouse model. Possible data cleaning problems can also be detected at this early part of the design. Conceptual modeling formalisms (both ad- hoc and UML-based) have been proposed in the literature [8,18,20]. In addition, several research approaches have been proposed toward the automation of the schema mapping procedure [10]; one of the most prominent examples is CLIO, which has also been adapted by commercial solutions proposed by IBM [2]. However, so far, the automatic schema mapping supports cases of simple ETL transformations. On the contrary, there exists a semi-automatic method that uses ontologies and semantic web technology to infer the appropriate interattribute mappings along with the respective transformations needed in an ETL process [16].

When this task ends, the design involves the *specification of a primary data flow* that describes the route of data from the sources toward the data warehouse, as they pass through the transformations of the workflow. The execution sequence of the workflow's transformation is determined at this point. The data flow defines what each process does and the execution plan defines in which order and combination. The flow for the logical exceptions – either integrity or business rules violations is specified, too. Control flow operations that take care of monitoring or failure occurrences can also be specified. Most ETL tools provide the designer with the functionality to construct both the data and the control flow for an ETL process.

Optimization. Usually, an ETL workflow must be completed in a specific time window and this task is realized periodically; e.g., each night. In the case of a failure, the quick recovery of the workflow is also important [6]. Hence, for performance reasons, it is necessary to optimize the workflow's execution time. Currently, although the leading commercial tools provide advanced GUI's for the design of ETL scenarios, they do not support the designer with any technique to optimize the created scenarios. Unlike relational querying, where the user declaratively expresses a query in a high-level language and the DBMS optimizer decides the physical execution of the query automatically, in the case of ETL workflows it is the designer who must decide the order and physical implementation for the individual activities.

Practical alternatives involve (a) letting the involved DBMS (in the case of DBMS-based scripts) do the optimization and (b) treating the workflow as a big multi-query. The solution where optimization is handed over to the DBMS for execution is simply not sufficient, since DBMS optimizers can interfere only in portions of a scenario and not in its entirety. Concerning the latter solution, it should be stressed that *ETL workflows are not big queries*, since:

- It is not possible to express all ETL operations in terms of relational algebra and then optimize the resulting expression as usual. In addition, the cases of functions with unknown semantics – "black-box" operations – or with "locked" functionality – e.g., an external call to a DLL library – are quite common.
- Failures are a critical danger for an ETL workflow. The staging of intermediate results is often imposed by the need to resume a failed workflow as quickly as possible.
- ETL workflows may involve processes running in separate environments, usually not simultaneously and under time constraints; thus their cost

estimation in typical relational optimization terms is probably too simplistic.

All the aforementioned reasons can be summarized by mentioning that neither the semantics of the workflow can always be specified, nor its structure can be determined solely on these semantics; at the same time, the research community has not come-up with an accurate cost model so far. Hence, it is more realistic to consider ETL workflows as complex transactions rather than as complex queries. Despite the significance of such optimization, so far the problem has not been extensively considered in research literature, with results mainly focused on the black-box optimization at the logical level, concerning the order with which the activities are placed in the ETL workflow [14,15].

Implementation and Execution. An ETL workflow can either be hand-coded, or specified and executed via an ETL tool. The hand-coded implementation is a frequent choice, both due to the cost of ETL tools and due to the fact that developers feel comfortable to implement the scripts that manipulate their data by themselves. Typically, such an ETL workflow is built as the combination of scripts written in some procedural languages with high execution speed (for example, C or Perl) or some vendor specific database language (PL\SQL, T-SQL, and so on). Alternatively, ETL tools are employed, mainly due to the graphical programming interfaces they provide as well as for their reporting, monitoring, and recovery facilities.

Key Applications

ETL processes constitute the backbone of the data warehouse architecture. The population, maintenance, evolution, and freshness of the warehouse depends heavily on its backstage where all the ETL operations are taken place. Hence, in a corporate environment there is a necessity for a team devoted to the design and maintenance of the ETL functionality.

However, ETL is not useful only for the refreshment of large data warehouses. Nowadays, with the advent of Web 2.0 new applications have emerged. Among them, mashups are web applications that integrate data that are dynamically obtained via web-service invocations to more than one sources into an integrated experience. Example applications include Yahoo Pipes (http://pipes.yahoo.com/), Google Maps (http://maps.google.com/), IBM Damia (http://services.alphaworks.ibm.com/damia/), and Microsoft Popfly (http://www.popfly.com/). Under the hood, the philosophy for their operation is "pure" ETL. Although, the extraction phase mainly contains functionality that allows the communication over the web, the transformations that constitute the main flow resemble those which are already built-in in most ETL tools. Different applications are targeting to gather data from different users, probably in different formats, and try to integrate them into a common repository of datasets; an example application is the Swivel (http://www.swivel.com/).

Future Directions

Although the ETL logic is not novel in computer science, several issues still remain open. A main open problem in the so called traditional ETL is the agreement upon a unified algebra and/or a declarative language for the formal description of ETL processes. However, there are some first results in the context of the data exchange problem [1]. As already mentioned, the *optimization* of the whole ETL process and of any individual transformation operators pose interesting research problems. In this context, parallel processing of ETL processes is of particular importance. Finally, *standardization* is a problem that needs an extra note of attention. The convergence toward a globally accepted paradigm of thinking and educating computer scientists on the topic is a clear issue for the academic community.

However, the ETL functionality expands into new areas beyond the traditional data warehouse environment, where the ETL is executed off-line, on a regular basis. Such cases include but are not limited to: (a) *On-Demand ETL processes* that are executed sporadically (typically for Web data), and they are manually initiated by some user demand [11]; (b) *Stream ETL* that involves the possible filtering, value conversion, and transformations of incoming streaming information in a relational format [11]; (c) *(near)Real-Time ETL* that captures the need for a data warehouse containing data as fresh as possible.

Finally, with the evolution of the technology and the broader use of internet from bigger masses of users, the interest is moved also *to multiple types of data*, which do not necessarily follow the traditional relational format. Thus, modern ETL applications should also handle novel kinds of data, like XML, spatial, biomedical or multimedia data efficiently.

Data Sets

Benchmarking the ETL process is a clear problem nowadays (2007). The lack of any standard, principled experimental methodology with a clear treatment of the workflow complexity, the data volume, the amount of necessary cleaning, and the computational cost of individual activities of the ETL workflows is striking. The only available guidelines for performing a narrow set of experiments are given in the TPC-DS standard [17], and the first publicly available benchmark for ETL processes is presented in [19].

Synonyms

Dynamic taxonomies; Faceted browsing; Hierarchical faceted metadata

Definition

The term *facet* means “little face” and is often used to describe one side of a many-sided object, especially a cut gemstone. In the context of information science, where the item being described is an information object, facets could refer to the object’s author, date, topic, etc. Facets are used to describe both the organization of information (faceted classification), and to interface techniques that provide flexible access to that information (faceted search). The motivation for faceted classification and search is that any single organizational structure is too limiting to accommodate access to complex domains. Multiple independent facets provide alternative ways of getting to the same information, thus supporting a wider range of end-user tasks and knowledge. The fields of faceted classification, information architecture, and data modeling provide theory and methods for identifying and organizing facets. The user interface challenge for faceted systems is in managing this added complexity, especially when working with very large and diverse information collections. Most interfaces to faceted information provide support for structured browsing (faceted navigation or browsing). In addition, some systems offer search capabilities and, more generally, tightly coupled views of the same information. This entry covers both the organization of information using facets, and the design of user interfaces to support searchers in accessing the information since the two aspects are closely related and should be considered together in designing information systems.

The term facet is widely used in the information science community. In other disciplines attribute, dimension, metadata, property, or taxonomy are used to refer to similar concepts. Faceted search is used in this entry to refer to flexible access to faceted information, using both browsing and search. Other terms such as hierarchical faceted metadata, faceted search and browsing, and dynamic taxonomies refer to similar concepts.

Historical Background

Shiyali Ramamrita Ranganathan, an Indian mathematician, first introduced the term “facet” in information science in the 1930s when he developed a theory of facet analysis, culminating with the publication of his book *Colon Classification* in 1933 [7]. The name comes from the use of colons to separate different facets in writing composite class numbers. Ranganathan applied the principles of faceted classification to organize all of human knowledge in libraries using five main facets – personality, matter or property, energy, space, and time. The Colon Classification system is still used in libraries in India, and the principles and techniques of facet analysis have been more widely influential as reviewed by Vickery [13]. Faceted classification is also called analytico-synthetic classification, after the two main processes involved – analysis which breaks down each subject into its basic concepts or facets, and synthesis which combines concepts to describe the subset of information of interest. Thus, in faceted classification, new classes are created by a searcher from the logical combination of facets and facet values. This is often contrasted with enumerative classification in which all classes of interest are specified by the indexer at the time of creation. Most well-known library classification systems (Dewey Decimal Classification (DDC), Universal Decimal Classification (UDC) and Library of Congress Classification (LCC)) are enumerative systems, although DDC and UDC have elements of faceted classifications as well.

In the 1950s, Calvin Mooers (who coined the term *information retrieval*) and Mortimer Taube developed new methods for searching information. Before this time, most access was based on pre-coordinated index terms. Index terms were assigned to objects and only those specific index terms could be used to retrieve items. This is very much the way that back-of-the-book indices work, with the index creator anticipating the compound subjects that people will want to search for. In contrast, in Mooers' Zatocoding system [5], there was one punch card per item and many index terms coded by notch positions on the cards. At retrieval time, a searcher used needles to isolate items sharing a common term, and multiple terms could be combined using Boolean logic. Taube, who coined the term *coordinate indexing*, developed a system in which each card represented a term (the so-called uniterm system), along with a coding of the documents to which it referred [12]. Again, flexible post-coordination of terms at retrieval time was supported. Although the early coordinate indexing systems focused on index terms, the emphasis on analyzing items of information so that retrieval could be performed by the Boolean operations on simple index entries made these ideas widely applicable to online faceted systems. The first online retrieval systems appeared in the 1960s, many containing quite sophisticated retrieval functionality. The 1980s and 1990s saw the development of much richer systems that combined browsing and searching in more flexible ways to support non-professional end users in finding information. Some early systems showing key capabilities of faceted search include Pollitt [6] and Remde et al. [8]. As described in more detail below, many of the ideas explored in these systems are seen today in faceted search systems and on some web sites, notably e-commerce sites.

Foundations

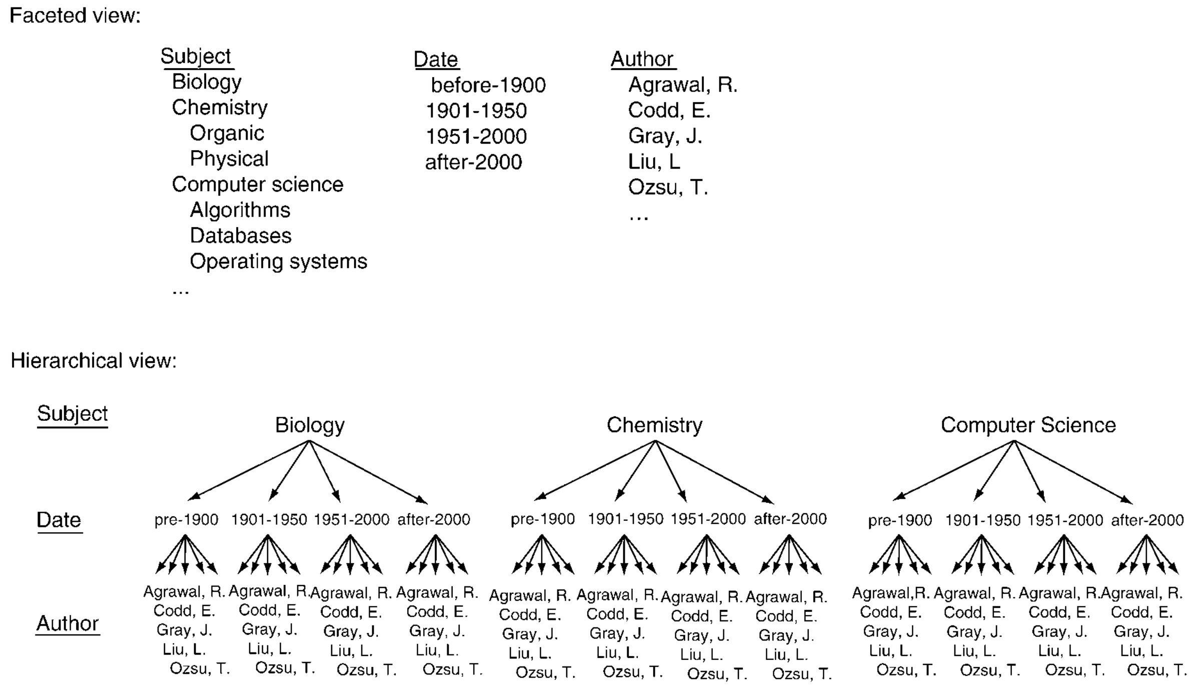
An Example

As a concrete example, consider organizing and providing access to a large collection of diverse technical publications. One way to do so is by general topic or subject area, much as the entries in this encyclopedia are organized. But there are many other facets in addition to Subject that can be used to characterize each publication – for example: Publication date, Author, Author's institution, Publication, Genre, Language, Length, Price, Tags, Download frequency, Citations by other publications, etc. In a faceted organization, each item is characterized by a value on each facet, and there are no explicit relationships among the facets. (There are a wide range of implicit relationships based on which items share facet values.) A single hierarchical structure can, of course, represent these same facets, with each level representing one of the facets. There are added storage costs since each facet needs to be replicated for every subcategory. More importantly, a single hierarchy imposes one fixed structure for navigation; each facet must be visited in the order provided by the hierarchy. Facets, on the other hand, provide many alternative ways of getting to the same information and can be combined in any order, thus providing much greater flexibility for searchers to find information. (See Fig. 1.)

Faceted Organization

Ranganathan pioneered principles and methods for identifying facets which Vickery and others extended and summarized. More recently the field of information architecture has developed these and related ideas in the context of large electronically available collections. Two important tasks are to identify the most appropriate facets for a collection and to assign a value to each item on each facet. Identifying facets is a challenging task and depends on the details of the collection, anticipated user tasks, etc. and will not be discussed in detail here. Rosenfeld and Morville [9] provide an overview of recent work on information architecture and data modeling.

The principles of faceted organization are widely applicable and flexible. Each individual *facet* can be organized in many ways, e.g., hierarchically, as a flat list, or using other relations. Each facet has a name (e.g., Subject) as well as values or labels (e.g., Biology, Chemistry, Computer Science). Each *item* in the collection is assigned one or more values on every facet.



Faceted Search. Figure 1. Comparison of faceted and hierarchical views.

For example, a technical publication will usually have only one Length or Date, but may have many Subjects, Authors or Tags. A probability or confidence can be associated with each value, as often happens when values are assigned algorithmically, although interfaces that expose this are rare. Any collection of items can be represented by a faceted organization – documents, web pages, images, videos, products, people, etc.

Once the facets for a collection have been determined, each item must be assigned values on every facet. In early library systems, all facets were assigned by trained human indexers, and many systems today still depend on human assignment of values for at least some of their facets. Machine learning techniques can also be used to provide facet values for items. Typically this involves a supervised learning phase in which items with known labels are used to build a predictive model, and an evaluation phase in which labels are assigned to new items; text classification systems are a widely-used example of this process. Sometimes values are captured implicitly via an application or use. For example, in email the sender and recipient are required for successful use of the application and are thus captured. Facets that reflect interaction with items (e.g., Download frequency, User-generated tags) are also captured implicitly as part of ongoing interactions with applications.

A key motivation for faceted systems is that any single organizational structure is too limiting to accommodate access to complex domains. Multiple facets provide many different ways of organizing information, thus enabling flexible end-user access to the information. Facets are a way of conveniently referring to a subset of items in the collection. Facets can be specified in any order, and the resulting sets can be combined using Boolean logic. The most common method for doing so (in interfaces) is to use AND to combine values from different facets and OR to combine values from within the same facet. Thus the resulting query is a conjunct of disjuncts over the selected facet labels. Other combination methods are possible, although there are interesting challenges in providing interfaces to do so. The ability to specify facets in any order and to combine them using Boolean logic illustrates the power and flexibility of faceted organization.

Compared to a single hierarchical organization of information, faceted systems provide many advantages. First, facets provide an efficient way of discriminating among sets of items. A single hierarchy with 100,000 nodes would be required to represent all the combinations that can be instantiated by 5 facets each with 10 values. Second, the ability to combine facets in any order provides users with more flexibility to specify their interests using whatever facets they are confident about for a particular search (as described in more detail below). Finally, facets are easier to manage and update, and efficient to use as input to machine learning algorithms.

Faceted Access

Developing a faceted organization of information is only the first step in any application. Using this representation to support end-users in finding information or in understanding large multi-dimensional information spaces is critical for any successful application. In this entry, the term faceted access is used to refer to faceted browsing, search, and the integration of the two.

Several faceted search systems have been designed and deployed during the last two decades. The success of any system in supporting end-users is highly dependent on details of the domain of interest (e.g., searcher's tasks, their familiarity with the facets, etc.). A brief summary of the key components is outlined below. Most systems show the query, the facet structure, the subset of results currently specified, and sometimes a detailed view of an individual item. (See Fig. 2.)

Browsing The most common access technique supported by facets is navigation. Faceted navigation is a way to browse information, guided by the facet structure. Selecting a facet label (e.g., Subject=Computer Science) results in a list of all items described by that label. Additional facet values can be selected at any time and in any order (e.g., Date=2000; Author= Dumais; Subject=Computer Science/Databases). Faceted browsing allows searchers to refine a long list of results, using multiple dimensions, in whatever order they choose. From the user experience perspective, the big challenge is in managing the scale and complexity of multiple facets, each of which may contain thousands of values organized in either a hierarchy or flat list. Consider how cumbersome it can be to navigate using the file explorer when there are hundreds of thousands of files. And this is only a single facet (based on file location); now add other facets such as file type, size, creation date, access patterns, etc. and the design issues become apparent.

One challenge is to provide compressed views of very large information structures in ways that balance overview (context) and detailed (focus) information. A common technique is to progressively expose details for hierarchical facets, guided by the user. Initially only the top level values for each facet are shown. Once a facet is selected the next level of labels are exposed, and previous levels may be collapsed to save space with only a breadcrumb remaining. Yee et al. [14] show several examples of this. Another technique is to truncate long lists of values by showing a few labels with an option to "see more." The values can be selected in any

Faceted Search. Figure 2. Example faceted search interface, illustrating facet browsing, searching, and tight coupling of the two.

number of ways. In some cases an ordered list may be binned (e.g., instead of showing all unique dates, the dates can be grouped: before 1960; 1961–1980; 1981–2000; after 2000). In other cases the values are chosen alphabetically or numerically, to span the space, or based on the most common user tasks. And, in some cases, search over facet values is provided as a means of quickly winnowing down a long list of possible values (e.g., [2]).

Another challenge is to select labels that are understandable to users, thus enabling them to know which facet to select to get to the desired information. This is relatively easy for some facets, like Date or Language or Author, but more difficult for others like Subject (e.g., is a paper describing a user study of faceted navigation in Subject=Computer Science or Subject=Psychology or both or neither?). In cases like this, facet labels can be expanded by including examples of labels at the next level (e.g., Subject=Computer Science (Algorithms, Databases, Human-Computer Interaction), thus improving the "information scent" of the description. Many web directories like the Open Directory (http://www.dmoz.org) label their categories in this manner.

An important technique for providing additional guidance about what will be found by selecting a facet value is called "dynamic query previews" (e.g., Greene et al. [3] Shneiderman [14]). The basic idea is to show some preview of the results that each query will generate. For facet browsing, this is commonly done by showing the number of results for each facet label next to the label (e.g., Biology (32); Chemistry (1); Computer Science (654); Geology (0)). Showing previews prevents also prevents users from selecting facets that will return no results. There are interesting challenges in efficiently providing such previews in distributed networked environments, and in cases where the set of items has been generated by some other means like a search.

Facet labels and query previews aid searchers in selecting the right facets. Interfaces should also allow for *both* specialization (narrowing a search) and generalization (broadening a search). Techniques like breadcrumbs are used to represent the current state of the "query" as it evolves over time through interaction. This provides a visible and actionable representation – searchers are able to understand the current set of items, and to quickly generalize as well as specialize.

In addition to supporting facet navigation, the interface should also show some representation of the current set of results. A simple list is one method for doing so. Richer list views in which the searcher can control the sort order along one or more facets are also used. Results sets can also be grouped by facet value to enable a greater diversity of results to be shown and to further reinforce the facet structure. Grouping is typically done using the next level for hierarchically organized facets [14], or the facet used for sorting [2]. In addition, some interfaces allow users to specify queries by example. Given a result or set of results, a new query can be generated to find other items that share one or more facets.

Searching (and Integrated Browsing and Searching)
Search is often contrasted with browsing, and suggested as a means for providing access to large, unstructured collections of information. In web search engines, for example, a query results in a long unstructured list of results. Many faceted browsing systems also provide a search capability that is largely independent of the facet structure.

An improved user experience can be achieved by tightly coupling faceted browsing and searching capabilities. The facet structure can be leveraged in several ways to do this. A simple integration is to use the facets to navigate to a subset of items of interest and then to search within that. The converse is to start with search and to show the distribution of search results in terms of their corresponding facet structure. For example, a query for "faceted search" returns results that have a distribution of values on the Subject facet – e.g., Computer Science (654); Biology (32); Chemistry (1); Geology (0).

The tightest coupling is to view both search and navigation as techniques for specifying subsets of information, and to allow either method to be used at all times. Thus search and navigation can be combined in any order at any time, while maintaining a consistent representation and interface. The Flamenco [14] and Phlat [2] systems support this kind of seamless integration between search and navigation. Effective data structures and algorithms have been developed to support quickly finding sets of results and summarizing the distributions of their facet values [1,10].

Scale and Details An important design challenge in faceted interfaces is handling scale – the overall size of the collection, the number of different facets, and the number of values per facet (especially for multi-valued facets like names or user-generated tags). Displaying all values for all facets is not possible in most realistic applications without requiring users to spend most of their time scrolling through very long lists or managing multiple windows. Methods for progressively exposing more detail for hierarchically organized facets, or for showing a limited set of key values for each facet, with more alternatives available on demand, are important techniques for managing scale. Using the facet structure to tightly couple browsing and searching is increasingly being used in e-commerce applications. This provides the searcher with tools that support a wide variety of tasks and states of knowledge.

There are still some capabilities that are difficult to implement in a usable and discoverable fashion. Searching over facet values when they are many values (e.g., Author names, Tags), multi-select operations within a facet, and using the same facet structure to support both access and tagging are all still challenging design issues. Decisions about which facets to display and how to do so depend critically on the application domain – e.g., price is very important in shopping but less so in finding technical materials; supporting range queries makes sense for Price, but probably not for Subject. Hearst et al. [4] provide a number of examples of how usability tests guided important interface design choices. These evaluations examine outcome measures such as task completion time and accuracy, subjective preferences, interaction trajectories, etc., and are used to iterate on the design until user performance goals are achieved.

Key Applications

Faceted search systems have been developed for a many applications in e-commerce (music, books, e-bay), bibliographic databases, image collections, and for finding files and email in the Windows and Macintosh operating systems. The following is a small list of applications available on the web, covering different domains.

- EBay Express, http://www.express.ebay.com/–general product information
- Flamenco, http://flamenco.berkeley.edu/demos.html – prototype applications for art images, architecture images and nobel prize winners
- NCSU Libraries http://www2.lib.ncsu.edu/catalog/–bibliographic records
- Tower Records, http://www.tower.com/–music, videos and books

These applications all in fairly narrow vertical domains and have readily available facet information. In the Flamenco prototypes, hand-generated metadata was available for each collection. In the NCSU application, the facets were populated using bibliographic records. And, in the e-commerce applications, many of the facets displayed are required for business purposes (e.g., price, manufacturer, etc.) and thus readily available.

Future Directions

New interface techniques for managing scale in existing applications will continue to be a fruitful area for innovation. Algorithms and architectures that can provide real-time dynamic previews of results in the context of the facet structure are required for distributed or networked applications. Developing methods for representing and displaying a confidence score for each facet value is another new direction.

Finally, it is interesting to consider why faceted interfaces are not widely available for general web search. There have been some attempts to structure the web using a topic hierarchy like Open Directory (http://www.dmoz.org) or Yahoo! in its early days. However this represents only a single facet (topic), and facet values are available for only a small subset of web content. Facet values could be assigned automatically using text classification techniques (e.g., topic, genre, commerciality), and Web pages already have some structure that could support faceted access (e.g., site names, creation date, modification date, language, usage history). Understanding which facets are most important to support the variety of information needs that people use the web for, and handling large-scale dynamic collections will be key in determining the success of faceted search methods for web content.

Definition

Just like any other software system, a data stream management system (DSMS) can experience failures of its different components. Failures are especially common in *distributed* DSMSs, where query operators are spread across multiple processing nodes, i.e., independent processes typically running on different physical machines in a local-area network (LAN) or in a wide-area network (WAN). Failures of processing nodes or failures in the underlying communication network can cause continuous queries (CQ) in a DSMS to stall or produce erroneous results. These failures can adversely affect critical client applications relying on these queries.

Traditionally, availability has been defined as the fraction of time that a system remains operational and properly services requests. In DSMSs, however, availability often also incorporates end-to-end latencies as applications need to quickly react to real-time events and thus can tolerate only small delays. A DSMS can handle failures using a variety of techniques that offer different levels of availability depending on application needs.

All fault-tolerance methods rely on some form of replication, where the volatile state is stored in independent locations to protect against failures. This entry describes several such methods for DSMSs that offer different trade-offs between availability and runtime overhead while maintaining consistency. For cases of network partitions, it outlines techniques that avoid stalling the query at the cost of temporary inconsistency, thereby providing the highest availability. This entry focuses on failures within a DSMS and does not discuss failures of the data sources or client applications.

Historical Background

Recently, DSMSs have been developed to support critical applications that must quickly and continuously process data as soon as they become available. Example applications include financial stream analysis and network intrusion detection (see Key Applications for more). Fault-tolerance and high availability are important for these applications because faults can lead to quantifiable losses. To support such applications, a DSMS must be equipped with techniques to handle both node and network failures.

All basic techniques for coping with failures involve some kind of replication. Typically, a system replicates the state of its computation onto independently failing nodes. It must then coordinate the replicas in order to recover properly from failures. Fault-tolerance techniques are usually designed to tolerate up to a predefined number, *k*, of simultaneous failures. Using such methods, the system is then said to be *k*-fault tolerant.

There are two general approaches for replication and coordination. Both approaches assume that the computation can be modeled as a deterministic state-machine [4,11]. This assumption implies that two non-faulty computations that receive the same input in the same order will produce the same output in the same order. Hereafter, two computations are called *consistent* if they generate the same output in the same order.

The first approach, known as the *state-machine* approach, replicates the computation on $k + 1 \geq 2$ independent nodes and coordinates the replicas by sending the same input in the same order to all [11]. The details of how to deliver the same input define the various techniques. Later sections in this entry describe variants that are specific to DSMSs. The state-machine approach requires $k + 1$ times the resources of a single replica, but allows for quick fail-over, so a failure causes little disruption to the output stream. This property is important for critical monitoring tasks such as intrusion detection that require low-latency results at all times.

The second general approach is known as *rollback recovery* [4]. In this approach, a system periodically packages the state of its computation into a *checkpoint*, and copies the checkpoint to an independent node or a non-volatile location such as disk. Between checkpoints, the system logs the input to the computation. Since disks have high latencies, existing fault-tolerance methods for DSMSs copy the checkpointed state to other nodes and maintain logs in memory. Upon failure, the system reconstructs the state from the most recent checkpoint, and replays the log to recover the exact pre-failure state of the computation. This approach has much lower runtime overhead at the expense of longer recovery times. It is useful in situations where resources are limited, the state of the computation is small, fault-tolerance is important, but rare moderate latencies are acceptable. An example application is fabrication-line monitoring using a server cluster with limited resources.

In some cases, users are willing to tolerate temporary inconsistencies to maintain availability at all times. One example is in the wide-area where network partitions are likely (e.g., large-scale network and system monitoring). To maintain availability in face of network partitions, the system must move forward with the computation ignoring the disconnected members. In this case, however, replicas that process different inputs will have inconsistent states. There are two general approaches for recovering from such inconsistencies after the network partition heals. One approach is to propagate all updates to all members and apply various rules for reconciling conflicting updates [6,9]. The other approach is to undo all changes performed during the partition and redo the correct ones [6,15].

This entry presents how these general approaches can be adapted to distributed DSMSs. The main challenge is to ensure that applications receive low-latency results during both normal processing and failures. To do so, the methods presented leverage the structure of continuous queries (CQs) in DSMSs.

This entry makes the following assumptions. A CQ is a connected directed-acyclic graph of query operators. The operators can be distributed among many processing nodes with possibly multiple operators per node. A processing node is the unit of failure. For simplicity of exposition, this entry focuses on the case of $k = 1$ (i.e., two query replicas) although all shown techniques can handle any k. This entry describes methods to tolerate node crash failures and temporary network partitions. Roughly speaking, a node has crashed if it visibly halts or simply becomes unresponsive [12]. A network partition splits nodes into two or more groups where nodes from one group cannot communicate with nodes in another.

Foundations

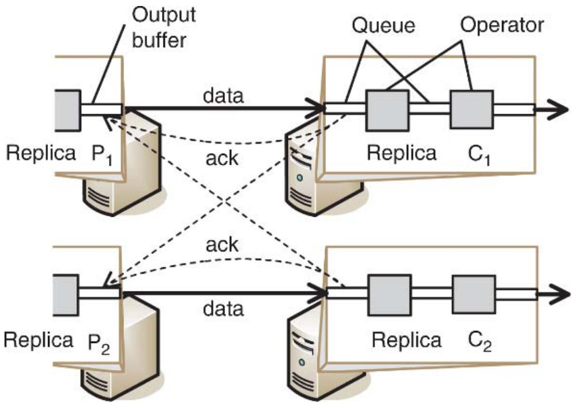
Techniques for Handling Crash Failures

This section describes new fault-tolerance techniques devised by applying the general fault-tolerance methods to continuous queries in DSMSs.

Active Replicas Active replicas are an application of the state-machine approach in which query operators are replicated and run on independently failing nodes. A simple variant of the active replicas approach uses the traditional process-pair technique to coordinate the replicas. The process-pair technique runs two copies of the query and specifies one to be the primary and the other to be the secondary. In this approach, the primary forwards all input, in the same order, to the secondary and works in lock-step with the secondary [5].

A DSMS can rely on a looser synchronization between the replicas by taking advantage of the structure of CQ dataflows. In a CQ dataflow, the operators obey a producer-consumer relationship. To provide high availability, the system replicates both the producer and consumer as illustrated in Fig. 1. In this model, there is no notion of a primary or secondary. Instead, each producer logs its output and forwards the output to its current consumer(s). Each consumer sends periodic acknowledgments to all producers to indicate that it has received the input stream up-to a certain point. An acknowledgment indicates that the input need not be resent in case of failure, so producers can truncate their output logs. Use of reliable, in-order network delivery (e.g., TCP) or checkpoints allows important optimizations where consumers send application-level acknowledgments to only a subset of producers [7,14].

The symmetric design of active replicas has some benefits. The normal-case behavior has few cases, so it is simple to implement and verify. Additionally, with sufficient buffering, each pipeline can operate at its own pace, in looser synchronization with the other.



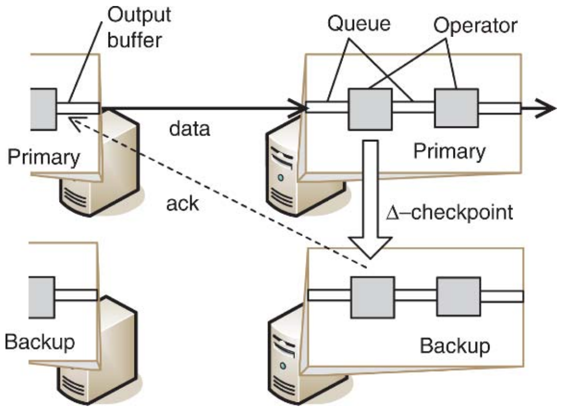
Fault-Tolerance and High Availability in Data Stream Management Systems. Figure 1. Active replicas. The operators on replicas P_1 and P_2 are the producers. The operators on C_1 and C_2 are the consumers.

The Flux [14] approach was the first to investigate this looser synchronization between replicated queries. Flux is an opaque operator that can be interposed between any two operators in a CQ. Flux implements a simple variant of this protocol and assists in recovery. The Borealis "Delay, Process, and Correct" (DPC) protocol [1,2] also uses the above coordination scheme, but differs from Flux in its recovery, as discussed later. The Flux and DPC approaches both ensure strict consistency in the face of crash failures: no duplicate output is produced and no output is lost.

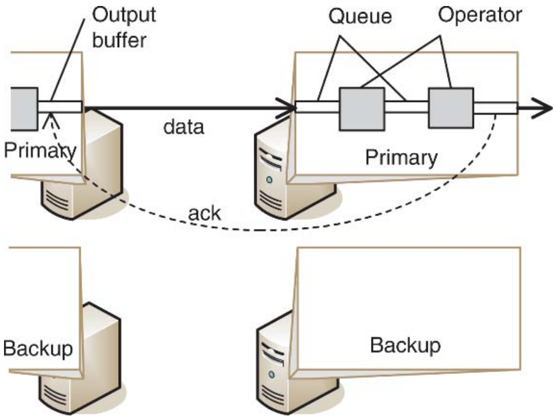
Passive Replicas There have been two applications of the rollback recovery approach to CQs [7,8]. The first, called *passive standby*, handles all types of operators. The second, called *upstream backup*, is optimized for more specific bounded-history operators that frequently arise in CQs.

In the passive standby approach, a primary node periodically checkpoints its state and sends that checkpoint to a backup. The state includes any data maintained by the operators and tuples stored in queues between operators. In practice, sending the entire state at every checkpoint is not necessary. Instead, each primary periodically performs only a *delta-checkpoint* as illustrated in Fig. 2. During a delta-checkpoint, the primary updates the backup by copying only the difference between its current state and the state at the time of the previous checkpoint.

Because of these periodic checkpoints, a backup always has its primary's state as of the last checkpoint.



Fault-Tolerance and High Availability in Data Stream Management Systems. Figure 2. Passive standby.



Fault-Tolerance and High Availability in Data Stream Management Systems. Figure 3. Upstream backup.

If the primary fails, the backup recovers by restarting from that state and reprocessing all the input tuples that the primary had processed since the last checkpoint. To enable backups to reprocess such input tuples, all primaries log their output tuples. If a downstream primary fails, each upstream primary re-sends its output tuples to the downstream backup. In a CQ, because the output of an operator can be connected to more than one downstream consumer operator, primaries discard logged output tuples only after *all* downstream backups have acknowledged a checkpoint.

For many important CQ operators, the internal state often depends only on a small amount of recent input. Examples of such operators include joins and aggregates with windows that span a short time-period or a small number of tuples. For such operators, DSMSs can use the upstream backup method to avoid any checkpointing overhead. In this approach, primaries log their output tuples, but backups remain idle as illustrated in Fig. 3. The primaries trim their logs based on notifications from operators 1-level (or more) downstream, indicating that the states of consuming operators no longer depend on the logged input. To generate these notifications, downstream operators determine, from their output, what logged input tuples can be safely discarded. If a primary fails, an empty backup rebuilds the latest state of the primary using the logs kept at upstream primaries.

Failure Recovery When a failure occurs, a DSMS must first detect and then recover from that failure. DSMSs detect failures using timeouts and, in general, rely on standard group membership mechanisms to keep consistent track of nodes entering and leaving the system [10,13]. Recovery ensues after failure detection.

There are two parts to failure recovery. The first part involves masking the failure by using the remaining replica to continue processing. For active replicas, this part is called *fail-over.* In both Flux and DPC, fail-over is straightforward. Consumers and producers adjust their connections to receive input data from or send output data to the remaining live copy of the failed node. To avoid stalls in the output stream, it is safe for active replicas to proceed with fail-over without waiting for group membership consensus [1,13]. For passive standby and upstream backup, this first part also involves bringing the state of the backup to the pre-failure state of the failed primary, as described earlier, before the backup starts sending data to downstream consumers.

The second part of recovery, called *repair*, allows the query to repair its failed pieces and regain its original level of fault-tolerance. In upstream backup, the system regains its normal fault-tolerance level when the new replica fills its output log with enough data to rebuild the states of downstream nodes.

For both active replicas and passive standby, repair can cause significant disruptions in the result stream depending on the granularity of coordination in the query. For example, if a system uses active replica coordination only at the input(s) and output(s) of a distributed query, the system must destroy the *entire* query affected by the failure, stall the *entire* remaining query, checkpoint its state, copy that state onto independent nodes, and reintegrate the new copy with the remaining query. The system must repair a query at a time because it has no control over inflight data in the network between nodes in a query. If the query state is large, e.g., tens of gigabytes, repair can take minutes, causing significant latencies in the result stream. Similarly, coarse coordination in passive standby would cause the first checkpoint after recovery to stall processing for a long time.

To remedy this problem, most high-availability CQ schemes (e.g., Flux [14,13], Borealis DPC [1,2], Active Standby [7], Passive Standby [7,8]) coordinate and repair in smaller chunks: between nodes (containing groups of operators), between operators, or even finer. Then, after failure, they can repair the lost pieces one at time, allowing the remaining pieces to continue processing and reduce the impact of stalls. In the presence of $k + 1 > 2$ replicas, DSMSs can use the extra replicas to further smooth the impact of stalls during repair. Also with finer coordination, DSMSs need to repair only the lost pieces, thereby reducing mean-time-to-recovery and improving system reliability, i.e., mean-time-to-failure [14].

Trade-Offs Among Crash Failure Techniques The above techniques provide different trade-offs between runtime overhead and recovery performance. Active replicas provide quick fail-over because replicas are always "up-to-date". With this approach, however, the runtime overhead is directly proportional to the degree of replication. Passive standby provides a flexible trade-off between runtime overhead and recovery speed through the configurable checkpoint interval. As the checkpoint interval decreases, the runtime computation and network overheads increase because the primaries copy more intermediate changes to the backups. However, recovery speed improves because the backups are in general more up-to-date when they take over. Finally, upstream backup incurs the lowest overhead because backups remain idle in the absence of failures. For upstream backup, recovery time is proportional to the size of the upstream buffers. The size of these buffers, in turn, depends on how much history is necessary to rebuild the state of downstream nodes. Thus, upstream backup is practical in small history settings.

Techniques for Handling Network Partitions

The previous techniques can mask crash failures and a limited set of network failures (by converting disconnected nodes into crashed nodes), but cannot handle network partitions in which data sources, processing nodes, and clients are split into groups that cannot communicate with each other.

In the presence of network partitions, a DSMS, like all distributed systems, has two choices. It can either suspend processing to ensure consistency, or continue processing the remaining streams with best-effort results to provide availability [3]. Existing work on fault-tolerance in distributed DSMSs has explored both options. The Flux protocol [13], originally set in the local-area where network partitions are rare, favors consistency. The Borealis's DPC protocol, designed for wide-area monitoring applications where partitions are more frequent, favors availability. During partitions, DPC generates best-effort result tuples which are labeled as *tentative*. Further, DPC allows applications to specify a maximum tolerable latency for flexibly controlling the tradeoff between consistency and availability [1,2].

Once a network partition heals, a stalled CQ node can simply resume. A node that continued processing with missing input, however, might be in a diverged state, i.e., a state different from that of a failure-free execution. To reconcile a node's diverged state, a DSMS can take two approaches. The system can revert the node to a consistent, checkpointed state and replay the subsequent, complete input, or the system can undo and redo the processing of all tuples since the network partition. To avoid stalling the output during reconciliation, a DSMS must take care not to reconcile all replicas of a node simultaneously. Moreover, nodes must correct their previous output tentative tuples to enable downstream nodes to correct their states, in turn, and to allow applications to ultimately receive the correct and complete output. The Borealis DPC protocol supports these techniques [1,2].

Optimizations

Flux: Integrating Fault Tolerance and Load Balancing A large-scale cluster is a dynamic environment in which DSMSs face not only failures but also load imbalances which reduce availability. In this setting, DSMSs typically split the state of operators into *partitions* and spread them across a cluster for scalability. A single overloaded machine, in this setup, can severely slow down an entire CQ. The Flux operator can be interposed between producer–consumer partitions to coordinate their communication. To absorb short delays and imbalances, Flux allows out-of-order processing of partition input. For long-term imbalances, it supports fine-grained, online partition state movement. The Flux operators interact with a global controller that coordinates repair and rebalancing, and uses the same state movement mechanism for both [13]. Integrating load balancing with fault tolerance allows a system to better utilize available resources as nodes enter and leave the system. These features allow smooth hardware refresh and system growth, and are essential for administering DSMSs in highly dynamic and heterogeneous environments.

Leveraging Replication for Availability and Performance in Wide-Area Networks In previous active replicas approaches, a consumer replica receives the output stream of only one of many producer replicas. In wide area networks, the connection to any single producer is likely to slow down or fail, thereby disrupting the subsequent processing until fail-over completes. To avoid such disruptions, each consumer replica in Hwang et al.'s method [7] merges streams from multiple producer replicas into a single duplicate-free stream. This scheme allows each consumer, at any instant, to use the fastest of its replicated input streams. To further reduce latency, they redesign operators to avoid blocking by processing input out-of-order when possible, while ensuring that applications receive the same results as in the non-replicated, failure-free case. Moreover, their scheme continually adjusts the replication level and placement of operator replicas to optimize global query performance in a dynamically changing environment.

Passive Standby: Distributed Checkpointing and Parallel Recovery The basic passive standby approach has two drawbacks: it introduces extra latencies due to checkpoints and has a slower recovery speed than active replicas. Hwang et al.'s distributed checkpointing technique overcomes both problems [8]. This approach groups nodes into logical clusters and backs up each node using the others in the same cluster. Because different operators on a single node are checkpointed onto separate nodes, they can be recovered in parallel. This approach dynamically assigns the backup node for each operator and schedules checkpoints in a manner that maximizes the recovery speed. To reduce disruptions, this approach checkpoints a few operators at a time. Such checkpoints also begin only at idle times.

Key Applications

There are a number of critical, online monitoring tasks that require 24×7 operation. For example, IT administrators often want to monitor their networks for intrusions. Brokerage firms want to analyze quotes from various exchanges in search for arbitrage opportunities. Phone companies want to process call-records for correct billing. Web site owners want to analyze and monitor click-streams to improve targeted advertising and to identify malicious users. These applications, and more, can benefit from fault-tolerant and highly available CQ systems.

Future Directions

Key open problems in the area of fault-tolerance and high availability in DSMSs include handling Byzantine failures, integrating different fault-tolerance mechanisms, and leveraging persistent storage. Techniques for handling failures of data sources or dirty data produced by data sources (e.g., sensors) are also areas for future work.

Experimental Results

See [1,2,7,8,13,14] for detailed evaluations of the different fault-tolerance algorithms.

Image indexing

Definition

Feature extraction for content-based image retrieval is the process of automatically computing a compact representation (numerical or alphanumerical) of some attribute of digital images, to be used to derive information about the image contents. It can be seen as a case of dimensionality reduction. A feature, or attribute, can be related to a visual characteristic, but it may also be related to an interpretative response to an image or to a spatial, symbolic, semantic, or emotional characteristic. A feature may relate to a single attribute or be a composite representation of different attributes. Features can be classified as general purpose or domain-dependent. The general purpose features can be used in any context, while the domain-dependent features are designed specifically for a given application. Every feature is intimately tied with the kind of information that it captures. The choice of a particular feature over another depends on the given application, and the kind (level) of information required.

Historical Background

The interest of the scientific community in the problem of image retrieval can be dated back to the early 1990s. One of the pioneering examples on image feature extraction is the work by Swain and Ballard [6] where the concept of color histogram is introduced for image indexing. Since then, color (in many forms and evolutions) has been one of the most widely used features exploited for indexing the image contents. This is mainly due to its power to visually capture perceptual properties, robustness with respect to many image transformations, and computation efficiency. While more complex and sophisticated general purpose and domain dependent features were being developed, two important issues became evident: the sensory gap and the semantic gap.

The sensory gap is the gap between the information of the real world, and the information in a computational description derived from a digital recording of a scene of the world. The semantic gap is the lack of coincidence between the information that one can extract from the visual data and the interpretation that the same data have for a user in a given application [5].

The problems of the sensory and semantic gaps are less relevant for very specific applications (e.g., medical imaging) where the domain may be so narrow that high knowledge can be embedded in few features. However, for general purpose applications, sensory and semantic gaps cannot be bridged by a few features alone. To cope with the sensory gap problem, current approaches try to combine different features (mostly at low or middle levels of information), and different representations of the same feature. One way to cope with the semantic gap problem is not to tackle it at the feature level but at the system-user interaction level with human-adaptive paradigms. For these paradigms, the user represents a central role for a content-based image retrieval system. User interaction allows the system to automatically adapt to the changing requests; for example, in the way the images are organized, evaluated, or retrieved [7].

Foundations

Since an image conveys information at different levels, the use of different features at the same time is a necessary requisite to develop effective indexing algorithms for content-based image retrieval. For example, any visual property can have different feature representations describing it. Visual properties can be low level properties such as color, shape or texture; middle level properties such as regions and spatial relationships; high level properties such as the localization and identification of objects or image categorization. The process of choosing the best features for a particular application is denoted as feature selection.

The selected features should ideally present the following basic properties:

1. Perceptual similarity: the feature distance between two images is great only if the images are not “similar”;
2. Efficiency: they can be rapidly computed;
3. Economy: their dimensions are small in order not to affect retrieval efficiency;
4. Sscalability: the performance of the system is not influenced by the size of the database;
5. Rrobustness: changes in the imaging conditions (i.e., illuminations, geometric transformations,. . .) of the database images should not affect retrieval.

Once the features have been selected, a similarity measure (one for each feature and/or a global one) is chosen in order to evaluate the user query against the images in the database, and rank the retrieved images. Ideally a similarity measure should be correlated with the user’s perception of image matching or *image similarity.*

Figure 1 shows the different levels of information that can be derived from an image: the dashed line indicates where the semantic gap starts to influence the feature extraction algorithms.

Figure 2 is an example of the different information that can be obtained from an image. At each level of information more complex features are required to capture that kind of information. Details of each level are as follows:

1. Digital image of a painting.
2. Pixels. The image is coded using a numerical representation of physical properties derived from the input device with implicit spatial relationships. This representation may capture color as well as pressure, range, heath, non visible wavelengths and

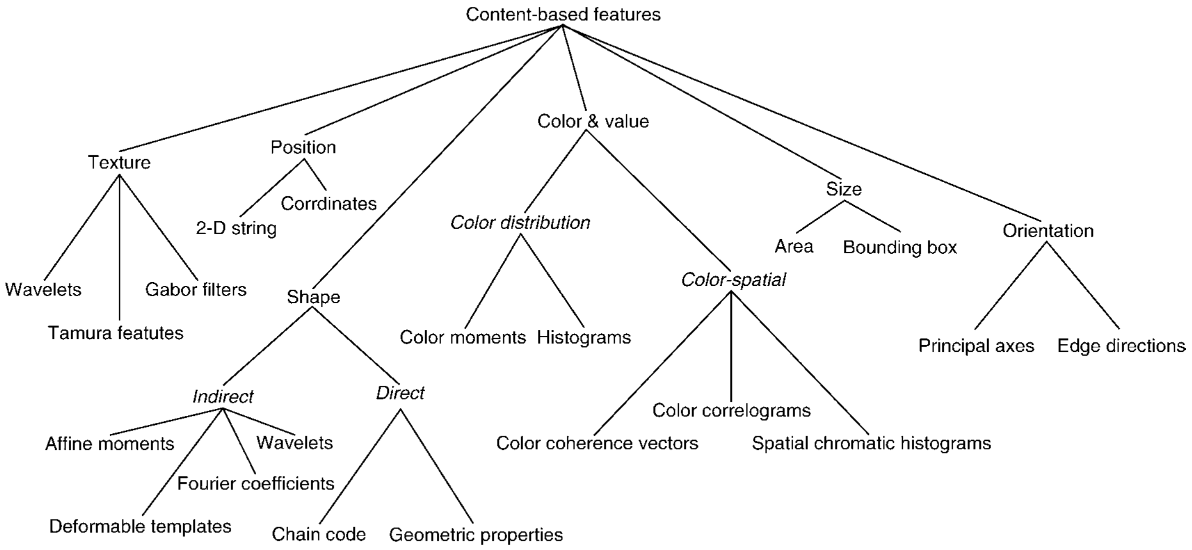
Feature Extraction for Content-Based Image Retrieval. Figure 2. Example of features corresponding to different levels of information. (a) the example image; (b) pixel level; (c) global low level features; (d) local low level features; (e) semantic regions; (f) semantic context; (g) external information.

so on. Each of these pieces of information physical information can be described using different numerical representations.

3. Low level information. These are global features that can describe the image contents from different perspectives in a compact way. The examples shown are: color contents in a quantized color space (top left), global edges computed with the Canny edge detector (bottom left), the gray level image (top middle), and horizontal, vertical, and diagonal edges computed from a wavelet transformation (to right, bottom middle, and bottom right respectively). This information is usually coded in terms of simple statistics (mean, variance,...), histograms, or signatures to improve their robustness to image variations, and reduce their dimensions for retrieval efficiency. The schema below shows an incomplete and non-exhaustive categorization of some low level visual properties, and their possible feature representations. Many representations and sub-representations are available for every feature (see Fig. 3). For further information interested readers may refer to [1,2,3,4].
4. Regions or "atomic objects." These are visually homogeneous regions that can be identified starting from the combination of different low level attributes (color, texture,...). *Data clustering* algorithms can be exploited for this task. Domain-dependent knowledge (for example specific spatial relationships between the areas) can be exploited to drive or refine the identification of these regions.
5. Objects/Actors. Identification of semantic objects or categories may be performed by the analysis of logically and spatially related regions. At this level features should cope with the problem of the semantic gap. The recognition of simple objects or



Feature Extraction for Content-Based Image Retrieval. Figure 3. Example of features, their corresponding representations and sub-representations.

categories is very complex, and is currently fully possible only for very narrow domains. Identification of semantic objects can be done exploiting pattern matching, *classification and decision tree* algorithms. These algorithms give a semantic tag or name to each candidate region (such as face, people, skin, sky, car, building, water, . . .). Generally one tag for each region is assigned, although multiple tags are sometimes allowed. This process is generally known as image annotation. Semantic tags can be expressed numerically or with more meaningful textual strings. Textual strings can be stored in traditional database systems to be used for image retrieval based on keywords.

6. Context semantics. This information relates to mutual spatial relationships as well as to specific actors/objects characteristics that may allow reconstruction/guessing of the overall image context. Some characteristics of the actors/objects may be derived using term taxonomies, synonyms, and dictionaries. Spatial relationships can also be described using textual strings by creating an ad-hoc language grammar such as A < B meaning that object A is at the left of object B or A ^ B meaning that object A is above object B, and so on. It should be noted that the classification and categorization of an image as a whole may involve information at the objects/actors level (the image itself is an object that can be annotated using low level features), and information at the semantic level (the presence of objects/actors, and some related characteristics can be used as clues in guessing the context of the image).
7. External information. This information does not describe some visual properties or intrinsic properties of the image. This auxiliary information cannot be derived or inferred directly from the image itself: external knowledge belonging to some entities (e.g., experts, common knowledge, etc. . .) is required. No automatic algorithm can be exploited with this kind of information: human intervention is the only viable approach in creating textual annotations usually given in free text form. The EXIF data also belong to this information category. These data, automatically embedded into the image by the hardware (e.g., camera), describe information about the device, device settings and scene information.

Key Applications

Feature extraction is a fundamental task for any application requiring the analysis of images. In particular, content-based image retrieval is important in many areas. The following is a sampling of possible content-based image retrieval applications:

1. Architecture and design (finding the right appearance)
2. Biochemical application (finding molecules)

3. Cultural heritage services (museum, art galleries)
4. Digital catalogs (browsing and searching)
5. Entertainment (image, film and video archive indexing)
6. Journalism (research and past exploration)
7. Medicine (pathology comparisons)
8. Remote sensing (localization and target finding)
9. Surveillance (identification and recognition)

Feature Selection for Clustering

Manoranjan Dash, Poon Wei Koot
Nanyang Technological University, Singapore, Singapore

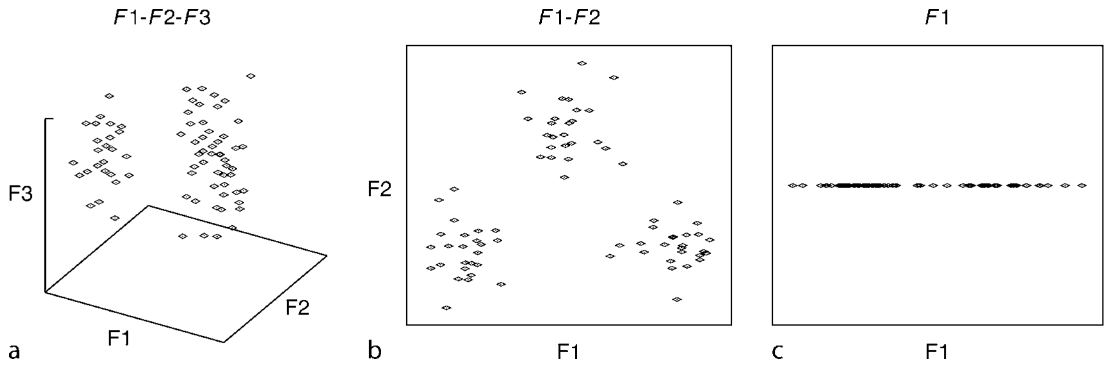
Definition

The problem of feature selection originates from the fact that while collecting data, one tends to collect all possible data. But for a specific learning task such as clustering not all the attributes or features are important. Feature selection is popular in supervised learning or for the classification task because the class labels are given and it is easier to select those features that lead to these classes. But for unsupervised data without class labels, or for the clustering task, it is not so obvious which features are to be selected. Some of the features may be redundant, some are irrelevant, and others may be "weakly relevant". The task of feature selection for clustering is to select "best" set of relevant features that helps to uncover the natural clusters from data according to the chosen criterion.

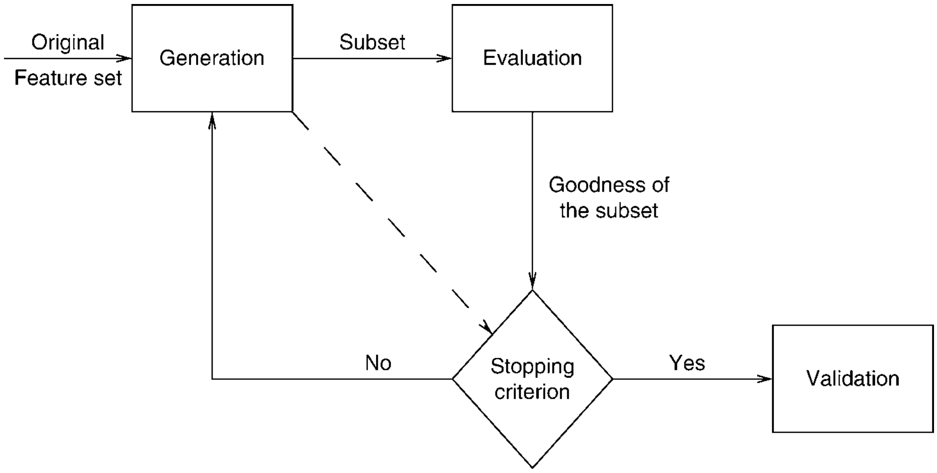
Figure 1 shows an example using a synthetic data. There are three clusters in *F*1–*F*2 dimensions which follow Gaussian distribution whereas *F*3, which does not define any cluster, follows a uniform distribution. When all three features are used the clusters are unnecessarily complex (see Fig. 1a), whereas no clusters can be found when one visualizes using only one feature *F*1 (Fig. 1c). Figure 1b with *F*1–*F*2 features shows three well-formed clusters. Selecting features *F*1 and *F*2 reduces the dimensionality of the data while forming well separated clusters. The goal of feature selection for clustering is to select important original features for clustering thus reducing the data size (and the computation time of other subsequent data mining tasks), solving the problem of curse of high-dimensionality and improving the knowledge discovery performance and comprehensibility. There are four basic steps in a typical feature selection method: a method to generate candidate subsets, an evaluation function, a stopping criterion, and a validation procedure (Fig. 2).

Historical Background

The literature for feature selection for classification, which is a supervised learning task, is very vast (see a review in [6]). On the other hand, there are only a few, mostly recent, feature selection methods for clustering, which is a unsupervised task. The reason behind this gap in research is it is easier to validate the selected features for classification (e.g., by accuracy of the classification) than to validate the selected features for clustering. Although there are many cluster validation techniques, the techniques have their limitations, and thus there is lack of unanimity among the researchers [19]. An issue that is yet to be resolved is how many clusters are there in a data set. Particularly in real-world



Feature Selection for Clustering. Figure 1. Effect of features on clustering.



Feature Selection for Clustering. Figure 2. Feature selection process with validation.

data sets often one encounters high-dimensional data sets with unknown number of cluster. It is shown that number of clusters and number of features have interrelation thus complicating the matter further [10].

Feature selection for clustering is the task of selecting important features for the underlying clusters. These methods can be divided using different categorization such as: global vs. local and wrapper (i.e., with feedback) vs. filter (i.e., without feedback – blind). Global methods select features for the whole data set whereas local methods select features for each individual cluster.

Examples of global methods are [5,12,17,22]. In [5] was proposed a filter method. A filter method is independent from the clustering algorithm to be used, whereas wrapper method uses the clustering method itself to select features. In this paper, the authors we proposed to measure entropy of the data set using point-to-point distances. Entropy is independent of number of features. Lower the entropy better the clustering. Features were ranked from most important to least important and a forward selection algorithm is used to select the relevant features. In [12] Dy and Brodley proposed a wrapper criterion for clustering. A candidate subset of features is used to cluster the data and the quality of clusters is evaluated using normalized cluster separability (for *K*-means) or normalized likelihood (for EM – expectation maximization – clustering). The bias on the feature subsets with respect to dimensionality is ameliorated by cross-projection normalization. In [11] the same authors used EM and trace measure (which is invariant for varying number of dimensions [9]) are used for evaluation. Visual aids to decide the optimal number of features were also proposed. The method described in [17] uses

K-means for evaluation of subsets of features. In [22] authors proposed an objective function for choosing the feature subset and finding the optimal number of clusters for a document clustering problem using a Bayesian statistical estimation framework.

Examples of local methods are [2,14,18,21]. In [14] authors proposed a distance measure. Using this measure with usual distance based clustering algorithms encourages the detection of subgroups of objects that preferentially cluster on subsets of features. The relevant feature subsets for each individual cluster can be different and partially or completely overlap with those of other clusters. In [18], feature saliency is integrated in EM algorithm so that feature selection is performed simultaneously with clustering process. Projected clustering (ProClus [1]) finds subsets of features defining (or important for) each cluster. ProClus first finds clusters using K-medoid considering all features and then finds the most important features for each cluster using Manhattan distance. The algorithm called CLIQUE in [2] divides each dimension into a user given divisions. It starts with finding dense regions (or clusters) in one-dimensional data and works upward to find higher-dimensional dense regions using candidate generation algorithm Apriori. In [20,21] Talavera used category utility to select features and these features are used to construct COBWEB [13] (COBWEB is a hierarchical clustering algorithm for categorical data.).

Foundations

This section first gives some insight into feature selection for clustering using an example method and then briefly discusses other methods and techniques used.

An Example of a Filter-Global Method

Figure 3 shows the histogram of point-to-point distances for two datasets: one with clusters and the other without clusters. The point-to-point distances are computed, normalized and are used to populate the bins of the histograms. An important distinction between the two histograms is that histogram for data without clusters has a predictable shape similar to bell shape. But the histogram for data with clusters has very different distribution. The smaller buckets (or distances) are mostly intra-cluster while the latter ones are mostly inter-cluster. *Typically, if the dataset consists of some clusters then, the majority of the intra-cluster distances will be smaller than the majority of the inter-cluster distances.* This observation is true for a wide range of data types. When clusters are very distinct this separation between intra-cluster and inter-cluster distances is quite distinguishable. In [5] a method is proposed which, without doing clustering, can distinguish between data with clusters and data without clusters.

Distance-based Entropy Measure From entropy theory it is known that entropy of a system can measure the amount of disorder in the system. Mathematically entropy of a dataset is given as:

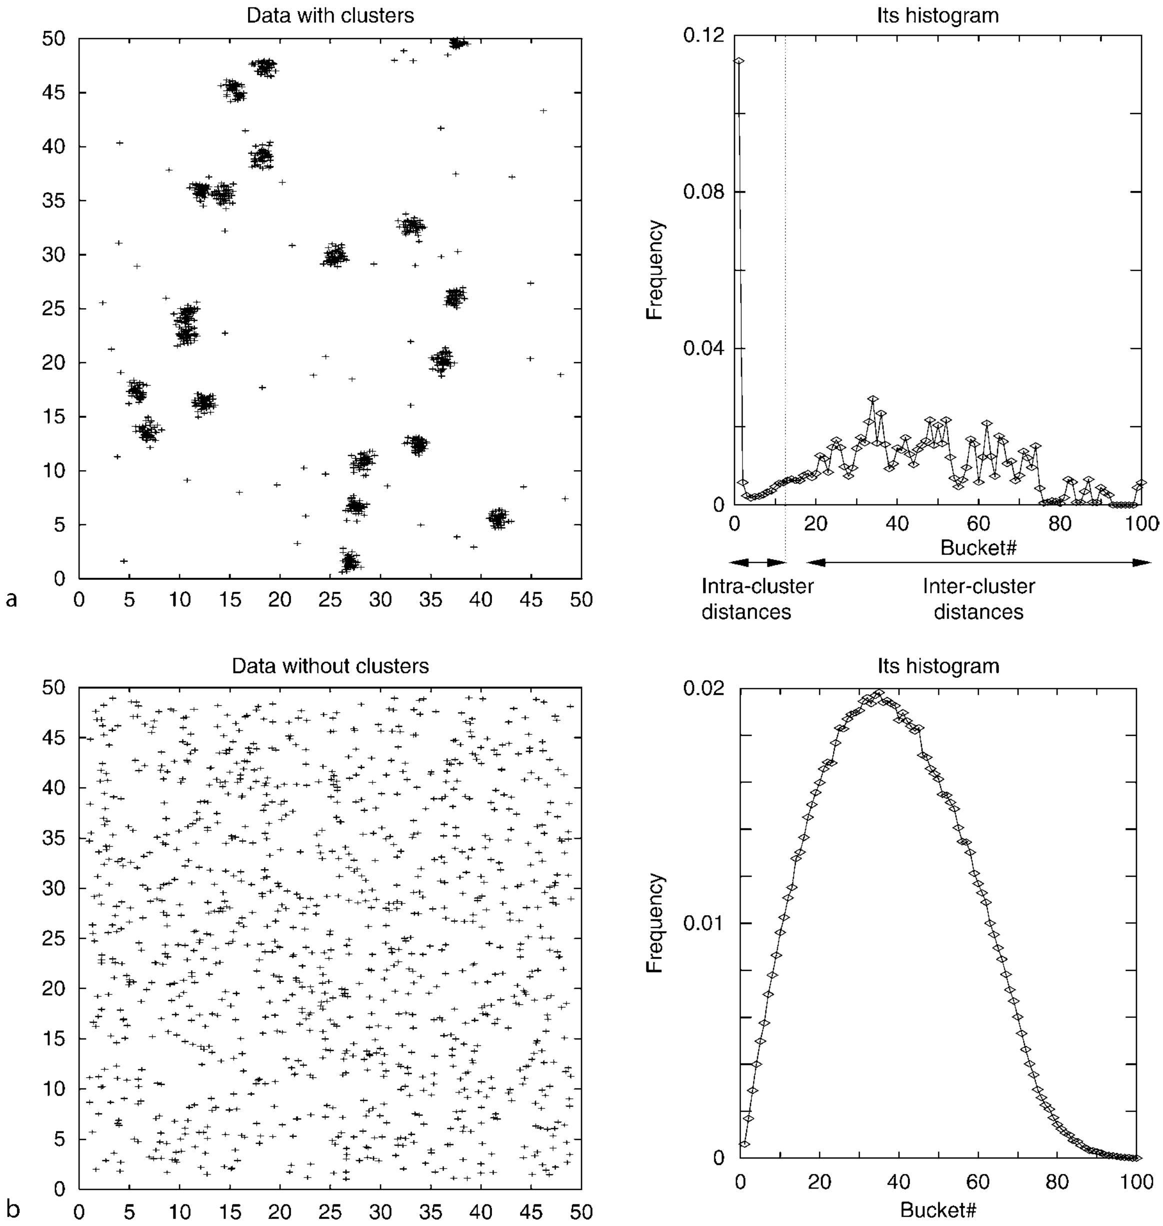
$$E = -\sum_{X_i} p(x_{i_1},\ldots,x_{i_M}) \log p(x_{i_1},\ldots,x_{i_M}) + (1 - p(x_{i_1},\ldots,x_{i_M})) \log(1 - p(x_{i_1},\ldots,x_{i_M})) \quad (1)$$

where $p(X_{i_1},\ldots,X_{i_M})$ is the probability or density at the point $(X_{i_1},\ldots,X_{i_M})$ where M is the dimensionality. The second term in the expression inside summation is used to make the expression symmetric. If the probability of each point is equal one is most uncertain about the outcome, and entropy is the maximum. This will happen when the data points are uniformly distributed in the feature space. On the other hand, when the data has well-formed clusters the uncertainty is low and so also the entropy. So, the entropy can be used to distinguish between data with clusters and data without clusters in different subspaces.

A straightforward method to compute the probability at each point is by substituting probability with distance in the following way:

$$E = -\sum_{X_i}\sum_{X_j} D_{ij} \log D_{ij} + \left(1 - D_{ij}\right) \log\left(1 - D_{ij}\right) \quad (2)$$

where D_{ij} is the normalized distance (This uses Euclidean (L_2) measure although other distances such as Manhattan (L_1) can be used.) in the range [0.0–1.0] between instances X_i and X_j. Figure 4a shows the relationship between entropy and distance after normalizing E to the range [0.0–1.0]. This measure assigns lowest entropy (0.0) for the minimum (0.0) or the maximum (1.0) distance and assigns highest entropy (1.0) for the mean distance (0.5). Although, to some extent, it works well in distinguishing data with clusters from data without clusters, it suffers from the following two drawbacks. (i) The mean distance of 0.5 can be an inter-cluster distance, but still it assigns the highest entropy. The reason is the meeting point



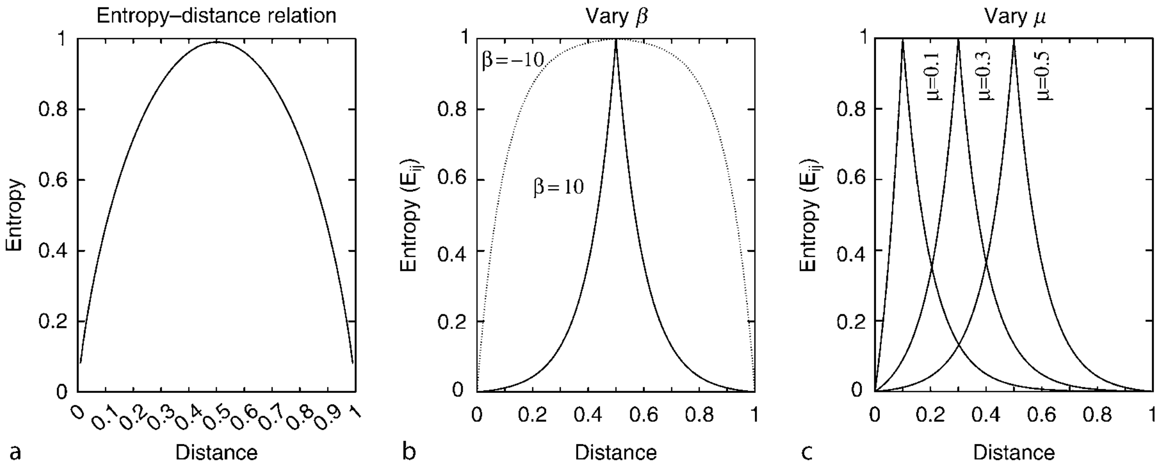
Feature Selection for Clustering. Figure 3. Distance histograms of data *with* and *without* clusters.

(μ) of the two sides (i.e., left and right) of the plot is fixed at distance 0.5. (ii) Entropy increases rapidly for very small distances thus assigning very different entropy values for intra-cluster distances. In summary, this measure does not work very well in assigning small entropy for both intra-cluster and inter-cluster distances. The second drawback can be easily overcome by incorporating a coefficient (β) in the equation and by using an exponential function in place of logarithmic function. Regarding the first drawback, the meeting point (μ) can be set so as to separate the intra-cluster and inter-cluster distances. Considering all these the following method was proposed:

$$E = \sum_{x_i} \sum_{x_j} E_{ij} \qquad (3)$$

$$E_{ij} = \begin{cases} \frac{exp\left(\beta * D_{ij}\right) - exp(0)}{exp(\beta * \mu) - exp(0)} & : \quad 0 \leq D_{ij} \leq \mu \\ \frac{\exp(\beta * (1.0 - D_{ij} - \exp(0)}{\exp(\beta * (1.0 - \mu)) - \exp(0)} & : \quad \mu \leq D_{ij} \leq 1.0 \end{cases} \qquad (4)$$

where E_{ij} is normalized to the range [0.01-1.0].



Feature Selection for Clustering. Figure 4. Relationship between entropy and distance with varying β and μ values.

Other Methods

Trace Measure In the wrapper and global methods feature subsets are evaluated by a clustering algorithm and the quality of clustering is evaluated using trace measure [12,7]. The Trace measure $(tr(S_W^{-1}S_B))$ is based on within and between cluster distances, where *tr* is *trace* os a matrix which is the sum of its diagonal elements; S_W is a within-cluster scatter matrix given as: $S_W = \sum_{i=1}^{c}\sum_{X\in\chi_i}(\mathbf{x}-\mathbf{m_i})(\mathbf{x}-\mathbf{m_i})^t$, and S_B is a bet-cluster scatter matrix given as: $S_B = \sum_{i=1}^{c}$ $(\mathbf{m_i} - \mathbf{m})(\mathbf{m_i} - \mathbf{m})^t$ where $\mathbf{x}$ is an instance vector, χ_i is the set of instances in *i*th cluster, $\mathbf{m_i}$ is the mean vector of *i*th cluster, $\mathbf{m}$ is the mean vector of the data. The higher the $tr(S_W{}^{-1}S_B)$, the higher the ratio of between-cluster to within-cluster scatter. If clustering is proper, then between cluster distance will be high and within cluster distance is low. Although there are many cluster validation techniques (see [16]), trace measure is especially selected because it is independent of number of features, i.e., irrespective of number of features in the subspace, trace measure can evaluate the clustering quality and compare among clusterings in different subspaces of equal or different dimensionality.

EM Method In [18], Law et al. cast the feature selection for clustering as an estimation problem rather than a search problem thus they avoided the combinatorial search through the feature space. Instead of selecting a subset of features they estimated a set of real-valued ([0,1]) quantities for each feature. They call it *feature saliency*. This estimation is carried out by an EM (Expectation Maximization) algorithm derived for the task. They avoided the situation where all the saliencies take the maximum possible value by adopting a minimum message length (MML) penalty. The MML criterion encourages the saliencies of the irrelevant features to go to zero. They combined the feature selection with EM clustering.

Conceptual Clustering Conceptual clustering is applicable for feature selection for clustering for data having only categorical features (e.g., COBWEB [13]). It creates a hierarchy or tree of clusters. As each data object is input to the system, the system categorizes the object by sorting it through hierarchy from the root node down to the leaves. At each level it determines whether (i) to create a new cluster, or (ii) to place the object in an existing cluster, and whether to restructure the hierarchy by (iii) merging two sibling clusters which were identified as the two best hosts for the new object or (iv) splitting the host cluster.

In [20,21] Talavera proposed two local methods for selecting features for conceptual clustering. In [21] Talavera used salience measure (this is different from the saliency measure in [18]) to select features. The higher the salience the greater is its relevance for the clustering. Salience measure originates from category utility measure.

Devaney and Ram [8] also used COBWEB to select features for clustering but they used it in a different way. The basic idea is to employ a wrapper approach with the average predictive accuracy over all features replacing the predictive accuracy of class labels. They used COBWEB as an evaluation function. The search through the feature space is either forward or backward. COBWEB is executed for each of these subsets and category utility is computed of the first partition (children of the root) of the resulting concept hierarchy, retaining the highest score.

Important Applications

Feature selection has gained a wider audience in the past few years due to the high-dimensionality of databases. Due to the high number of low level features, a lot of the current methods of clustering in low dimensionality will fail miserably. Thus the only way is to identify the most important features and reduce dimensionality. In terms of applications, there are numerous possibilities.

An important application of feature selection is in the area of bioinformatics, using gene expression microarray data. Due to the nature of high dimensionality (thousands of genes) and sparsity of the data in feature space, clustering is exceptionally difficult. In [23] this issue is addressed using CLIFF, an algorithm based on normalized cut with their feature selection process. In [24] Malik et al. paper, he proposed another method for gene expression using recursive cluster elimination (RCE) with SVM, and claimed to have improved accuracy compared to other methods. In [14] an application of local feature selection for clustering is shown over Yeast gene expression data set with 6,141 genes (features) measured on 213 samples (instances).

Bekkerman et al. [4] applied feature selection with SVM to the problem of text categorization to yield high performance accuracy. Datasets used are: 20-Newgroups, Reuters-21578 and WebKB. The 20-Newsgroups contains 19,997 articles from the Usenet newsgroup collection, while Reuters-21578 corpus contains 21,578 articles from the Reuters newswire, and WebKB is a collection 8,282 web pages from four academic domain.

Bach et al. [15] applied feature selection to the reduction of attribute in image face recognition for male/female classification. Datasets consist of 1,450 images (1,000 train, and 450 for test) with 5,100 features.

In [3], feature selection is applied to PrimeClub, a game designed to teach prime numbers to sixth and seventh grade students. The objective is to keep the students continue learning, maintaining a high level of engagement as the game progresses. Biometric devices are attached to each student to detect the mental and emotional state of their expressions. In it, 28 features are recorded, and of those, only 4 are deemed important for clustering.

While not going into details, some of the other applications of feature selection are: customer relationship management, image retrieval, text mining, protein classification and intrusion detection.

URL

While not many author published their programs or code in the internet, there exist a few that do make theirs available for others to download and compare. "RCE classification and feature selection" as described in [24] is available for download at "http://showelab.wistar.upenn.edu/"

Mark Hall wrote a feature selection program for Weka, described in his PhD dissertation "Correlation-based Feature Subset Selection for Machine Learning."

CLOP is a Matlab package developed on top of the Spider for the WCCI 2006 performance prediction challenge, and it has produced some very good result in the NIPS 2003 feature selection challenge.

RapidMiner, a freely available open source for data mining and machine learning, has functionality for feature selection. It is written in Java and works on all major operating systems, available for download at "http://rapid-i.com/content/blogcategory/38/69/"

INTERACT is a feature selection method using inconsistency and symmetrical uncertainty measurements for finding interacting features. It is describe in "http://www.public.asu.edu/∼huanliu/INTERACT/INTERACTsoftware.html," and available for download from the site.

Definition

3D objects are an important type of data with many applications in domains such as engineering and computer aided design, science, simulation, visualization, cultural heritage, and entertainment. Technological progress in acquisition, modeling, processing, and dissemination of 3D geometry leads to the accumulation of large repositories of 3D objects. Consequently, there is a strong need to research and develop technology to support the effective retrieval of 3D object data from 3D repositories.

The feature-based approach is a prominent technique to implement content-based retrieval functionality for 3D object databases. It relies on extracting characteristic numerical attributes (so-called features) from a 3D object, usually forming high-dimensional vectors which represent the 3D object, or parts of it. The 3D feature vectors in turn are used to estimate object similarity for content-based retrieval, and can also be used for multidimensional indexing of 3D database content. There exist several degrees of freedom in obtaining 3D features. Important specifications to be made include the type of 3D characteristics or its level of detail considered, or invariance properties required, among others. Finding efficient and effective features for a given 3D repository is usually addressed by benchmarking.

Historical Background

The development of 3D object retrieval methods can be regarded as part of the larger multimedia retrieval research area. The availability of increasing volumes of multimedia data such as digital images, digital video, or digital audio induced the need to develop content-based retrieval methods supporting these data types. Image retrieval has roots in image processing and database research of the 1980s, and was joined in the 1990s by similar efforts in the video and audio domains. Roughly, beginning by 2000, 3D objects increasingly came into focus of multimedia retrieval research. Driving motivation in the research and development of 3D retrieval methods are the increasing use of 3D object data in a range of application areas.

While retrieval of 3D objects is a prominent topic in multimedia database research, the definition of similarity notions for 3D data is also considered in related disciplines. In geometry processing, the registration or alignment of geometry is of interest, using certain definitions of geometric similarity. Computer vision is concerned with the recognition of objects in images taken by a camera or other scanner device, requiring appropriate segmentation and description methods for the objects in the scene under concern. In shape analysis, shapes and scenes are often analyzed for certain structural features, supporting e.g., classification and compression.

From the multimedia database research perspective, the focus of 3D retrieval implementations not only concerns the effectiveness of the retrieval, but also, their efficiency, demanding for real-time query processing on large repositories. The feature vector approach is therefore especially suited, as it allows the efficient evaluation of object similarity, usually by calculating a Minkowski distance between feature vectors representing underlying 3D objects.

Foundations

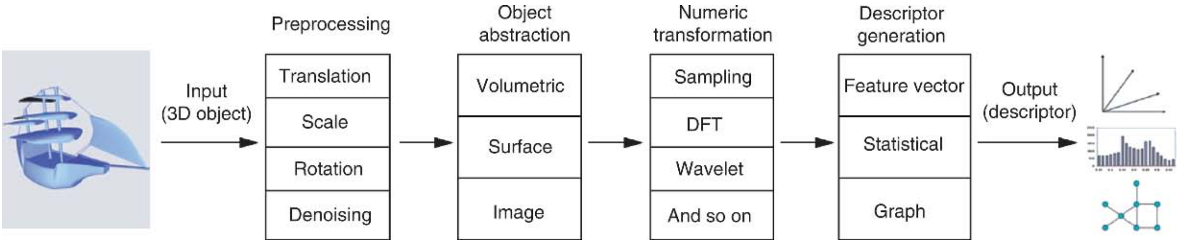
To represent 3D object data as points in feature vector space, it is necessary to find characteristics that describe the objects in a meaningful, discriminating way. A suitable feature extraction function calculates characteristic features from the 3D objects, thereby mapping them into *d*-dimensional feature vector space. With these feature vector representations, a similarity query in the original 3D object space is reduced to a search for close points in *d*-dimensional feature vector space.

Common Requirements of 3D Feature Extraction

For 3D object data, based on the given retrieval application, certain properties of the features extracted can be deemed desirable. The features may be required to be invariant with respect to changes in rotation, translation, and scale of the 3D models in their reference coordinate frame. Ideally, an arbitrary combination of translation, rotation and scale applied to one object should not affect its similarity measure with respect to another object. Another desirable property is robustness with respect to variation of the level-of-detail in which the 3D objects are given, and to small geometry and topology variations of the models. These invariance and robustness properties are especially important if the retrieval is expected to support 3D objects from heterogeneous data sources. This is because in such cases, the reference frames or levels-of-detail in which the models are represented may differ, and it cannot be assumed that respective meta data is available from all possible object sources.

3D Feature Extraction Process Model

A process model of 3D feature extraction is depicted in Fig. 1 and can be described as follows. Firstly, if required by the application, a preprocessing step normalizes the 3D object to approximate invariance to rotation, translation, scaling, and reflection [11]. A second step abstracts the 3D object according to a selected shape characteristic. For example, one can abstract a 3D object as a volume, or as an infinitely thin surface with precisely defined properties of differentiability, or as a set of 2D images formed by



Feature-Based 3D Object Retrieval. Figure 1. Feature extraction process for 3D objects.

projections from different perspectives. The third step captures the main features of the 3D object under the selected abstraction by means of a numeric transformation. As a result of this step, a numerical representation of the original 3D object is obtained. The last step of the feature extraction process model produces the final descriptor of the object from the numerical description. Generally, the descriptor may be a vector of numerical features, but it may also be a histogram of the measured characteristics, or a graph-based representation of the analyzed 3D object. Feature-based methods for 3D model retrieval usually are efficient, robust, and easy to implement. This does not imply, however, that statistical or graph-based methods should be disregarded. In fact, most of those methods have their particular strengths and may well be the ideal candidate for a specific application.

3D Feature Types

As surveys indicate [2,7,10], there is a wealth of different features that so far have been used to build 3D retrieval systems. The situation is comparable to content-based image retrieval (CBIR), where also, many different features have been proposed over the recent years. It can be stated that many of the 3D features proposed were heuristically introduced, motivated by techniques and practices from computer graphics (e.g., projection-based features), geometry processing (e.g., features based on surface curvature statistics), or Signal Processing (e.g., features obtained by representing object samples in the frequency domain). Some of the most effective 3D feature vector extractors proposed to date rely on features extracted from 2D projections of 3D objects.

Usually, it is a priori unclear which of the potentially many different features should be preferred for addressing the 3D retrieval problem. Each of the many possible descriptors captures specific model information, and their suitability for effective retrieval in a given application domain needs to be experimentally evaluated. In practice, it often shows that the effectiveness of 3D retrieval systems can benefit from using not a single, but several different types of features in combination.

Efficient 3D Object Retrieval

Similarity queries in 3D object databases may be answered by performing a sequential scan on the database, comparing the query object with all 3D objects stored in the database. This naive method might be too slow for real-world applications. In feature-based 3D object retrieval, the search system may use an index structure (e.g., spatial access methods or metric access methods) for efficient retrieval if the distance function used to compute the (dis)similarity of two 3D objects holds the properties of a metric (strict positiveness, symmetry, and the triangle inequality).

Spatial access methods [1] (also known as multidimensional indices) are index structures especially designed for vector spaces which, together with the metric properties of the distance function, use geometric information to discard points from the search space. Usually, these indices are hierarchical data structures that use a balanced tree to index the database. Metric access methods [4] (also known as metric indices) are index structures that use the metric properties of the distance function (especially the triangle inequality) to filter out certain zones of the space, thus avoiding the sequential scan.

Key Applications

Content-based 3D retrieval methods are potentially useful in all applications involving 3D object repositories, from which elements need to be retrieved based on geometric similarity. Several exemplary applications are detailed in the following, more exist.

Industrial Applications

Engineering and industrial design, the animation, and the entertainment industry heavily rely on digitized models of products or parts thereof. Computer-aided design allows the digital modeling of 3D content. Given effective retrieval capabilities, the re-usage of content from existing repositories can be supported for more efficient production processes [5].

Medicine

In medical imaging applications, often 3D volume data is generated, e.g., using MRI scans. A possible application lies in automatic diagnosis support by analysis of organ deformations, by matching actual images with medical database of known deformations.

Molecular Biology

Structural classification is a basic task in molecular biology. This classification can be supported by geometric similarity search, where proteins and molecules are modeled as 3D objects, which can be compared against bio-molecular reference databases using geometric similarity measures.

Future Directions

Feature-based 3D retrieval research is still in a rather early stage. Current approaches mostly consider features describing the geometry of whole models, that is, they support global similarity between objects. Recently, approaches also considering local features based on identification of salient object regions have been proposed. These are expected to support not only the retrieval of complete models, but also, be suited for retrieval based on local similarity. Future work will address 3D retrieval under additional similarity models, including similarity models invariant with regard to non-rigid and structural object deformations. It is also expected that application specific, specialized similarity notions will become increasingly important.

Experimental Results

The effectiveness of 3D features for retrieval is usually determined experimentally based on reference benchmarks, and measured by information retrieval metrics [3]. Well-known 3D retrieval benchmarks include the Princeton Shape Benchmark [9] and the Purdue Engineering Shape Benchmark [8]. The SHREC contest [6] is an International shape retrieval contest held regularly that involves different 3D retrieval challenges.

Field-Based Information Retrieval Models

VASSILIS PLACHOURAS
Yahoo Reasearch Barcelona, Barcelona, Spain

Definition

A document *D* consists of a set of *n* document fields, and it is represented by a set of *n* vectors, where each vector corresponds to a document field. A field-based Information Retrieval (IR) model assigns a score or Retrieval Status Value (RSV) to a document *D* and a query *Q* by distinguishing the occurrences of query terms in the different field vectors, and by weighting the contribution of each field appropriately.

Historical Background

Textual documents, whether they are news wire items, scientific publications, or Web pages, are rich in structure. For example, depending on its length, a text can be organized in chapters, sections, paragraphs, and each of those can have a concise description in the form of a title. Shorter texts, such as emails, also consist of free text and formatted text. In information retrieval (IR), however, documents are usually represented as a single vector, the dimensions of which correspond to terms occurring in the document. Such a representation ignores the structure within a document because it does not distinguish between the occurrence of terms in different parts of a document, such as the document title, or the document abstract.

Field-based IR models overcome this limitation of representing the document as one vector, or as a bag-of-words, by incorporating in the document weighting process the fact that a term may appear in different document fields, and assigning different importance to the occurrences in each field. Information retrieval with document fields has a long history. Switzer [14] described a model where each index term is a vector image of the basic index terms. A document is represented by a title image, an author image, and citation images, constructed from bibliographic references. In such a representation, the title image is the average of vector images of the index terms appearing in the title. Fox [2] extended the boolean model and the vector space model with multiple concept types or fields. In the extended vector space model, a document is represented as a vector of subvectors. The ranking of documents in the extended vector space model is performed according to the weighted sum of the similarities between each of the subvectors and the queries. Fox also investigated the characteristics of several concept types related to bibliographic citations, as well as the weighting of the contribution of each of the subvectors [3]. Wilkinson studied the contribution of different fields, or document representations to retrieval effectiveness and found that improvements in early precision were obtained by using both the whole documents and their fields [16].

Foundations

There have been several proposed models to combine information from different document fields. One approach involves the use of structured document retrieval models, which allow for contained elements. Myaeng et al. [10] proposed a model in which documents and their elements or fields are represented as nodes in a network. Then, elements are ranked according to their support for the query, considering the contained elements as well. Lalmas [6] introduced a model where a document is represented as a tree. The leaf nodes of the tree correspond to the elements or fields of the document and the non-leaf nodes correspond to aggregates of its child nodes.

One other approach involves performing retrieval independently from each field and then, merging the ranked lists of results [1]. In this case, the combination of document fields takes place by merging the ranked lists of documents corresponding to each document field. This approach can be used to combine any source of evidence since it is based on the ranks of the retrieved documents, and not on their scores.

In the context of language modeling, the combination of fields, or different document representations, can be achieved with a linear combination of language models computed for each of the fields or document representations [11]. Similarly to the extended vector space model introduced by Fox [2], the combination of the different fields is also performed by computing a score or RSV for each of the document fields independently, and then performing a weighted sum of the computed scores.

The integration of information from the different fields in a retrieval model is not straightforward, because each document field may have different characteristics and the term frequency distribution can be different [5]. Thus, performing normalization and weighting independently for the various fields allows to take into account the different characteristics of the fields, and to achieve their most effective combination.

Robertson et al. [13] suggested that it is more appropriate to weight and combine the frequencies of terms from different fields in a *pseudo-frequency*, before applying a term weighting model. They argue that it is more intuitive to combine term frequencies rather than scores or RSVs assigned by scoring functions, which are not necessarily linear with respect to the term frequencies. Indeed, the linear combination of scores computed for each of the fields independently can lead to an overestimation of the importance of a term in a document. Then, Robertson et al. [13] proposed extending the BM25 weighting model to perform a weighted combination of document fields. The BM25 weighting model is given as follows:

$$w(D,Q) = \sum_{t \in D \cap Q} \frac{(k_1+1)tf}{(k_1(1-b)+b(l/\bar{l}))+tf} \cdot \log \frac{N-n_t+0.5}{n_t+0.5} \qquad (1)$$

where k_1, k_3, and b are free parameters, tf is the frequency of term t in D, l is the length of D, $\bar{l}$ is the average document length in the collection of documents, N and n are the number of documents and the document frequency of t in the collection. In the above equation, the frequency of terms in the query Q is not included. The proposed extension replaces tf in the above equation with a weighted sum of the term frequencies from each of the n document fields:

$$tf = \sum_{i=1}^{n} w_i \cdot tf_i \qquad (2)$$

where tf_i is the frequency of term t in the i-th field and w_i is the weight of the i-th field. The described extension gives only a partial solution because it does address the combination of fields, but the term frequency normalization component is applied after computing the weighted sum of the term frequencies.

Zaragoza et al. [17] proposed BM25F, an extension of BM25 where length normalization is applied on a per-field basis. The formula of BM25F is given below:

$$\begin{aligned} w(D,Q) &= \sum_{t \in Q} \frac{tfn}{k_1 + tfn} \cdot \log \frac{N-n_t+0.5}{n_t+0.5} \\ \text{where } tfn &= \sum_{i=1}^{n} w_i \cdot \frac{tf_i}{(1+b_i(l_i/\bar{l}_i))} \end{aligned} \qquad (3)$$

In the above equation, b_f is a field-dependent normalization parameter, similar to the parameter b of BM25, k_1 is a parameter that controls the saturation of tfn, similar to the parameter k_1 of BM25; $\bar{l}_i$ is the average length of the i-th field in the document collection; and l_i is the length of the i-th field in D. The parameter w_i is the weight of the i-th field.

The Divergence From Randomness (DFR) framework has also been extended to handle multiple document fields, and to apply per-field term frequency normalization and weighting. DFR is a framework for generating families of probabilistic retrieval models consisting of three components. The weighting

Field-Based Information Retrieval Models. Figure 1. An illustration of combination of document fields in the term frequency normalization component(top) and in the probabilistic retrieval model (bottom).

models of the Divergence From Randomness framework are based on combinations of three components: a randomness model $\mathcal{RM}$; an information gain model $\mathcal{GM}$; and a term frequency normalization model. Given a collection C of documents, the randomness model $\mathcal{RM}$ estimates the probability $P_{\mathcal{RM}}(t \in D|C)$ of having *tf* occurrences of a term t in D. The information gain model $\mathcal{GM}$ estimates the informative content $1 - P_{risk}$ of the probability P_{risk} that a term t is a good descriptor for a document. The third component of the DFR framework is the term frequency normalization model, which adjusts the frequency *tf* of the term t in d, given the length l of d and the average document length $\bar{l}$ in D.

There have been two ways proposed to extend the DFR weighting models with document fields. The first way to incorporate fields is by extending the term frequency normalization component of the DFR framework [12]. The frequency tf_i of term t in the i-th field is normalized and weighted independently of the other fields. Then, the normalized and weighted term frequencies are combined into one pseudo-frequency.

When combining the term frequencies in the length normalization component, as it happens in BM25F and in normalization 2F, it is implied that the term frequencies are drawn from the same distribution, even though the nature of each field may be different. The second way to incorporate fields in the DFR framework is by using multinomial randomness models [12]. Using the multinomial distribution, the probability that a term occurs tf_i times in the i-th field of D is given as follows:

$$P_{\mathcal{M}}(t \in D|C) = \binom{TF}{tf_1 \quad tf_2 \cdots tf_n \quad tf'} p_1^{tf_1} p_2^{tf_2} \cdots p_n^{tf_n} p'^{tf'} \qquad (4)$$

In the above equation, TF is the frequency of t in the collection, $p_i = \frac{1}{n \cdot N}$ is the prior probability that a term occurs in a particular field of D, and N is the number of documents in the collection C. The frequency $t' = TF - \sum_{i=1}^{n} tf_i$ corresponds to the number of occurrences of t in documents other than D. The probability $p' = 1 - n\frac{1}{n \cdot N} = \frac{N-1}{N}$ corresponds to the probability that t does not appear in any of the field-s of D. The use of the multinomial distribution as a randomness model requires the computation of several factorials, which can be expensive and also may introduce approximation errors. To overcome the need to compute these factorials, Plachouras and Ounis [12] also used an information theoretic approximation of the multinomial distribution.

The models described above require additional information from the index to compute efficiently scores of documents. In both the cases of BM25F and the DFR field-based weighting models, the index must contain the frequency of a term in each of the document fields, rather than just the frequency of the term in the whole document. For each document, it is also required to have the length of each field to perform length normalization on a per-field basis.

Key Applications

There is a wide range of applications for which field-based IR models enhances the retrieval effectiveness. One of the most important and widely used ones is Web search, where useful fields are the title of Web documents as well as the anchor text of incoming hyperlinks. A different application in which retrieval effectiveness increases by using document fields is email search [17] where the email from, to and date, as well as the quoted text, can be considered as a different field. In general, field-based IR models can be readily applied to search tasks in which documents have metadata elements associated or in which parts of the documents are annotated.

Future Directions

The introduction of fields increases the complexity of the retrieval models by introducing parameters related to the weighting of each field, but also to other factors such as the length normalization of each field. As an example, BM25F [17] requires the tunning of $2n + 1$ parameters when using n different document fields. Similarly, PL2F [8] introduces $2n$ parameters when using n different fields. Since the fields are not necessarily independent, setting the parameters for one field depends also on the parameter setting for the other ones. As the number of fields and the number of parameters increases, performing an exhaustive search becomes prohibitive. The application of an extension of gradient descent has been proposed to set the document field parameters among other parameters [15]. Developing parameter-free field-based IR models, however, is still an open problem.

Data Sets

There are several available data sets that allow experimentation with field-based IR models. The most commonly used ones are the standard TREC Web test collections WT10g, .GOV and .GOV2, which have been used for a range of search tasks, such as ad-hoc retrieval, named page and home page finding, as well as topic distillation. All these tasks have been evaluated in the context of Web track of Text REtrieval Conference (TREC) [4]. Another standard test collection that has been used for expert search finding and email search in mailing lists is the W3C collection, a crawl of the World Wide Web Consortium Web site available from TREC as well.

The INitiative for the Evaluation of XML Retrieval (INEX) [9], has also developed collections using XML. The first one consists of articles marked up in XML from a number of the IEEE Computer Society's publications. Other collections correspond to the contents of Wikipedia and to the contents of travel guides, marked up in XML.

Field-Based Spatial Modeling

MICHAEL F. GOODCHILD
University of California-Santa Barbara, Santa Barbara, CA, USA

Definition

A field (or continuous field) is defined as a mapping from location **x** to a function *f*. In modeling geographic phenomena the domain of **x** is most often the two dimensions of geographic space, but may include the third spatial dimension for applications that extend above or below the Earth's surface, and may include time for dynamic phenomena. Fields can also be defined on one-dimensional networks embedded in two- or three-dimensional space. Moreover, most applications are limited to a specified sub-domain of geographic space, such as the limits of a country or county, or of a map sheet or arbitrarily defined study area. The domain of *f* includes scalar measurements on interval and ratio scales, nominal and ordinal classifications, and vectors describing such directional phenomena as wind or topographic gradient. Field-based spatial modeling can in principle be employed in the representation of any space, including the spaces of the human brain, the surfaces of other planets, or complex buildings.

Fields are one of two ways of conceptualizing the geographic world. By contrast, the discrete-object conceptualization imagines a world that is empty except where it is occupied by discrete, countable objects that maintain identity and geometric form through time. This conceptualization is more often adopted in the representation of biological organisms, manufactured objects, and man-made structures, whereas the continuous-field conceptualization is more appropriate for variables that can be defined at every location in space, such as air temperature, terrain height, soil moisture content, or wind speed.

Historical Background

The field/object distinction has ancient roots. Its significance for geographic information science was first recognized in the late 1980s and early 1990s [1,3], and it has come to be acknowledged as the most important distinction underpinning the entire field of geographic data modeling [5,7]. Consider, for example, the section of the US county boundary map shown in Fig. 1. If counties are regarded as discrete objects then one should be able to move them around as pieces of a jigsaw, possibly overlapping and modifying the coastline of the US, as shown on the left. On the other hand if the variable *county* is regarded as a single-valued function of location **x**, defined everywhere inside the boundary of the US, then the boundaries merely indicate where the value of *county* changes. Edits that move common boundaries are feasible, but not edits that move the coastline, or edits such as that shown, which attempts to move vertices of the boundary outside the coastline. Conceptualizing the phenomenon as a field clearly results in a more consistent representation that is more appropriate to the nature of the phenomenon.

Figure 2 shows an area-class map, depicting the variation in vegetation cover class across a geographic domain. If such a map were conceptualized as a collection of discrete objects, then the issue of accuracy would come down to such questions as "Is the number of areas correct?," "Are the boundaries in the correct places?," and "Are the classes assigned to each area correct?" However uncertainty would be addressed very differently under a field conceptualization; one could ask only one form of question, "Is the value recorded at **x** correct?" It turns out that this second conceptualization is far more productive and tractable than the first [8].

Strong associations have been recognized between the two alternative conceptualizations and patterns of human thought. Many would argue that the discrete-object view is more compatible with human cognition – that human brains are in effect hard-wired to segment any visual image into a collection of discrete objects, and to track their movements through time. On the other hand the continuous-field view underlies many of the most significant advances in science, including electro-magnetism (the Maxwell equations), hydrodynamics (the Navier-Stokes equation), and quantum mechanics (the Schrödinger equation). Some of the most challenging problems in science are described in partial differential equations defined on fields, and solved using a variety of computational methods. The distinction is strongly linked to concepts of scale, as for example when the behavior of a group of ants is modeled at very detailed scale as interactions between discrete objects, or at a coarser scale as modifications to a continuous field of ant density. Very crudely, continuous-field conceptualizations tend to be more common in the natural and physical sciences, while discrete-object conceptualizations are more often found with reference to social phenomena.

Foundations

Computers are fundamentally discrete machines, founded on the representation of information in a two-valued alphabet, and as a result discrete-object conceptualizations are more readily implemented in spatial databases. There is little ambiguity, for example, in the representation of the current location of every aircraft in an airline's fleet as a point in space. However other phenomena are inherently continuous across space, including terrain, rivers, roads, and the tracks of moving objects, and their representation necessarily involves some form of discretization. A river, for example, may be broken into reaches, either at junctions or at points where the direction of the river changes significantly. Each reach will be represented using a simple mathematical function, most often a straight

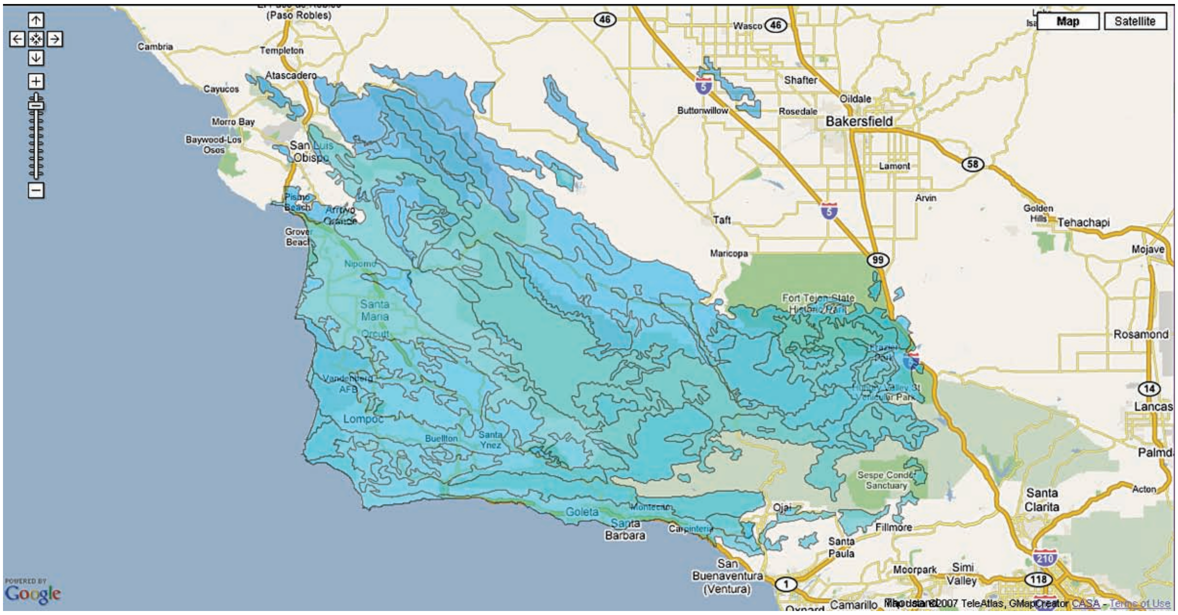
Field-Based Spatial Modeling. Figure 1. Counties conceptualized as (a) discrete objects and (b) a continuous field. As a discrete object, any county is free to move independently of its neighbors and the coastline. As a continuous field, however, only the common boundaries where county values change can be moved, and not so far as to intersect the coastline (the edit shown would not be accepted).

line but sometimes as an arc of a circle or a spline function. Roads in a road network may be broken into segments at intersections, or at other points where direction changes. These stages necessarily modify the phenomena they are used to represent, since the discretized object will in most cases differ geometrically from the original, and discretization is essential if a geometric shape that is potentially infinitely complex is to be represented in a digital store of finite capacity. Thus in almost all cases the representation of real-world geometry requires the loss of some degree of detail.

This stage of discretization is necessary whenever an arbitrarily shaped geographic feature must be represented in digital form. But a further stage is needed when the characteristics of the phenomenon also vary continuously over space, in other words in the representation of phenomena conceptualized as continuous fields. Figure 3 shows the six methods most commonly



Field-Based Spatial Modeling. Figure 2. A map of vegetation cover class conceptualized as a nominal field, superimposed on the Santa Barbara area. Each area denotes a particular type of vegetation.

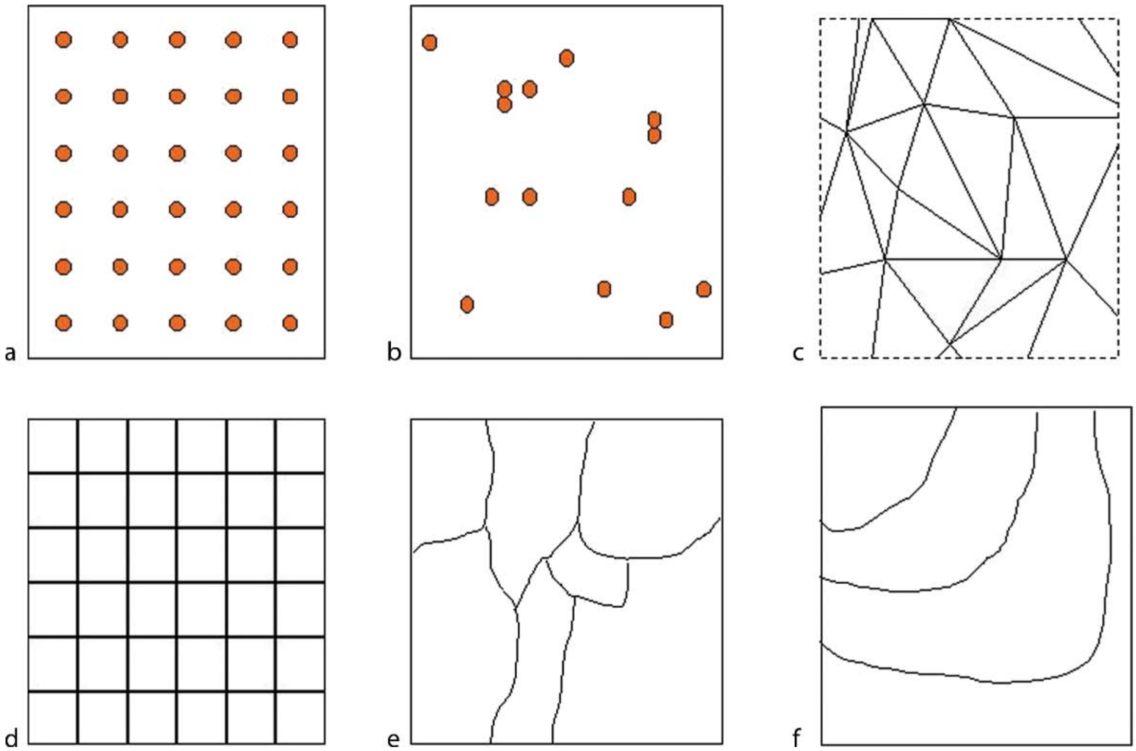
employed in spatial databases and geographic information systems. Two are based on a raster, in other words the discretization of space into a regular array with finite spacing, while the remaining four use vector methods, specifying the position of each element of the discretization as coordinates and representing volumes as collections of polygonal faces, areas as polygons, and lines as polylines.

Figure 3a shows one of the raster options, the representation of a spatially continuous phenomenon as a collection of sample values regularly spaced over a rectangular array. This is the method most commonly employed in the representation of terrain, in what are known as digital elevation models (DEMs). The spacing of sample heights implies a well-defined level of spatial resolution. Note, however, that since it is impossible to lay a rectangular grid over a curved surface, it is similarly impossible to construct a DEM of a significant part of the Earth's surface with a precisely constant spatial resolution.

Figure 3d shows the other raster option. Here the study area has been divided into rectangular cells, and a single measurement provided in each cell. This is often the mean value in the case of measurements on interval and ratio scales, but in other cases may be a modal value or some more complex function of the values of the field within the cell. Again spatial resolution is constant and well defined. This approach is most commonly encountered in the discretization of images, such as those obtained from satellites.

Figure 3b shows a vector option. In this case the field has been sampled at a set of irregularly spaced locations, and the value of f reported. Sample locations may be selected using some specified rule, or may be a historic artifact, as they are in the case of weather data, when the points correspond to weather-observation stations. Nothing is known about the values of f between sample locations, though a wide range of techniques exist for making intelligent guesses under the rubric of spatial interpolation.

Figure 3c shows another vector option involving irregularly spaced sample points, though in this case a set of triangles have been created by connecting them. The field variable is assumed to vary linearly between points, ensuring continuity of value across triangle edges. In essence this option, which is generally known as a triangulated irregular network (TIN) or triangular mesh, adds a specific method of spatial interpolation to Option 3b. It is commonly used as a method for representing terrain, where it is particularly efficient for terrains characterized by long uniform slopes and sharp ridges; and as an internal representation in contouring algorithms.



Field-Based Spatial Modeling. Figure 3. The six common methods of discretizing a field. See text for explanation.

Figure 3e shows the discretization of a field as a collection of space-exhausting, non-overlapping areas, that will themselves be discretized geometrically as polygons. The field variable is assumed uniform within each area. This is the most common discretization when the field variable is nominal or ordinal, as it is for maps of soil class and land cover class for example. It is also commonly used to represent data collected by statistical agencies and aggregated by reporting zones such as counties or census tracts. In such cases, the number of variables recorded for each reporting zone may be very large. For some of these variables, termed spatially intensive, the value reported will represent the mean within the zone of a variable such as average income, or a proportion such as percent black, or a density per unit area. In other cases the reported value will be a total, such as total population or total income, corresponding to the integration of a density over the reporting zone's area; this type of value is termed spatially extensive.

Finally, Fig. 3f shows the last example, in which the field is represented as a collection of digitized isolines. This method is commonly used to capture the contours shown on topographic maps. While it is effective for visual purposes, its value from an analytic perspective is far less than the DEM or TIN because of the very uneven sampling that is achieved.

Key Applications

Many examples of phenomena conceptualized as fields have already been cited; this section addresses the functions that are commonly applied to field representations, and the software that implements them. The functions described in this section are commonly found in GIS packages, and they and many others are reviewed by De Smith, Goodchild, and Longley [2].

A variety of functions are available to manipulate representations of topography. Most use the DEM option (3a) though very powerful algorithms have been described for similar operations on TINs. Visualization is a common requirement, and functions have been developed to compute surface gradient and hence simulated illumination; to compute and plot isolines; and to compute solar insolation as a key variable in understanding vegetation patterns on rugged topography. Another class of algorithms concern visibility, and can be used to compute the area visible by an observer positioned a given height above the terrain. Algorithms have been described for computing the most exposed and most concealed points on a landscape, as well as most exposed and most concealed routes; and to position a minimal number of observers such that the entire landscape can be observed.

Another important collection of algorithms concerns drainage. Starting with a DEM, it is possible to compute drainage directions as a vector field, and to integrate these into catchments and stream channels. DEMs are used to predict and manage flooding, and to plan modifications to the landscape such as the construction of levees.

Reference was made earlier to methods of spatial interpolation, which address the task of predicting the value of a field at locations where it has not been measured. Most often these methods are applied to the representations illustrated in Fig. 3a and 3b, but a related technique known as areal interpolation has been devised for the task of predicting the values associated with areas that do not match (cut across the boundaries of) the reported areas of 3d and 3e.

Of particular interest are algorithms that produce representations of fields from collections of discrete objects. They include density estimation, which produces a field of feature density, most often of points; and calculation of the distance from any point in the plane to the nearest of a collection of discrete objects.

The most powerful collections of field-based manipulation functions clearly exist for raster data, because of the possibility that a collection of fields can be represented using a set of co-registered rasters. This is the principle of raster GIS, most clearly illustrated by packages with firm roots in raster-based discretizations, such as Idrisi and GRASS. Most have adopted a common language for expressing instructions known as map algebra [6]. A powerful alternative geared particularly to simulation is PCRaster (http://pcraster.geo.uu.nl), developed at the University of Utrecht and having its own manipulation language that is considerably more succinct and powerful than map algebra.

Future Directions

The comparative importance of continuous fields and discrete objects is a matter of continual debate. On the one hand, the majority of GIS applications occur in worlds where the objects of interest are well-defined and often man-made. On the other hand, many phenomena in the natural world are essentially continuous, and representing them as collections of discrete objects invites error and misuse. Cognitive scientists would argue that humans are hard-wired to see the world as a collection of discrete objects, while environmental scientists might argue that continuous fields are one of the most significant breakthroughs in the history of science, lying at the root of such developments as the calculus and hydrodynamics. Many of the forms of analysis commonly used in the environmental sciences are based on fields; while most of those commonly used in the social sciences are based on discrete objects.

GIS software today embraces both conceptualizations. But it does so in a somewhat unsatisfactory manner, in which representations of continuous fields must be reduced to collections of discrete objects, without any record of that process of reduction. Thus it is impossible for the user of a GIS database to enquire whether a collection of points in the database represents a set of points sampling a field, or a set of isolated point-like objects in an otherwise empty space. Unfortunately this means that inappropriate operations can easily be performed. Nothing prevents the GIS user from applying spatial interpolation to points conceptualized as discrete objects, or from computing a density field of sample points; the former is of course more disastrous than the latter. Similarly nothing prevents a GIS user from moving an isoline so that it crosses another, or from making two polygons in a Fig. 3e representation overlap.

Several interesting and potentially powerful research directions have been pursued in the hope of eventually improving this situation. One approach has been to argue that the user should be able to interact with the concept of a field directly, rather than with the elements of one of the six representations of Fig. 3 as at present. Another has been to search for a visual paradigm for handling fields that matches and has similar power to the visual representation of sets of discrete objects that is found in UML (Unified Modeling Language) and related methods. Now that GIS technology includes the capability to design databases in UML and to create and populate the necessary tables automatically, it would make good sense to develop parallel methods for handling fields. Finally, much recent effort has gone into finding ways of reconciling and bridging the field/object dichotomy [4].

First-Order Logic: Semantics

VAL TANNEN
University of Pennsylvania, Philadelphia, PA, USA

Synonyms

Predicate calculus; Predicate logic
FOL

Definition

This entry should be read in conjunction with the companion entry *First-Order Logic: Syntax* where the terms vocabulary, variable, formula, etc. are defined.

To give semantics to first-order sentences, first-order *structures* (a.k.a. models or interpretations), and the "*holds true*" (a.k.a. satisfaction or validity) relationship is used between sentences and structures. Both are detailed below. This allows the definition of *logical consequence* (a.k.a. logical implication), $\Gamma \models \varphi$, whose meaning is that the sentence φ holds true in any structure in which the sentences in the set Γ hold true. Proof systems for first-order logic should be assessed against logical consequence whether *sound* and/or *complete*. The semantic of FOL is also used for *definability*, a concept that helps understanding the limitations of formalisms based on FOL.

As introduced by E. F. Codd into database technology, the *relational model* is based on finite first-order structures for a vocabulary that has only relational symbols.

Key Points

Fix a first-order vocabulary. A *structure* $\mathcal{A}$ for this vocabulary consists of a non-empty set A (sometimes called the "universe (of discourse)" of the structure) together with a mapping that assigns to every symbol s in the vocabulary a corresponding *meaning* $s^{\mathcal{A}}$ over A. For constants c, $c^{\mathcal{A}}$ is just an element of A, for n-ary relation symbols R, $R^{\mathcal{A}}$ is an n-ary relation over A (i.e., a subset of A^n), and for n-ary function symbols f one has a function $f^{\mathcal{A}} : A^n \to A$.

Next, the goal is to define when a sentence φ *holds true* in a structure $\mathcal{A}$, written $\mathcal{A} \models \varphi$. To do this, one should use *assignments*, which are partial functions from the set of all variables to the universe A of $\mathcal{A}$. It

$$\begin{array}{rcl} \bar{\mu}(x) & = & \mu(x) \\ \bar{\mu}(c) & = & c^{\mathcal{A}} \end{array} \qquad \bar{\mu}(f(t_1,\ldots,t_n)) \;=\; f^{\mathcal{A}}(\bar{\mu}(t_1),\ldots,\bar{\mu}(t_n))$$

$$\begin{array}{rll} \mathcal{A},\mu \models t_1 = t_n & \textit{iff} & \bar{\mu}(\mathrm{t}_1) = \bar{\mu}(\mathrm{t}_2) \\ \mathcal{A},\mu \models \textit{true} & & \\ \mathcal{A},\mu \models \varphi_1 \vee \varphi_2 & \textit{iff} & \mathcal{A},\mu \models \varphi_1 \text{ or } \mathrm{A},\mu \models \varphi_2 \\ \mathcal{A},\mu \models \neg\varphi & \textit{iff} & \mathcal{A},\mu \not\models \varphi \end{array} \qquad \begin{array}{rll} \mathcal{A},\mu \models R(t_1,\ldots,t_n) & \textit{iff} & (\bar{\mu}(t_1),\ldots,\bar{\mu}(tn)) \in R^{\mathcal{A}} \\ \mathcal{A},\mu \not\models \textit{false} & & \\ \mathcal{A},\mu \models \varphi_1 \wedge \varphi_2 & \textit{iff} & \mathcal{A},\mu \models \varphi_1 \text{ and } \mathcal{A},\mu| = \varphi_2 \\ \mathcal{A},\mu \models \varphi_1 \rightarrow \varphi_2 & \textit{iff} & \mathcal{A},\mu \models \varphi_2 \text{ whenever } \mathcal{A},\ \mu \models \varphi_1 \end{array}$$

$$\begin{array}{rll} \mathcal{A},\mu \models \exists x\,\varphi & \textit{iff} & \textit{there is } a \in A \text{ such that } \mathcal{A},\mu[x := a] \models \varphi \\ \mathcal{A},\mu \models \forall x\,\varphi & \textit{iff} & \textit{for each } a \in A,\ \mathcal{A},\mu[x := a] \models \varphi \end{array}$$

suffices to consider assignments of finite domain (defined only on finitely many variables). By extending assignments $\mu\ :Vars{\rightarrow}A$ to $\bar{\mu}\ :Terms\ \rightarrow\ A$, define $\mathcal{A},\mu \models \varphi$ where φ is a formula and such that μ is defined on (at least) all the free variables of φ:
where $\mu[x := a]$ is the same as μ except that $\mu[x := a]$ $(x) = a$. The definition above is uncomfortably "circular" if one thinks of FOL or other logical formalisms as part of a foundation for mathematics. But this definition of truth is part of a more useful point of view, due to Hilbert and Tarski, in which logic is a mathematical symbol "game" and one can use ordinary math to study it (this use of math is called "metamathematics").

If φ is a sentence it is possible to define when it holds in a structure $\mathcal{A}$: $\mathcal{A} \models \varphi$ means $\mathcal{A}, \emptyset \models \varphi$ where $\emptyset$ is the assignment defined nowhere (empty domain). A sentence is *valid* if it holds in all structures. At first validity seems computationally absurd (there isn't even a "set of all structures", because Russell's Paradox would be lurking in the fold). However, a very important result in metamathematics, Gödel's Completeness Theorem [2], shows that validity is equivalent to provability in one of the many equivalent proof systems for FOL. It follows that the set of all valid sentences is in fact recursively enumerable (r.e.), a reasonable foundation for attempting automated theorem-proving for FOL. However, Church and Turing have shown that validity is undecidable [2], an important inherent limitation that also affects applications to databases.

In fact, Gödel's Completeness Theorem shows more. If Γ is a set of sentences and φ a sentence, one defines *logical consequence* by

$$\Gamma \models \varphi \quad \textit{iff} \quad \textit{for all } \mathcal{A},\ \textit{if } \mathcal{A} \models \psi \textit{ for each } \psi \in \Gamma \textit{ then } \mathcal{A} \models \varphi$$

Fix a proof system with provability relation ⊢. The proof system is *sound* if $\Gamma \vdash \varphi$ implies $\Gamma \models \varphi$ and is *complete* if $\Gamma \models \varphi$ implies $\Gamma \vdash \varphi$. Gödel's Completeness Theorem shows that any of the equivalent proof systems for FOL is sound and complete.

A sentence is *finitely valid* if it holds in all finite structures. Finite validity is co-r.e. (just enumerate finite structures up to isomorphism). However, Trakhtenbrot's Theorem [3] shows that it is undecidable, hence it cannot be r.e. (in fact, it shows that it is co-r.e.-complete). Therefore, one cannot hope to find a sound and complete proof system for just the finitely valid sentences.

Finally, consider a structure $\mathcal{A}$ and an n-ary relation $D \subseteq A^n$. Say that D is *first-order definable in* $\mathcal{A}$ if there exists an FOL formula φ with exactly n distinct free variables $x_1,\ldots,x_n$ such that

$$\textit{for all } a_1,\ldots,a_n \in A, \qquad (a_1,\ldots,a_n) \in D \quad \textit{iff} \\ \mathcal{A}, [x_1 := a_1,\ldots,x_n := a_n] \models \varphi$$

Definability in a given structure is trivial if the structure is finite. For finite structures look at the definability of *queries*.

First-Order Logic: Syntax

VAL TANNEN
University of Pennsylvania, Philadelphia, PA, USA

Synonyms

Predicate calculus; Predicate logic; FOL

Definition

First-order logic (FOL) is a formalization of the most common kind of mathematical reasoning. It is characterized by the *quantification* of *variables* that range over a "universe of discourse" (a set of values). Less complex reasoning is captured by *propositional* (a.k.a. Boolean or sentential) logic. More complex reasoning is captured by *second-order* or even *higher-order* logic.

The syntactic aspects of FOL comprise a *vocabulary* (a.k.a. language or signature), *formulae* and, in particular, *sentences* (a.k.a. assertions), and a *proof system* (one of many equivalent ones!), *structures* (a.k.a. models or interpretations), and the *satisfaction* (a.k.a. truth or validity or "holds in") relationship between sentences and structures. All are detailed below.

FOL is the source of the *relational* paradigm that was introduced by E. F. Codd in 1970 and has been dominating database technology for 30+ years.

Key Points

A first-order *vocabulary* consists of a set of *constant* symbols, for each integer $n \geq 0$ a set of n-ary *relation* (a.k.a. predicate) symbols, for each integer $n \geq 1$ a set of n-ary *function* symbols. For some authors the constants are the 0-ary function symbols. The 0-ary relation symbols are called "propositional constants" (although, in propositional logic they are called "variables"!). In addition, first-order vocabularies are often assumed to contain the equality symbol—a distinguished binary relation symbol – as well as *true* and *false* as distinguished propositional constants. For applications in Computer Science, these sets of symbols are usually finite.

Next, a vocabulary and an infinite set of *variables* are fixed. First-order *terms* are defined by the grammar

$$t ::= c \mid x \mid f(t_1,\ldots,t_n)$$

where c ranges over constants, x over variables, f over n-ary function symbols, and t, $1,\ldots,t_n$ over terms, for each integer $n \geq 1$. First-order *formulae* (sometimes called *well-formed formulae* of *wff's* are defined by the grammar

$$\begin{gathered}\varphi ::= R(t_1,\ldots,t_n) \mid t_1 = t_2 \mid \mathit{true} \mid \mathit{false} \mid \\ (\varphi_1 \vee \varphi_2) \mid (\varphi_1 \wedge \varphi_2) \mid (\neg\varphi) \mid \\ (\varphi_1 \rightarrow \varphi_2) \mid (\exists x\varphi) \mid (\forall x\varphi)\end{gathered}$$

where R ranges over n-ary relation symbols, t_1, $t_2,\ldots,t_n$ over terms (for each integer $n \geq 0$), x over variables, and φ, φ_1, φ_2 over formulae. Formulae of the form $R(t_1,\ldots,t_n)$, $t_1 = t_2$, *true* or *false* are called *atoms* (a.k.a atomic formulae). The logical connectives for disjunction, conjunction, negation, and implication are as in propositional logic. Characteristic of first-order logic is *existential* ($\exists$) and *universal* ($\forall$) quantification with variables x ranging over a "universe of discourse". The parentheses are typically omitted based on simple precedence and associativity rules.

Next, one defines when a variable x *is free* (a.k.a. "occurs free") in a formula φ (inductively on the syntax of φ): (i) if α is an atom, then x is free in it iff it is used to build one of the terms that make up α; (ii) x is free in $(\varphi_1 \vee \varphi_2)$ or in $(\varphi_1 \wedge \varphi_2)$ or in $(\varphi_1 \rightarrow \varphi_2)$ iff it is free in φ_1 or in φ_2; (iii) x is free in (φ) iff it is free in φ; (iv) x is free in $(\exists y\, \varphi)$ or $(\forall y, \varphi)$ iff it is free in$\varphi$and $x \neq y$. Every formula has a finite set of variables that occur syntactically in it. Some of these are free, as defined above. The others are called *bound* because they must appear in some quantified subformula: $(\exists y\, \psi)$ or $(\forall y\, \psi)$, in which case it is said that ψ is the *scope* of the (bound) quantified variable y. For clarity, it is good practice to use fresh variables for each quantification. However, this is not required by the definition, for example

$$\begin{aligned}\exists x\, E(a,x) \wedge (\exists y\, E(x,y) \wedge (\exists x\, E(y,x) \\ \wedge (\exists y\, E(x,y) \wedge E(y,b))))\end{aligned}$$

says that there exists a path of length five from vertex a to vertex b in a directed graph with edge relation E, and it does so with only two bound variables although there are four intermediate vertices. Bound variable "reusing" can be exploited, see *finite variable logics* [3].

A formula without free variables is called a *sentence*. Sentences are logical assertions that may or may not be *true* by themselves. However, to give them meaning, one needs to give meaning more generally to formulae.

Still part of the syntax of FOL are the *proof systems* which describe effective procedures for deriving sentences from other sentences. A common style of proof system, due to Hilbert, uses sentences that are asserted as *axioms*, such as *tautologies* from propositional logic (eg., De Morgan's Laws) or the *substitution* axioms ($\forall x\varphi \rightarrow \varphi[x := t]$ where $\varphi[x := t]$ is the result of substituting every free occurrence of x in φ with the term t) and *inference rules* such as *modus ponens* (from φ and $\varphi\rightarrow \psi$ infer ψ). In such a system, a proof is a list of sentences such that each of them is either an axiom or is inferred by some rule from previously listed sentences. The proof is for the last sentence in the list. The sentences proved in a proof system are called *theorems*. More generally, a proof system defines a *provability* (a.k.a. inference or derivability) relationship between sentences φ and sets Γ of sentences: $\Gamma \vdash \varphi$ iff there exists a proof of φ that can use sentences in Γ as additional axioms (in particular, φ is a theorem iff $\emptyset \vdash \varphi$.

Quite a few styles of proof systems have been proposed, for FOL and for other logics, moreover the choice of axioms/rules often varies within each style. Of course, all the proof systems for FOL have been shown to be equivalent, that is, they define the same provability relationship, in particular the same theorems. More importantly, all proof systems are characterized by the following; (i) proofs are finite objects; (ii) it is decidable whether a proof is correctly formed; (iii) the proved sentence is totally computable from the proof. It follows that the theorems of FOL form a recursively enumerable set (although, by the result of Church and Turing, not a decidable one).

Synonyms

Constant span

Definition

A time span is *fixed* if it possesses the special property that its duration is independent of the assumed context.

Key Points

As an example of a fixed span, "one hour" always, assuming a setting without leap seconds, has a duration of 60 minutes. To see that not all spans are fixed, consider "one month," which is a prime example of a variable span in the Gregorian calendar. The duration of this span may be any of 28, 29, 30, and 31 days, depending on the context, i.e., the specific month.

Flex Transactions

Aidong Zhang[1], Bharat Bhargava[2]
[1]State University of New York at Buffalo, Buffalo, NY, USA
[2]Purdue University, West Lafayette, IN, USA

Synonyms

Flexible transactions; S-transactions; ConTracts

Definition

In database systems, a *transaction* is a sequence of actions performed on data items in a database. In a distributed database environment, a *global transaction* is a set of subtransactions, where each *subtransaction* is a transaction accessing the data items at a single local site. The flex transaction model supports flexible execution control flow by specifying two types of dependencies among the subtransactions of a global transaction: (i) execution ordering dependencies between two subtransactions, and (ii) alternative dependencies between two subsets of subtransactions.

Key Points

Flexible transaction models, such as ConTracts, Flex Transactions, S-transactions, and others [1–3], increase the failure resilience of global transactions by allowing alternate subtransactions to be executed when a local database site fails or a subtransaction aborts. In a non-flexible transaction, a global subtransaction abort is followed either by a global transaction abort decision or by a retry of the global subtransaction. With the flexible transaction model, there is an additional option of switching to an alternate global transaction execution. The alternative global transaction execution is achieved by executing alternative or contingency transactions.

Flexibility allows a flexible transaction to adhere to a weaker form of atomicity, termed *semi-atomicity*, while still maintaining its correct execution in the distributed database environment. Semi-atomicity allows a flexible transaction to commit as long as a subset of its subtransactions that can represents the execution of the entire flexible transaction commit. Flexible transactions, S-tractions, and ConTracts are instances of Open-nested Transaction Model. The following example is illustrative:

A client at bank b_1 wishes to withdraw \$50 from her savings account a_1 and deposit it in her friend's checking account a_2 in bank b_2. If this is not possible, she will deposit the \$50 in her own checking account a_3 in bank b_3. With flexible transactions, this is represented by the following set of subtransactions:

t_1: Withdraw \$50 from savings account a_1 in bank b_1
t_2: Deposit \$50 in checking account a_2 in bank b_2
t_3: Deposit \$50 in checking account a_3 in bank b_3

In this global transaction, either $\{t_1,t_2\}$ or $\{t_1,t_3\}$ is acceptable, with t_3 being a contingency of t_2 but $\{t_1,t_2\}$ preferred. If t_2 fails, t_3 may replace t_2. The entire global transaction thus may not have to be aborted even if t_2 fails.

Definition

Given a multi-set S of values from a domain $\mathcal{D}$, the *distinct-values estimation* problem is to estimate the number of distinct values in S, using only one pass over S and only small working space. The *FM Synopsis* algorithm, developed by Flajolet and Martin in the mid-1980s [7], provides provably accurate distinct-values estimation using only $O(\log(|\mathcal{D}|))$ space. The basic technique makes use of a hash function $h()$ that maps each value in $\mathcal{D}$ to one of $m \approx \log(|\mathcal{D}|)$ bit positions, according to a geometric distribution. Specifically, $h()$ maps half the values in $\mathcal{D}$ to position 0, one-quarter of the values in $\mathcal{D}$ to position 1, one-eighth of the values in to position 2, and so on. The steps of the FM Synopsis algorithm are:

1. Initialize a bit vector M of m bits to all 0s.
2. For each item in S do: Set $M[h(v)]$ to 1, where $v \in \mathcal{D}$ is the value of the item.
3. Estimate the number of distinct values as $2^Z/.77351$, where Z is the position of the least significant unset bit in M.

To reduce the variance in this estimator, Flajolet and Martin take the average over tens of applications of this procedure, with different random hash functions $h()$.

Historical Background

Distinct-values estimation was one of the first non-trivial data stream problems studied. A decade before data stream synopsis structures and their desirata were defined and popularized, the FM Synopsis met the desirata for a data stream synopsis structure: (i) it needs only one pass through the data, (ii) it yields highly accurate answers regardless of the data distribution, (iii) it takes only logarithmic space, and (iv) it requires only constant per-item processing time and only constant time to produce an estimate given the synopsis structure.

Prior to the popularization of the FM Synopsis algorithm, a common approach for estimating the number of distinct values in a multi-set S was to collect a random sample of S and then apply sophisticated estimators based on the distribution of the values in the sample [2]. However, all known sampling-based estimators provide unsatisfactory results on some data sets of interest, and moreover, estimating the number of distinct values within a small constant factor (with probability $> \frac{1}{2}$) requires (in the worst case) that *nearly all of S be sampled* [3]. Thus, streaming approaches, such as the FM Synopsis algorithm, are preferred over sampling-based approaches, whenever feasible.

Recent work has built upon the FM Synopsis approach, improving the accuracy guarantees on the estimation, proving lower bounds, and considering other settings such as sliding windows and distributed streams.

Foundations

Figure 1 depicts two data sets, S_1 and S_2, where the number of distinct values, also called the zeroth frequency moment F_0, is 15 for S_1 and 6 for S_2. These data sets can help illustrate the challenges of sampling-based estimators for F_0. Consider the following 33% sample of a data set of 24 items:

A, T, A, R, E, T, P, H

Given this 33% sample (with its 6 distinct values), does the entire data set have 6 distinct values, 18 distinct values (i.e., the 33% sample has 33% of the distinct values), or something in between? Note that this particular sample can be obtained by taking every third item of either S_1 (where $F_0 = 15$) or S_2 (where $F_0 = 6$) from Fig. 1. Thus, despite sampling a large (33%) percentage of the data, estimating F_0 remains challenging, because the sample can be viewed as fairly representative of either S_1 or S_2 – two data sets with very different F_0s.

Data set S_1: R, X, A, D, A, T, Y, R, A, A, T, R, T, U, E, A, C, T, F, L, P, B, V, H

Data set S_2: T, A, A, R, H, T, A, T, A, E, T, R, A, T, E, P, H, T, R, P, P, E, A, H

FM Synopsis. Figure 1. Two example data sets of $n = 24$ items from a domain $\mathcal{D} = \{A, B, \ldots, Z\}$.

Now consider the FM Synopsis algorithm outlined above. Using a hash function ensures that all items with the same value will select the same bit position; thus the final bit vector M is independent of any duplications among the item values. Flajolet and Martin's analysis assumes an idealized random hash function that maps each value $v \in \mathcal{D}$ to a bit position $b \in [0..m-1]$ such that $b = i \in [0..m-2]$ with probability $2^{-(i+1)}$ and $b = m-1$ with probability $2^{-(m-1)}$. Accordingly, $M[i]$ is expected to be set if there are at least 2^{i+1} distinct values. Because bit $Z-1$ is set but not bit Z, there are likely greater than 2^Z but fewer than 2^{Z+1} distinct values. Flajolet and Martin's analysis shows that $E[Z] \approx log_2(.77351 \cdot F_0)$, so that $2^Z/.77351$ is a good choice in that range.

To reduce the variance in the estimator, Flajolet and Martin take the average over tens of applications of this procedure (with different hash functions). Specifically, they take the average, $\bar{Z}$, of the Z's for different hash functions and then compute $\lfloor 2^{\bar{Z}}/.77351 \rfloor$. An example is given in Fig. 2.

The error guarantee, space bound, and time bound are summarized in Theorem 1. The space bound does not include the space for representing the hash functions, and the time bound assumes that computing $h(v)$ is a constant time operation.

Theorem 1 [7] *Consider a multi-set* S *of* n *items with values from a domain* $\mathcal{D}$. *The FM Synopsis algorithm with* k *(idealized) hash functions produces a distinct-values estimator with standard error* $O(1/\sqrt{k})$, *using* k · m *memory bits for the bit vectors, for any* $m > \log_2(\min(n, |\mathcal{D}|)) + 4$. *For each item, the algorithm performs* O(k) *operations on memory words of at most* $\max(m, \log_2(|\mathcal{D}|))$ *bits.*

Optimizations

The space needed for the k bit vectors, $M_1[\cdot], M_2[\cdot],\ldots, M_k[\cdot]$, can be significantly reduced, using the following simple compression technique [4,7,10]. Note that at any point during the processing of the data set, each bit vector $M_j[\cdot]$ consists of three parts, where the first part is all 0s, the second part (the *fringe*) is a mix of 0s and 1s, and the third part is all 1s (as in Fig. 2). Moreover, the bit vectors are likely to share many bits in common, because each $M_j[\cdot]$ is constructed using the same algorithm on the same data. The technique is to interleave the bits, as follows:

$$M_1[m-1], M_2[m-1], \ldots, M_k[m-1],$$
$$M_1[m-2], \ldots, M_k[m-2], \ldots, M_1[0], \ldots, M_k[0],$$

and then run-length encode the resulting bit vector's prefix of all 0s and suffix of all 1s. Specifically, a simple encoding scheme is used that ignores the all 0s prefix and consists of (i) the interleaved bits between the all 0s prefix and the all 1s suffix and (ii) a count of the length of the all 1s suffix. An example is given in Fig. 3. Note that the interleaved fringe starts with the maximum bit set among the k fringes and ends with their minimum unset bit. Each fringe is likely to be tightly centered around the current $\log_2(F_0)$, e.g., for a given hash function and $c > 0$, the probability that no bit than $\log_2(F_0)$ + c or larger is set is $(1 - 2^{-(\log_2(F_0)+c)})^{F_0} \approx e^{-1/2^c}$. At any point in the processing of the data set, a similar

Item number	Item value *v*	Hash function 1 b	Hash function 1 $M_1[\cdot]$	Hash function 2 b	Hash function 2 $M_2[\cdot]$	Hash function 3 b	Hash function 3 $M_3[\cdot]$
1.	R	1	000010	1	000010	0	000001
2.	X	0	000011	2	000110	0	000001
3.	A	0	000011	1	000110	0	000001
4.	D	0	000011	0	000111	0	000001
5.	A	0	000011	1	000111	0	000001
6.	T	1	000011	0	000111	1	000011
7.	Y	3	001011	0	000111	1	000011
8.	R	1	001011	1	000111	0	000011
			$Z = 2$		$Z = 3$		$Z = 2$

The estimate for F_0 is $\left\lfloor \frac{2^{(2+3+2)/3}}{.77351} \right\rfloor = 6.$

FM Synopsis. Figure 2. Example run of the FM Synopsis algorithm on the first 8 items of S_1, using $k = 3$ hash functions. Each bit vector $M[\cdot]$ is $m = 6$ bits long, with $M[0]$ being the rightmost bit (the least significant bit). The estimate, 6, matches the number of distinct values in the first 8 items of S_1.

argument shows that the interleaved fringe is expected to be fewer than $O(\mathrm{k} \log \mathrm{k})$ bits. Also, the count of the all 1s suffix is at most $k \cdot m$. Thus, the encoding is expected to use fewer than $\log_2 m + O(k \log k)$ bits.

The number of operations per data item can be reduced from $O(k)$ to $O(1)$, using a variant of the FM Synopsis algorithm called *Probabilistic Counting with Stochastic Averaging (PCSA)* [7]. In the PCSA algorithm (see Fig. 4), k bit vectors are used (for k a power of 2) but only a single hash function g(). The (idealized) random hash function g() is assumed to map each value $v \in \mathcal{D}$ to a uniformly random value in $\mathcal{D}$. For each data item with value v, the $\log_2 k$ least significant bits of $g(v)$ are used to select a bit vector. Then the remaining $m - \log_2 k$ bits of $g(v)$ are used to select a position within that bit vector, according to a geometric distribution (as in the basic FM Synopsis algorithm). To compute an estimate, PCSA averages over the positions of the least significant 0-bits, computes 2 to the power of that average, and divides by the bias factor .77351. To compensate for the fact that each bit vector has seen only $1/k$th of the distinct items on average, the estimate is multiplied by k.

The error guarantee, space bound, and time bound are summarized in the following theorem. The space bound does not include the space for representing the hash function. The time bound assumes that computing g and b are constant time operations. Although some of the operations use only m-bit words, the word size is dominated by the $\log_2 n$ bits for the item value v. The analysis assumes that the bit vectors are compressed using the optimization in Fig. 3.

Theorem 2 *Consider a multi-set S of n items with values from a domain $\mathcal{D}$. The PCSA algorithm with* k *bit vectors and an (idealized) hash function produces a distinct-values estimator with standard error* $0.78/\sqrt{k}$, *using an expected* $\log_2 m + O(k \log k)$ *memory bits for the bit vectors, for any* $m > \log_2(\min(n, |\mathcal{D}|)/k) + 4$. *For each item, the algorithm performs* $O(1)$ *operations on memory words of at most* $\max(m, \log_2(|\mathcal{D}|))$ *bits.*

Extensions

There has been considerable follow-on work since the introduction of the FM Synopsis algorithm. Some highlights are provided below; further details can be found in [8].

Alon, Matias and Szegedy [1] showed how a variant of the FM Synopsis algorithm could obtain guaranteed accuracy without the assumption of idealized hash functions. Specifically, they consider standard *linear hash functions* of the form $g(v) = a \cdot v + b$, where a and b are chosen uniformly and independently at random from a suitable range and all arithmetic is computed modulo that range. Their variant estimates F_0 as 2^R, where R is the position of the most significant bit that is set to 1. Moreover, it directly keeps track of the maximum position set to 1, instead of maintaining a bit vector.

Durand and Flajolet [5] presented a variant that uses only $\approx k \log_2 \log_2(\min(n, |\mathcal{D}|)/k)$ bits for its synopses and provides a standard error of $1.05/\sqrt{k}$, assuming idealized hash functions.

The FM Synopsis approach can be readily extended to handle item *deletions* by replacing each bit in $M[\cdot]$ with a running counter that is incremented on

```
     M_j[·]'s:   00001111, 00001011, 00000111, 00010111, 00011111, 00001111
  Interleaved:     000000000000000000000110110011101111111111111111
  End-encode:                        11011001110, 16
```

FM Synopsis. Figure 3. Example FM Synopsis compression, for $k = 6$ and $m = 8$.

```
1. for $j := 1,\ldots, k$ and $i := 0,\ldots,m - 1$ do $M_j[i] := 0$
2. for each item in $S$ do:
      $x := g(v) \bmod k$, where $v \in \mathcal{D}$ is the value of the item // Note: $k$ is a power of 2
      $b :=$ the largest $i \geq 0$ such that the $i$ rightmost bits in $\lfloor g(v)/k \rfloor$ are all 0
      $M_x[b] := 1$
3. return $\left\lfloor \frac{k}{.77351} 2^{\bar{Z}} \right\rfloor$, where $\bar{Z} := \frac{1}{k}\sum_{j=1}^{k} \min\{i : M_j[i] = 0\}$ // least significant unset bit
```

FM Synopsis. Figure 4. The PCSA algorithm [7].

insertions and decremented on deletions. This increases the synopsis space by a logarithmic factor. Similarly, the FM Synopsis approach can be extended to handle *sliding windows*, where the problem is to estimate the number of distinct values over a sliding window of the w most recent items, for some fixed w. The idea is to keep track of the sequence number of the most recent item that set each FM bit. Then, when estimating the number of distinct values within the current sliding window, only those FM bits whose associated sequence numbers are within the window are considered to be set. This too increases the synopsis space by a logarithmic factor. See [8] for an overview of algorithms that improve upon these basic schemes for deletions and sliding windows.

Finally, note that the FM Synopsis approach can be readily adapted to a *distributed* setting in which a set of observers each processes the portion of the multi-set S that it sees. The goal is to estimate the number of distinct values in S by (i) having each observer compute a small synopsis for the values it sees, and then (ii) combining the synopses to output a highly accurate estimate. The FM Synopsis algorithm is perfectly suited for this task. It can be applied to each data set portion independently, using the exact same hash function at all observers, to generate a bit vector $M[\cdot]$ for each portion. Because the same hash function is used by all observers, the bit-wise OR of their bit vectors yields the exact bit vector that would have been produced by running the FM Synopsis algorithm on any interleaving of the data portions. Thus, estimating F_0 from this bit-wise OR provides the same error guarantees as in the original algorithm. Moreover, the per-observer space bound and the per-item time bound also match the space and time bounds in Theorems 1 and 2.

Key Applications

Estimating the number of distinct values in a data set is a well-studied problem with many applications. The statistics literature refers to this as the problem of estimating the number of *species* or *classes* in a population. The problem has been extensively studied in the database literature, as a tool for summarizing the diversity of data values in a data set, both to help guide query optimization and to provide fast approximate answers to distinct-value queries (e.g., a select count(distinct) query in SQL). Distributed distinct-values estimators are useful for network resource monitoring, in order to estimate the number of distinct destination IP addresses, source-destination pairs, requested urls, etc. In network security monitoring, determining sources that send to many distinct destinations can help detect fast-spreading worms.

Distinct-values estimation can also be used as a general tool for duplicate-insensitive counting: Each item to be counted views its unique id as its "value," so that the number of distinct values equals the number of items to be counted. Duplicate-insensitive counting can be used to avoid double-counting items that are counted while in motion, to compute the number of distinct neighbors at a given hop-count in a network, and to compute the size of the transitive closure of a graph. In a sensor network, duplicate-insensitive counting together with multi-path in-network aggregation enables robust and energy-efficient answers to count queries [9]. Moreover, duplicate-insensitive counting is a building block for duplicate-insensitive computation of other aggregates, such as sum and average.

Experimental Results

The number of bit vectors, k, in the FM Synopsis algorithm is a tunable parameter trading off space for accuracy. The relative error as a function of k has been studied empirically in [4,7,9,10] and elsewhere, with $< 15\%$ relative error reported for $k = 20$ and $<10\%$ relative error reported for $k = 64$, on a variety of data sets. These studies show a strong diminishing return for increases in k. Theorems 1 and 2 show that the standard error is $O(1/\sqrt{k})$. Thus, reducing the standard error from 10% to 1% requires increasing k by a factor of 100! In general, to obtain a standard error at most ε it is required that $k = \Theta(1/\varepsilon^2)$. Estan, Varghese and Fisk [6] present a number of techniques for further improving the constants in the space versus error trade-off, including using multi-resolution and adaptive bit vectors.

[2]Yahoo! Inc., Santa Clara, CA, USA

Synonyms

Harmonic mean of recall and precision

Definition

Assume an information retrieval (IR) system has recall R and precision P on a test document collection and an information need. The *F-measure* of the system is defined as the weighted harmonic mean of its precision and recall, that is, $F = \frac{1}{\alpha\frac{1}{P}+(1-\alpha)\frac{1}{R}}$, where the weight $\alpha \in [0,1]$. The balanced F-measure, commonly denoted as F_1 or just F, equally weighs precision and recall, which means $\alpha = 1/2$. The F_1 measure can be written as $F_1 = \frac{2PR}{P+R}$.

Key Points

The F-measure can be viewed as a compromise between recall and precision. It is high only when both recall and precision are high. It is equivalent to recall when $\alpha = 0$ and precision when $\alpha = 1$. The F-measure assumes values in the interval [0,1]. It is 0 when no relevant documents have been retrieved, and is 1 if all retrieved documents are relevant and all relevant documents have been retrieved.

Synonyms

Web resource discovery; Topic-directed Web crawling

Definition

The world-wide Web can be modeled as a very large graph with nodes representing pages and edges representing hyperlinks. Thanks to dynamically generated content, the Web graph is infinitely large. Page content and hyperlinks change continually. Any centralized Web search service must first fetch a large number of Web pages over the Internet using a Web crawler, and then subject the local copies to indexing and other analysis. At any time during its execution, a Web crawler has a set of pages that have been fetched, and a frontier of unexplored hyperlinks encountered on fetched pages. Given finite network resources, it is critical for the crawler to choose carefully the subset of frontier hyperlinks it should fetch next. Depending on the application and user group, it may be beneficial to preferentially acquire pages that are highly linked, pages that pertain to specific topics, pages that are likely to mention specific structured information, pages that score highly with respect to queries submitted frequently to the search engine, pages that change frequently, and so on. Focused Web crawling is a generic term for employing hyperlink and text mining techniques to prioritize the crawl frontier to maximize the harvest of qualified or preferred pages, while minimizing communication and computation effort on other pages. The network resources thus saved may be used, for example, to monitor crawled pages more aggressively for changes. Focused Web crawling is commonly used to build vertical search services catering to one or few topical interests.

Historical Background

Despite giant leaps in communication, storage and computing power during the last decade, crawlers have always struggled to keep up with Web content generation and modification. The Web graph is actually infinite, owing to dynamically generated hyperlinks and pages. A crawler begins with URL references to a fraction of nodes in the Web graph. Many of these URLs are stale because the pages they referred to are inaccessible. The number of pages collected by the crawler makes little sense in this context, compared to which specific pages are collected.

Around 1997, researchers began to propose objectives that a crawler may seek to optimize, and several forms of crawl prioritization. Some objectives [8,14] were related to the Web graph structure. Others were determined by textual content of pages [4,12]. The term "focused crawling" is generally used for the latter class, although later generations of focused crawlers use all available features and clues [7,10,17,] to guide themselves, including workloads collected from query logs [15]. As of late 2007, work on prioritizing crawls and crawl refreshing continues apace, with increased stress on balancing resources between monitoring crawled pages for changes and discovering new sites and pages.

The success of focused Web crawling depends on benign patterns and regularities in the Web graph, which started to get seriously investigated as social network phenomena around 1999. The Web as a whole and many major communities have a strongly connected core of authoritative and popular pages [2,11]. Well-connected subgraphs of the Web are also likely to be topically coherent [6,9]. Without these helpful properties, focused crawlers cannot succeed.

Foundations

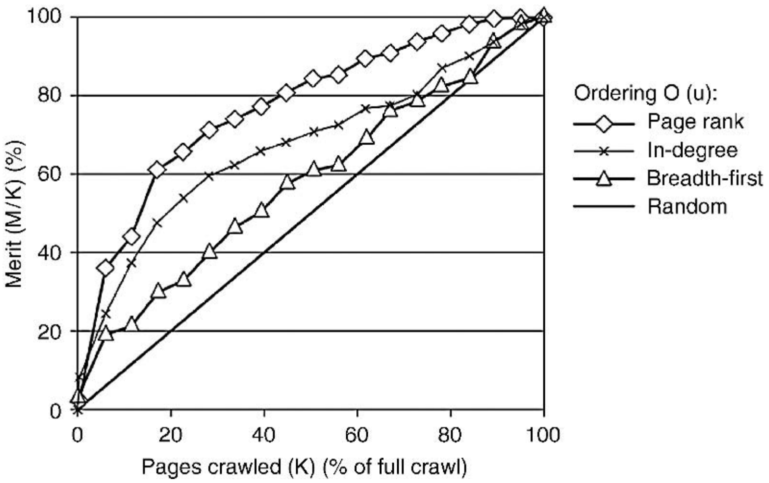
Setting Crawl Priorities Using Web Graph Properties

Initial work on focused Web crawling set reasonable fixed policies and evaluated their effect on various measures of crawl quality [8]. To characterize crawl quality, each page u is assigned an *importance* $I(u)$. For simplicity, one can initially assume that the crawler starts from just one URL u_0, and stops when K pages have been fetched. The perfect crawler collects K of the N pages reachable from u_0 by following hyperlinks with the largest possible importance. Let these "hot pages" have importance scores $I(u_1) \leq ... \leq I(u_K)$. An imperfect crawler will also fetch K pages, but only M of those will have importance at least $I(u_k)$. Then the figure of merit of the crawler will be M/K. As a baseline, if a "random" crawler could somehow collect K random samples from the N reachable pages without following links, the expected number of hot pages in the sample would be MK/N leading to a figure of merit equal to K/N.

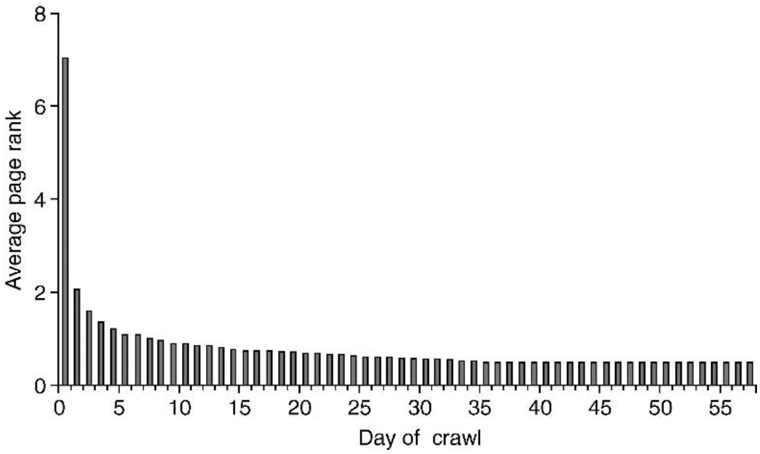
Suppose $I(u)$ is the indegree of u in the "whole" Web graph (suppose some arbitrary subset of the infinite graph is fixed a-priori as the "universe"). In this case, $I(u)$ can be known only after crawling the universe. Another global property is PageRank [16]. At any time, a real crawler only has access to the subgraph crawled thus far. It may use the indegree and PageRank computed on the crawled subgraph as approximations to the true indegree and PageRank.

Figure 1 [8] shows M/K as a percent plotted against K/N also plotted as a percent. The random crawler is understandably the worst, and all the other crawlers fare better. Somewhat surprisingly, the best crawler is the one that is guided not by indegree but PageRank computed with respect to the currently crawled subgraph. A later breadth-first crawl [14] starting from http://www.yahoo.com, covering 7 million hosts and 328 million pages, confirmed that pages with large true PageRank are acquired very quickly using the breadth-first policy (see Fig. 2).

Cho et al. [8] also considered page importance defined by the occurrence of query words on the page, and showed that favoring URLs v that were frequently referred from pages u with query words in or near the anchor text of the (u, v) link resulted in



Focused Web Crawling. Figure 1. Comparison of harvest rates of large indegree pages using various frontier prioritization policies [8].



Focused Web Crawling. Figure 2. Page fetched early on in a breadth-first crawl from well-known seed URLs tend to have high PageRank [14].

improved acquisition rate for relevant pages. Similar results were reported by Hersovici et al. [12].

Basic Topic-Focused Crawler

During 1997–1998, document classification witnessed renewed interest and enhancements from the use of hyperlinks [5]. Rather than use occurrence of a few query words as an indicator of payoff during a crawl, Chakrabarti et al. [4] coupled a pre-trained text classifier with a crawler as shown in Fig. 3. The classifier may be trained on a topic taxonomy such as the one published by Yahoo! or the Open Directory Dmoz, and a few topics (nodes) c^* in the taxonomy (and all their descendants, by inheritance) flagged as positive or rewarding for the crawler.

This organization depends on the (verified [9,6]) premise that pages within a short link distance of each other are topically similar or related. In particular, if $\Pr(c^*|u)$ is large and hyperlink (u, v) exists, then the hypothesis is that $\Pr(c^*|v)$ is also likely to be large quite often. For reasonably broad topics about which there are sufficiently dense link communities on the Web, this hypothesis holds up well and leads to reliable rates of page collection. Some sample results are shown in Fig. 4.

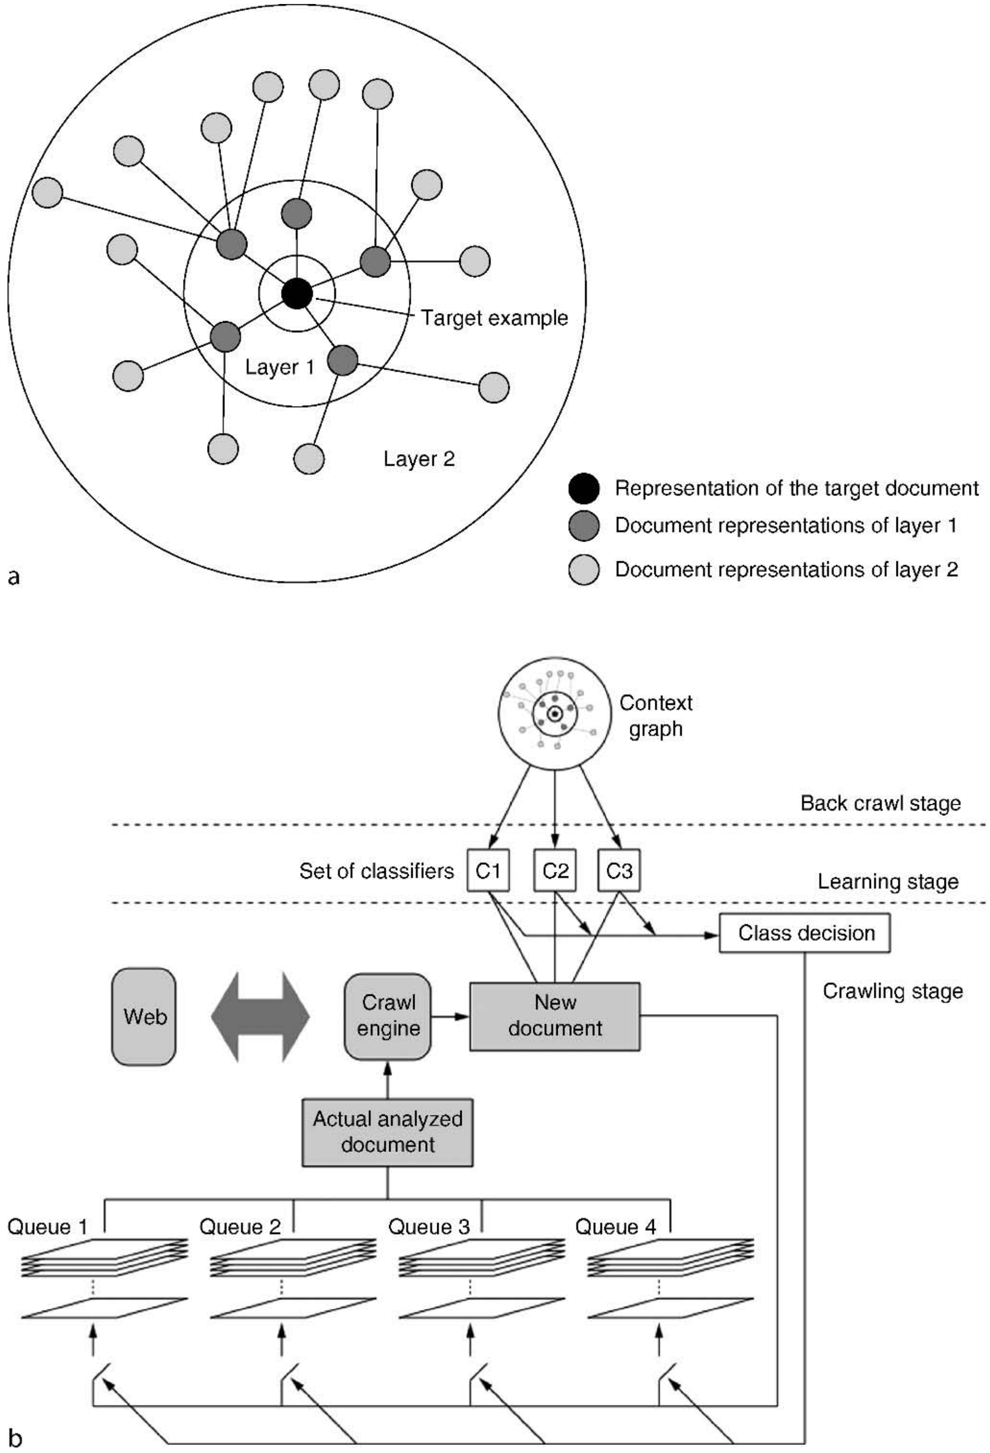
(b) Started from different seed URLs, the focused crawler navigates to the dominant communities on the focus topic and visits largely overlapping sites and pages [4].

Focused Crawling Using Context Graphs

The next enhancement to focused crawling was the use of *context graphs* [10]. The first generation of topic-focused crawlers was myopic: the relevance of page u was used as a surrogate for the benefits of crawling outlink (u, v), and this prediction was limited to only one hop. In Reinforcement Learning [18], an area of Machine Learning, techniques have been evolved to anticipate more distant payoffs. In focused crawling with context graphs, during the training phase, the trainer presents to the system paths $u_1,...,u_g$ of various lengths (up to some modest limit, say, four hops) leading to goal nodes. The goal node u_g is a node on the topic/s of focus. The system includes a supervised learning module that then learns to predict, given a node u, the (minimum) distance to a goal node. When the trained crawler is deployed, after fetching page/node u, it estimates the shortest link distance from u to a goal node, and uses this as the priority for expanding outlinks of u; see Fig. 5.

Figure 6 shows the benefits from going beyond a greedy one-hop prediction paradigm. A similar technique

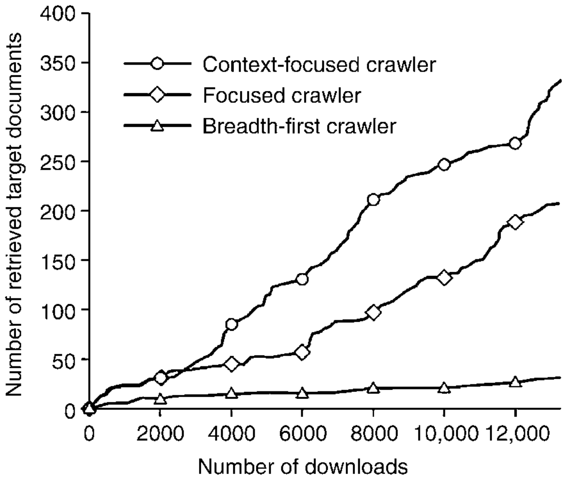


Focused Web Crawling. Figure 5. Focused crawling using context graph [10].

has been implemented by McCallum et al. [17]. More recently, Baberia et al. [1] have cast the problem of estimating the distance to a goal node as an ordinal regression, and given scalable and effective algorithms.

Training a Focused Crawler Online

The focused crawlers discussed thus far are all trained once, off-line, and then start harvesting the Web. The next generation of focused crawlers [7] "learn on the job." Compare Fig. 7 with the basic focused crawler shown in Fig. 3. In the new edition, once a page *u* is approved by the baseline topic classifier for getting its outlinks visited, each outlink (*u*, *v*) is submitted to an *apprentice*. Initially, the apprentice is inexperienced, and might assign the same priority to each outlink (*u*, *v*) that the baseline learner does. As pages continue to be fetched, the baseline classifier classifies each of them, and the apprentice "watches." The baseline classifier acts as a *critic*, pointing out where the apprentice was right and wrong. The apprentice uses features not only from the whole of *u*, but also features specific to the outlink (*u*,*v*), exploiting the DOM tree of *u*.

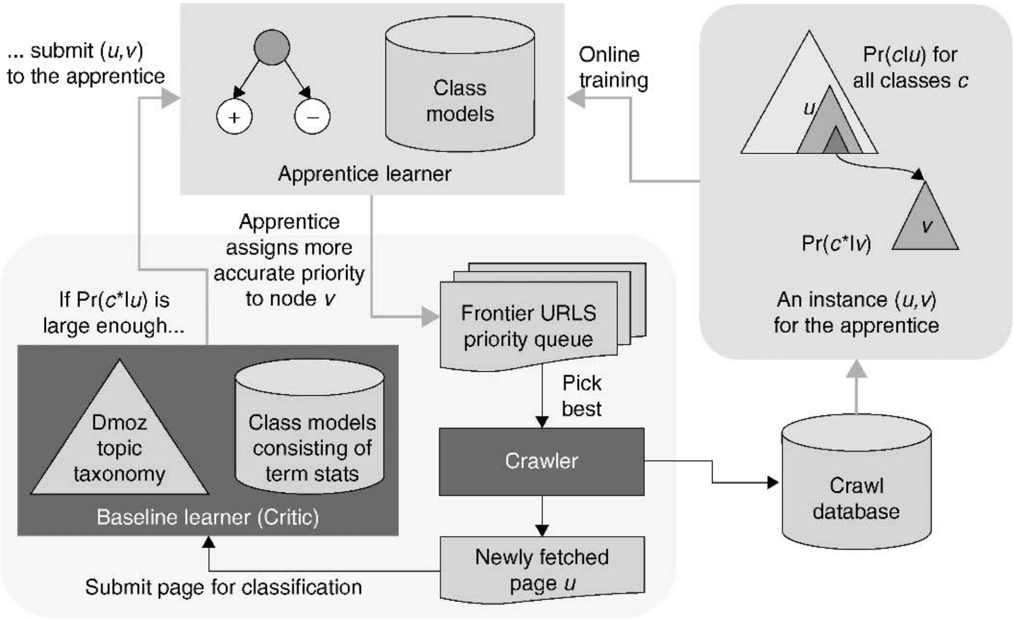


Focused Web Crawling. Figure 6. Context graphs increase harvest of relevant pages [10].

Gradually, the apprentice learns to predict, over and above the critic's relevance judgment of *u*, the expected profit from traversing link (*u*,*v*). Continually training the apprentice is much easier than training the baseline classifier. The apprentice can be a simple regression algorithm, whereas the baseline classifier has to handle much more data and many topics. As the apprentice is switched into the decision process, the number of fetched pages that must be discarded because they are off-topic, also called the "loss rate," drops dramatically. This is shown in Fig. 8a. Overall, as Fig. 8b shows, a focused crawler that learns online can significantly reduce the loss rate and thus boost the harvest rate.

Reinforcement Learning Using Markov Models

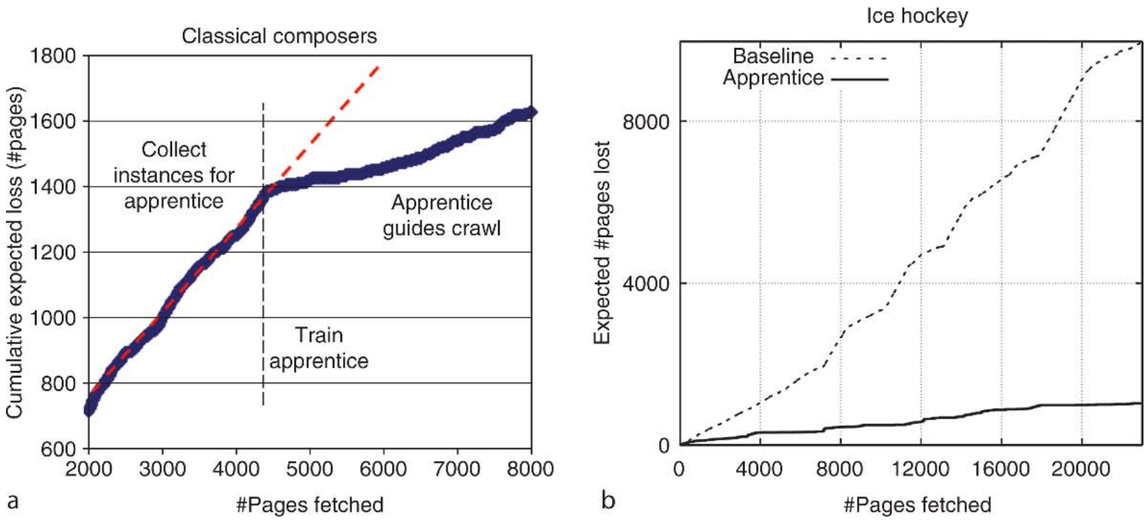
The next step in improving the ability of focused crawlers to spot distant rewards was taken by learning a more detailed representation of the path from the current node to a goal node, rather than just the estimated distance [19]. This is expected to be effective especially for crawling tasks where paths leading into goal nodes have some regularity. For example, paths leading from the root page of a Computer Science



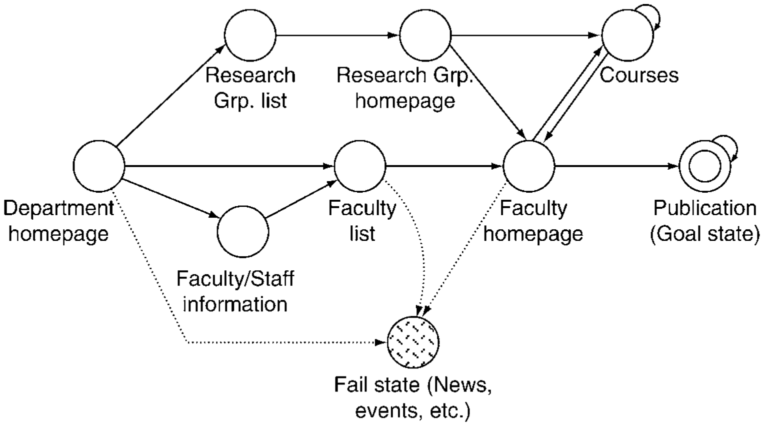
Focused Web Crawling. Figure 7. Topic-focused crawler that learns online during a crawl [7].

Department to research papers about computer vision, or paths leading from the root page of a company to a set of profiles of its top officers, are fairly regular. In fact, one can even give informal but crisp descriptions of the intermediate pages. In the first example, the intermediate pages will most likely be a roster of faculty members with research interests, followed by a faculty homepage, which either has links to PDF files, or links to a page listing publications, which then links to PDF files. In the second example, a surfer is most likely to navigate through an "about us" page, which may list the top office-bearers, each with a link to a profile page, or the profiles may be inlined. An example state transition diagram is given in Fig. 9.

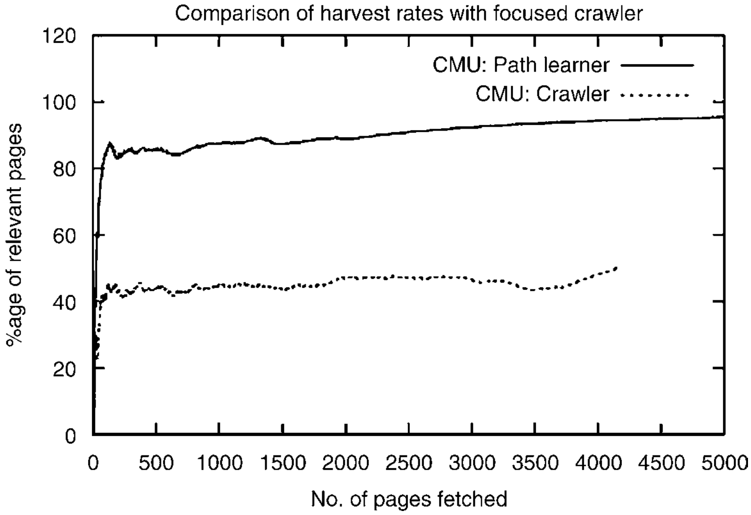
A hidden Markov model (HMM) is ideal for capturing this form of regularity. For label prediction in HMMs, Conditional Random Fields (CRFs) [13] are the best-known technique. Training the CRF involves slightly more work than in the case of context graphs: here, intermediate nodes must be assigned labels. Once this is done, the problem of learning a transition model is very similar to other sequence-labeling applications, like part-of-speech tagging (nodes are words, labels are parts of speech) and named-entity recognition (nodes are words, labels are named entity types like *person* or *location*). Over and above the general framework, smart state and feature design are a must for good accuracy. Also, during crawling, the crawl path up to



Focused Web Crawling. Figure 8. A focused crawler that "learns on the job" improves harvest rate significantly [7].



Focused Web Crawling. Figure 9. Example state transitions modeling paths from a department homepage to research papers [19].



Focused Web Crawling. Figure 10. Using a CRF to predict the expected reward continuing from the current path leads to significantly improved harvest [8].

the current node is assigned various label sequences with various probabilities, and these must contribute to a distance-discounted reward function as in reinforcement learning [18]. For crawling tasks with path regularities, this form of reward prediction is more accurate than the standard topic-focused crawler, leading to substantially improved page harvest rates; see Fig. 10.

Key Applications

Focused crawling, broadly interpreted as goal-directed crawl prioritization with resource constraints, is of interest to almost anyone that has to run a crawler of any substantial scale. All crawlers include a module for frontier prioritization, but only some degree of machine learning usually qualifies it to be explicitly called a "focused crawler." Focused crawling is especially beneficial in applications where content pertaining to a limited topic area must be collected from a much larger Web collection, possibly the whole Web, and subjected to topic-specific post-processing, such as information extraction specific to particular people, regions, languages, or products and services.

Future Directions

Focused crawlers are now available in the public domain (see http://ivia.ucr.edu/ and http://combine.it.lth.se/). Many companies in the vertical Web search space implement focused crawlers. While many of the technical issues around focused crawling are now reasonably solved, the operational details of starting, monitoring, and maintaining a focused crawler remain relatively unknown in the public domain.

FOL Modeling of Integrity Constraints (Dependencies)

Alin Deutsch
University of California-San Diego, La Jolla, CA, USA

Synonyms

Relational integrity constraints; Dependencies

Definition

Integrity constraints (also known as *dependencies* in the relational model) are domain-specific declarations which indicate the intended meaning of the data stored in a database. They complement the description of the structure of the data (e.g., in the relational model the structure is given by listing the names of tables and the names and types of their attributes). Integrity constraints express properties that must be satisfied by all instances of a database schema that can arise in the intended application domain (e.g., "no two distinct employees may have the same ssn value", "departments have a single manager", etc.).

Historical Background

The reference textbook [1] provides a comprehensive, unifying overview of the many special classes of relational dependencies, their modeling in first-order logic (FOL), and the key problems in the study of dependencies. This entry is a condensed form of Chap. 10 in [1] (excluding the material on reasoning about dependencies). For more detail on the motivation and history of relational dependency theory, see the excellent survey papers [10,14,22].

Historically, *functional* dependencies were the first class to be introduced (by Codd [3]). *Multi-valued* dependencies were discovered independently in [5,9,24]. These were followed by a proliferation of dependency classes, typically expressed using ad hoc syntax. These include *join* dependencies, and *inclusion* dependencies (a.k.a. referential integrity constraints) [4]. Fagin [9] first introduced *embedded multi-valued* dependencies (MVDs that hold in the projection of a relation), while [15] introduced the distinct class of *projected* JDs. Other classes include *subset* dependencies [20], *mutual* dependencies [17], *generalized mutual* dependencies [16], *transitive* dependencies [18], *extended transitive* dependencies [19], and *implied* dependencies [12].

The movement towards ever-refined classifications of dependencies was prompted mainly by research on automatic reasoning about dependencies, in particular their axiomatization. This movement was soon countered by the drive to unify the treatment of the various classes by finding a formalism that subsumes all of them. Nicolas [17] is credited with first observing that FDs, MVDs and others have a natural representation in first-order logic. In parallel, Beeri and Vardi [2] introduced *tuple-generating* and *equality-generating* dependencies expressed in a tableaux-based notation, shown to be equivalent in expressive power to Fagin's *typed embedded dependencies* [8], which were expressed in first-order logic. The class DED$^{\neq}$ was introduced in [7] as an extension of embedded dependencies with disjunction and non-equalities (see also [13] for a particular case of DED$^{\neq}$s). Deutsch et al. [6] further extends the DED$^{\neq}$ class to allow negated relational atoms. Research on using arbitrary first-order logic sentences to specify constraints includes [11,17,21].

In contrast, *algebraic dependencies* are an alternative unifying framework developed by Yannakakis and Papadimitriou [23]. Algebraic dependencies are statements of containment between queries written in relational algebra, and have the same expressive power as first-order logic.

Foundations

This section lists a few fundamental classes of relational dependencies, subsequently showing how they can be expressed in first-order logic. In the following, $R(U)$ denotes the schema of a relation with name R and set of attributes U.

Functional Dependencies

A *functional dependency (FD)* on relations of schema $R(U)$ is an expression of the form

$$R : X \rightarrow Y, \tag{1}$$

where $X \subseteq U$ and $Y \subseteq U$ are subsets of R's attributes. Instance r of schema $R(U)$ is said to *satisfy* FD fd, denoted $r \models fd$, if whenever tuples $t_1 \in r$ and $t_2 \in r$ agree on all attributes in X, they also agree on all attributes in Y:

$$r \models fd \iff \text{for every } t_1, t_2 \in r \text{ if } \pi_X(t_1) = \pi_X(t_2) \text{ then } \pi_Y(t_1) = \pi_Y(t_2).$$

Here, $\pi_X(t)$ denotes the projection of tuple t on the attributes in X.

For instance, consider a relation of schema

review(paper, reviewer, track)

listing a conference track a paper was submitted to, and a reviewer it was assigned to. The fact that every paper can be submitted to a single track is stated by the functional dependency

$$review : \ paper \longrightarrow track.$$

Key Dependencies

In the particular case when $Y = U$, a functional dependency of form (1) is called a *key dependency*, and the set of attributes X is a called a *key for R*.

Join Dependencies

A *join dependency (JD)* on relations of schema $R(U)$ is an expression of the form

$$R : \bowtie [X_1, X_2, \ldots, X_n], \tag{2}$$

where for each $1 \leq i \leq n$, $X_i \subseteq U$, and $\bigcup_{1 \leq i \leq n} X_i = U$. Instance r of schema $R(U)$ *satisfies* JD jd, denoted $r \models jd$, if the n-way natural join of the projections of r on each of the attribute sets X_i yields r:

$$r \models jd \Leftrightarrow r = \Pi_{X_1}(r) \bowtie \Pi_{X_2}(r) \bowtie \ldots \bowtie \Pi_{X_n}(r).$$

Here, $\Pi_X(r)$ denotes the projection of relation r on the attributes in X.

In the example, assume that a paper may be submitted for consideration by various tracks (e.g., poster or full paper), and that reviewers are not tied to the tracks. It makes sense to expect that for any given paper p, any track information listed with a reviewer of p is also listed with all other reviewers of p, since track and reviewer information are not correlated. This is expressed by requiring that the join of the projection of *review* on *paper, track* and of the projection on *paper, reviewer* yields the *review* table:

$$review : \bowtie [\{paper,\ track\}, \{paper,\ reviewer\}].$$

Multi-Valued Dependencies

In the particular case when $n = 2$, a join dependency of form (2) is called a *multi-valued dependency (MVD)*. Because MVDs were historically introduced and studied before JDs, they have their own notation: an MVD $R : \bowtie [X_1, X_2]$ is denoted

$$R: \ X \twoheadrightarrow Y, \tag{3}$$

where $X = X_1 \cap X_2$ and $Y = X_1 \setminus X_2$.

In the running example, the join dependency turns out to be a multi-valued dependency, which can be expressed using the following MVD-specific syntax:

$$review: \ paper \twoheadrightarrow track.$$

Inclusion Dependencies

Functional and join dependencies and their special-case subclasses each pertain to single relations. The following class of dependencies can express connections between relations. An *inclusion dependency (IND)* on pairs of relations of schemas $R(U)$ and $S(V)$ (with R and S not necessarily distinct) is an expression of the form

$$R[X] \subseteq S[Y], \tag{4}$$

where $X \subseteq U$ and $Y \subseteq V$. Inclusion dependencies are also known as *referential constraints*. Relations r and s of schemas $R(U)$, respectively $S(V)$ satisfy inclusion dependency id, denoted $r, s \vDash id$, if the projection of r on X is included in the projection of s on Y:

$$r, s \models id \Leftrightarrow \ \Pi_X(r) \subseteq \Pi_Y(s).$$

When R and S refer to the same relation name, then $r = s$ in the above definition of satisfaction.

In the running example, assume that the database contains also a relation of schema

$$PC(member, \ affiliation)$$

listing the affiliation of every program committee member. Then one can require that papers be reviewed only by PC members (no external reviews allowed) using the following IND:

$$review[reviewer] \subseteq PC[member].$$

Foreign Key Dependencies

In the particular case when Y is a key for relations of schema S ($S : Y \rightarrow V$), INDs of form (4) are called *foreign key dependencies*. Intuitively, in this case the projection on X of every tuple t in r contains the key of a tuple from the "foreign" table s.

In the running example, assuming that every PC member is listed with only one primary affiliation, *member* is a key for PC, so the IND above is really a foreign key dependency.

Expressing Dependencies in First-Order Logic

Embedded Dependencies Despite their independent introduction and widely different syntax, it turns out that all classes of dependencies illustrated above (and many more, including the ones mentioned in the historical background section) can be expressed using a fragment of the language of first-order logic. This fragment is known as the class of *embedded dependencies*, which are formulas of the form

$$\begin{aligned}&\forall x_1 \ldots \forall x_n \ \varphi(x_1, \ldots, x_n) \rightarrow \\ &\exists z_1 \ldots \exists z_k \ \psi(y_1, \ldots, y_m),\end{aligned} \tag{5}$$

where $\{z_1,\ldots,z_k\} = \{y_1,\ldots,y_m\} \setminus \{x_1,\ldots,x_n\}$, and φ is a possibly empty and ψ is a non-empty conjunction of relational and equality atoms. A *relational atom* has form $R(w_1,\ldots,w_l)$, and an *equality atom* has form $w = w'$, where each of $w,w',w_1,\ldots,w_l$ are variables or constants. The particular case when all atoms in ψ are equalities yields the class known as *equality-generating dependencies (EGD)*, while the case when only relational atoms occur in ψ defines the class of *tuple-generating dependencies (TGD)*.

The power of embedded dependencies is illustrated next by expressing the classes of dependencies described above.

Functional Dependencies

Assume without loss of generality that in (1), $|X| = k$, $|Y| = l$, and $|U \setminus (X \cup Y)| = m$, and that the ordering of attributes in U is $U = X, Y, Z$. Then any functional dependency of form (1) is expressible as the embedded dependency (actually an EGD):

$$\begin{aligned}&\forall x_1 \ldots \forall x_k \ \forall y_1 \ldots \forall y_l \ \forall y'_1 \ldots \forall y'_l \ \forall z_1 \ldots \forall z_m \\ &\forall z'_1 \ldots \forall z'_m \\ &R(x_1, \ldots, x_k, y_1, \ldots, y_l, z_1, \ldots, z_m) \ \wedge \\ &\quad R(x_1, \ldots, x_k, y'_1, \ldots, y'_l, z'_1, \ldots, z'_m) \rightarrow \\ &\quad y_1 = y'_1 \wedge \ldots \wedge y_l = y'_l\end{aligned}$$

In the particular case when X is a key, $m = 0$ and there are no z_i, z_i' variables in the above embedded dependency.

The functional dependency $review : paper \rightarrow track$ in the running example, can be expressed as the following embedded dependency:

$$\forall p \forall r \forall t \forall r' \forall t' \; review(p, r, t) \wedge review(p, r', t') \rightarrow t = t'.$$

Join Dependencies

Join dependencies of form (2), are expressed by observing that for every relation r of schema $R(U)$, the inclusion

$$r \subseteq \Pi_{X_1}(r) \bowtie \Pi_{X_2}(r) \bowtie \ldots \bowtie \Pi_{X_n}(r)$$

holds trivially. Therefore only the opposite inclusion needs to be expressed,

$$\Pi_{X_1}(r) \bowtie \Pi_{X_2}(r) \bowtie \ldots \bowtie \Pi_{X_n}(r) \subseteq r.$$

This end requires the following notation. Recalling that the set of attributes U in the schema of R is ordered, let $pos(A)$ denote the position of an attribute $A \in X$ in the ordered set U. For a set of attributes $X \subseteq U$, $pos(X)$ denotes the set $\{pos(A) | A \in X\}$. In the following, given a tuple of variables $\bar{u}$, $\bar{u}[k]$ denotes the kth variable in $\bar{u}$.

1. Let $\{\bar{u}_i\}_{1 \leq i \leq n}$ be a family of tuples of $|U|$ variables each, such that for every $1 \leq i < j \leq n$ and every $1 \leq k \leq |U|$, $\bar{u}_i[k] = \bar{u}_j[k]$ if and only if $k \in pos(X_i \cap X_j)$.
2. Let $\bar{w}$ be a tuple of $|U|$ variables, such that for every $1 \leq k \leq |U|$ and every $1 \leq i \leq n$, if $k \in pos(X_i)$ then $\bar{w}[k] = \bar{u}_i[k]$. It is easy to check that $\bar{w}$ is well-defined: indeed, since $\bigcup_i X_i = U$, for each k there is at least one i with $k \in pos(X_i)$. Moreover, by definition of the family $\{\bar{u}_i\}_i$, $\bar{u}_i[k] = \bar{u}_j[k]$ whenever $k \in pos(X_i)$ and $k \in pos(X_j)$.
3. Finally, let $V = \{v_1, \ldots v_m\} = \bigcup_{i=1}^{n} \bar{u}_i$ (with each tuple $\bar{u}_i$ viewed as a set of variables). Notice that variables occurring in several $\bar{u}_i$ tuples appear just once among V.

Then the join dependency of form (2) is given by the embedded dependency (a TGD, really):

$$\forall v_1 \ldots \forall v_m \; R(\bar{u}_1) \wedge \ldots \wedge R(\bar{u}_n) \rightarrow R(\bar{w}).$$

Join dependency $review : \bowtie[\{paper, track\}, \{paper, reviewer\}]$ is expressed as the following embedded dependency:

$$\forall p \forall r_1 \forall t_1 \forall r_2 \forall t_2 \; review(p, r_1, t_1) \wedge$$
$$review(p, r_2, t_2) \rightarrow review(p, r_2, t_1).$$

Inclusion Dependencies

To express inclusion dependencies, assume without loss of generality that in (4) $R(U) = R(Z, X)$ and $S(V) = S(Y, W)$. Then the inclusion dependency (4) is captured by the following embedded dependency (TGD):

$$\forall z_1 \ldots \forall z_{|Z|} \; \forall x_1 \ldots \forall x_{|X|} \; R(z_1, \ldots, z_{|Z|}, x_1, \ldots, x_{|X|})$$
$$\rightarrow \exists w_1 \ldots \exists w_{|W|} \; S(x_1, \ldots, x_{|X|}, w_1, \ldots, w_{|W|}).$$

In the running example, the inclusion dependency $review[reviewer] \subseteq PC[member]$ is expressible as the embedded dependency

$$\forall p \forall r \forall t \; review(p, r, t) \rightarrow \exists a \; PC(r, a).$$

Other Classes of Dependencies

Embedded dependencies turn out to be sufficiently expressive to capture virtually all other classes of dependencies studied in the literature.

Other Constraints

By employing more expressive sub-languages of first-order logic, one can capture additional, naturally occurring constraints. For instance, extending embedded dependencies with disjunction, one obtains the language of *disjunctive embedded dependencies (DED)* of form

$$\forall \bar{x} \; \varphi(\bar{x}) \rightarrow \bigvee_{i=1}^{l} \exists \bar{z}_i \; \psi_i(\bar{y}_i), \tag{6}$$

where $\bar{x}$ is a tuple of variables, and so are $\bar{z}_i$, $\bar{y}_i$ for every $1 \leq i \leq l$. Analogously to (5), $\bar{z}_i = \bar{y}_i \setminus \bar{x}$. φ and each ψ_i are conjunctions of relational and equality atoms as in (5). If in addition one allows *non-equality atoms* of the form $w \neq w'$, one obtains the class of DEDs with non-equality, DED$^{\neq}$, which is in turn a fragment of first-order logic.

Cardinality Constraints

The language DED$^{\neq}$ can express cardinality constraints. In the running example, $\delta_1 \in$ DED$^{\neq}$ states that every paper has at least two reviews:

$$(\delta_1) \quad \forall p \forall r_1 \forall t \; review(p, r_1, t) \rightarrow$$
$$\exists r_2 \; review(p, r_2, t) \wedge r_1 \neq r_2.$$

δ_2 below states that every paper receives at most two reviews:

$$(\delta_2)\quad \forall p \forall r_1 \forall r_2 \forall r_3 \forall t\ review(p, r_1, t) \wedge review(p, r_2, t) \wedge review(p, r_3, t) \wedge r_1 \neq r_2 \rightarrow r_3 = r_1 \vee r_3 = r_2.$$

Note that the conjunction of δ_1 and δ_2 requires each paper to receive precisely two reviews.

Domain Constraints

The language $\text{DED}^{\neq}$ can be employed to restrict the domain of an attribute. Such restrictions are commonly known as *domain constraints*. For instance, in the running example, this is how to specify that the conference has only three kinds of tracks: "research", "industrial" and "demo":

$$(\delta_3)\ \forall_p \forall_r \forall_t\ review(p, r, t) \rightarrow t = \text{"}research\text{"} \vee t = \text{"}industrial\text{"} \vee t = \text{"}demo\text{"}.$$

Representational Constraints

Many application are based on data models that are richer than the relational model (e.g., object-oriented, object-relational, XML, RDF models). However, they often leverage the mature relational technology by supporting the storage of their data in a relational database. The resulting relations satisfy certain constraints that stem from the original data model. This entry refers to them as *representational constraints*. In order to maintain the relational storage and to efficiently process queries over it, it is imperative to exploit these representational constraints. An obstacle to doing so is the fact that, depending on the original model they encode relationally, representational constraints tend to not fit neatly into any of the classes of relational integrity constraints devised for native relational data. Again, first-order logic comes to the rescue.

Representational constraints for the relational representation of XML are illustrated next. While there are many possible representations, they are all equivalent to the following simple one [7] which captures the fact that in the XML data model, elements are the tagged nodes of a tree. The tree is represented using the following relations (among others):

$$elem(node, tag)$$
$$child(source, target)$$
$$desc(source, target)$$

where the *elem* relation lists for every element *e*, the identifier of the tree node modeling *e*, and the tag of *e*; the *child* table is the edge relation of the XML tree, according to which *source* is the identifier of the parent node and *target* the identifier of the child node; *desc* is the descendant relation in the tree, whose *target* node is a descendant of the *source* node. Any instance storing an actual XML tree in these tables must satisfy, among others, the following constraints, all expressible in $\text{DED}^{\neq}$: every element has at most one tag (expressed in (7) below); every element has at most one parent (8); children of a node are also descendants of this node (9); the descendant relation is transitive (10); if two elements have a common descendant, then they either coincide or one is the descendant of the other (11).

$$\forall n \forall t_1 \forall t_2\ elem(n, t_1) \wedge elem(n, t_2) \rightarrow t_1 = t_2, \quad (7)$$

$$\forall n \forall p_1 \forall p_2\ child(p_1, n) \wedge child(p_2, n) \rightarrow p_1 = p_2, \quad (8)$$

$$\forall s \forall t\ child(s, t) \rightarrow desc(s, t), \quad (9)$$

$$\forall s \forall u \forall t\ desc(s, u) \wedge desc(u, t), \rightarrow desc(s, t), \quad (10)$$

$$\forall n_1 \forall n_2 \forall d\ desc(n_1, d) \wedge desc(n_2, d), \rightarrow n_1 = n_2 \vee desc(n_1, n_2) \vee desc(n_2, n_1). \quad (11)$$

Key Applications

The role of integrity constraints is to incorporate more semantics into the data model. This in turn enables an improved schema design, as well as the delegation to the database management system (DBMS) of the task of enforcing and exploiting this semantics.

Schema Design

Integrity constraints are useful for selecting the most appropriate schema for a particular database application domain. It turns out that the same information can be stored in tables in many ways, some more efficient than others with respect to avoiding redundant storage of data, improved update and query performance, and better readability. While in the early days of database application development, appropriate schema selection started out as an art, it quickly evolved into a science enabling automatic schema design tools (also known as "wizards"). Such tools are based on database theory research that proposes schema design methodology starting from a single, "universal relation", which is then decomposed into new relations that satisfy desirable normal forms that take advantage of the known integrity constraints [1]. For instance, in the running example, both the FD *review* : *paper* → *track* and the MVD *review* : *paper* →→ *track* suggest decomposing relation *review* into two tables, one associating papers with their track, and one associating papers with their reviewers, to avoid the redundant listing of track information with every reviewer.

Automatic Integrity Enforcement

For the purpose of integrity enforcement, the DBMS automatically checks every update operation for compliance with the declared integrity constraints, automatically rejecting non-compliant updates. The database administrator can therefore rest assured that the integrity of her data will be preserved despite any bugs in the applications accessing the database. This guarantee is all the more important when considering that several applications are usually running against the same database. These applications are not always under the control of the database administrator, and are often developed by third parties, which renders their code unavailable for verification. Even with full access to the application code, verification (like all software verification) is technically challenging and does not scale well with increasing number of applications or modifications to their code.

Query Optimization

The query optimizer can exploit its constraint-derived understanding of the data to automatically rewrite queries for more efficient execution. Delegating this task to the DBMS ensures that queries are efficiently executed even when they are issued by applications whose developers write the queries in sub-optimal forms due to insufficient insight into the integrity constraints. More importantly, automatic optimization inside the DBMS handles the queries generated by tools rather than human developers. These queries are usually quite far from optimal. This problem is especially prevalent when queries over a rich data model *M* are translated to relational queries over the relational representation of *M* (e.g., XQuery queries over relational storage of XML). The *chase* is a very powerful tool for reasoning about (and exploiting in optimization) dependencies specified in first-order logic (see [1] for references to the papers that independently discovered the chase, for various classes of dependencies).

A Unified View of Dependencies

Given the plethora of classes of dependencies formulated and studied independently in the literature, the task of specifying the meaning of an application domain via integrity constraints would be daunting if the developer had to fit them into these classes. In addition, tailoring the tasks of schema design, optimization and integrity enforcement to every class of dependencies (and every combination of such classes) is impractical. First-order logic provides a formalism for the simple specification of integrity constraints, with well-understood semantics and sufficient expressive power to capture all common classes of dependencies, and beyond. The insight that virtually all dependency classes are expressible in the same formalism set the foundation for their uniform treatment in research and applications.

Forever

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Infinity; Positive infinity

Definition

The distinguished value *forever* is a special valid-time instant, namely the one following the largest granule in the valid-time domain. Forever is specific to valid time and has no transaction-time semantics.

Key Points

The value *forever* is often used as the valid end time for currently-valid facts. However, this practice is semanticallys incorrect, as such an end time implies that the facts are true during all future times. This usage occurs because database management systems do not offer means of storing the ever-changing current time, *now*, as an attribute value. To fix the incorrect semantics, the applications that manipulate and query the facts may interpret the semantics specially. However, the better solution is to extend the database management system to support the use of the variable *now* as an attribute value.

Concerning the synonyms, "infinity" and "positive infinity" both appear to be more straightforward, but have conflicting mathematical meanings. In addition, the time domain used for valid time may be finite, making the use of "infinity" inappropriate. Furthermore, the term positive infinity is longer and would imply the use of "negative infinity" for its opposite. Forever is intuitive and does not have conflicting meanings.

Forms-based interfaces

Definition

Paper-based forms are structured documents with empty slots that can be filled in by a user. In database systems, a form is an interface containing interaction elements that allow a user to input, update or query data in a database. Forms may also contain static displays of data taken from the database. Documents containing only structured query results and no interaction elements are generally referred to as reports rather than forms. Database interfaces comprising of a series of on-screen forms are referred to as forms-based interfaces.

Commonly a single form corresponds with one table in relational databases and one form instance corresponds with one record. More complex forms may contain or update data from multiple tables. Forms are also used to interact with other databases such as object-oriented or XML databases.

Forms can be designed and created using various visual programming tools such as: Forms specification languages; GUI Builders; Automatic GUI Generation Systems; or by using third and fourth generation programming languages directly. Such tools may be included in the DBMS itself, in a related suite of proprietary programs or be independent applications.

Historical Background

With the advent of more general-purpose commercial database systems in the mid-1960s, the provision of forms-based interfaces for business applications became an issue for developers. Early applications were however still being custom built using various programming languages which was a very time intensive development effort. By the late 1970s/early 1980s a number of tools were becoming available to alleviate the load on the developer, for example, the Forms Application Development System (FADS) developed at U.C. Berkeley between 1979 and 1982. Later the ideas from FADS would develop into the widely used and more sophisticated Application-By-Forms (ABF) tool developed by Ingres Corporation between 1983 and 1986 [11]. Equally, the Oracle database system also introduced a tool for developing forms called Fast Forms (later called SQL*Forms) in 1984 [8]. Other examples include Control Center Forms module in dBASE IV, Forms EXPRESS in R:BASE, Paradox 3.0, Formanager, NFQL [3]. These forms were designed to be used with the alphanumerical terminals then in common usage and accordingly, the forms were character-based with some menus. These forms also tended to be relatively simple, conforming to the underlying database structure with one form usually representing one table and one record per screen.

As Graphical User Interfaces (GUIs) became available and popular for business applications in the late 1980s/1990s, forms took advantage of the new medium. Standard GUI techniques such as multiple windows, checkboxes and point and click selection were employed (e.g., Figure1). Both DBMS and stand alone tools continued to provide support, with updated visual programming tools for GUI based forms (e.g., Oracle-Forms, Ingres's W4GL, Microsoft Access's Form Tool/Wizard). The more powerful DBMS independent development tools had facilities for supporting skilled designers to build forms-based interfaces. While this sped development and empowered designers, it did not support inexperienced designers in avoiding bad designs and still required substantial developer resources. The trend of including forms generation as part of a DBMS or a related application suite that aimed to empower the end-user in customizing their own relatively simple forms has thus continued to date. DBMS provided tools, while increasing in sophistication, are however still restricted to either relatively simple applications or require an expert application developer. Attempts to reduce the reliance on developers by making greater use of automatic GUI creators (including the DBMS tools) have not been generally successful in generating complex forms-based interfaces.

In the last decade, the emphasis has shifted from a traditional client-server delivery method for forms, to a web-based one. Web forms are now prevalent across the internet (e.g., Figure 2). These web forms use HTML with various types of scripting or more recent alternatives such as XForms, XQForms [9].

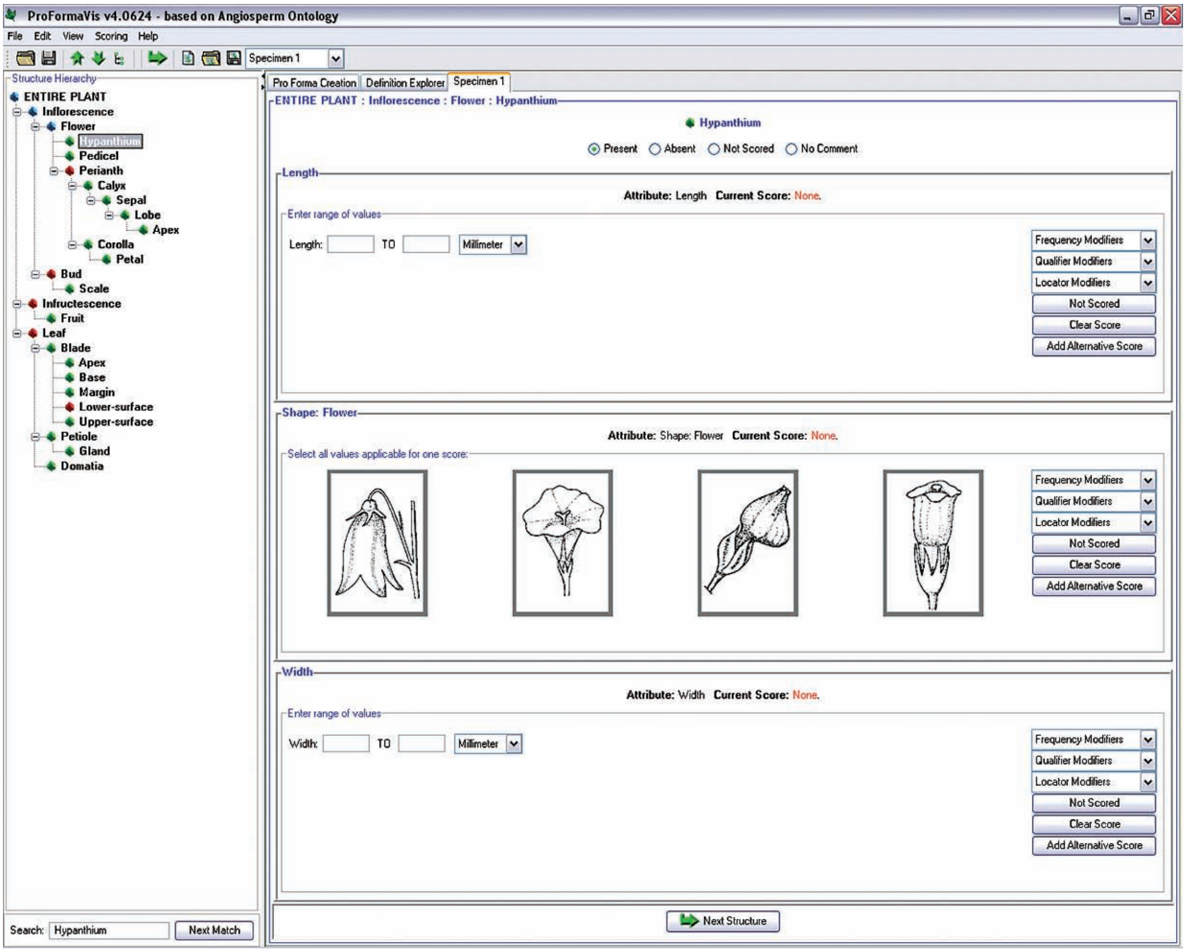
Foundations

Form Composition

In database systems, a form is an interface containing interaction elements that allow a user to input, update or query data in a database. Each form instance normally equates with a single database record, although exceptions exist and one database record may be spread over multiple forms.

Forms can be character-based, GUI-based (Fig. 1) or web-based (Fig. 2), but all basically comprise of four main elements that are tied together within logical containers such as a windows or frames:

1. Data entry interaction objects
2. Static labels



Form. Figure 1. Example of a GUI form for data entry [8].

3. Displayed data
4. Control elements

The data entry interaction objects are the slots into which data can be entered or altered by users. These elements are each bound to an associated attribute of a database table (or equivalent in non-relational databases). These comprise of such elements as text boxes, checkboxes, calendar objects, or any other of the interaction widgets that can be used to enter data. They may be initially blank or contain data, either taken from the existing record in the database (i.e., the current values of the bound attribute), from another section of the database (e.g., a range of possible values from a related table), from default attribute values specified in the database or from default values programmed into the form. The entered data can be used to fill a new record, update an existing one or query the database according to the underlying application logic. Each of the data entry interaction objects is usually associated with a static label specifying to the form user what data should be inserted. These are not usually bound to an attribute of the database. Other static data displayed in a form include existing data from the database of relevance to the form (e.g., other identifying data from the record being edited) or the results of user queries. This data may be a direct representation or it may be data manipulated by calculations programmed into the form. The last main elements of a form are control elements such as menus or buttons. These provide the form user with navigational and other controls over form operations. The most obvious examples of these are submit controls, that commit changes to the database.

Underlying business logic is programmed into a form to provide relevant database interaction, navigation controls, error checking and data validation. SQL or other query language code is normally embedded into

form fields to support data updates or queries. A form can also contain hidden fields that are also sent to a database along with any other update or query (e.g., user id). This coding may be implemented directly by a developer using a third or fourth generation programming language or semi-automatically by development tools based on user interaction or totally automatically by forms generation tools directly from database schema.

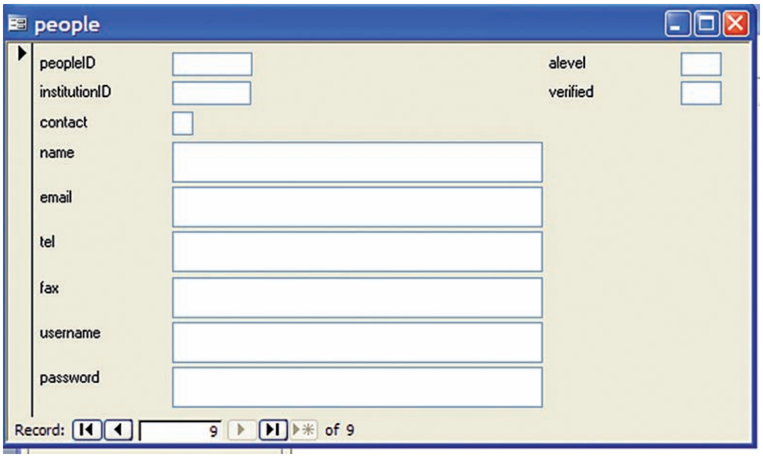
Generating Forms

Forms-based interfaces include sets of forms and the application logic that ties them together. Traditionally their generation has been a task for an expert application developer. To decrease that reliance, there have been attempts to allow end-users to develop their own forms-based interfaces. The main methods of generation are similar to any other user interface.

Traditional programming with languages that support database calls remain a common method for generation by application developers, particularly with fourth Generation languages and their associated Interface Development Environments. They permit powerful customized applications to be built.

Other visual development tools are also used both by application developers and more causal users. These can be stand-alone tools or linked to proprietary DBMS. The latter option is increasingly common, providing specific support for forms-based database interfaces. These all generally work on similar principles where the forms are designed visually with tools that allow fields, labels and other elements to be placed on the screen, using a WISYWIG system. The underlying application logic is then either selected with menus (often point and select) or by adding code in a database query language, programming or scripting language. Web based development for a forms-based interface is similar in nature (e.g., Macromedia's ColdFusion, Adobe's Dreamweaver).

Some DBMS visual development tools (e.g., MS Access, OracleForms, Paradox) have support for automatically generating forms from the database schema (Fig. 3), though the resulting interfaces are certainly at the simpler end of the forms and applications, being tied to a simple view of the database schema (such as in Figure 3), with only basic validation by data type for example being possible (for example by dragging the table attributes to XHTML form controls [10]).



Form. Figure 3. Example of a simple form created using Microsoft Access Form Wizard.

Other non-DBMS tools support automatic generation of the forms from various abstractions, where a presentation model controls the selection and layout of user interfaces, based on the modeled tasks and/or domain. These are known as model based approaches. The various approaches use different models, but usually focus on a task or domain/data model. Some approaches support completely automatic interface generation (e.g., MECANO, JANUS) and others provide support and guidance to designers to finalize an interface (e.g., MASTERMIND). Most of the approaches claim to connect to relational databases and one, Teallach, claims to connect to any object-orientated database [1]. These approaches have not, however, been widely adopted despite a strong research base [12], partly since they are generic systems and it is difficult to get good abstract domain and presentation models for specific applications. A related ontology based approach exists where an end-user edits a lightweight ontology to define the data model for a particular application. The system can then produce a forms-based data entry interface for that data model, based on a domain specific presentation model determined by the application developer [2].

Key Applications

Business Database Applications

The primary use for forms-based interfaces remains business applications, although as database technology continues to become more accessible, an increasing number of other casual users are utilizing databases and attendant forms-based interfaces for hobby and other leisure uses.

End-User Programming and Domain Specific Application Development

Empowering domain users to take over some of the application developer workload in creating forms for their own applications promises gains in development efficiency by reducing the need for a developer to learn about a domain and potentially in the applicability of the resulting forms. Improving the usability and utility of the various Integrated Development Environments for end-users is one way that database researchers can achieve this.

Ubiquitous Computing

A variety of new interface challenges must be met on different types of displays such as PDAs, mobile phones, and wall screens. It seems likely that the forms metaphor will continue to be used on these new devices and means of effectively tailoring forms to the requirements of the various displays and interaction methods must be found.

Data Quality

The phrase 'Garbage-In, Garbage-Out' remains as true today as at the dawn of computing. With forms being used constantly for data entry and updates, the control of entered data remains an important consideration. The design and data validation constraints placed on forms will continue to affect the quality of the data entered by users.

Meta-Data Capture

Forms-based interfaces are the norm for many systems such as data repositories and content management systems, which require to capture meta-data. The design and applicability of the forms used in these applications are vital to encourage users to enter meta-data, a task they are generally reluctant to undertake.

Knowledge Bases

Forms-based interfaces are also used by various ontological systems to populate knowledge bases (e.g., Protégé Frames). Existing ontology based approaches for data entry are, however, generally still limited to using automatically generated forms-based data entry interfaces unless manual editing is used. A form tends to be generated for each class instance with the choice of interaction widgets derived from the slot data types. Links between forms are based on class subsumption relationships.

Forms-based Interfaces

▶ Form

Fourth Normal Form

Marcelo Arenas
Pontifical Catholic University of Chile, Santiago, Chile

Synonyms

4NF

Definition

Let $R(A_1,...,A_n)$ be a relation schema and Σ a set of unctional and multivalued dependencies over $R(A_1,...,A_n)$. Then (R, Σ) is said to be in Fourth Normal Form (4NF) if for every nontrivial multivalued dependency $X \twoheadrightarrow Y$ implied by Σ, it holds that X is a superkey for R.

Key Points

In order to avoid update anomalies in database schemas containing functional and multivalued dependencies, 4NF was introduced by Fagin in [2]. As for the case of BCNF, this normal form is defined in terms of the notion of superkey as shown above. For example, given a relation schema $R(A, B, C)$ and a set of functional dependencies $\Sigma = \{A \rightarrow B\}$, it does not hold that $(R\ (A, B, C), \Sigma)$ is in 4NF since $A \twoheadrightarrow B$ is a nontrivial multivalued dependency implied by Σ and A is not a superkey for R. Similarly, relation schema $S\ (A, B, C)$ and set of multivalued dependencies $\Sigma = \{A \twoheadrightarrow C\}$ is not in 4NF since A is not a superkey for S. On the other hand, relation schema $T(A,B,C)$ and set of functional and multivalued dependencies $\Sigma = \{AB \rightarrow C, AC \rightarrow B, A \twoheadrightarrow B\}$ is in 4NF since AB, AC and A are all superkeys for T.

It should be noticed that relation schema $S\ (A, B, C)$ above is in BCNF if $\Sigma = \{A \twoheadrightarrow C\}$ since no nontrivial functional dependency can be inferred from Σ. In fact, 4NF is strictly stronger than BCNF; every schema in 4NF is in BCNF, but there exist schemas (as the one shown above) that are in BCNF but not in 4NF.

For every normal form two problems have to be addressed: How to decide whether a schema is in that normal form, and how to transform a schema into an equivalent one in that normal form. As for the case of BCNF, it can be tested efficiently whether a relation schema is in 4NF. A relation schema (R, Σ) is in 4NF if and only if for every nontrivial functional dependency $X \rightarrow Y \in \Sigma$, it holds that X is a superkey, and for every nontrivial multivalued dependency $X \twoheadrightarrow Y \in \Sigma$, it holds that X is a superkey. Thus, it is possible to check efficiently whether (R, Σ) is in 4NF by using a polynomial time algorithm for functional and multivalued dependency implication [1]. On the negative side, given a relation schema S, it is not always possible to find a database schema S' such that S' is in 4NF and S' is a lossless and dependency preserving decomposition of S.

FQL

Peter M.D. Gray
University of Aberdeen, Aberdeen, UK

Definition

At about the same time that Shipman was developing DAPLEX, Buneman and Frankel proposed the highly influential FQL functional query language [1], based on Backus's FP functional programming paradigm. A major motivation for this work was that it is in principle possible to combine arbitrary *computable functions* with *stored database functions* into a functional query language which is not limited to a predefined set of operators.

FQL was intended for implementation over existing DBMSs and an abstract implementation based on the lazy evaluation of stream data was described. In later publications [2,3], FQL was extended with features from the functional programming language ML. In this version, function definition is simpler than in the variable-free FP-like syntax and new higher-order functions can be defined in addition to the built-in ones. Also a set of built-in metalevel functions is provided, as in EFDM. Thus, object-level querying and meta level querying can be carried out in the same functional syntax.

Key Points

FP includes a built-in set of *functionals*, like higher-order functions, including function composition, $\circ$, and sequence construction. In addition to these, FQL provides the functionals !, * and ^.

Given an abstract entity type A, !A is a 0-argument function which returns a *stream* of all entities of type A. For example, given the abstract entity type COURSE, !COURSE returns a stream of all the entities of type COURSE.

Given any type A, *A is the type consisting of streams of entities of type A. For example, given the abstract entity types STUDENT and COURSE, the function `ATTENDS : STUDENT -> *COURSE` takes a STUDENT and returns a stream of the COURSEs attended by the STUDENT.

Given a function f: A → B, *f is the function of type *A → *B which takes as an argument a stream of entities of type A, a_1, a_2,... say, and returns the stream f(a_1), f(a_2),.... For example, given the function `CNAME : COURSE -> STRING` the query `COURSE o *CNAME` returns the name of every COURSE.

Given a function f: A → B or f: A → *B, the function ^f: B → *A is the inverse (or converse) of f. In a later version of FQL [2], the functionals ! and ^ are dropped.

Fractal

Ke Deng
University of Queensland, Brisbane, OLD, Australia

Synonyms

Koch snowflake; Space-filling curve

Definition

A fractal is "a rough or fragmented geometric shape that can be subdivided in parts, each of which is (at least approximately) a reduced-size copy of the whole" [2]. This term is introduced by French mathematician Benoit Mandelbrot (born 1924) in 1975 and was derived from the Latin fractus meaning "broken" or "fractured". A simple fractal example is Koch snowflake. The method of creating this shape is to recursively replace each line segment with 4 line segments in a finer scale as shown in Fig. 1.

Key Points

Fractals are self-similar structures (at least approximately or stochastically) which are appropriate for representing the geometry in nature. Some examples include clouds, snow flakes, coastlines, crystals, cauliflower or broccoli, and mountain ranges. In fractal geometry, the fractal dimension, D, is a statistical quantity that gives an indication of how completely a fractal appears to fill space, as one zooms down to finer and finer scales. Among several choices, Hausdorff dimension (also known as the Hausdorff-Besicovitch dimension) is a popular definition of fractal dimension and it is:

$$D = \lim_{\varepsilon \to 0} \frac{\log N(\varepsilon)}{\log(1/\varepsilon)}.$$

Where $N(\varepsilon)$ is the number of balls of radius at most ε to cover the fractal. The Hausdorff dimension of Koch snowflake is:

$$D = \frac{\log 4^n}{\log 3^n} = \frac{\log 4}{\log 3} = 1.2618...$$

Another case of fractals is the space-filling curves which is first described by Giuseppe Peano (1858–1932) and has Hausdroff dimension $D = 2$. Space-filling curve is useful in computer science in two general situations, managing multi-dimensional points and storing k-dimensional array on the disk [1]. This attributes to two features. (i) Space-filling curve is a continuous curve capable of mapping from d-dimensional space to 1-dimensional space. Using this mapping, a point in the cube can be described by its spatial coordinates, or by the length along the curve, measured from one its ends. Any one dimensional data structure can be used such as binary search trees, B-trees or Hash tables. (ii) Space-filling curve has good locality preserving behaviour such that points

are close together in the 1-dimensional space are mapped from points that are close together in the d-dimensional space. The reverse property is not true, i.e., not all adjacent cells in the d-dimensional space are adjacent or even close on the curve. A group of contiguous cells in d-dimensional space will typically be mapped to a collection of segments on the space-filling curve. There segments are called clusters. Z-order curve and Hilbert curve are space-filling curves as shown in Fig. 2a,b.

Frequency Moments

David Woodruff
IBM Almaden Research Center, San Jose, CA, USA

Synonyms

L_p norms; L_p distances

Definition

Consider a stream (i.e., an ordered list) $\mathcal{S} = a_1, a_2,\ldots, a_n$ of elements $a_i \in [m] \overset{\text{def}}{=} \{1,2,\ldots,m\}$. For $i \in [m]$, its frequency f_i is the number of times it occurs in $\mathcal{S}$. The k th frequency moment F_k of $\mathcal{S}$, for real $k > 0$, is defined to be $F_k(\mathcal{S}) = \sum_{i\in[m]} f_i^k$. Interpreting 0^0 as 0, one can also define F_0 this way, so that it equals the number of distinct elements in $\mathcal{S}$. Observe that $F_1 = n$ is the length of $\mathcal{S}$. In the database community, F_2 is known as the repeat rate or Gini's index of homogeneity. It is also natural to define $F_\infty = max_{1\leq i\leq m} f_i$.

It is usually assumed that n is very large and that algorithms which compute the frequency moments do not have enough storage to keep the entire stream in memory. It is also common to assume that they are only given a constant (usually one) number of passes over the data. It is further assumed that the stream is presented in an arbitrary, possibly worst-case order. This necessitates the use of extremely efficient randomized approximation algorithms. An algorithm A (ϵ, δ)-approximates the k th frequency moment F_k if for any input stream $\mathcal{S}$, $\Pr[|A(\mathcal{S}) - F_k(\mathcal{S})| \leq \epsilon F_k(\mathcal{S})] \geq 1 - \delta$, where the probability is over the coin tosses of A. Here, $A(\mathcal{S})$ means that A is presented items in $\mathcal{S}$ one-by-one. Efficiency is measured in terms of the amount of memory and update time of the algorithm.

Key Points

The frequency moments were introduced by Alon, Matias, and Szegedy [1] in their seminal paper in 1996, and are important statistics for massive databases. Indeed, efficient algorithms for estimating F_0 can be used by query optimizers for finding the number of unique values of an attribute without having to perform an expensive sort on the entire column. Efficient algorithms for F_2 are useful for determining the output size of self-joins and for error estimation in the context of query result sizes and access plan costs. Moreover, F_k for $k \geq 2$ can indicate the amount of skew of a data stream, and this can determine which algorithms to use for data partitioning. These values can also be used to detect denial-of-service attacks. In general, F_k for large k can be used to approximate the most frequent value, potentially more efficiently than computing this value directly.

There is a large body of work on bounding the memory required of F_k-approximation algorithms. In their original work, Alon, Matias, and Szegedy surprisingly showed that F_2 can be (ϵ, δ)-approximated using only $O(\frac{\lg 1/\delta}{\epsilon^2}(\lg n + \lg m))$ bits of memory. It is now known that F_k for $k \leq 2$ can be (ϵ, δ)-approximated in 1-pass using $O(\frac{\lg 1/\delta}{\epsilon^2})$ bits of space, up to a *polylog nm* factor, and there is an almost matching $\Omega(1/\epsilon^2)$ lower bound for 1-pass algorithms. For $k > 2$, a sequence of work showed that F_k can be approximated in $O(m^{1-2/k} log 1/\delta)$ space, up to a *poly* $(lognm, 1/\epsilon)$ factor, and there is an almost matching $\Omega(m^{1-2/k})$ bound. The memory required for approximating F_∞ is $\Theta(m)$. Note that for $k > 2$ the memory required depends polynomially on m, whereas for $k \leq 2$ the dependence is logarithmic. The known algorithms use a clever combination of hashing (with limited independence), sketching, and bucketing ideas. The corresponding lower bounds come from reductions from problems in communication complexity, and draw from tools in extremal combinatorics and information theory.

There are several natural questions about the computational complexity of frequency moments which remain unanswered. For instance, for constant δ, it is unknown if F_k for $0 \leq k \leq 2$ can be approximated more efficiently if more than one pass (but still a constant number) is allowed. Also, it is unknown how efficiently F_k can be approximated if the stream elements arrive in a random order.

Graph database mining

Definition

There are three key concepts in mining graph databases: (i) labeled graph, (ii) subgraph isomorphism, and (iii) graph support value. Based on the concepts, the problem of frequent subgraph mining could be defined in the following discussion.

Definition 1. *A **labeled graph** G is a quadruple G = (V, E, Σ, λ) where V is a set of vertices or nodes and $E \subseteq V \times V$ is a set of undirected edges. Σ is a set of (disjoint) vertex and edge labels, and λ: $V \cup E \rightarrow \Sigma$ is a function that assigns labels to vertices and edges. Typically a total ordering is defined on the labels in Σ.*

With the previous definition, a *graph database* is a set of labeled graphs.

Definition 2. *A graph $G' = (V', E', \Sigma', \lambda')$ is **subgraph isomorphic** to $G = (V, E, \Sigma, \lambda)$, denoted by $G' \subseteq G$, if there exists a 1-1 mapping $f: V' \rightarrow V$ such that*

- $\forall v \in V', \lambda'(v) = \lambda(f(v))$
- $\forall (u,v) \in E', (f(u),f(v)) \in E$, *and*

- $\forall(u,v) \in E', \lambda'(u,v) = \lambda(f(u), f(v))$.

The function f is a *subgraph isomorphism* from graph G' to graph G. For simplicity, G' *occurs* in G if $G' \subseteq G$. Given a subgraph isomorphism f, the image of the domain V' ($f(V')$) is an embedding of G' in G.

Example 1. *Figure 1 shows a graph database of three labeled graphs. The mapping (isomorphism) $q_1 \rightarrow p_3$, $q_2 \rightarrow p_1$, and $q_3 \rightarrow p_2$ demonstrates that graph Q is isomorphic to P and so Q occurs in P. Set $\{p_1, p_2, p_3\}$ is an embedding of Q in P. Similarly, graph S occurs in graph P but not Q.*

Definition 3. *Given a graph database $\mathcal{G}$, the* support *of a graph C, denoted by sup(C), is the fraction of graphs in $\mathcal{G}$ in which C occurs.*

Problem Statement: Given a graph database $\mathcal{G}$ and a support threshold $0 < \sigma \leq 1$, the *frequent subgraph mining* problem is to identify all graphs whose support value is at least σ.

There are several possible extensions to the problem of frequent subgraph mining. For example, the node may contain multiple label rather than one [2] and the identified patterns may contain node with or without labels [6]. Special cases for frequent subgraph mining include frequent tree mining, frequent path mining, and frequent cycle mining from graphs. The current introduction emphasizes the fundamental problem frequent subgraph mining and covers little about the mentioned extensions.

Historical Background

Graph database mining is an active research field. Recent graph mining algorithms can be roughly divided into three categories. The first category uses a level-wise search strategy, including AGM [6] and FSG [7]. The second category takes a depth-first search strategy, including gSpan [11] and FFSM [4]. The third category works by first mining frequent trees and then construct cyclic graphs based on tree pattern. This category includes SPIN [5] and GASTON [8]. See [1] for a recent survey.

The following description of frequent subgraph mining is mainly based on the algorithms FFSM and SPIN. Both algorithms are built on top of a data structure termed CAM tree (graph Canonical Adjacency Matrix tree), which is a compact representation of a space of graphs. Using CAM tree, FFSM (Fast Frequent Subgraph Mining, [4] supports an incremental subgraph isomorphism check and hence is scalable for large graphs. SPIN (SPanning tree based mINing, [5]) reduces the total number of mined patterns by identifying only the *maximal* ones, i.e., the set of frequent subgraphs such that none of their supergraphs is frequent.

Foundations

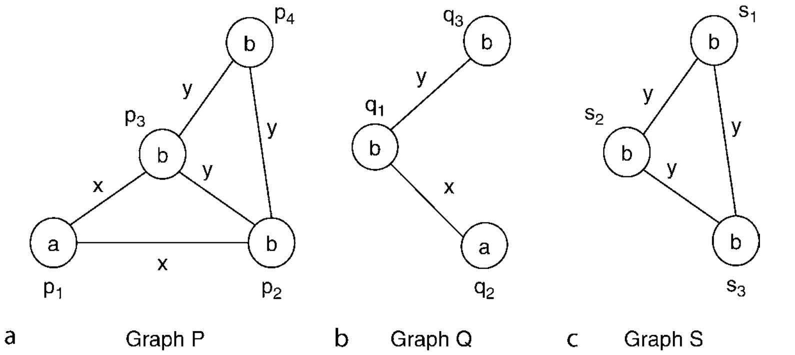
Three topics are important for designing efficient subgraph mining algorithms:

1. Graph Canonical Form.
2. Candidate Graph Proposing.
3. Candidate Support Value Computation.

In the following, the three topics are discussed in details.

Canonical Adjacency Matrix

For labeled graph, a natural way to present a graph is using an modified adjacency matrix. In this representation, every diagonal entry of the modified adjacency matrix is filled with the label of the corresponding node and every off-diagonal entry is filled with the label of the corresponding edge, or zero if there is no



Frequent Graph Patterns. Figure 1. A database of three labeled graphs.

edge. This is slightly different from the widely used adjacency matrix representation for unlabeled graphs.

One of the critical problems in graph mining is the graph isomorphic problem: given two graphs P and Q, determine whether P is isomorphic to Q. This problem may be solved following a common theme such that a graph is first transformed to a unique presentation (referred to as the *canonical form* of the graph) and secondly, two graphs are compared using the transformed presentations. A graph canonical form is specially designed such that if two graphs are isomorphic to each other, their canonical forms are the same and vice versa.

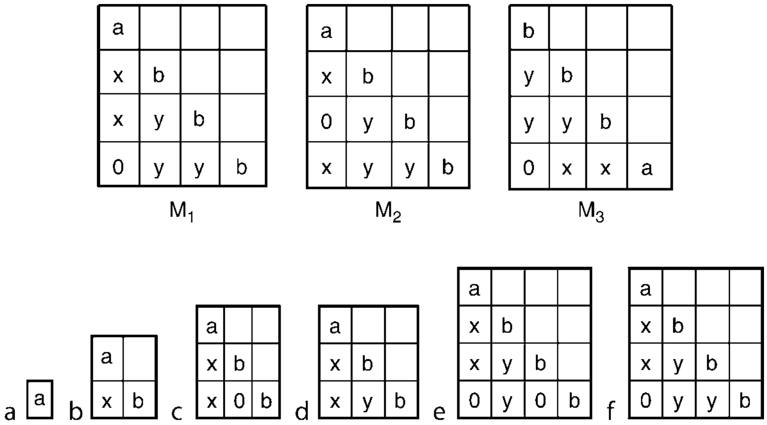
Following convention, in the following a capital letter is used to denote an adjacency matrix and the corresponding lower case letter (augmented with subscripts) is used to denote an individual entry of the adjacency matrix. For instance, $m_{i,j}$ denotes the entry on the ith row and jth column of an $n \times n$ adjacency matrix M, $0 < j \leq i \leq n$. Note that the adjacency matrix is not unique for a given graph: a permutation of the set of vertices in a graph may generate a different adjacency matrix. There is a total of $n!$ different permutations for a graph vertex set with size n, there may be up to $n!$ adjacency matrices for the graph. Figure 2 (top) shows three adjacency matrices for the labeled graph P in Fig. 1 (Only the lower triangular part of an adjacency matrix is drawn since the upper half is a mirror of the lower half.). In order to enable a unique representation for each graph, the code of adjacency matrices is defined below. Graph code helps in defining a total order among all adjacency matrices.

Definition 4. *Given an $n \times n$ adjacency matrix M of a graph G with n vertices, the* **code** *of M, denoted by code (M), is the sequence formed by concatenating lower triangular entries of M (including diagonal entries) in the order: $m_{1,1}m_{2,1}m_{2,2}...m_{n,1}m_{n,2}...m_{n,n-1}m_{n,n}$ $(0 < j \leq i \leq n)$.*

For an adjacency matrix M, each diagonal entry of M is a *node entry* and each off-diagonal none-zero entry in the lower triangular part of M is an *edge entry*. Edge entries are ordered according to their relative positions in the code of the matrix. For example the *first* edge entry of M is $m_{2,1}$ and the *last* edge entry is the one appears rightmost in *code*(M).

Example 2. *Figure 2 shows codes and edge entries for the labeled graph P showing in Fig. 1. For example for adjacency matrix M_1, the edge entry set is $\{m_{2,1}, m_{3,1}, m_{3,2}, m_{4,2}, m_{4,3}\}$ where $m_{2,1}$, $m_{4,3}$, and $m_{4,2}$ are the first, last, second-to-last edge entries of M, respectively. After applying the total ordering, the relationships are: code (M_1) = "axbxyb0yyb" $\geq$ code(M_2) = "axb0ybxyyb" $\geq$ code(M_3) = "bybyyb0xxa." Submatrices of CAM are shown at the bottom. Matrix 3.a is the proper maximal submatrix of matrix 3.b, which itself is the proper maximal submatrix of 3.c and so on so forth.*

Standard lexicographic order on sequences is usually used to define a total order of two arbitrary codes p and q. Given a graph G, its *canonical form*, denoted by $\varphi(G)$, is the maximal code among all its possible codes. The adjacency matrix M that produces the canonical form is the G's *canonical adjacency matrix* (CAM). For example, the adjacency matrix M_1 shown in Fig. 2 is the CAM of the graph P in Fig. 1, and *code*(M_1) is the canonical form of the graph.



$$M_1 = \begin{array}{|c|c|c|c|}\hline a & & & \\ \hline x & b & & \\ \hline x & y & b & \\ \hline 0 & y & y & b \\ \hline\end{array} \quad M_2 = \begin{array}{|c|c|c|c|}\hline a & & & \\ \hline x & b & & \\ \hline 0 & y & b & \\ \hline x & y & y & b \\ \hline\end{array} \quad M_3 = \begin{array}{|c|c|c|c|}\hline b & & & \\ \hline y & b & & \\ \hline y & y & b & \\ \hline 0 & x & x & a \\ \hline\end{array}$$

$$a \ \begin{array}{|c|}\hline a \\ \hline\end{array} \quad b \ \begin{array}{|c|c|}\hline a & \\ \hline x & b \\ \hline\end{array} \quad c \ \begin{array}{|c|c|c|}\hline a & & \\ \hline x & b & \\ \hline x & 0 & b \\ \hline\end{array} \quad d \ \begin{array}{|c|c|c|}\hline a & & \\ \hline x & b & \\ \hline x & y & b \\ \hline\end{array} \quad e \ \begin{array}{|c|c|c|c|}\hline a & & & \\ \hline x & b & & \\ \hline x & y & b & \\ \hline 0 & y & 0 & b \\ \hline\end{array} \quad f \ \begin{array}{|c|c|c|c|}\hline a & & & \\ \hline x & b & & \\ \hline x & y & b & \\ \hline 0 & y & y & b \\ \hline\end{array}$$

Frequent Graph Patterns. Figure 2. Top: three adjacency matrices for the graph P in Fig. 1. Bottom: examples of maximal proper submatrices.

CAM Tree

Efficient frequent subgraph mining algorithm relies on efficient data structure. Below a widely data structure called CAM tree is discussed. CAM tree utilizes a key property of the previous canonical form, i.e., a “prefix” of the canonical form is also maximal, which is stated in the following theorem.

Definition 5. *Given an $n \times n$ matrix N and a $m \times m$ matrix M, let $m_{l,k}$ be the last edge entry of M, a matrix N is the* ***maximal proper submatrix*** *of M if N is obtained by removing $m_{l,k}$ from M*

Several examples of the maximal proper submatrices are given at the bottom of Fig. 2.

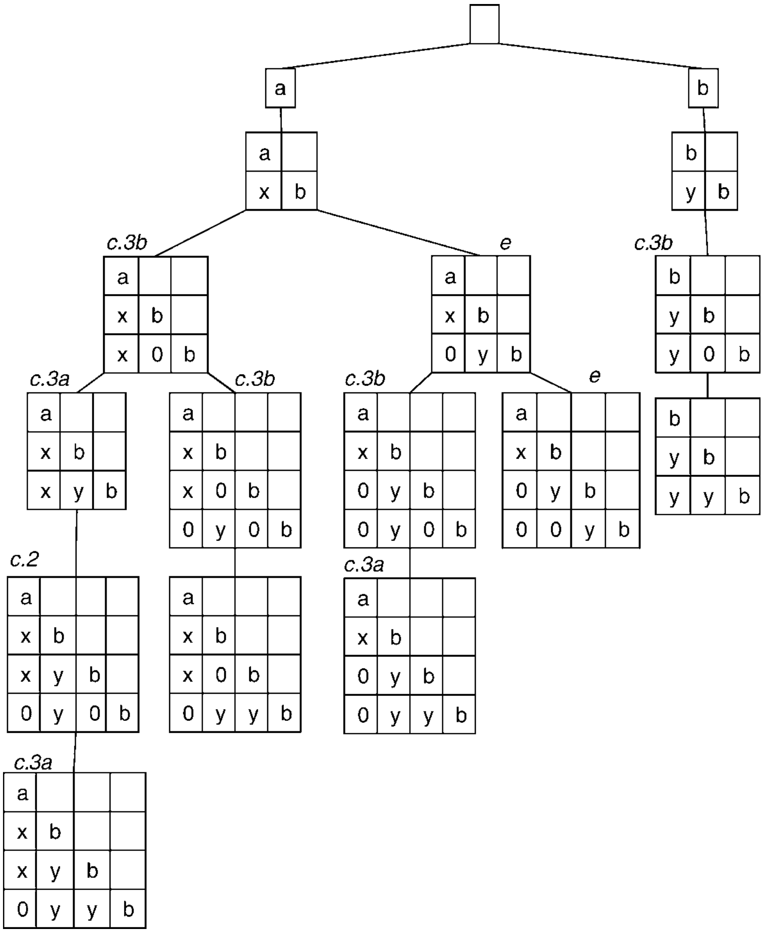
Corollary 1 *Given a CAM M of a connected graph G and a submatrix N of M, N represents a connected subgraph of G.*

Proof 1 *Since N must represent a subgraph of G, it is sufficient to show that the subgraph N represents is connected. To prove this, it is sufficient to show that in N there is no such row i (with the exception of the first row) that i doesn't contains any edge entry. The rest of the proof is trivial and could be found in* [6].

Corollary 2 *Given a connected graph G with CAM M, a submatrix N of M, and a graph H which N represents, N is the CAM of H.*

Proof 2 *For simplicity, M is assumed to have only one edge entry in the last row. It is trivial to show that code (N) is a prefix of code(M). This suggests that code$(N) \geq$ code$(CAM(H))$, where $CAM(H)$ stands for the canonical adjacency matrix of graph H. Therefore N must be the CAM of the graph H.*

For a CAM with at least two edge entries in the last row, a similar proof could be used.



Frequent Graph Patterns. Figure 3. The CAM Tree of the graph *P* in Fig. 1. Every matrix obtained by a join operation is specified by a label starting with c. and then the type of the join operation e.g., c. 3a stands for join case3a. A CAM obtained by an extension operation is labeled with e.

Usually an empty matrix is considered as the maximal proper submatrix of any matrix with size 1. With this assumption, all the CAMs of connected subgraphs of a graph *G* may be organized as a rooted tree as follows:

- The root of the tree is an empty matrix;
- Each node in the tree is a distinct connected subgraph of *G*, represented by its CAM;
- For a given none-root node (with CAM *M*), its parent is the graph represented by *M*'s maximal proper submatrix;

The tree obtained in this fashion is denoted as the *CAM tree* of the graph *G*. Figure 3 shows the CAM tree of the graph *P* from Fig. 1.

Frequent Subgraph Mining of a Graph Database

With the CAM tree data structure, the space of subgraphs could be organized in a single CAM tree. If such a tree is built in advance (regardless of the required space and computational capacity), any traversal of the tree (depth-first, level-wise, random) reveals the set of distinct subgraphs of the graph database. For each of such subgraph, its support value may be determined by a linear scan of the graph database and finally frequent ones can be reported. This method clearly suffers from the huge number of available subgraphs in a graph database and hence has poor scalability to large databases.

In the following pseudo code, an algorithm which takes advantage of the following simple fact is presented: if a subgraph *G* is infrequent (support of *G* is less than a user posted threshold), none of its supergraphs are frequent. This suggests that an algorithm can stop building a branch of the tree as early as its finds out that the current node has insufficient support.

In the pseudo code below, symbol *CAM*(*G*) denotes the CAM of the graph *G*. *is CAM* is a function computes whether the matrix *X* is the CAM of the graph it represents or not.

FFSM

input: a graph database *GD* and a support threshold $f\,(0 < f \leq 1)$

output: set S of all *G*'s connected subgraphs.

```
$C \leftarrow$ {the CAMs of the frequent edges}
$F \leftarrow$ {the CAMs of the frequent nodes and edges}
FFSM-Explore ($C$,$F$);
```

FFSM-Explore

input: *C*, a suboptimal CAM list and *F*, a set of frequent connected subgraphs' CAMs

output: set *F* contains CAMs of all frequent subgraphs searched so far.

```

Key Applications

Frequent subgraph mining has many applications. Below two applications in the emergent area of bioinformatics and cheminformatics are reviewed. Other applications of frequent subgraph mining could be found in recent reviews.

Pattern Discovery from Chemical Structures

Several investigators have applied the idea of frequent subgraph mining in cheminformatics. In these applications, a graph is used to model a chemical structure where a node represents an atom and an edge represents a chemical bond in the chemical structure. Frequent subgraph mining is then utilized to discover task-relevant and problem-specific features (*descriptors* as usually called in cheminformatics literature) in the chemical structures. Finally the features are utilized to build a predictive model to map chemical structures to their target properties [9].

Pattern Discovery from Protein Structures

Huan et al. have applied data mining algorithms to analyze 3D structures of biomoelcules including proteins and chemicals. Their approach adopted geometric graph representations of protein 3D structure using a geometric technique called Delaunay Tessellation and its recent extension to almost-Delaunay. These techniques produce sparser but information-preserving graph representations than conventional distance-based methods. With the graph database mining techniques, they have identified structure patterns that occur frequently in a family of proteins but rarely in other families, or *protein family-specific fingerprints*. It has been demonstrated that patterns obtained from comparing multiple structures have clear linkages to known functional features such as the catalytic sites in enzymes [3].

Frequent Items on Streams

AHMED METWALLY
Google Inc., Mountain View, CA, USA

Synonyms

Frequent elements; Heavy hitters; Hot items

Definition

Frequent items are the items that mostly represent the stream, since these are the items that occur more than a given user threshold. Formally, given a stream, S, of size N from an alphabet, A, a *frequent item*, $E_i \in A$, is an item whose *frequency*, or number of occurrences, F_i exceeds a specific user support ϕN, where $0 \leq \phi \leq 1$. There cannot be more than $\lfloor \frac{1}{\phi} \rfloor - 1$ such items. Finding the frequent items exactly in one pass requires $O(min(A,N))$ in-memory space [6]. Frequent items can be defined on the entire stream or on a sliding window of fixed or variable size (see Stream Models). Similarly, frequent items can be defined on append-only streams as well as streams with item deletions (see Stream Mining).

Historical Background

Even before the stream processing model was proposed, the early work in [3], and [9] searches for a majority item that occur more than $\frac{N}{2}$ times. This work was extended in [15] to search for $\lfloor \frac{1}{\phi} \rfloor - 1$ items, each occurring more than ϕN times.

Foundations

Due to the high cost of the exact solution of the frequent items problem, researchers proposed approximate problem definitions. This section discusses the problem approximations and their proposed algorithms.

Problem Approximations

The approximate problem definition in [3,9,15] is to report $\lfloor \frac{1}{\phi} \rfloor - 1$ items regardless of the number of items that really satisfy the frequency constraint. However, all the really frequent items should be among the reported set of items. This introduces *false positives*, which are reported items whose frequencies do not really exceed ϕN.

The *hot items* problem [6], is to report the frequent items with high probability. This raises the issue of having both false positives and *false negatives*, where a false negative is a frequent item that is not reported.

Finding the ε-*deficient* frequent items was proposed by Manku and Motwani [13] to report all the items with frequencies exceeding $\lceil \phi N \rceil$. In addition, no reported item can have a frequency less than $\lceil (\phi - \varepsilon) N \rceil$, where $\varepsilon \in [0, \phi]$ is a user-defined error. The estimated frequencies of the reported items also have to be reported.

Proposed Algorithms

Several algorithms [6,7,8,10,11,13,14] were proposed to solve the approximate frequent items problems. In [14], these algorithms are classified into *Counter-based* and *Sketch-based* algorithms.

Counter-Based Techniques

Counter-based algorithms monitor the frequency of a subset of A. They keep a counter for each monitored item. The counter of a monitored item, E_i, is updated whenever E_i is observed in the stream. The algorithms mainly differ in how they handle non-monitored items.

The *Sticky Sampling* algorithm [13] solves the ε-deficient frequent items probabilistically. It slices S into rounds of exponentially increasing length. The probability an item is sampled, i.e., starts to be monitored, at any round, r, is $\frac{1}{r}$. At rounds' boundaries, for every monitored item, a coin is tossed until a success occurs. The counter is decremented for every unsuccessful toss, and is deleted if it reaches 0. Since decrementing counters follow a geometric distribution, the probability of sampling an item is constant throughout S. *Sticky Sampling* has a space bound of $O(\frac{2}{\epsilon}\ln(\phi^{-1}\delta^{-1}))$, where δ is the failure probability.

The *Lossy Counting* algorithm [13] solves the ε-deficient frequent items with success probability of 1, though with a space bound greater than that of *Sticky Sampling*. S is broken up into rounds of equal length, $\frac{1}{\epsilon}$. Throughout every round r, non-monitored items are added to the monitored set. When a new item is added in round r, it is given the benefit of doubt. Its initial count is set to $r - 1$, and the maximum possible overestimation, $r - 1$, is recorded for the new item. Thus, *Lossy Counting* guarantees that monitored items can have their frequencies overestimated by no more than εN, and never underestimated. At the end of each ound, r, every item, E_i, whose estimated frequency s less than r is evicted in order to reduce the space footprint. *Lossy Counting* [13] has a space bound of $O(\frac{1}{\epsilon}\ln(\epsilon N))$.

The *Frequent* algorithm [7] solves the problem of [15], which asks for a maximum of $\lfloor \frac{1}{\phi} \rfloor - 1$ items, each of which has frequency exceeding ϕN. *Frequent*, a rediscovery of the algorithm proposed by [15], outputs a list of exactly $\frac{1}{\phi} - 1$ items with no guarantee on which items, if any, have frequency more than ϕN. This algorithm extends the early work done in [3,9] for finding a majority item using only one counter. The algorithm in [3,9] monitors the first item in the stream. For each observation, the counter is incremented if the observed item is the monitored one, and is decremented otherwise. If the counter reaches 0, it is assigned the next observed item, and the algorithm is then repeated. When the algorithm terminates, the monitored item is the candidate majority item. *Frequent* [7] keeps $\frac{1}{\phi} - 1$ counters to monitor items. If a monitored item is observed, its counter is incremented, else all counters are decremented in an $O(1)$ operation, using a lightweight data structure. In case any counter reaches 0, it is assigned the next observed item. The discussion assumes hashing takes constant time. If the data structure is not used, decrementing all counters has an $O(1)$ amortized cost. The algorithm uses only $\frac{1}{\phi} - 1$ counters, but reports back all the monitored items, which could yield a high ratio of false positives. The same algorithm and data structure were proposed independently in [11].

The *Space-Saving* algorithm [14] solves the ε-deficient frequent items with success probability of 1 with a space bound of $\frac{1}{\epsilon}$, and gives the same guarantees on overestimation error of *Lossy Counting*. Moreover, the guaranteed error rate, ε, provably decreases with the increase in data skew. If the observed item, x, is monitored, its counter is incremented. If x is not monitored, i.e., no counter is assigned to x, then the item that currently has the least estimated hits, *min*, is evicted and the counter is assigned to x. The intuition behind replacing the item with the least hits is to sacrifice the least amount of information about the stream history. Since the actual hits of x can be any number between 1 and $min + 1$, *Space-Saving* assumes x has been observed $min + 1$ times, since it gives items the benefit of doubt not to underestimate frequencies. Like *Lossy Counting*, for each monitored item the algorithm keeps track of its maximum possible over-estimation resulting from the initialization of its counter when starting monitoring it. To guarantee constant processing time per observation, the item with the least estimated hits has to be identified in

$O(1)$ time. To do that, *Space-Saving* uses a data structure similar to that in [7] in order to keep the counters always sorted by their estimated hits. However, not using the data structure still guarantees an amortized constant time per stream observation.

In general, counter-based techniques have fast per-item processing since counters can be stored in hash tables.

Sketch-Based Techniques

Sketch-based techniques do not monitor a subset of items, but rather provide, with less stringent guarantees, frequency estimation for all items by using arrays of counters. Usually, each counter monitors the frequencies of a subset of the item domains. Similarly, each item is hashed into the space of counters using a family of hash functions, and the hashed-to counters are updated for every hit of this item. These "representative" counters are then queried for the item frequency.

The *GroupTest* algorithm [6] solves the hot items problem, with a probability of failure of δ. The *FindMajority* algorithm was first devised to detect the majority item, by keeping a system of a global counter and $\lceil log(|A|) \rceil$ counters. Assuming that items' IDs are in the range $1...|A|$. A hit to item E is handled by updating the global counter, and all counters whose index corresponds to a 1 in the binary representation of E. At any time, counters whose value are more than half the global counter correspond to the 1s in the binary representation of the candidate majority item, if it exists. *GroupTest* is a simple generalization of *FindMajority*, which keeps only $O(\frac{\frac{1}{\phi}-1}{\delta}\log(\frac{1}{\phi}-1))$ of such systems, and uses a family of universal hash functions to map each item to $O(\frac{\log(\frac{1}{\phi}-1)}{\delta})$ *FindMajority* systems that monitor the occurrences of the item. When queried, the algorithm discards systems with more than one, or with no hot items. Also proposed is an elegant scheme for suppressing false positives by checking that all the systems a hot item belongs to report this item as being hot. *GroupTest* is generally accurate and can handle streams with both item insertions and deletions. However, it offers no information about items' frequencies or order.

The *Multistage Filters* approach, proposed by [8], which was also independently proposed by [10], is similar to *GroupTest*. The *Multistage Filters* algorithm hashes every item to a number of counters that are updated every time the item is observed in the stream. The item is considered to be frequent if the smallest of its representative counters satisfies the user required support. The algorithm by [8] judges an item to be frequent or not while updating its counters. If a counter is estimated to be frequent, it is added to a specialized set of counters for monitoring frequent items, the *flow memory*. To decrease the false positives, [8] proposed some techniques to reduce the over-estimation errors in counters. First, once an item is added to the flow memory, its counters are not monitored anymore by the *Multistage Filters*. Second, the algorithm increments only the counter(s) of the minimum value. Without the second error-reduction technique, the algorithm can be used for streams of both item insertions and deletions.

The *hCount* algorithm [10], does not employ the error reduction techniques employed by [8]. However, it keeps a number of imaginary items, which have no hits. At the end of the stream, all the items in the alphabet are checked for being frequent, and the over-estimation error for each of the items is estimated to be the average number of hits for the imaginary items. Both the *hCount* algorithm [10], and the *Multistage Filters* [8] require a number of counters bounded by $\frac{e}{\epsilon} * \ln\left(\frac{-|A|}{\ln\delta}\right)$.

In general, sketch-based techniques are not affected by the ordering of items in the stream, and are usually capable of handling streams with item insertions and deletions. On the other hand, they are probabilistic, and an item observation or a query about its frequency entails calculations across several counters.

Generalization for Sliding Windows

In [1], generalizations of the algorithm in [15], and *Sticky Sampling* were proposed for sliding windows of fixed and variable sizes (see Stream Models). Limiting the discussion to the deterministic [15] algorithm and the fixed size sliding window, the generalization monitors the stream at several levels of exponentially increasing granularities. That is, the finest granularity level, *level*-0, keeps copies of the algorithm that tracks the frequent items in sub-windows of size $f(W, \varepsilon)$, where W is the fixed size of the sliding window. These sub-windows are non-overlapping and contiguous such that their union is equivalent to the whole sliding window, modulo the oldest sub-window that contains expired items. The second finest granularity, *level*-1, keeps copies of the algorithm that tracks the frequent items in sub-windows of size $2 \times f(W, \varepsilon)$, and so forth. A boundary of a sub-window at any level has to cooccur with a boundary at the next finer level. Due to keeping several levels, and keeping several algorithm copies at each level, the space requirement is $O(\frac{1}{\epsilon}(\log(\epsilon N))^2)$.

The case for variable size sliding window was handled essentially by forming new levels of coarser granularity from existing levels when the window size multiplies by a factor of 2. The requirement here is to be able to merge two copies of the algorithm, each has observed n items, to form a copy of the algorithm that is equivalent to observing the entire 2 × n items. If the window shrinks to be a smaller size than the granularity of the coarsest level, the coarsest level is dropped.

At query time, the results of the algorithm copies at all levels are combined together to discover the frequent items in the entire sliding window. This requires the ability to combine the output of several algorithm copies while maintaining the error guarantees of the algorithm. The combining process does not include algorithm copies monitoring sub-windows containing expired items, does not include algorithm copies monitoring items that are already combined, and favors copies of the algorithm at the coarser levels.

The generalization of [15] to sliding windows at [12] does not keep several copies of the algorithm. Instead, the counters are incremented in a way that expires occurrences of the item that are older than the sliding window boundary. The space requirement is still $O(\frac{1}{\epsilon})$, thought the time for processing each element is also $O(\frac{1}{\epsilon})$. The case for variable size sliding window was handled essentially by adding new levels when the window size multiplies by a factor of 2. The requirement here is to be able to from a copy of a sliding window algorithm with error $2 \times \varepsilon n$ from another copy with error εn, where n is the number of items observed by the original copy. Like [1], if the window shrinks to be a smaller size than the granularity of the coarsest level, the coarsest level is dropped. The work done by Lee and Ting [12] was recently improved further in [16] to require $O(1)$ for processing each stream element using a doubly circularly-linked list to link the occurrences of the items sorted by their expiration time. Hence, the algorithm can expire occurrences of the items more efficiently.

Key Applications

Current motivation of the stream frequent items problem include network traffic analysis which is important for caching, routing, accounting, detecting network-level attacks, and maintenance [7,8]. In [14], the problem was applied for the application of increasing the revenue of Internet advertising networks. Motivated by these networks applications, [2] implemented *Space-Saving* and *Lossy Counting* on network processing units (NPUs), a special networking architecture with associative memories. In addition, [13] considered using frequent items queries to alleviate finding frequent itemsets (see Association rules), as well as iceberg queries and iceberg cubes. In specific, [5] generalized the problem to the case of multi-dimensional items in the presence of domain hierarchies (see Hierarchical heavy hitter mining on streams).

Experimental Results

Recently, Cormode and Hadjieleftheriou [4] conducted experiments comparing the most promising algorithms on both real and synthetic data, and noticed the competitive benefits of *Space-Saving* when processing append-only streams. In the case of streams with deletions, different sketch-based algorithms had different advantages.

In [13], the two proposed algorithms, *Lossy Counting* and *Sticky Sampling*, were compared on synthetic Zipfian data. *Lossy Counting* perform bettered even though the theoretical space bound of *Sticky Sampling* is better. However, the experiments were run with relatively small alphabets.

In [6], the algorithms *GroupTest*, *Lossy Counting*, and *Frequent* were compared on both real telephone connection and synthetic data. The data had both item insertions and deletions. Both *Lossy Counting* and *Frequent* were made to handle item deletions by decrementing the counters of the deleted items if such counters exist. Under these conditions, on synthetic data *GroupTest* performed best, followed by *Frequent*, and then *Lossy Counting* had the least precision and recall (the highest false positives and negatives). However, *GroupTest* used approximately 3× the space used by *Lossy Counting*, and 6× the space used by *Frequent*. On real data, *Lossy Counting* performed better than *Frequent*, but *GroupTest* was more accurate than both.

In [8], the proposed techniques were compared against commercial sampling-based algorithms for traffic measurement on real Internet backbone traffic traces. The results favored the *Multistage Filters* technique.

In [14], the algorithms *Space-Saving*, *GroupTest*, and *Frequent* were compared on real Internet advertising traffic as well as synthetic data, both with large alphabets. Throughout the experiments, *Frequent* attained a precision of less than 0.2. *Space-Saving* was the only algorithm that neither reported false positives nor reported false negatives, even though it consumed roughly the same space of *Frequent*. On real data, *Space-Saving* consumed approximately one fifth of the space used by *GroupTest*, and on synthetic data, *Space-Saving* consumed at most one eighth of the space used by *GroupTest*.

Nagender Bandi et al. [2] compared how the hardware and software implementations of *Space-Saving* and *Lossy Counting* perform. The results of *Lossy Counting* conformed with those in [13]. *Lossy Counting* can use space much smaller than its bounds under small alphabets. *Lossy Counting* used less space than *Space-Saving* when the data was skewed and the skew was not estimated. However, *Space-Saving* used less space when the data skew was estimated since it monitored less items. The hardware implementation of *Space-Saving* ran significantly faster than *Lossy Counting*, while the software implementation ran only slightly faster.

Frequent Itemset Mining with Constraints

CARSON KAI-SANG LEUNG
University of Manitoba, Winnipeg, MB, Canada

Synonyms

Constrained frequent itemset mining; Frequent pattern mining with constraints; Frequent set mining with constraints

Definition

Let $\mathtt{Item} = \{ item_1, item_2, \ldots, item_m\}$ be a set of domain items, where each item represents an object in a specific domain. Each object is associated with some attributes or auxiliary information about the object. A transaction $t_i = \langle tID, I_i \rangle$ is a tuple, where *tID* is a unique identifier and $I_i \subseteq \mathtt{Item}$ is a set of items. A set of items is also known as an *itemset*. A transaction database *TDB* is a collection of transactions. An itemset *S* is *contained* in a transaction $t_i = \langle tID, I_i \rangle$ if $S \subseteq I_i$.

The *support* (or *frequency*) of an itemset *S* in a database *TDB* is the number (or percentage) of transactions in *TDB* containing *S*. An itemset is *frequent* if its support exceeds or equals a user-specified support threshold *minsup*. A user-specified constraint *C* is a predicate on the powerset of `Item` (i.e., $C: 2^{\texttt{Item}} \mapsto \{\text{true, false}\}$). An itemset *S satisfies* a constraint *C* if *C*(*S*) evaluates to true. Hence, given (i) a transaction database *TDB*, (ii) a user-specified support threshold *minsup* and (iii) user-specified constraints *C*, the problem of *frequent itemset mining with constraints* is to find from *TDB* a set of frequent itemsets that satisfy *C*.

Historical Background

The research problem of frequent itemset mining was first introduced by Agrawal et al. [1] for market basket analysis in the context of association rule mining. Specifically, frequent itemset mining, which aims to find frequent itemsets from a transaction database, is an important first step of association rule mining. Once the frequent itemsets are found, they are used in the second step to generate association rules. The rules reveal the buying patterns in consumer behavior. For instance, they tell how the presence of some itemsets is associated with the presence of some other itemsets in the shopping baskets of consumers. This information is useful in making decisions in applications such as customer targeting, shelving, and sales promotion.

Besides the mining of association rules, frequent itemset mining also plays an essential role in many important data mining tasks – such as the mining of maximal itemsets, closed itemsets, correlation, causality, and sequential patterns. This explains why frequent itemset mining has been the subject of numerous studies since its introduction. Most of these studies focused either on improving efficiency of frequent itemset mining (e.g., the Apriori frequent itemset mining framework [2] and its tree-based counterpart [7]) or on extending the initial notion of frequent itemsets to other patterns such as maximal itemsets, closed itemsets, and correlated itemsets. Regardless whether they focused on these performance or functionality issues, these studies basically considered the data mining exercise in isolation. They relied on a computational model in which the computer does almost everything and the user is *not* engaged in the mining process. In other words, this model does not explore how data mining can interact with the human user. Consequently, the model provides little or no support for user focus.

However, in many applications, it is not uncommon for the user to have certain broad phenomena in mind, on which to focus mining. Without user focus, the mining process is treated as an impenetrable black-box – only allowing the user to set the support threshold *minsup* at the beginning and to get all the frequent itemsets at the end. The user does not have the opportunity to specify his interest via the use of constraints. As a result, the user often needs to wait for a long period of time for numerous frequent itemsets, out of which only a tiny fraction may be interesting to the user. This motivates the introduction of the research problem of *frequent itemset mining with constraints*, which gives the user opportunities to express his focus in mining by means of a rich set of constraints that captures application semantics.

Foundations

When compared with its traditional unconstrained counterpart, *frequent itemset mining with constraints* provides user focus in the sense that the user has opportunities to express his interest – via the use of constraints. By using the constraints, mining can be focused and computation can be saved. Over the past decade, several studies on frequent itemset mining with constraints have been proposed. For example, Ng, Lakshmanan and their colleagues [8,9,11] proposed a framework and algorithms for mining frequent itemsets with constraints. Within their framework, the user can use a rich set of constraints – which captures the semantics of itemsets – to guide the mining process for finding only those frequent itemsets that satisfy the constraints. These constraints include SQL-style aggregate constraints as well as domain constraints. The *SQL-style aggregate constraints* are of the following form:

$$agg(S.attribute)\ \theta\ constant,$$

where *agg* is an SQL-style aggregate function (e.g., *min*, *max*,*sum*,*avg*) and θ is a Boolean comparison operator (e.g., $=,\neq,<,\leq,\geq,>$). For example, by specifying the aggregate constraint $min(S.Price) \geq \$20$, the user expresses his interest in finding every itemset *S* such that the minimum price of all items in *S* is at least $20. Other examples of aggregate constraints include $avg(S.Temperature) < -18^{\circ}\mathrm{C}$ (which expresses that the average temperature of items in *S* is below $-18^{\circ}\mathrm{C}$) and $max(S.Qty) > 15$ (which expresses that the maximum quantity of items in *S* is more than 15). *Domain* *constraints*, which are non-aggregate constraints, can be of the following forms:

1. *S.attribute* θ *constant*, where θ is a Boolean comparison operator (e.g., $=,\neq,<,\leq,\geq,>$);
2. *constant* $\in$*S.attribute*;
3. *constant* $\notin$ *S.attribute*; or
4. *S.attribute* φ *set of constants*, where φ is a set comparison operator (e.g., $\subseteq,\not\supseteq,\subset,\not\subset,=,\neq,\supseteq,\not\supseteq,\supset,\not\supset$).

Examples of domain constraints include *S.ManufactureYear* $\neq$ 2008 (which expresses that each item in *S* is not manufactured in 2008), 2kg $\in$*S.Weight* (which expresses that a 2kg-item must be in *S*) and *S.Type* $\supseteq$ {*snack*, *soda*} (which expresses that *S* must contain some snacks and soda). These aggregate constraints and domain constraints can be categorized into several overlapping classes – such as *anti-monotone constraints*, *succinct constraints*, *monotone constraints*, and *convertible constraints* – based on properties of constraints. Figure 1 shows the characterization of some commonly used constraints.

To find frequent itemsets that satisfy the aforementioned constraints, Ng, Lakshmanan and their colleagues proposed algorithms – called *CAP* (Constrained Apriori) [11] and *DCF* (Dynamic Constrained Frequent-set computation) [8] – that exploit properties of these constraints. By doing so, both CAP and DCF ensure that the computational effort in mining frequent itemsets satisfying the constraints is proportional to the selectivity of the constraints. For instance, both CAP and DCF algorithms exploit a nice property of *anti-monotone constraints*: For an anti-monotone constraint C_{am} (e.g., *min*(*S.Price*) $\geq$ \$20, *S.ManufactureYear* $\neq$ 2008), if an itemset *S* does not satisfy C_{am} then supersets of *S* are guaranteed not to satisfy C_{am}. Hence, whenever *S* does not satisfy C_{am}, both CAP and DCF do not need to generate any superset of *S* as a candidate and thus do not need to count its support (or frequency). Consequently, by pushing C_{am} into the mining process, the mining algorithms save computation.

Note that many algorithms for mining frequent itemsets with or without constraints (e.g., Apriori [2], CAP [11] and DCF [8]) have also been exploiting a special anti-monotone constraint – namely, the *frequency constraint support*(*S*) $\geq$*minsup*, which states that the support (or frequency) of a frequent itemset *S* should equal or exceed the user-specified support threshold *minsup*. If *S* is infrequent, then the mining algorithms do not consider supersets of *S* because they are guaranteed to be infrequent. This property is commonly known as the Apriori property.

In addition to anti-monotone constraints, both CAP and DCF algorithms also exploit *succinct constraints* (e.g., *min*(*S.Price*) $\geq$ \$20, 2kg $\in$ *S.Weight*). For frequent itemset mining without constraint, it is well known that mining algorithms based on the Frequent-Pattern tree (FP-tree) [7] outperform their

Frequent Itemset Mining with Constraints. Figure 1. Characterization of commonly used domain, aggregate and frequency constraints.

Apriori-based counterparts. As both CAP and DCF are Apriori-based, Leung et al. [10] proposed an FP-tree based algorithm – called *FPS* (*FP*-tree based mining of *S*uccinct constraints) – for mining frequent itemsets that satisfy succinct constraints. By pushing the succinct constraint C_{suc} into the mining process, all three algorithms (CAP, DCF and FPS) directly generate precisely all and only those itemsets that satisfy C_{suc} by using a precise "formula" called a *member generating function* (*MGF*). As a result, there is no need to generate and then exclude itemsets not satisfying C_{suc}. For example, itemsets satisfying the succinct constraint $min(S.Price) \geq \$20$ can be generated by first selecting items with price at least \$20 from the domain `Item` and then combining these selected items:

$$\{X | X \subseteq \sigma_{Price \geq \$20}(\text{Item}),\ X \neq \emptyset\}.$$

As another example, itemsets satisfying the succinct constraint 2kg $\in S.Weight$ can be generated by combining at least one 2kg-item (i.e., at least one mandatory item) with some optional items of any weight:

$$\{Y \cup Z | Y \subseteq \sigma_{Weight=2\text{kg}}(\text{Item}),\\ Y \neq \emptyset,\ \ Z \subseteq \sigma_{Weight \neq 2\text{kg}}(\text{Item})\}.$$

As the third example, itemsets satisfying the succinct constraint $S.Type \supseteq \{snack, soda\}$ can be generated by combining some snacks and some soda (which are mandatory items) with some optional items of other types:

$$\{X \cup Y \cup Z | X \subseteq \sigma_{Type=snack}(\text{Item}),\ X \neq \emptyset,\\ Y \subseteq \sigma_{Type=soda}(\text{Item}),\ Y \neq \emptyset,\\ Z \subseteq \sigma_{Type \neq snack \wedge Type \neq soda}(\text{Item})\}.$$

Among the succinct constraints in these three examples, the first one is also anti-monotone but the last two are not. In general, itemsets satisfying a succinct and anti-monotone constraint can be generated using only mandatory items (e.g., those with price $\geq$ \$20), whereas itemsets satisfying succinct but not anti-monotone constraints require both mandatory items and optional items.

Besides anti-monotone constraints and succinct constraints, there have been studies that handle other classes of constraints. For instance, Grahne et al. [6] exploited *monotone constraints* when finding correlated frequent itemsets. Since supersets of any itemset S satisfying a monotone constraint C_m (e.g., 2kg $\in$ *S. Weight*) are guaranteed to satisfy C_m, Grahne et al. pushed C_m into the mining process so that they do not need to perform further constraint checking on any superset of S once S satisfies C_m. Hence, computation is saved. Bucila et al. [4] proposed a dual mining algorithm – called *DualMiner* – that exploits both anti-monotone constraints and monotone constraints simultaneously to find itemsets satisfying the constraints.

Knowing that some constraints such as avg(*S. Temperature*) $< -18°$C are not anti-monotone or monotone in general, Pei and his colleagues [12,13] converted these "tough" constraints into anti-monotone constraints or monotone constraints by sorting items in each transaction in some order. They proposed the $\mathcal{FIC}$ algorithms (mining *F*requent *I*temsets with *C*onvertible constraints) to handle these *convertible constraints*. Specifically, the $\mathcal{FIC}^{\mathcal{A}}$ algorithm deals with *convertible anti-monotone constraints*, and the $\mathcal{FIC}^{\mathcal{M}}$ algorithm deals with *convertible monotone constraints*. For example, by arranging items in non-descending order of temperature, $\mathcal{FIC}^{\mathcal{A}}$ does not need to consider an itemset S if its prefix does not satisfy a convertible anti-monotone constraint C_{cam}. This is because S is guaranteed not to satisfy C_{cam} whenever the prefix of S does not. Similarly, by arranging items in non-ascending order of temperature, $\mathcal{FIC}^{\mathcal{M}}$ does not need to perform further constraint checking on an itemset S' if its prefix satisfies a convertible monotone constraint C_{cm}. This is because S' is guaranteed to satisfy C_{cm} whenever the prefix of S' does. Along this research direction, Bonchi and Lucchese [3] exploited "tough" constraints involving the aggregate functions variance and standard deviation.

Besides the aforementioned domain and aggregate constraints, the user can also express his interest by specifying other constraints. For example, Srikant et al. [14] considered *item constraints* that allow the user to impose a Boolean expression over the presence or absence of items in the itemset. Gade et al. [5] mined closed frequent itemsets that satisfy *block constraints*, which determine the significance of an itemset S by considering the dense blocks formed by items within S and by transactions associating with S. Yun and Leggett [15] proposed an algorithm for mining *weighted* frequent itemsets with *length decreasing support constraints*.

Key Applications

Frequent itemset mining – with or without constraints – plays an essential role in the mining of various patterns and relationships, which include maximal itemsets, closed itemsets, association rules, correlation, causality, sequential patterns, episodes, partial periodicity, emerging patterns, as well as frequent structures and trends. Moreover, frequent itemset mining is also useful in many data mining tasks such as associative classification, outlier detection, iceberg-cube computation, and stream mining. The knowledge discovered from frequent itemset mining can reveal important information in many real-life applications. Examples of these applications include market basket analysis (e.g., modeling of customer purchase behaviors, customer targeting, shelving, sales promotion), bioinformatics (e.g., order-preserving clustering of microarray data), Web mining (e.g., mining of Web contents, Web structures, or Web usages), mining for software reliability (e.g., software bug mining), as well as network management and intrusion detection (e.g., finding frequent routing paths, detecting signatures for intrusions).

Data Sets

Data sets commonly used for experimental evaluation for frequent itemset mining with constraints are similar to those used for frequent itemset mining *without* constraints. These data sets include the following:

1. IBM synthetic data generated by a data generator program developed at the IBM Almaden Center [2] (www.almaden.ibm.com/cs/projects/iis/hdb/Projects/data_mining/datasets/syndata.html)
2. Data from the UCI Machine Learning Repository (archive.ics.uci.edu/ml/)
3. Data from the Frequent Itemset Mining Dataset Repository (fimi.cs.helsinki.fi/data/)
4. Real-world data sets from the KDD Cup 2000, where the data sets contain purchase data from a real online retailer (www.sigkdd.org/kddcup/index.php?section=2000&method=task).

Frequent Itemsets and Association Rules

Hong Cheng, Jiawei Han
University of Illinois at Urbana-Champaign, Urbana, IL, USA

Synonyms

Frequent Patterns; Large Itemsets

Definition

Let $I = \{ i_1, i_2, \ldots, i_n\}$ be a set of items, and $DB = \{ T_1, T_2, \ldots, T_m\}$ be a transaction database, where T_i ($i \in [1\ldots m]$) is a transaction containing a set of items in I. The *support* (or occurrence frequency) of an itemset A, where A is a set of items from I, is the number of transactions containing A in DB. An itemset A is *frequent* if A's support is no less than a user-specified *minimum support threshold* θ. An itemset A which contains k items is called a k-itemset.

Historical Background

Frequent itemset mining was first proposed by Agrawal et al. [2] for market basket analysis in the context of association rule mining. It analyzes customer buying habits by finding associations between the different items that customers place in their "shopping baskets." For instance, if customers are buying milk, how likely are they going to also buy cereal (and what kind of cereal) on the same trip to the supermarket? Such information can lead to increased sales and maximize the profit by helping retailers do selective marketing and arrange their shelf space.

Since there are usually a large number of distinct single items in a typical transaction database, and their combinations may form a very huge number of itemsets, it is challenging to develop scalable methods for mining frequent itemsets in a large transaction database. The first frequent itemset mining algorithm was Apriori, proposed by Agrawal and Srikant [3]. An interesting *downward closure* property, called Apriori property, was observed: A *k-itemset is frequent only if all of its sub-itemsets are frequent.* This implies that frequent itemsets can be mined by first scanning the database to find the frequent 1-itemsets, then using the frequent 1-itemsets to generate candidate frequent 2-itemsets, and check against the database to obtain the frequent 2-itemsets. This process iterates until no more frequent k-itemsets can be generated for some k. This is the essence of the Apriori algorithm.

Scientific Fundamentals

In many cases, the Apriori algorithm significantly reduces the size of candidate sets using the Apriori principle. However, it can suffer from two nontrivial costs: (i) generating a huge number of candidate sets, and (ii) repeatedly scanning the database and checking the candidates by pattern matching.

Han et al. [10] devised an FP-growth method that mines the complete set of frequent itemsets without candidate generation. FP-growth works in a *divide-and-conquer* way. The first scan of the database derives a list of frequent items in which items are ordered in frequency-descending order. According to the frequency-descending list, the database is compressed into a frequent-pattern tree, or *FP-tree*, which retains the itemset association information.

An example database from [10] is shown in Table 1 and the corresponding FP-tree is shown in Fig. 1. In this way, the problem of mining frequent patterns in databases is transformed to that of mining the FP-tree.

The FP-tree is mined by starting from each frequent length-1 pattern (as an initial suffix pattern), constructing its *conditional pattern base* (a "subdatabase," which consists of the set of prefix paths in the FP-tree co-occurring with the suffix pattern), then constructing its conditional FP-tree, and performing mining recursively on such a tree. The pattern growth is achieved by the concatenation of the suffix pattern with the frequent patterns generated from a conditional FP-tree. Continue with the example in [10], Fig. 2 shows the recursive mining process on the conditional FP-tree of item m. It derives three frequent patterns $(am : 3)$, $(cm : 3)$ and $(fm : 3)$. Recursive calls of the FP-growth algorithm construct the conditional FP-trees of am, cm and fm (the conditional FP-tree of fm is empty in this example) respectively. The recursive mining process on these conditional FP-trees is shown in Fig. 2.

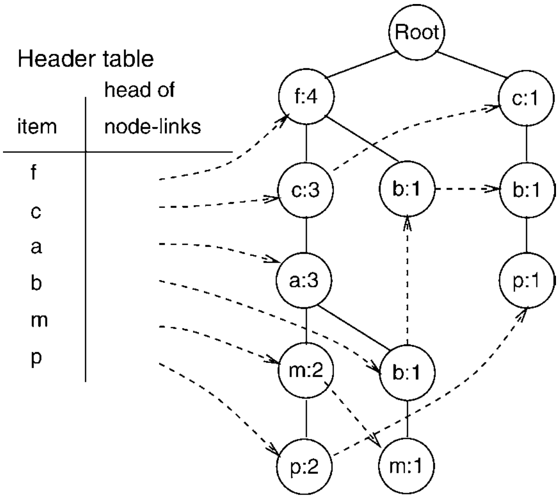
The FP-growth algorithm transforms the problem of finding long frequent patterns to searching for shorter ones recursively and then concatenating the suffix. It uses the least frequent items as a suffix, offering good selectivity. Performance studies demonstrate that the method substantially reduces search time.

Both the Apriori and FP-growth methods mine frequent patterns from a set of transactions in *horizontal data format* (*i.e.*, {*TID: itemset*}), where TID is a transaction-id and *itemset* is the set of items bought in the transaction TID. Alternatively, mining can also be performed with data presented in *vertical data format* (i.e., {*item: TID_set*}).

Zaki [20] proposed Eclat (Equivalence CLASS Transformation) algorithm by exploring the vertical data format. The first scan of the database builds the TID_set of each single item. Starting with a single item ($k = 1$), the frequent ($k + 1$)-itemsets grown from a previous k-itemset can be generated according to the Apriori property, with a depth-first computation order similar to FP-growth [10]. The computation is done by intersection of the TID_sets of the frequent k-itemsets to compute the TID_sets of the corresponding ($k + 1$)-itemsets. This process repeats, until no frequent itemsets or no candidate itemsets can be found.

Frequent Itemsets and Association Rules. Table 1. Example transaction database *D*, $\theta = 3$

TID	Items bought	(Ordered) frequent items
100	*f,a,c,d,g,i,m,p*	*f,c,a,m,p*
200	*a,b,c,f,l,m,o*	*f,c,a,b,m*
300	*b,f,h,j,o*	*f,b*
400	*b,c,k,s,p*	*c,b,p*
500	*a,f,c,e,l,p,m,n*	*f,c,a,m,p*



Frequent Itemsets and Association Rules. Figure 1. The FP-tree for database in Table 1.

Besides taking advantage of the Apriori property in the generation of candidate ($k + 1$)-itemset from frequent k-itemsets, another merit of this method is that there is no need to scan the database to find the support of ($k + 1$)-itemsets (for $k \geq 1$). This is because the TID_set of each k-itemset carries the complete information required for counting such support.

There are many alternatives and extensions on frequent itemset mining, e.g., hashing technique [14], partitioning technique [16], sampling approach [18], dynamic itemset counting [4], and so on. A FIMI (Frequent Itemset Mining Implementation) workshop dedicated to the implementation methods of frequent itemset mining was reported by Goethals and Zaki [9].

Key Applications

Association and Correlation Analysis

Frequent itemset mining naturally leads to the discovery of associations and correlations among items in large transaction data sets. The concept of association rule was introduced together with that of frequent itemset [2]. An association rule r takes the form of $\alpha \rightarrow \beta$, where α and β are itemsets, and $\alpha \cap \beta = \phi$. support and confidence are two measures of rule

interestingness, where $support(r) = support(\alpha \cup \beta)$ and $confidence(r) = \frac{support(\alpha \cup \beta)}{support(\alpha)}$ for a rule r.

Sometimes, an association rule may not be interesting, especially when mining at a low support threshold or mining for long patterns. To mine interesting rules, a correlation measure has been used to augment the support-confidence framework of association rules. This leads to the correlation rules of the form $\alpha \Rightarrow \beta[support, confidence, correlation]$. There are various correlation measures including lift, χ^2, *cosine* and *all_confidence*.

Frequent Pattern-based Classification and Clustering

Frequent itemsets have been demonstrated to be useful for classification, where association rules are generated and analyzed for use in classification [6,11,13]. The general idea is that strong associations between frequent patterns and class labels can be discovered. Then the association rules are used for prediction. In many studies, associative classification has been found to be more accurate than some traditional classification methods, such as C4.5.

Cluster analysis in high-dimensional space is a challenging problem. Since it is easy to compute frequent patterns in subsets of high dimensions, it provides a promising direction for high-dimensional subspace clustering. Two algorithms CLIQUE [1] and ENCLUS [5] were proposed, both of which used the Apriori property to mine interesting subspaces.

Biological Data Analysis

An important experimental application of frequent itemsets is the exploration of gene expression data, where the joint discovery of both the set of conditions that significantly affect gene regulation and the set of co-regulated genes is of great interest. Wang et al. proposed pCluster [15], a pattern similarity-based clustering method for microarray data analysis, and demonstrated its effectiveness and efficiency for finding subspace clusters in high-dimensional space.

Cong et al. [7] proposed to discover top-k covering rule groups for each row of gene expression profiles. It uses a row enumeration technique and introduces several pruning strategies to make the rule mining process very efficient. A classifier is constructed from the top-k covering rule groups.

Web Mining and Software Bug Mining

Frequent itemset mining can also be applied to other application domains like Web and software debugging. Association rules discovered for pages that are often visited together can reveal user groups [8] and cluster web pages. Web access patterns via association rule mining in web logs were proposed in [15,17].

Frequent pattern mining has started playing an important role in software bug detection and analysis. PR-Miner [12] uses frequent itemset mining to extract application-specific programming rules from source code. A violation of these rules might indicate a potential software bug.

Future Directions

First, the set of frequent itemsets derived by most of the current mining methods is too huge for effective usage. The bottleneck of frequent itemset mining is not on whether users can derive the complete set of frequent patterns under certain constraints efficiently but on whether they can derive a compact but high quality set of patterns that are most useful in applications. There are proposals on reduction of such a huge set, including closed patterns, maximal patterns, approximate patterns, condensed pattern bases, representative patterns, etc. However, it is still not clear what kind of patterns will give satisfactory pattern sets in both compactness and representative quality for a particular application. Much research is still needed to substantially reduce the size of derived pattern sets and enhance the quality of retained patterns.

Second, although there are efficient methods for mining precise and complete set of frequent itemsets, approximate frequent patterns could be the best choice to handle noise or variations in many applications such as bioinformatics. How to define the approximate constraint and design efficient mining algorithms is an open question. Much research is still needed to make such mining effective and efficient.

Third, to make frequent itemset mining an essential task in data mining, much research is needed to further develop pattern-based mining methods. For example, classification is an essential task in data mining. How to construct a better classification model using frequent patterns than most other classification methods? What kind of frequent patterns are more effective and discriminative than other patterns? How to mine such patterns directly from data? These questions need to be answered before frequent patterns can play an essential role in several major data mining tasks, such as classification.

Experimental Results

In general, for every proposed method, there is an accompanying experimental evaluation in the corresponding reference. In addition, [9] in FIMI workshop provided a detailed and comprehensive experimental evaluation of many mining methods on a large set of benchmark data.

Data Sets

An IBM Quest synthetic data generator is available at http://www.almaden.ibm.com/cs/projects/iis/hdb/Projects/data_mining/datasets/syndata.html.

A large collection of real datasets can be found at http://fimi.cs.helsinki.fi/data/.

Frequent Partial Orders

Antti Ukkonen
Helsinki University of Technology, Helsinki, Finland

Definition

Given a set D of n *partial orders* on S, and a threshold $\sigma \leq n$, a partial order P is a *frequent partial order* (FPO) if it is compatible with more than σ partial in D. Typically D contains total orders either on S or arbitrary subsets of S.

Historical Background

A natural extension of association rule mining is to make use of temporal information. This was first done in [1], where the authors present algorithms for mining *frequently occurring sequences* of sets of items in a database of transactions. Each of such sequences can be seen as a partial order on the complete set of items. For more recent work on the same topic please see [13,812]. The slightly different problem of mining *frequent episodes* from a sequence of events is presented in [7]. In this case an episode is a partial order over the set of all possible events. The problem differs from the one of [1] by considering a stream of events (for example notifications and alerts generated by devices in a telecommunications network) instead of a stationary set of transactions. The same problem is also discussed e.g., in [4,5].

Common for the references above is that they do not explicitly call the mined patterns partial orders. One of the first papers to do so is [6], where the authors discuss the problem of finding a number of partial orders that are a good compact description for a set of input sequences. The approach taken differs from the traditional setting of frequent pattern mining, however. A similar problem is addressed recently in [3], albeit in a more theoretical setting.

The problem of finding frequent partial orders as defined in this article was first addressed in [9,10]. The authors present an efficient algorithm for finding frequent closed partial orders (The term closed appears in the same meaning as in the context of *frequent closed itemsets*.) in a database of strings with the restriction that each symbol of the alphabet may occur only once or not at all in a string.

Foundations

The basic idea of frequent pattern mining can be formalized as follows: given a database D, a pattern class $\mathcal{P}$ and a threshold σ, find all instances of $\mathcal{P}$ that are supported by more than σ rows of D. The precise definition of a support depends on the contents of D and the pattern class $\mathcal{P}$. In case of frequent partial orders the pattern class is the set of all partial orders on some fixed set S, and the database can contain either total or partial orders on S. All orders in D that are compatible with the partial order P form the *support* of P, denoted $s(P)$. Given D and a threshold σ, the problem is to find all partial orders P so that $|s(P)| \geq \sigma$.

A pattern is *closed* if it can not be augmented without decreasing the size of its support. According to this definition the partial order P is closed in the database D if $|s(P \cup (u, v))| < |s(P)|$ for all $u, v \in S$. It can be argued that finding only the frequent closed patterns is of interest, as the non-closed ones contain less information but can be considered only equally "reliable," as they have the same support as a closed pattern. In the remainder of this section two methods for finding *frequent closed partial orders* are discussed. The first one is based on using existing algorithms for mining *frequent closed itemsets*, while the second one is a dedicated method for finding frequent partial orders.

Finding Frequent Closed Partial Orders Using Frequent Itemset Mining Algorithms

Since its original development in the early 1990s, association rule mining and especially the discovery of frequent itemsets has been a widely studied topic. As a result, there currently exist a myriad of efficient algorithms for mining frequent closed itemsets. Turns out that any of these can be used to find frequent closed partial orders if the input is in a suitable format.

Let D contain total orders on S. Usually each total order $T \in D$ is given as a list of symbols. For example, let $T = \langle a, b, c, d, e \rangle$, meaning that a comes first in T, b comes second, and so on. This is the *list representation* of T, which is a compact and intuitive way of representing total orders, but can not as such be used with frequent itemset mining algorithms, because they only consider the occurrence of a symbol and not their position relative to the other symbols in the list.

Any order relation can also be expressed as a set of ordered pairs (u, v). The pair (u, v) belongs to T when u appears before v in the list representation of T. Returning to the example, the *set representation* of T is

$$T = \{(a,b),(a,c),(a,d),(a,e),(b,c),(b,d),(b,e),\\ (c,d),(c,e),(d,e)\}.$$

This differs from the list representation by having pairs of symbols instead of single symbols as "items." Thus, if two total orders have the same pair (u, v), they must agree on the order between u and v.

Given a database D of total orders in the list representation, each member of D is converted to the set representation. The resulting database is denoted $\hat{D}$. Each row of $\hat{D}$ is a set of (u, v) pairs that form a total order $T \in D$. This representation of the input has the consequence that every closed itemset (set of (u, v) pairs) that is frequent in $\hat{D}$ given the threshold σ can in fact be interpreted as a frequent closed partial order. An itemset I is closed if no more items can be added to I without decreasing the size of its support.

Note that it is important to find the frequent closed itemsets, as a frequent itemset might not correspond to a partial order. The closedness guarantees that the resulting sets of (u, v) pairs form a transitive relation, which is required of a partial order.

Using the set representation for finding frequent partial orders works, but it has some drawbacks. First of all, the storage requirements for $\hat{D}$ are much larger than for D, as each total order with a list representation of l symbols must be replaced with a set containing $\frac{1}{2}l(l-1)$ elements. In addition, $\hat{D}$ might not be sparse, meaning the number of items in each row (total order) is not necessarily small when compared to the total number of items. This in turn may lead to poor performance of the frequent itemset mining algorithms.

The most important problem with the above approach is, however, that in general a complete partial order P is not required. Very often it is sufficient to find its *transitive reduction* $tr(p)$. All of the ordering information contained in P is retained in $tr(p)$, which is better suited for analysis purposes. For example, when visualizing partial orders as directed acyclic graphs, it is in general better to use $tr(p)$. Obviously the transitive reduction can be computed afterwards given the frequent itemsets, but this is another computationally intensive step. Also, frequent partial orders can be found more efficiently when the transitive reduction is mined directly.

Finding Transitive Reductions of Frequent Closed Partial Orders Directly

Details of the approach are given in [10], this is only a summarization of the key ideas. This algorithm (called Frecpo in [10]) operates directly on the list representations in D and returns the set of the transitive reductions of all closed partial orders that are frequent in D given the threshold σ.

The basic framework is based on enumerating all representations of transitive reductions of partial orders in a depth-first fashion using a recursive algorithm. All closed partial orders that can not be frequent are pruned as soon as possible. The pruning is based on the observation that the frequency of the partial order $P \cup (u, v)$ is upper bounded by the frequency of P. In general this is called *antimonotonicity* of a pattern.

When entering a recursive call the algorithm has already constructed a frequent partial order P in the previous steps. This is called the *current pattern*, which is initially Ø. The algorithm first computes a list L of pairs that are added to P one after the other to create a new frequent partial order. For a pair (u, v) to be included in this list it must (i) belong to a transitive reduction and (ii) the frequency of the pattern $P \cup (u, v)$ must be above the threshold σ. When computing this list the algorithm only considers total orders that belong to the support of the current pattern P, denote this with D_P. Initially $D_P = D$.

To construct the list L, the algorithm computes a table called the *detection matrix*. In this matrix for each pair (u, v) is stored the number of times u precedes v in D_P, and the set of items that appear between u and v in every total order where u precedes v. These items are called *anchors*. The frequency information can be used to prune infrequent pairs. If the frequency of the pair (u, v) is below σ in D_P, the partial order $P \cup (u, v)$ can not be frequent either. However, if the frequency of (u, v) is above σ in D_P, then $P \cup (u, v)$ must be a frequent partial order as well.

The set of anchors is used to identify forbidden pairs. A pair is forbidden if it's set of anchors is not empty. This is because a pair (u, v) can not belong to the transitive reduction if an item (the anchor) occurs between u and v in every total order where u and v occur. All pairs that are not infrequent or forbidden are added to the list L.

For details of the algorithm the reader is referred to [10], where it is also shown experimentally that Frecpo outperforms the algorithm based on frequent itemset mining by a considerable margin.

Key Applications

Frequent partial orders can be of interest in any application where the data can be viewed as a set of orders (or rankings) of some finite set.

For example, in certain voting systems the voters do not only place a single vote on one candidate, but are expected to rank the alternatives (or a subset thereof) according to their preferences. This voting mechanism is employed for instance in the general election of Ireland. Finding FPOs of the candidates from this data can give more insight to the behavior of voters than traditional opinion polls. Preference data in general is a natural application for FPOs. Such data can be based on questionnaires, but also other sources.

A related application is clickstream analysis. Based on server log files it is possible to reconstruct the sequence in which a user visited different pages of a website. Finding FPOs from these sequences can give information about user preferences (if the pages correspond to different products, for example) or potential usability problems associated with navigation on the website in question.

Another promising application is in bioinformatics in the context of gene expression analysis. A gene expression data set usually contains expression levels of several genes in a number of conditions or tissues. Instead of looking at the actual expression value, which can be very noisy, the conditions or tissues can be ranked in decreasing order of expression and use the resulting rankings for further analysis. In this case the FPOs can be seen as a generalization of the order preserving submatrices, originally proposed in [2].

Fully-Automatic Web Data Extraction

Cai-Nicolas Ziegler
Siemens AG, Munich, Germany

Synonyms

Web content extraction; Automatic wrapper induction; Web information extraction

Definition

Web documents contain abundant hypertext markup information, both for indicating structure as well as for giving page rendering hints, next to informative textual content. Fully-automatic Web data extraction is geared towards extracting all relevant textual information from HTML documents, without requiring human intervention throughout the process. Commonly, two types of automatic Web extraction paradigms are distinguished in this vein. First, the extraction of one single block of informative content, e.g., in case of news pages, which is also referred to as page cleaning [4]. Second, the extraction of recurring patterns across multiple blocks, typically the case for the extraction of search engine results. In the latter case, the extraction system will commonly also assign *labels* to the single atoms of each identified recurring block, such as the search result record's title, snippet, and URL.

Historical Background

Systems for extracting information from Web pages date back to the late mid-nineties. First approaches, coined wrapper induction systems [6], extracted structured information from HTML documents in a semi-automated fashion, see, e.g., [1] and [9]. A wrapper hereby refers to a set of learned rules that extract structured information records from HTML pages of like style, i.e., dynamically generated pages for which the same template has been used. One may think of two product pages from Amazon.com as an example. The rules have been learned inductively, by means of humans labeling a sufficient number of pages.

While these wrapper induction systems have been continuously improved to require less human intervention and less time for designing wrappers, they still do not scale to efforts that require the extraction of massive amounts of information from diverse types of Web document sources: Even with an effort of only five minutes per site template, coping with several thousands of those requires too many human resources for most project budgets.

Two areas have been identified where extraction works in a fully-automated fashion, the first referring to the extraction of results from any type of search engine, such as Web search engines like Google and Yahoo, product finders as they are found on Amazon and friends, and so forth. These systems are able to automatically generate wrappers as they exploit the fact that search result pages commonly feature large numbers of recurring patterns. Moreover, these automated search engine result wrappers also assign labels to the components of each entry found, such as the title of the search result snippet, the URL, and body text.

A second breed of automated page wrappers has evolved at the end of the nineties. Theses wrappers aim at extracting the purely informative content from Web pages, particularly *news* Web pages. As opposed to the automated search engine result wrappers, no labels are assigned to the different blocks of information. Hence, the generated output is commonly one single plain text document which contains the informative textual content only. Extractors of informative textual content have also been referred to as "page cleaners" [1].

Foundations

For the extraction of informative content from Web pages, also referred to as Web page cleaning [1], a broad range of diverse techniques has been investigated. Some systems use simple heuristics (see, e.g., [1] and [5]) and obtain accuracy scores that are reasonably good. For example, such heuristics comprise of rules that take into account the number of characters and text tokens which occur in one cohesive textual block [1]. Other approaches compute a set of features for each text block and implement a decision function which tells whether to discard or keep the block at hand. Such approaches are depicted in [1,6,7]. The respective decision functions are learned by means of non-linear optimization methods or common classifier training [7].

Fully-Automatic Web Data Extraction. Figure 2. Sample search result entry (a) and its abstract shape (b), as used in ViNTS [13].

Next to approaches that operate either on the text level or logical structure of a Web page, e.g., its DOM tree, the exploitation of visual cues has been likewise researched: The location-based segmentation approach described in [8] constructs an M-tree to represent the HTML document's physical representation as seen in the browser window. To this end, the browsers screen coordinates of block segments are taken into account. The screen is divided into five areas: header, left and right menu, footer, and the center of the page (see Fig. 1). Heuristics are used to assign HTML blocks to the defined areas, the informative content is assumed to reside in the center of the page.

For extracting *recurring* information blocks from Web pages, in particular Web search engine results, state-of-the-art wrapper generators also exploit visual cues by analyzing an HTML page's graphical representation as rendered by a Web browser engine [9,10]. ViNTs [10] automatically generates search result record extraction rules using visual context features and tag structure information. To this end, ViNTS first analyzes the graphical representation without considering the tag structure to identify content regularities by means of so-called content lines (see Fig. 2 for a content line typical of search results on Amazon). Next, structural regularities among HTML blocks are combined with these visual features to generate wrappers. To weight the relevance of different extraction rules, visual and non-visual features are considered.

The ViPER system [9] builds on similar techniques as ViNTS, but extends its capabilities by not only allowing to identify recurring blocks that are aligned vertically, but also those aligned in a horizontal fashion. Horizontally aligned search results are becoming increasingly popular among online retailers, such as Overstock (http://www.overstock.com). Next to the exploitation of visual cues, ViPER used multiple sequence alignment techniques, known from bio-informatics, to identify structure and patterns in HTML tag sequences.

Key Applications

The extraction and automatic labeling of search results sees its application in various domains, primarily product-related data integration. For instance, price robots access large numbers of online retail shops and need to interpret search results for product searches so as to digest and incorporate the found information into their own databases. Moreover, meta search engines also have an increasing demand for the automated extraction of search results, as their operation is based on the merging of search results from several hundreds of search engines, for which the manual design of extraction wrappers is enormously time-consuming. Moreover, manually crafted wrappers may break easily, when the structural template of presented results changes. Automatically generated search engine wrappers are less prone to these deficiencies.

The extraction of informative content from arbitrary HTML documents serves many purposes. Clearly, when used as processing step for Web search engines, it can help to improve the precision of search results dramatically, as only an HTML document's informative content is considered for inclusion in the search index. Pages where the search terms only occur in non-informative content, such as an advertisement or as part of a link list, are not considered as hits anymore.

Next to general-purpose search engines, the extraction of informative page content is likewise essential for special-purpose applications based on retrieval, such as reputation monitoring platforms [3,11]: These systems record the number of mentions of monitored keywords, such as company, brand, or product names, in order to allow for timeline-based trend analysis. Citation count numbers hence become more reliable, for the same reasons as those stated for Web search engines.

Automated Web content extraction for page cleaning is also at the heart of the CLEANEVAL competition (See *http://cleaneval.sigwac.org.uk/* for details.), which has become part of the "Web as Corpus" initiative (WAC) as of May 2007. The objective of WAC is to collect massive textual information from the Web in order to use it for natural language processing (NLP) and linguistic research, forming representative background corpora and language models.

Data Sets

For the CLEANEVAL competition, a dataset containing both unlabeled documents (for testing purposes) and labeled documents (for classifier training) can be downloaded from the indicated URL. The relatively new dataset is expected to serve as publicly accepted benchmark in the future.

For automatic extraction of search engine results, several smaller datasets are available, among those the Omini dataset (Available from Sourceforge via *http://sourceforge.net/projects/omini/*.) and MDR collection [8]. None of them may count as standard dataset, though.

Functional Data Model

PETER M. D. GRAY
University of Aberdeen, Aberdeen, UK

Definition

Functional Data Models are a form of *Semantic Data Model* which appeared early in database history. They use the mathematical formalism of *function application* to represent and follow associations between data items. Functions are usually applied to variables whose values may be object identifiers or record instances. Thus if P represents an entity instance of type Person, then *forename(P)* would return a string (e.g., "Peter"). (Note however that different systems may write this in a LISP style as (forename P) or in JAVA style as P. forename.) The function *town(P)* could be used to represent an *association* by returning the identifier for Peter's home town. This allows *function composition* so that *name(town(P)) = P.town.name = "Aberdeen".*

Using functions gives several obvious advantages. Firstly the syntax is universally understood, and provides a means of expressing schemas, queries and constraints independently of any supplier-dependent language. This is very handy for integrating data held in heterogeneous databases – one of the earliest applications [11]. Secondly, functional expressions follow the rule of *Referential transparency* – expressions of equal value can be substituted for variables without altering the sense or value of the expression. This avoids the problems of side-effects in nested *procedure calls* found in programming languages. In consequence, optimizing functional expressions is much easier, as is parallel evaluation. In particular, the whole mathematical theory of *Comprehensions* worked out for functional programming can be applied to *Functional Query Languages.*

Historical Background

Functions provided an underlying formalism for data models from as early as Abrial's *access functions* for representing binary relationships between entities [1] and Florentin's *property functions* for representing the attributes of entities [4].

Kerschberg and Pacheco's *Functional Model of Data* [8] integrated these two uses for functions, modeling the universe of discourse by means of *entity sets* and *total functions.* Entity sets are represented by labeled nodes and functions by labeled arcs in a directed graph.

The main motivation for the Functional Model of Data was ease of conceptual modeling, and [8] showed how functional data models can be automatically transformed into relational and CODASYL data models for implementation within a DBMS.

The Functional Model of Data was further developed by Sibley and Kerschberg in [14]. In this development, the universe of discourse is again represented by labeled nodes and arcs. The arcs are again total functions, but the nodes are either entity sets or *value sets* (as opposed to a single set of character strings, C). A major motivation for this work was to derive a general, unifying conceptual data model which could then be specialized into either relational or CODASYL data models.

IS-EMPLOYEE	HAS-SALARY		
emp-id	name	emp-id	salary
Paul	"Paul"	Paul	19,000
Mary	"Mary"	Mary	22,000
John	"John"	John	19,000
...	...	...	...

At about the same time, Hammer and McLeod proposed the Semantic Data Model [7], as a higher-level model better suited to conceptual modelling of an application domain. A key innovation of the Semantic Data Model was the recognition of the importance of entity attributes based on *derived information.* Shipman used functions to implement a Semantic Data Model representing both data and derived information in the very influential DAPLEX language [13]. It was used to integrate a heterogeneous database network MULTIBASE [11].

Following this came fore-runners of *Object-Oriented Databases.* The GENESIS query language [2] supported a functional data model and was intended as a front end for DBMSs supporting either a relational or nested relational data model. The PROBE database system [3] supported the representation and manipulation of arbitrarily complex objects by means of a functional data model.

Foundations

The earliest functional data models were based on binary relational data, where every relational table had only two columns. The name of the table, considered as a verb relating the two columns, became the function name. One column was chosen to be the argument and the other to be the result. Where possible, this is done to make the function single-valued, as usual.

Consider two such tables representing facts such as

```
Paul is-employee ``Paul''
Mary is-employee ``Mary''
```

```
...
Paul has-salary 19000
Mary has-salary 22000
```

where each row refers to an individual employee and the right-hand column entries for that employee give their name and current salary respectively. Note that Paul and Mary are surrogates for object-identifiers, in order to make the example more readable.

A functional view could specify this information as the functions

```
is-employee :: emp-id -> name
has-salary :: emp-id -> salary
```

Where the relationship is one-to-many, as for example with

```
Paul has-child Jane
Paul has-child Sue
Paul has-child Norman
Mary has-child James
```

Then the function must return a *set of* emp-id. Thus *children*(*Paul*) = {*Jane*,*Sue*,*Norman*} and *children*(*Mary*) = {*James*}. Some values will be empty sets e.g., *children*(*John*) ={}. Historically, only garbage-collected languages (such as LISP and FP and Prolog) could deal with such variable-length lists, and they did not suit analysts used to the conventions of fixed-length tables in Codd's normal form! It was only gradually that people realized that it was perfectly straightforward to hold data in relational tables and to use the Functional Data Model as a high-level *View* on the same data. With the coming of Java, one did not even have to use a special purpose list processing language in order to handle or print such values. Likewise, although some implementations stored facts in a specially designed triple store [9], it was not essential to do so. Interestingly, such storage techniques are becoming favored again for storing RDF triples of web data (see below).

Note that the functional approach is specifying information in smaller units, that is with a finer semantic granularity than with a single n-ary table. Thus further information can readily be added, such as the function:

```
line-manager :: emp-id -> emp-id
```

A powerful argument for the functional approach, in addition to its greater flexibility, is that it facilitates the incremental development of systems where the schema evolves as more data is collected. Note also the convenience with which one can ask who is the line manager of a particular employee's line manager, by contrast with the SQL approach:

```
line-manager (line-manager(Paul))
```

instead of

```
  SELECT L2.line-manager FROM line-manager
L1 L2
  WHERE L1.emp-id = Paul AND L2.emp-id = L1.
line-manager
```

In the DAPLEX language, new abstract entities are created by means of the directive A NEW and values of base functions are assigned by means of the directive LET. For example, to create a new Student of name "Fred Jones" who attends the Biology and Biochemistry courses:

```
FOR A NEW Student
  BEGIN
    LET Name(Student) = "Fred Jones"
LET Attends(Student) =
      {THE CourseOfName("Biology"),
THE CourseOfName("Biochemistry")}
END
```

Note here the use of CourseOf Name(Biology) instead of just "Biology" as in a relational database. This is because variables in DAPLEX can denote actual *object identifiers* (as in Java, for example) whereas the analogous values in relational database columns will be *foreign key* values in order to identify the object. This is a big difference from the relational model and is common to most functional data models.

Semantic Web Vision and RDFS

The *semantic web* vision is to enable rich machine processing of web information sources. RDF stands for Resource Description FrameWork Model, which was first accepted by W3C as a Data Model described in *RDF Schema* in February 1999. (http://www.w3.org/TR/REC-rdf-syntax) A data interchange format is defined using XML syntax with tags starting < *rdf* : to encode *subject–predicate–object triples*. The *predicate* is just a function name, for example has-salary.

Thus, RDF is not unlike the Entity-Relational data model in its use of Entity identifiers as *subject*, and Property or Relationship names as *predicate* in RDF triples. However, it also includes features of object data models in its use of object identifiers and subclasses. This makes it very similar to the Functional Data Model.

The comparison below is illuminating and shows how schemas can be mapped between the two models.

Mapping a Functional Model to RDFS

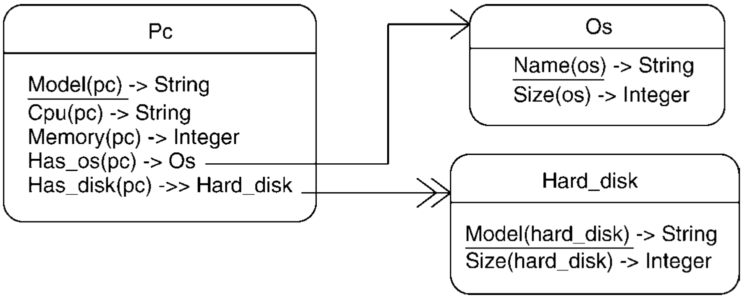
The RDFS Data Model abstracts over relational storage, flat files and object-oriented storage, following the principle of data independence. Thus, it shares with the Functional Data Model the advantage of not tieing one to any particular storage system. This is a great advantage to the programmer. The mapping to a particular knowledge source or data source can then take place separately through a wrapper. This makes it very much easier to integrate data from different sources, as is often required over the Web.

Consider the following example [5], where the functional data model schema of Fig. 1 is used to describe the pc and os classes and their relationship has_os in an application domain where components are put together to configure a workable PC.

The Functional Data Model is, of course, an extended ER model and it can be automatically mapped into an RDFS specification. A mapping program reads metadata from the database and *generates* the corresponding RDFS, as in Fig. 2, making this knowledge web-accessible. Related work by Risch [12] also shows how RDFS resources can be integrated and accessed by a functional query language. The basic rules used when mapping the schema declarations to RDFS are as follows:

- A class *c* defined as an entity (declared as *c* ->> entity) maps to an RDF resource of type rdfs: Class (where rdfs is the namespace prefix for the RDFS descriptions).
- A class *c* declared to be a subtype of another class *s* (declared as *c* ->>*s*) maps to an RDF resource of type rdfs:Class, with an rdfs:subClassOf property the value of which is the class named *s*.
- A function *f* declared on entities of class *c*, with result type *r* (declared as *f*(*c*) ->*r*) maps to an RDF resource of type rdf:Property with an rdfs: domain of *c* and an rdfs:range of *r*.

Mapping a functional schema into RDFS has the advantage of making the domain model available to



Functional Data Model. Figure 1. This functional schema shows three entity classes. The single arrow means that each pc may have only one os installed. A double arrow means that a pc can have multiple hard-disk.

```
<rdfs : Class rdf : ID= "pc">
    <rdfs : subClassOf rdf : resource = "#Resource"/>
</rdfs : Class>

<rdfs : Class rdf : ID = "os">
    <rdfs : subClassOf rdf : resource = "#Resource"/>
</rdfs : Class>

<rdf : Description rdf : ID = "has_os">
    <rdf : type rdf : Property/>
    <rdfs : domain rdf : resource = "#pc"/>
    <rdfs : range rdf : resource = "#os"/>
</rdf : Description>
```

Functional Data Model. Figure 2. RDFS (RDF Schema) representation of schema of Fig. 1.

RDFS-ready software. Some semantic information is lost, because the cardinality of each attribute is not expressed in RDFS. Also information on the *key* of each entity class is omitted. However, this information could be represented by an extra metadata class declared in RDFS.

Constraints

Integrity Constraints are a very important part of data modelling. Sometimes this is just considered as part of type checking or range checks on values, but in a *Semantic Data Model* one can express constraints that represent semantics applying to data in a particular domain, that may not be obvious from a casual inspection of tables, or even from applying Data Mining techniques. For example, in DAPLEX one can enforce that all Students attend at least four courses:

```
   DEFINE   CONSTRAINT   Number_of_courses
(Student) =>
   COUNT(Attends(Student)) > 3
```

Comprehensions in *P/FDM* are also used to describe the semantics of *Integrity Constraints*, representing invariants that must be held true under updates. For this purpose the nested loop syntax used in queries is adapted, similarly to constraints in EFDM [10]:

```
   constrain each t in seniortutor
   each s in advisees(t) to have grade(s) > 60;
```

This constrains each person in the class `seniortutor` to have only advisees with grades over 60. Both universal(each) and existential(some) quantifiers are allowed, in any combination. Such integrity constraints are particularly important in Functional Data Models, since they provide a way to *extend the data model* with rich semantics defined with the full power of a Comprehension (like range-restricted FOL). By contrast, SQL and relational languages are often restricted to just providing range checks on data items.

Updating Functional Data

In DAPLEX, the value of a multi-valued function for a particular argument can be modified by using the built-in operators INCLUDE and EXCLUDE. For example, to modify one of the courses attended by Fred Jones from BioChemistry to Physiology:

```
   FOR  THE  Student  SUCH  THAT  Name
   (Student) = "Fred Jones"
     BEGIN
       EXCLUDE  Attends(Student)  =  THE
CourseOfName("BioChemistry")
       INCLUDE  Attends(Student)  =  THE
CourseOfName("Physiology")
     END
```

It is immediately clear that the *updating* of functions defining a functional database contradicts the basic assumption of referential transparency. In a functional database, the essence of a function is conveyed by its name and its type, with which is associated its real-world semantics, and not by its current mapping, which will change as a result of database updates. The function `has-salary` specifying a person's salary as used earlier is a case in point.

The partial loss of referential transparency due to updates does not, however, alter the other considerable advantages of functional programs: that they represent a high-level, non-procedural but executable specification of what is required, and enable programs to be created in a top-down fashion with local detail encapsulated within the specification of the functions to which these details relate. Moreover a functional program that does not involve updates but accesses a database in read-only mode will be referentially transparent. Even with updates there is what might be termed local referential transparency between such updates; thus some advantages can nonetheless be gained [15].

Key Applications

The integration of data held in heterogeneous databases continues to be a very challenging problem. At one time people thought that all data could be forced into relational storage through the dominance of SQL. However, the emergence of semi-structured data, much of it held on the Web, has changed all that.

Future Directions

Functional data models have the right abstractions for dealing with heterogeneous data, but they need to be packaged for more convenient use with Web data. Interestingly, functional languages such as Python and Jython have a secure following among scientific users and others wanting to advance beyond Visual Basic. Once again, if they could be combined with a functional data modelling package that provides a view over data stored in different kinds of databases then the idea could very likely catch on.

Functional Dependencies for Semi-Structured Data

Gillian Dobbie[1], Tok Wang Ling[2]
[1]University of Auckland, New Zealand
[2]National University of Singapore, Sigapore, Singapore

Synonyms

Path functional dependencies; Extended functional dependencies

Definition

Functional dependencies are used in relational database design to show that the value of a set of attributes depends on the value of another set of attributes. Theory has been developed to manipulate a set of functional dependencies to describe equivalences of sets of functional dependencies. Semi-structured data differs from relational data in two important ways: semi-structured data is hierarchical and the structure of the data is less consistent. Traditional functional dependencies do not capture these differences so new functional dependencies with associated theory has been defined for semi-structured data.

Key Points

Functional dependencies for semi-structured data have been defined in the three recommended readings. While the syntax of functional dependencies defined over semi-structured data varies, the semantics is similar. In this article the syntax of Arenas and Libkin [1] is used but the notation differs a little since there is no distinction between attributes and subelements. There is a notion of an XML tree and a path in an XML tree. Consider the XML document in Fig. 1a, and the XML tree for that document in Fig. 1b. The internal nodes of an XML tree are labelled with tag-name:node-ID, e.g., the node label *student:v5* means this node represents an element *student* with node ID *v5*.

A path through this XML tree is something like *department.course.code*. A tree tuple is a subtree containing at most one occurence of each path. Note that there are two occurences of paths such as *department.course.student* in Fig. 1a, so there are two tree tuples, one including the paths for the student with student number *123456* and the other including the paths for the student with student number *234567*. The tree tuples will be called t_1 and t_2 respectively. Below it is shown how the tree tuples t_1 and t_2 assign values to the paths in the XML tree in Fig. 1b:

The symbol, *S*, is a reserved symbol, and for a path *p.S*, if $t(p)=v$ then $t(p.S)$ is the value of the element or attribute at *v*. A functional dependency is an expression of the form $X \rightarrow Y$ where both *X* and *Y* are sets of paths. An XML tree satisfies a functional dependency $X \rightarrow Y$ if for any two tree tuples t_1 and t_2 in the tree $t_1(X)=t_2(X)$ then $t_1(Y)=t_2(Y)$. Note that $t_1(X)=t_2(X)$ means that $t_1(p)=t_2(p)$ for all $p \in X$. Using functional dependencies, key constraints, dependencies among attributes, and dependencies among object classes can be expressed.

The key constraint, that no two course elements will have the same code, is expressed as:

department.course.code.S → *department.course*

If there were another course in the document shown in Fig. 1a with code *"CS101"*, then this functional dependency would no longer hold.

A functional dependency is used to show that there is only one record of a student taking a course. The functional dependency represents that two student subelements of the same course cannot have the same student number. This constraint is represented as:

{*department.course,department.course.student.stuNo.S*} → *department.course.student*

In contrast, the following functional dependency expresses that no two student elements will have the same student number:

{*department.course.student.stuNo.S*} → *department.course.student*

The constraint, that two student elements with the same value for *stuNo* must have the same value for *stuName*, is written:

department.course.student.stuNo.S → *department.course.student.stuName.S*

Note that this definition of functional dependencies combines node and value equality. This allows functional dependencies to be used to express not

t_1 (*department*) = υ0

Functional Dependencies for Semi-Structured Data. Figure 1. XML document and its corresponding XML tree.

only what the keys are but also to differentiate between absolute and relative constraints. That is, all students in a document have a unique student number can be expressed using an absolute constraint, and all students in a course have a unique student number can be expressed using a relative constraint. Note that the relative constraint is relative to another element or object class, in this case *course*, while the absolute constraint applies to the whole document. However, the richness of expressibility also means that functional dependencies in the semi-structured setting are more complicated than functional dependencies in the relational setting.

FD

Definition

Given a relation schema $R[U]$, a *functional dependency (FD)* is an expression of the form $X \to Y$, where $X,Y \subseteq U$. An instance I of $R[U]$ satisfies $X \to Y$, denoted by $I \models X \to Y$, if for every two tuples t_1,t_2 in I, $t_1[X] = t_2[X]$ implies $t_1[Y] = t_2[Y]$. That is, whenever two tuples contain the same values for attributes in X, they must have the same values for attributes in Y. A functional dependency $X \to Y$ is called *trivial* if $Y \subseteq X$.

A *key dependency* is a functional dependency of the form $X \to U$. Then X is called a *superkey* for relation R. If there is no proper subset Y of X such that Y is a superkey, then X is called a *key*.

Key Points

Functional dependencies form an important class of integrity constraints that play a critical role in maintaining the integrity of data, query optimization and indexing, and especially schema design. The focus of the *normalization* technique in schema design is on avoiding redundancies caused by functional and other types of dependencies in relational databases. An example of such redundancies can be seen in the *year* column of the following table, where the functional dependency *title* →*year* holds.

In database design theory, there are normal forms that put restrictive conditions on data dependencies to control this kind of redundancy. Well-known normal forms that deal with FDs are second normal form (2NF), third normal form (3NF), and Boyce-Codd Normal Form (BCNF).

The implication problem for FDs can be solved in linear time. That is, given a set Σ of FDs, it is possible to check whether an FD $X \to Y$ is logically implied by Σ, denoted by $\Sigma \models X \to Y$, in the time that is linear in the size of Σ and $X \to Y$. A key concept for solving the implication problem is the *closure* of a set of attributes X, which is the set of attributes $A \in U$, denoted by X^+, such that $\Sigma \models X \to A$. There are efficient algorithms for finding the closure of a set of attributes [1].

The implication problem of functional dependencies can also be axiomatized. That is, there is a finite sound and complete set of inference rules, called *Armstrong axioms*, that can be used to solve the implication problem:

Reflexivity: If $Y \subseteq X$, then $X \to Y$.
Augmentation: If $X \to Y$, then $XZ \to YZ$.
Transitivity: If $X \to Y$ and $Y \to Z$, then $X \to Z$.

Functional Query Language

Peter M. D. Gray
University of Aberdeen, Aberdeen, UK

Definition

Functional Query Languages came from two lines of development:

1. From new functional programming languages such as FP that showed the value of *referential transparency*; this ensures that complex nested functional expressions can be evaluated inside-out (bottom-up) or top-down or even split up and done in parallel, with the same result. For optimization purposes this is vastly better than state-altering algorithms used in early CODASYL systems, or even code used today with embedded SQL (as in ODBC).

2. From requirements to provide a single query language and a single integrated schema over multiple autonomous, heterogeneous, distributed databases. This happened in the MULTIBASE project and resulted in the DAPLEX language [10]. It was the first functional query language to compute over instances of a *Functional Data Model*, for the purpose of abstracting away details of different storage schemas in a distributed DB.

Historical Background

No full implementation of DAPLEX was undertaken. However, later systems Adaplex, EFDM and *P/FDM* implemented large parts of the language. These showed how to integrate base functions (from the data model), derived functions, views, and integrity constraints into a single functional framework. The main drawback of DAPLEX was that for general computation it required either calling out to foreign functions, or embedding in a host programming language.

ADAPLEX was an embedding of a subset of DAPLEX into the programming language ADA. The data types of DAPLEX are reconciled with those of ADA by associating base functions with abstract entity types when these are declared. Also, derived functions are defined procedurally in ADA rather than in DAPLEX (this is an example of calling out to foreign functions).

EFDM [8] extended DAPLEX with procedural computation, recursive functions over abstract types and scalar types, built-in metalevel functions for interrogating the meta data, and a construct which can store EFDM statements in the database (like stored SQL procedures). The underlying database used persistent object storage techniques, similar to commercial object-oriented databases. The facilities for semantic integrity constraints considerably extend those of DAPLEX.

Following *FQL*, The functional database languages FDL [9] and PFL concentrated on a more general, computationally complete, functional language based on the lambda calculus.

This work was followed by the development of several functional languages, such as FAD [1] and FUGUE, for complex object and *object-oriented databases*. These capitalized on the fact that DAPLEX already had a built-in notion of *object identifier* for *entity* instances in its data model, but without committing to any particular implementation. This also inspired the Iris object-oriented database system, which used a LISP-like functional syntax. Iris in turned influenced the development of the original *AMOSQL* language used in active mediation of distributed data sources [5].

The OSQL query language [2] was intended for use with object-oriented databases. It unified functional and relational modeling by extending SQL to include entities and functions. It included primitives for creation of entities, for assignment of base function values, and for updating multi-valued base functions. Derived functions were defined by means of a SELECT clause and queries had an SQL-like syntax.

Foundations

One common thread running through almost all Functional Query Languages is the use of the functional programming concept of a *Comprehension* (q.v.) which deserves to be much more widely known. Buneman et al. [3] have generalized it for database use to include set and bag comprehensions. Fegaras [6] has related it to the algebraic structure of monoids which underlies *OQL*. This section makes general use of the notion of a Comprehension, because it describes precisely almost all the computations done in functional query languages, despite their very different surface syntax!

The comprehension crosses the borders between the lambda calculus and the predicate calculus since functions, just like predicates, can be used either as generators or as filters in collecting up sets of values. However, what matters is the mathematical theory worked out in connection with functional programming, which can be used, for example, to develop and prove correct new analysis and optimization techniques for queries. Generators may just be based on finite sets (or subranges) of integers, and filters can also do calculations. For example, suppose one wants the set of all right-angled triangles with whole-number sides less than 50. The comprehension for this neatly expresses the mathematical requirements:

```
[(x,y,z) | x <- [1..50]; y <- [1..50];
z <- isqrt(x*x + y*y); z*z = x*x + y*y;
z <50]
```

Here for each value of `x` between 1 and 50, one must explore all `y` values between 1 and 50, generate a value for the longest side `z` using a function to calculate the integer part of the square root, and then test that `z` is less than 50. The results are returned in the form of triples, such as `(3,4,5)`. This is a typical use of functions in numerical calculation. It also introduces the subject of *nested loops*. Notice that where one generator appears to the right of another, then its values have to be considered in combination with all values from the previous one, which is just like using nested loops in an ordinary programming language.

Now consider a query involving nested generators, which corresponds to the use of joins in SQL, but which appears in the OQL object database query language [4] as:

```
select x.name
from x in students, y in x.takes, z in y.
taught_by
where z.rank = "full prof"
```

This gives the names of students who take courses taught by full professors. The equivalent comprehension is

```
[name(x) | x <- students; y <- takes(x);
z <- taught_by(y);rank(z) = "full
prof"]
```

In a programming language supporting assignment and `for` loops, one would write the computation using nested loops, which show more clearly the role of the generators:

```
result := [];
for x in students()
  for y in takes(x)
    for z in taught_by(y)
      if rank(z) = "full prof"
      then result := result ++ [name(x)];
```

Note that the variables are now treated as holding object identifiers. More significantly, each variable is only introduced once with an arrow, and this must come before it is used in a predicate or as a parameter of another generator. Apart from this, generators and predicates can be reordered without altering the value of the comprehension, since it behaves like a conjunction of booleans.

This reordering is made easier by using *converse functions* of the form `f_inv` (equivalent to `Conv f` used in Functional Programming); just like an *inverted index*, this may enable one to move selections nearer to generators, so as to gain efficiency. For example, the following comprehension produces the same result more quickly by applying the filter on full professor much earlier:

```
[name(x) | z <- lecturers; rank(z) =
"full prof";
  y <- taught_by_inv(z); x <- takes_inv
  (y)]
```

This technique is widely used. Note that it is not necessary for the end users themselves to use `f_inv`; this need only happen within the query optimizer module of the DBMS.

In order to show that list comprehensions can be more complex, consider another query which returns the codes of all courses that have some section taught by a senior lecturer:

```
  [code(c) | c <- course;
  some([t | s <- sections(c); t <-
  lecturer(s);
    p <- position(t); p="SL"]) ]
```

Here, the inner comprehension depends on the variable `c` representing a course, which is bound by the outer comprehension. The function `some` is a predicate that tests whether its parameter (the inner comprehension) returns a non-empty list. It corresponds to the EXISTS predicate in SQL. In fact, the whole query can be translated into SQL automatically.

The following subsections show how comprehensions are used in a number of different query languages. Despite variations in syntax and in emphasis, all these systems make use of the same mathematical theory for their transformation and optimization.

Comprehensions in P/FDM and Constraints

P/FDM, like the examples in *AMOSQL* [5], uses list comprehensions internally but provides an equivalent query language syntax which suits regular programmers. In P/FDM the above comprehension is rendered as

```
for each c in course such that
  some t in lecturer(sections(c)) has
position(t)="SL"
    print(code(c));
```

This syntax is very close to Shipman's original DAPLEX language.

Comprehensions in P/FDM are also used to describe the semantics of integrity constraints, representing invariants that must be held true under updates. For this purpose the nested loop syntax used in queries is adapted, similarly to constraints in EFDM:

```
constrain each t in seniortutor
  each s in advisees(t)
    to have grade(s) > 60;
```

This constrains each person in the class `seniortutor` to have only advisees with grades over 60. It requires that the following list comprehension always computes an empty list:

```
[ t | t <- seniortutor; s <- advisees
(t); not (grade(s) > 60)]
```

The constraint is equivalent to the following formula in predicate logic, which shows the correspondence between the generators and the nested quantifiers and also the similarity in use of conjunctions. This demonstrates a fascinating connection between comprehensions and the predicate calculus:

$$(\forall t)\ seniortutor(t) \Rightarrow ((\forall s,g)\ advisee(t,s) \wedge grade(s,g) \Rightarrow g>60)$$

Comprehensions in Kleisli – Records, Lists and Mixed Types

In Kleisli [11], comprehensions are written with a comma as separator for conjunctions in place of a semicolon. Also, the first time that a variable iterates over a set of values (in some generator), its name needs to be prefixed with a backslash. Subsequent uses of the unprefixed variable, either in filters or in generators, make use of these bindings. Lastly, record field names are prefixed by a `#`. Thus, the initial example would read:

```
{p.#surname | \p <- person, \f <- p.
#forename, f = "Jim"}
```

If one wishes to create a *list* comprehension or *bag* comprehension, one simply encloses the above expression in different brackets `[ ... | ...]` or `{| ... | ...|}` respectively.

Thus the end user basically works with comprehensions, while the full power of functional programming is reserved for the implementers, working in Standard ML. This is an elegant use of functional programming but note that it is not essential to use a functional language for optimising comprehensions; for example, P/FDM uses Prolog while AMOS uses a version of LISP. Any good list processing language will do but functional languages are, of course, better at type checking.

Comprehensions in FDL and PFL

The functional database languages FDL [9] and PFL incorporate list comprehensions as part of a more general, computationally complete, functional language based on the lambda calculus. In such languages, comprehensions can be formalised as successive applications of a higher order function `flatmap`. Thus, for example, the following comprehension from earlier in this section:

```
[surname(p) | p <- person; f <- forename
(p); f = "Jim"]
```

would translate into the following expression:

```
flatmap (lambda p.
  flatmap (lambda f.if f = "Jim"
      then [surname(p)]
      else [])
    forename(p))
  person
```

`flatmap` is also an example of a *parametric polymorphism*, in that its type can be inferred to be `(a->[b])->[a]->[b]`, where `a` and `b` are *type variables* each of which can be replaced by *any* type. For example, the first occurrence of `flatmap` above has type `(Person->[String])->[Person]->[String]` while the second occurrence has type `(String->[String])->[String]->[String]`.

PFL has a similar type system to FDL, but uses a class of functions called *selectors* which allow storage, querying and update of sets of values of the same type.

Key Applications

The fundamental advantage of list comprehensions as a database abstraction is that they preserve *Data Independence* in a very clean and simple way. They do it by working entirely in terms of sets and functional relationships, regardless of how they are stored. This will seem strange to programmers who are used to carefully choosing between arrays of records or parallel arrays or linked lists or B-trees etc.

Database people know that large collections of data may exist in different forms on different computers, and may need to change form by restructuring on a single computer. Thus it is necessary to do the translation from a list comprehension expressed against a conceptual schema into a specific storage schema at compile time (often close to run time). Likewise it may be necessary to send part of a query to a remote server, since data is increasingly distributed in different forms. Thus the list comprehension is a good choice for passing a complex computational request between computers, free from assumptions about data storage or whether functions are computed or based on stored values.

Future Directions

About a decade ago, Stonebraker was predicting that SQL would become *Galactic Dataspeak*. With the widespread adoption of JDBC and PHP to access MySQL or much bigger commercial SQL databases, this would appear to be so. However, on the Internet there is increasing pressure to provide functionality as *Web Services* which can work on various encapsulated forms of structured and semi-structured data. Functional Query languages may well find a niche as convenient scripting languages for implementing such Web services. They allow a much richer variety of computation and can easily evolve to cope with new storage schemas, because they adhere to the Principle of Data Independence. As such, they should prove much easier to maintain in the fast-changing world of the Web. The functional language *Python* and its JAVA version *Jython* are increasingly popular, and have an explicit syntax for *Comprehensions.*

Fuzzy information retrieval

Definition

The application of Fuzzy Set Theory to Information Retrieval is aimed to the definition of retrieval techniques capable of modeling, at least to some extent, the subjectivity, vagueness and imprecision that is intrinsic to the process of locating information relevant to some user's needs. In particular, Fuzzy Set Theory has been applied in the context of IR to the following main aims:

- To define generalizations of the Boolean retrieval model
- To deal with the imprecision and subjectivity that characterize the document indexing process
- To manage the user's vagueness in query formulation
- To soften the associative mechanisms, such as thesauri and documents' clustering algorithms, which are often employed to extend the functionalities of the basic IR scheme
- To define flexible aggregation strategies in meta search engines and to define flexible approaches to distributed IR
- To represent and inquiry semi-structured information (XML documents)

Historical Background

In 1979 one of the first proposals of application of Fuzzy Set Theory to IR was presented by Tadeusz Radecki [7]. His seminal paper, titled "Fuzzy set theoretical approach to document retrieval" constituted a first generalization of the Boolean retrieval model, followed by several subsequent proposals.

Fuzzy Set Theory was defined as a generalization of classical Set Theory, on which the Boolean information retrieval model is based [8]. A fuzzy set is a class of elements with unsharp boundaries suitable to represent vague concepts. Formally, a fuzzy subset A of a universe of discourse U is defined through a membership function μ_A: U → [0,1]; the value 1 indicates full membership of an element of U to A, the value 0 no membership, and a value between 0 and 1 partial membership. A finite fuzzy subset A of a set U is denoted by A = $\{\mu_A(u)/u\}$ with $u \in U$, in which the notation $\mu_A(u)/u$ indicates that with each element u of the universe U a membership degree $\mu_A(u)$ (in [0,1]) is associated, which denotes the membership of u to the subset.

The main aim of fuzzy generalizations of the Boolean IR model was to overcome its limitations, and to model relevance as a gradual property of documents with respect to a user's query, with the consequence of making an Information Retrieval System able to produce a document ranking [1,4,6]. In a fuzzy IR model a document is formally represented as a fuzzy subset of index terms (the membership value associated with a term represents its index term weight), and the Boolean query language can be extended by allowing the association of weights with query terms. In a generalized Boolean query, each term weight is interpreted as a specification of term importance, and it is formally defined as a flexible constraint (that is a constraint satisfied up to a partial extent) on the document representation. For example, a query term weight may be interpreted as a threshold, i.e., as a constraint satisfied by the documents having the indexing weight higher than the specified query term weight [1,4]. The exact matching of the Boolean model is in this way relaxed to a partial matching in fuzzy IR models, where the matching degree of a document to a query (the so called Retrieval Status Value of a document) is computed on the basis of an evaluation of the satisfaction of the flexible constraints specified in the query (by weighted terms).

Since Radecki's seminal paper, several new applications of Fuzzy Set Theory to IR have been proposed; some of them are described in the following section.

Foundations

In this section a more extensive explanation of Fuzzy IR models is presented, related in particular to the definition of flexible query languages (the key point of the above mentioned fuzzy generalizations of the Boolean model). Some other key applications of Fuzzy Set Theory to IR are also presented in distinct subsections.

Definition of Generalizations of the Boolean Query Language

By means of Fuzzy Set Theory two main generalizations of the Boolean query language have been proposed: the introduction of query term weights, and a generalization of the aggregation operators (the connectives AND and OR in the Boolean query language).

The first fuzzy models proposed in the literature introduced query term weights, by allowing the association of a weight with each query term. In this way the basic constraint specified in a query is a weighted term, identified by a pair <term, weight>. Query term weights express the "importance" of query terms as descriptors of users' needs, and are interpreted as flexible constraints on the index terms weights in each document representation. By such an extension, the structure of a Boolean query is maintained, by allowing weighted query terms to be aggregated by the AND, OR connectives and negated by the NOT operator. In the first fuzzy models query term weights were defined as numeric values in the range [0,1]. A numeric query term weight identifies a flexible constraint on the weighted document representations; such a constraint depends on the semantics of the query weight. Distinct semantics have been proposed for query weights, corresponding to distinct fuzzy generalizations of the Boolean model (distinct fuzzy IR models) [1,4,6]. The three main semantics for query term weights are: the relative importance semantics (query weights express the relative importance of pairs of terms in a query), the threshold semantics (a query weight expresses a threshold on index term weights), and the ideal index term weight semantics (a query weight expresses the "perfect" index term weight).

The choice of one out of the three proposed query weight semantics implies a distinct definition of the partial matching function which evaluates a weighted query term. A flexible constraint imposed by a weighted query term <t, *weight*> is formally defined as a fuzzy subset of the set [0,1] of the index term weights. For a given document d, the membership value μ_{weight}(F(d,t)) is interpreted as the degree of satisfaction of the flexible constraint imposed by the *weight* associated with query term t by the index term weight of t in document d (the value F(d,t)). This means that the partial evaluation function is the membership function of the fuzzy subset identified by the query term weight (i.e., the function μ_{weight}). The result of the evaluation of a weighted query term is a fuzzy set: {μ_{weight}(F(d,t))/d)}, in which the membership degree of a document is interpreted as the degree of relevance of the document to the query (the Retrieval Status Value), and is used to rank the documents.

In structured Boolean queries, the evaluation of the AND and OR connectives is applied to the fuzzy subsets returned by the weighted query terms evaluations.

In the context of Fuzzy Set Theory the connectives AND and OR are defined as aggregation operators belonging to the class of T-norms and T-conorms respectively. Usually, the AND is defined as the *min* (minimum) aggregation operator, and the OR as the *max* (maximum) aggregation operator. A Boolean expression on weighted query terms is usually evaluated by a bottom-up evaluation procedure (except in the case of relative importance semantics): first, each atomic selection condition (flexible constraint. i.e., each weighted term) in the query is evaluated for a given document, and then the aggregation operators are applied to the obtained values starting from the inmost operator in the query to the outermost operator.

As the association of a numeric value forces the user to quantify the qualitative concept of importance of query terms, some late models proposed in the literature have formalized linguistic extensions of the Boolean query language, based on the concept of linguistic variable [1,4]. The values of a linguistic variable are linguistic terms formally defined as fuzzy subsets of a given reference domain; for example in the case one wants to define *age* as a linguistic variable, some possible linguistic values can be *young*, *old*, formally defined as fuzzy subsets of the set [0,130] of the possible numeric values for the age of a human being. By using linguistic query weights, query terms can then be labeled by the words "*important*," "*very important*" or "*fairly important*." Similarly to the evaluation of numeric query term weights, a pair <t, *important*> expresses a flexible constraint evaluated by the function $\mu_{important}$ on the index term weights (the F(d,t) values). The evaluation of the relevance of a given document d to a query consisting of the pair <t, *important*> is then computed by applying the function $\mu_{important}$ to the value F(d,t). Also in this case the membership function of the fuzzy set associated with a linguistic weight depends on the weight semantics.

A second kind of generalization of the Boolean query language has concerned the definition of aggregation operators (AND and OR in the Boolean query language) [1,4,6]. When employing the Boolean retrieval model, if the AND is used for aggregating *M* keywords in a user query, a document indexed by all keywords but one is not retrieved, thus causing the possible rejection of useful items. The opposite behavior characterizes the aggregation by OR. To express more flexible aggregations, the use of linguistic quantifiers (formally defined within Fuzzy Set Theory) has been proposed. Linguistic quantifiers, such as *at least 2* and *most*, specify more flexible document selection strategies. Linguistic quantifiers have been formally defined as averaging aggregation operators, the behavior of which lies between the behavior of the AND and the OR connectives, which correspond to the *all* and the *at least one* linguistic quantifiers.

Another recent research direction is aimed at the definition of flexible query languages to inquire XML documents. Fuzzy set theory is being applied to define extensions of XML query languages so as to make possible the expression of flexible selection conditions on both the documents' structure and contents.

Flexible Indexing of Semi-Structured Documents

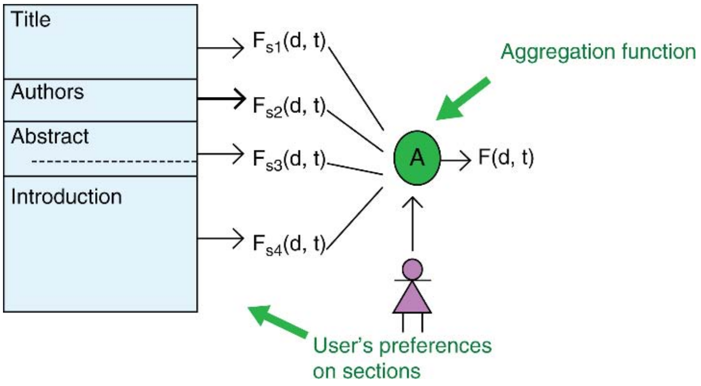
The diffusion of semi-structured documents has encouraged the definition of indexing models which take into account the information conveyed by the "structure" of the documents.

The usual tf*idf indexing schema adopted by IRSs does not take into account the distinct informative role that a term occurrence may have in distinct document sections. For example, considering the structure of a scientific paper, usually organized in sections such as *title, authors, abstract, introduction, references*, an occurrence of a term in the *title* has a distinct informative role than its occurrence in the *references* section. Moreover the usual indexing functions produce the same document representation to all users; this enhances the system's efficiency but implies a loss of effectiveness. In fact, when examining a structured document, users have their personal views of the document's information content. Users would naturally privilege the search in some subparts of the documents' structure, depending on their preferences. This observation has supported the idea of flexible and personalized indexing, first proposed in 1995 [2]. Such an indexing model is constituted by a static component and by an adaptive query-evaluation component; the static component provides an a priori computation of an index term weight for each logical section of the document.

The adaptive component may be activated by a user interaction during query formulation and provides an aggregation strategy of the *n* index term weights (where *n* is the number of sections) into an overall index term weight. The user is allowed to express preferences on the document sections, outlining those that the system should more heavily take into account in computing the overall index term weight. This user preference on the document structure is exploited to enhance the computation of index term weights: the importance of index terms is strictly related to the importance to the user of the logical sections in which they appear. The user may also decide which kind of aggregation to apply for producing the overall significance degree (see Fig. 1). This can be done by the specification of a linguistic quantifier such as *at least k* (with k an integer number) and *most*.

By adopting such an indexing model a same query may produce different document rankings if formulated by distinct users expressing distinct preferences on the documents sections.

More recently, an increasing number of approaches have proposed IR models which are based on concepts rather than keywords, thus modeling document representations at a higher level of granularity, trying to



Fuzzy Models. Figure 1. Sketch of the flexible indexing model.

describe the topical content and structure of documents. These efforts gave raise to the so called concept-based Information Retrieval, which aims at retrieving relevant documents on the basis of their meaning rather than their keywords. In this context some fuzzy set approaches to concept-based Information Retrieval have been proposed.

Fuzzy Associative Mechanisms

Associative retrieval mechanisms are defined to enhance the retrieval capability of traditional IRSs. They work by retrieving additional documents not directly indexed by the terms in a given query but indexed by terms associated to those specified in the query. The most common type of associative retrieval mechanism is based on the use of a thesaurus to associate entry terms with related terms. In traditional associative retrieval the associations are crisp.

The fuzzy associative retrieval mechanisms (first proposed in 1976) are based on the concept of fuzzy association [1,4,5]. A fuzzy association between two sets $X = \{x_1,...,x_m\}$ and $Y = \{y_1,...,y_n\}$ is formally defined as a fuzzy relation $f: X \times Y \rightarrow [0,1]$: the value $f(x, y)$ represents the degree of strength of the association existing between the values $x \in X$ and $y \in Y$.

In Information Retrieval, different kinds of fuzzy associations can be modeled depending on the semantics of the sets X and Y. Fuzzy associative mechanisms are represented by fuzzy thesauri, fuzzy pseudo-thesauri, and fuzzy clustering techniques.

Some authors have proposed the definition of fuzzy thesauri, where the links between terms are weighted to indicate strength of association. Moreover, this notion includes generalizations such as fuzzy pseudo-thesauri, and fuzzy associations based on a citation index [5].

Fuzzy associative mechanisms based on thesauri or clustering techniques have been defined in order to cope with the incompleteness characterizing either the representation of documents or the users' queries. Fuzzy thesauri and pseudo-thesauri can be used to expand the set of index terms of documents with new terms by taking into account their varying significance in representing the topics dealt with in the documents; the degree of significance of the associated terms depends on the strength of the associations with the documents' descriptors. An alternative use of fuzzy thesauri and pseudo-thesauri is to expand each of the search terms in the query with associated terms, by taking into account their distinct importance in representing the concepts of interest; the varying importance is dependent on the associations' strength with the search terms.

Fuzzy Approaches to Distributed Information Retrieval

In distributed information retrieval, there are two main models. In the first model, the information is considered as belonging to a unique, huge, centralized database which is distributed but centrally indexed for retrieval purposes. A second model is based on the distribution of the information on distinct repositories, independently indexed, and thus constituting distinct information sources. In this second case, the repositories reside on distinct servers, each of which can be provided with its own search engine (IRS).

The multi-source information retrieval paradigm is more complex than the centralized model. This paradigm presents additional problems, such as the selection of an appropriate information source for a given information need. This task of distributing retrieval is affected by uncertainty, since a decision must be taken based on an incomplete description of the information source. Furthermore, a common problem in both models is the list fusion task.

Some fuzzy methods have been defined to address the above mentioned problems of source selection and ranked list fusion [3]. In particular, a meta-search model has been recently proposed where the fusion of overlapping ordered lists into an overall ordered list is regarded as a group decision making activity in which the search engines play the role of the experts, the documents are the alternatives that are evaluated based on a set of criteria expressed in a user query, and the decision function is a soft aggregation operator which allows to take into account the lists priority, allowing to model a specific user retrieval attitude [3].

Key Applications

The main applications of Fuzzy Models in IR are aimed at defining new Information Retrieval Systems, to enhance query languages, to define new indexing algorithms, and to define associative mechanisms.

Fuzzy Multicriteria Decision Making

▶ Fuzzy Set Approach

Fuzzy Relation

Vilém Novák
University of Ostrava, Ostrava, Czech Republic

Definition

An n-ary fuzzy relation R is a fuzzy set (see FUZZY SET) in the universe $U_1 \times \ldots \times U_n$, i.e., $R \underset{\sim}{\subseteq} U_1 \times \ldots \times U_n$. A special case is a binary fuzzy relation in the universe $U \times V$, i.e., $R \underset{\sim}{\subseteq} U \times V$.

Key Points

Mathematically, an n-ary fuzzy relation is a function R: $U_1 \times \ldots \times U_n \rightarrow L$ where L is a residuated lattice.

Let $R \underset{\sim}{\subseteq} U \times V$ and $S \underset{\sim}{\subseteq} V \times W$ be two binary fuzzy relations. The *composition* of R and S is a fuzzy relation $R \circ S$ determined by the membership function

$$(R \circ S)(x, z) = \bigvee_{y \in V} (R(x, y) \wedge S(y, z)), \qquad x \in U, z \in W. \tag{1}$$

The operation $\wedge$ in ((1)) can be replaced by arbitrary t-norm.

Fuzzy Set

Vilém Novák
University of Ostrava, Ostrava, Czech Republic

Definition

A fuzzy set is a function $A : U \rightarrow L$ where U is an ordinary set of elements called *universe* and L is a scale which is usually supposed to have the structure of a residuated lattice (see RESIDUATED LATTICE). The function A is at the same time called also *membership function*, i.e., fuzzy set is identified with its membership function.

If $x \in U$ is an element then $A(x) \in L$ is a *membership degree* of x in the fuzzy set A. It can also be interpreted as a *degree of truth* of the fact that the element x belongs to the fuzzy set A. If U is a universe and A a fuzzy set then it is convenient to write $A \underset{\sim}{\subseteq} U$.

Key Points

Fuzzy sets can be explicitly written in the form

$$\{a/u \mid a \in L, u \in U\}$$

where $a \in L$ is a membership degree of an element $u \in U$.

Given a residuated lattice (see RESIDUATED LATTICE) as the structure of truth values, the basic operations with fuzzy sets can be defined as follows:

$$\begin{aligned} &(\mathrm{union}) && (\mathrm{A} \cup \mathrm{B})(\mathrm{x}) = \mathrm{A}(\mathrm{x}) \vee \mathrm{B}(\mathrm{x}), \\ &(\mathrm{intersection}) && (\mathrm{A} \cap \mathrm{B})(\mathrm{x}) = \mathrm{A}(\mathrm{x}) \wedge \mathrm{B}(\mathrm{x}), \\ &(\mathrm{complement}) && \overline{\mathrm{A}}(\mathrm{x}) = \neg \mathrm{A}(\mathrm{x}) \end{aligned}$$

for all $x \in U$ where $\neg$ is a negation in residuated lattice. If the latter is a standard Łukasiewicz MV-algebra then

$$\overline{A}(x) = 1 - A(x).$$

Many other possible operations with fuzzy sets can be defined on the basis of operations in residuated lattice. In case that $L = [0,1]$, the union can be more generally defined using a t-conorm and the intersection using a t-norm.

Note that $\langle \{0,1\}, \vee, \wedge, \wedge, \rightarrow, 0, 1\rangle$ is also a residuated lattice because in this case $\otimes = \wedge$ is the ordinary conjunction and $\rightarrow$ is the classical boolean (material) implication. Therefore, the above operations naturally generalize classical set operations.

The *support* of a fuzzy set $A \underset{\sim}{\subset} U$ is a classical set $\mathrm{Supp}(A) = \{x \mid A(x) > 0\}$. The *kernel* of a fuzzy set is a set $\mathrm{Ker}(A) = \{x \mid A(x) = 1\}$. A fuzzy set A is *normal* if $\mathrm{Ker}(A) \neq \emptyset$.

A fuzzy set $A \subseteq \mathbb{R}$ is called a *fuzzy number* if it has one element kernel $\mathrm{Ker}(A) = \{x_0\}$, bounded support, and $A(x) \geq A(y) \wedge A(z)$ holds for all $y \leq x \leq z$. Such a fuzzy set can thus be taken as interpretation of the expression "approximately x_0."

The above notions can be illustrated on a simple example. Let the universe be a finite set $U = \{a, b, c, d, e\}$ and let L be the standard Łukasiewicz MV-algebra $\langle [0, 1], \max, \min, \otimes, \rightarrow, 0, 1\rangle$. (see RESIDUATED LATTICE) Let

$$\begin{aligned} A &= \{^{0.1}/a,^{1}/b,^{0.8}/c\}, \\ B &= \{^{0.7}/b,^{0.3}/c,^{0.9}/d,^{0.2}/e\} \end{aligned}$$

(The omitted elements have membership degree equal to 0.). Then

$$\begin{aligned} A \cap B &= \{^{0.7}/b,^{0.3}/c\}, \\ A \cap B &= \{^{0.1}/a,^{1}/b,^{0.8}/c,^{0.9}/d,^{0.2}/e\}, \\ \overline{A}(x) &= \{^{0.9}/a,^{0.2}/c,^{1}/d,^{1}/e\}, \\ \mathrm{Supp}(A) &= \{a, b, c\}, \\ \mathrm{Ker}(A) &= \{b\}. \end{aligned}$$

Example of other operation can be bold intersection

$$A \boxtimes B = \{^{0.7}/b,^{0.1}/c\}$$

using a Łukasiewicz product (this is also a t-norm) where, e.g., $(A \boxtimes B)(c) = \max\{0, 0.8 + 0.3 - 1\} = 0.1$.

Fuzzy Set Approach

VILÉM NOVÁK
University of Ostrava, Ostrava, Czech Republic

Synonyms

Fuzzy MCDM; Fuzzy multicriteria decision making

Definition

The classical multicriteria decision making theory is based on the assumption that all the criteria can be characterized precisely so that it is possible to decide unambiguously, whether each alternative fulfils the given criterion or not. However, this is rarely the case in practice and so, the fuzzy set approach has been proposed which makes it possible to assume that the criteria can be evaluated imprecisely, for example "high quality, low reliability, very low weight," etc. Unlike classical approach which first dissolves imprecision and then constructs a decision model, the fuzzy set approach dissolves imprecision only at the very end, if necessary.

The basic concepts of fuzzy decision making are the following:

1. Decision based on the imprecisely defined set of alternatives, i.e., a fuzzy set of alternatives. This is called *decision in a fuzzy environment*.

2. Decision based on aggregation of imprecisely defined (fuzzy) preferences among alternatives.
3. Decision based on evaluation of alternatives using linguistic description of the decision situation.

The linguistic description in Case 3 consists of a set of fuzzy/linguistic IF-THEN rules, i.e., special expressions of the form

$$\text{IF } X \text{ is } \mathcal{A} \text{ THEN } Y \text{ is } \mathcal{B}$$

where X, Y are criteria and $\mathcal{A}, \mathcal{B}$ are imprecise characterizations (for example, evaluative expressions of natural language) of how well the given alternative meets the criteria. The linguistic expressions are often interpreted using fuzzy sets in various ways. The most advanced possibility takes fuzzy IF-THEN rules as conditional sentences of natural language.

A problem related to decision making is *classification*. The main task is to assign the given alternative to one of several classes. In practice, this may be quite difficult since the classes themselves can also be imprecise. For example, shoe numbers represent imprecise classes of foot sizes. The most advanced fuzzy classification methods are based on application of fuzzy IF-THEN rules.

Historical Background

The first paper on fuzzy multicriteria decision making has been written by Bellman and Zadeh in 1970 [1]. Their idea was very simple but at the same time quite powerful and it gave inspiration to many authors of the subsequent papers on fuzzy decision making. The paper started research leading to various kinds of approaches that improved the proposed method on one side and brought a lot of other new ideas and methods on the other side. After period of spontaneous development that lasted until mid of 1980s, the first systematic works appeared, namely the books [4,8].

A significant step forwards is the book by J. Fodor and M. Roubens [6] which is the first sound introduction to valued preference modeling using systematic use of fuzzy set theory and functional equations. Since then, many other papers and books have been published, e.g., [3,13]. Notable is the book by T. J. Saaty [11] which describes the, so called, *Analytic Hierarchy Process* that now belongs to one of the most widely used decision methods in practice.

The number of works on fuzzy multicriteria decision making now counts to thousands. There is also a working group EUROFUSE which regularly organizes various kinds of meetings or co-organizes conferences.

Foundations

Decision making in a fuzzy environment is realized as follows: Let a finite set of alternatives $A = \{a_1,\ldots,a_n\}$ be given. The goal is to choose the best alternative according to m criteria that, however, may be delineated only imprecisely, for example *reasonable price, nice view, great reliability, high safety*, etc.

The criteria are specified by means of defining a fuzzy set of alternatives that fulfil the given criterion in various degrees. Hence, each criterion G_j, $j = 1,\ldots,m$ is identified with a fuzzy set $G_j \underset{\sim}{\subset} A$ of alternatives fulfilling it. The membership degree $G_j(a_i)$ expresses the degree, in which the given alternative $a_i \in A$ fulfils the criterion G_j.

At the same time also constraints must be specified with respect to each criterion, for example *affordable price, view to the forest, acceptable reliability, acceptable safety*, etc. Similarly as the criteria, the constraints are also specified as fuzzy sets of alternatives. This means that each constraint C_j is defined as a fuzzy set $C_j \underset{\sim}{\subset} A$ of alternatives fulfilling C_j in various degrees. Consequently, for each j, $j = 1,\ldots,m$, two fuzzy sets of alternatives are specified: a fuzzy set G_j representing criterion and a fuzzy set C_j representing constraint.

For example, the criterion G_j can be *reasonable price* while the constraint C_j can be *affordable price*. The latter means that not each reasonable price can be for the decision-maker at the same time also affordable. If a_i is a certain house that a decision-maker wants to buy then the membership degree $G_j(a_i)$ represents the degree in which the price of a_i is reasonable (e.g., $G_j(a_i) = 0.8$ means that it is in 80% true that the price of a_i is reasonable). Quite analogously, the membership degree $C_j(a_i)$ is a degree in which the price of a_i is affordable for the decision-maker. For example, the set A of houses (alternatives) may contain also a castle a_k at a very reasonable price – several millions of dollars – but this price can be completely non-affordable for the decision-maker because he/she has, say, less than one million at disposal. In this case, set $C_j(a_k) = 0$.

The final decision is a fuzzy set of alternatives obtained by composition

$$D = (G_1 \alpha C_1)\beta \ldots \beta(G_m \alpha C_m) \tag{1}$$

where α, β are suitable fuzzy set operations. The best alternative is an alternative $a_k \in A$ with the highest membership degree $D(a_k)$.

Setting $\alpha = \beta = \cap$ (intersection) leads to *pessimistic decision*. With respect to the above example, $G_j(a_j) \wedge C_j(a_j)$ is a minimum of the degrees in which the house a_j has a reasonable and affordable price, i.e., the worse of both. Hence, for the castle a_k it is immediately obtained that $G_j(a_k) \wedge C_j(a_k) = 0$ and so $D(a_k) = 0$ which means that the castle is surely not chosen as the best alternative.

Setting $\beta = \cup$ (union) leads to *optimistic decision*. The best, however, seems compensatory decision which combines both intersection as well as union in various degrees. More details can be found in [19,14].

It is also possible to omit constraints from (1) and to consider the criteria $G_1,\ldots,G_m$ only. Then, the problem is raised how all the membership degrees $G_j(a_i)$ should be aggregated to obtain the global satisfaction degree $D(a_i)$ of the given alternative a_i. This requires the use of a specific *aggregation operator* $\mathcal{H}^m$ so that

$$D(a_i) = \mathcal{H}^m(G_1(a_i),\ldots,G_m(a_i)).$$

The symbol $\mathcal{H}^m$ denotes actual number of arguments of $\mathcal{H}$ (their number can vary).

Basic properties of aggregation operators are the following:

$$\begin{aligned}
&\mathcal{H}^1(a) = a,\\
&\mathcal{H}^m(0,\ldots,0) = 0 \text{ and } \mathcal{H}^m(1,\ldots,1) = 1,\\
&\text{if}\,(a_1,\ldots,a_m) \le (b_1,\ldots,b_m) \text{ then}\\
&\quad \mathcal{H}^m(a_1,\ldots,a_m) \ \le\ \mathcal{H}^m(b_1,\ldots,b_m).
\end{aligned}$$

Many other conditions can be imposed on aggregation operators, for example continuity, symmetry, associativity, idempotency, compensation, etc. The possible operators are classified as *conjunctive operators* (e.g., t-norms), *disjunctive operators* (e.g., t-conorms), *mean operators* (e.g., arithmetic mean), or more specific ones, such as *compensative operators* or *order weighted averaging operators* (OWA operators). Many details can be found in [2,7,13].

The criteria, however, are usually not equally important. Their relative importance is expressed using weights that can be numbers assigned to each criterion or/and constraint. The most popular method for weights assignment is *Analytical Hierarchy Process* (AHP) that itself can be used as a specific fuzzy decision method. It involves structuring multiple choice criteria into a hierarchy, assessing the relative importance of these criteria, comparing alternatives for each criterion, and determining an overall ranking of the alternatives. Thus, it can be divided into four phases:

1. *Decomposing*, i.e., the problem is structured into humanly-manageable sub-problems.
2. *Weighing*, i.e., a relative weight is assigned to each criterion, based on its importance within the node to which it belongs. A global priority is computed that quantifies the relative importance of a criterion within the overall decision model.
3. *Evaluating*, i.e., alternatives are scored and compared each one to others.
4. *Selecting*, i.e., an alternative fitting best the requirements is selected.

For the details about AHP, see [11].

Imprecisely defined preference is mathematically modeled using a binary *fuzzy preference relation* $R \underset{\sim}{\subseteq} A \times A$. This is determined by triple of binary fuzzy relations $\langle P, I, J \rangle$ where $P \underset{\sim}{\subseteq} A \times A$ is a strict fuzzy preference, $I \underset{\sim}{\subseteq} A \times A$ is a fuzzy indifference, and $J \underset{\sim}{\subseteq} A \times A$ is a fuzzy incomparability. This means, that $P(a_i, a_j)$ is a degree, in which the alternative a_i is strictly preferred to a_j. Similarly, $I(a_i, a_j)$ is the degree in which a_i is indifferent to a_j, and $J(a_i, a_j)$ is the degree in which a_i is incomparable with a_j. In other words, the given relation need not hold in full but only partially. This corresponds well with the real situations in which it needs not be fully convincing that, for example, "high building" is strictly nicer than "low" one, etc.

The definition of P, I, J and their further properties depend on the choice of the structure of truth values which is a specific residuated lattice. The solution is not unique and depends on other conditions that can be imposed on these relations. One possible solution is to assume that truth values form the standard Łukasiewicz MV-algebra and to put

$$P(a_i, a_j) = R(a_i, a_j) \wedge \neg R(a_j, a_i), \tag{2}$$

$$I(a_i, a_j) = R(a_i, a_j) \otimes R(a_j, a_i), \tag{3}$$

$$J(a_i, a_j) = \neg R(a_i, a_j) \otimes \neg R(a_j, a_i) \tag{4}$$

where $\bigotimes$ is the Łukasiewicz conjunction $a \bigotimes b = 0 \vee (a + b - 1)$. The detailed analysis and justification can be found in [6,13].

A very powerful general technique suitable also for applications in decision making as well as in classification are fuzzy/linguistic IF-THEN rules. The given decision situation is described using linguistic description and then, each alternative is judged using it on the basis of the measured characteristics for each criterion. The linguistic form of fuzzy/linguistic IF-THEN rules makes it possible to distinguish sufficiently subtly and, at the same time, aptly, various degrees of fulfilment of the respective criteria, their various importance and, moreover, it may also overcome possible discrepancies. Hence, the problem of assignment of weights to the criteria disappears. This makes fuzzy/linguistic IF-THEN rules very attractive for decision-making because the problem of weights assignment belongs to the most controversial problem in its applications. Another advantage is the possibility to include also information that can be quantified with great difficulties. For example "aesthetic quality," "overall impression," etc. are criteria which people can evaluate using expressions of natural language such as "very high, quite low, great, medium," etc. Such expressions (they are called *evaluative linguistic expressions*), however, can be used in fuzzy/linguistic IF-THEN rules without problems.

The procedure for decision support using fuzzy/linguistic IF-THEN rules is analogous to the AHP procedure mentioned above with the exception that the weighing phase is omitted. The first phase consists in decomposition of the decision problem into subproblems, each of which being characterized by a specific linguistic description. Hence, the decision situation is described using a hierarchical system of linguistic descriptions which, at the same time, renders evaluation:

$$\mathcal{R}_{1k} : \text{IF } G_{k1} \text{ is } \mathcal{A}_{11} \text{ AND } \dots$$
$$\text{AND } G_{kn(k)} \text{ is } \mathcal{A}_{1n(k)} \text{ THEN } H_k \text{ is } \mathcal{B}_1$$

....

$$\mathcal{R}_{1p(k)} : \text{IF } G_{k1} \text{ is } \mathcal{A}_{p(k)1} \text{ AND } \dots$$
$$\text{AND } G_{kn(k)} \text{ is } \mathcal{A}_{p(k)n(k)} \text{ THEN } H_k \text{ is } \mathcal{B}_{p(k)}$$

$k = 1,\dots,r$ and

$$\mathcal{R}_1 : \text{IF } H_1 \text{ is } \mathcal{A}_{11} \text{ AND } \dots$$
$$\text{AND } H_r \text{ is } \mathcal{A}_{1r} \text{ THEN } H \text{ is } \mathcal{B}_1$$

....

$$\mathcal{R}_s : \text{IF } H_1 \text{ is } \mathcal{A}_{s1} \text{ AND } \dots$$
$$\text{AND } H_r \text{ is } \mathcal{A}_{sr} \text{ THEN } H \text{ is } \mathcal{B}_s$$

where $H_1,\dots,H_r$ are local evaluations, H is a global evaluation and $\mathcal{A}$'s and $\mathcal{B}$'s are evaluative linguistic expressions. The final decision is made on the basis of the values of the global evaluation H (usually, the higher, the better). A typical example of the above rules is, for example, "IF price is small AND maintenance is more or less medium THEN economical conditions are good," or "IF house is stylish AND place is very nice THEN aesthetic quality is significantly high," etc. On the basis of initial information about each alternative for all aspects, the inference proceeds. The most convenient inference method at this step is *perception-based logical deduction*. Note that other methods can be used as well but one must be careful about defining the shapes of fuzzy sets and so, the advantage of using natural language is limited. The best alternative is selected on the basis of the highest (or, possibly, the lowest) value of the global evaluation H.

A specific task belonging also to the realm of decision making is *classification*. In general this is a procedure that assigns an element from a finite set $\Omega = \{\omega_1,\dots,\omega_c\}$ to a vector $\mathbf{x} \in S$, $S \subset \mathbb{R}$ of numbers. The set S is a *feature space* and Ω is a set of classes that can be, e.g., pieces of a figure, psychological categories, shoe numbers, diseases, etc. The need for fuzzy classification is raised in the moment when there is not a sufficient or precise information available or the character of classes is imprecise so that membership in them can be unclear and only some degree can be provided, etc. Such situations are very usual in the real life.

A specific case are fuzzy IF-THEN classifiers that are linguistic descriptions with clearly distinguished consequences. The latter can be either crisp or fuzzy numbers. Further elaboration is the same as above.

Key Applications

There are several thousands of real applications of fuzzy multicriteria decision making. One of the earliest of them was evaluation of the credit-worthiness of credit applicants developed in Germany (see [14]).

Other essential application is Yamaichi Fuzzy Fund which handles 65 industries and a majority of the stocks listed on Nikkei Dow. It is based on the application of fuzzy IF-THEN rules which are determined monthly by a group of experts and modified by senior business analysts when necessary. The system was tested for 2 years, and its performance in terms of the return and growth exceeds the Nikkei Avarage by over 20%. For comparison, the system recommended "sell" 18 days before the Black Monday in 1987. The system went to commercial operations in 1988.

Some other ones are, evaluation of weapon systems, technology transfer strategy selection in biotechnology, aggregation of market research data and thousands others. Evaluation of weapon systems has been provided using the Analytical Hierarchy Process (AHP) based on fuzzy scales.

Typical features of the weapon system evaluation were the following: the objectives of the evaluations are generally multiple and generally in conflict, and the descriptions of the weapon systems are usually linguistic and vague. The details are in [5]. It should be stressed that such features are typical for most practical decision problems and this is the main reason for using fuzzy set theory. In case of linguistically provided information, especially fuzzy IF-THEN rules taken as conditional statements of natural language are convenient tool since they make possible to include also non-quantifiable information. Such application was described in [10].

Fuzzy/Linguistic IF-THEN Rules and Linguistic Descriptions

VILÉM NOVÁK
University of Ostrava, Ostrava, Czech, Republic

Definition

Fuzzy/linguistic IF-THEN rules are structured expressions of natural language having the form

$$\mathcal{R} : \text{IF } X \text{ is } \mathcal{A} \text{ THEN } Y \text{ is } \mathcal{B} \tag{1}$$

where X, Y are variables and $\mathcal{A}, \mathcal{B}$ are expressions such as *small, very small, medium, roughly medium, more or less big, big*, etc. The latter are called *evaluative linguistic expressions*. Modeling their meaning in fuzzy set theory makes it possible to model the meaning of the whole rule. The part before THEN is called *antecedent*, the part after it is called *consequent*.

A *linguistic description* is a finite set of fuzzy/linguistic IF-THEN rules

$$\begin{array}{rl} \mathcal{R}_1 : & \text{IF } X \text{ is } \mathcal{A}_1 \text{ THEN } Y \text{ is } \mathcal{B}_1 \\ & \dotfill \\ \mathcal{R}_m : & \text{IF } X \text{ is } \mathcal{A}_m \text{ THEN } Y \text{ is } \mathcal{B}_m. \end{array} \tag{2}$$

Linguistic description can be taken as a special structured text in natural language which describes some situation.

Key Points

There are two possible ways how fuzzy/linguistic IF-THEN rules can be interpreted in fuzzy set theory:

(a) IF-THEN rule is assigned a fuzzy relation,

(b) IF-THEN rule is assigned a function from the set of contexts to the set of fuzzy relations.

Case (b) is more complicated but more realistic as a model of the meaning of linguistic expressions since (1) can be taken in this case as a conditional expression of natural language.

In case (a), the whole linguistic description (2) is assigned a fuzzy relation constructed using one of two possible formulas: let each of the expressions of the form “X is $\mathcal{A}_i$” be assigned a fuzzy set $A_i \underset{\sim}{\subset} U$ and “Y *is* $\mathcal{B}_i$,” $i = 1,\ldots m$ a fuzzy set $B_i \underset{\sim}{\subset} V$. Two possible fuzzy relations can be considered:

$$R^A(x, y) = \bigvee_{i=1}^{m} (A_i(x) \otimes B_i(y)), \qquad (3)$$

$$R^I(x, y) = \bigwedge_{i=1}^{m} (A_i(x) \rightarrow B_i(y)), \qquad (4)$$

where $\otimes$ is a t-norm and $\rightarrow$ is a residuation. Then (3) is called *disjunctive normal form* in which each IF-THEN rule is interpreted as *conjunction*; (4) is called *conjunctive normal form* in which each IF-THEN rule is interpreted as *implication*. Both forms (3) and (4) are two possible interpretations of the linguistic description (2).

The second interpretation of (2) is a set of functions $I(\mathcal{R}_i)$ assigned to the rules $\mathcal{R}_i$ in (2), $i = 1,\ldots,m$. Each function has the form

$$I(\mathcal{R}_i) : C_X \times C_Y \longrightarrow L^{U \times V} \qquad (5)$$

where C_X, C_Y are sets of *contexts* for the variable X and Y, respectively. Each context $w_X \in C_X$ and $w_Y \in C_Y$ is a certain interval of elements in U and V, respectively. The couple of contexts $\langle w_X, w_Y \rangle$ is assigned via (5) a fuzzy relation of the form $A_i(x) \rightarrow B_i(y)$, $x \in U$, $y \in V$. This approach leads to a mathematical model of the meaning of the text (2). Human understanding to such expressions and deriving conclusions on the basis of them can be mimicked. The details can be found in [2].

Gazetteers

Linda L. Hill
University of California-Santa Barbara, Santa Barbara, CA, USA

Synonyms

Place names; Toponyms; Knowledge organization systems; Ontologies

Definition

A simple definition is that gazetteers are dictionaries of placenames. The digital gazetteer as a component of georeferenced information systems, however, is more formally modeled. A gazetteer is defined as a collection of gazetteer entries, each of which contains, at a minimum, the tuple *N, F, T* where *N* is a place name, *F* is a formal expression of geographic location – a *footprint*, and *T* is a place type expressed with a term (or code) from a typing scheme. Applications often require, in addition, relationships between gazetteer entries, documentation of time frames, and additional information (as described below). The gazetteer model is a type of knowledge organization system (KOS) – or ontology – which can be modified to represent other classes of spatial-temporal information, such as named time periods and named events [3].

Key Points

Gazetteers support bidirectional translation between *informal* georeferencing using names (e.g., Las Vegas) and *formal* georeferencing using coordinates (e.g., 36°10′30″N, 115°08′11″W) or similar mathematical reference within a geospatial framework. The need for such translation is common, For example, to calculate routes and distances and to support information retrieval by either place names or coordinates. A common use for gazetteers is to answer the "where is" question: "where is Baltimore?" can be answered by a map display showing the locations of places called "Baltimore" in the world.

In addition to place names and geospatial location, a third basic component of a gazetteer entry is a classification according to a typing scheme; that is, assigning a type term to a place to indicate that it is a populated place, a river, an island, a country, a bank, etc. There is no single typing scheme for named places. Instead, there are multiple typing schemes, usually unique for a particular application.

All of the descriptive data associated with named places have time dimensions. To deal with these temporal dimensions adequately, a gazetteer data structure must incorporate time ranges for places as well as for most of the elements of description.

Since different names can be used for the same place (e.g., in multiple languages), gazetteers must support multiple names and, ideally, document the source and time frame of each name. Supporting multiple footprints and information about a place from multiple sources is also needed for some applications.

A gazetteer is a collection of gazetteer entries [5]. Inherent spatial relationships exist between gazetteer entries. It can be determined which places are located within the footprint of another place – at least, theoretically. Actually, the ability to do this adequately depends on the quality of the footprints. Explicit relationships between gazetteer entries can also be added to the descriptive information. It can be documented, for example, that Chicago *is part of* Illinois and that Illinois *is part of* the US or that Topeka *is capital of* Kansas.

The International Organization for Standardization (ISO), the Open Geospatial Consortium, and the Alexandria Digital Library at the University of

California, Santa Barbara, have published gazetteer standards, protocols, and place typing schemes; see references [2,4–6].

Gene Expression Arrays

Mehmet M. Dalkiliç
Indiana University, Bloomington, IN, USA

Definition

A gene expression array (or DNA microarray) is a miniature, massively parallel, and semi-automated process that measures levels of gene products (or mRNA or transcripts). The DNA of an organism (cell or cells) is a set of instructions used to direct its existence. A genetic message is transcribed from DNA into mRNA (messenger RNA), then typically translated into protein. By measuring the levels of mRNA, an indirect glimpse can be taken into the functioning of a cell. The relative and absolute levels of the transcripts are called expressions, and this instantaneous set of expressions is called the expression profile. Profiles can be used, for example, to indicate a disease state.

Historical Background

DNA and RNA are bio-molecules that *hybridize* bonding due to complementary structure. Hybridization has been used for several decades as means of identifying DNA and RNA present in an organism (cell or cells). Until microarray technology was invented, utilizing hybridization was slow and could only be perfomed on a relatively small scale. The microarry process is often associated with the Pat Brown laboratory in 1995 [6] and by Affemetrix [5].

Foundations

The fundamental purpose of gene expression arrays (or DNA microarrays) is to understand how an organism functions through measuring levels of proteins – molecules that perform a vast array of functions necessary for the life of the organism. Together with its genome (the DNA of an organism), DNA microarrays provide a global perspective into how regulation takes place, in other words, how the organism makes use of its DNA. The measurements are not directly made on the protein levels themselves, but intermediaries between the DNA and protein called RNA. Specifically, messenger RNA (mRNA) is first transcribed from the DNA, then translated into protein. The basic mechanism underlying microarray technology is *hybridization* – the chemical pairing of complementary molecules. DNA can hybridize to itself and to RNA, and this property has been used for decades in Southern and Northern blotting that measures amounts of hybridized DNA and RNA, respectively, typically tagged through radioactive labeling. The weakness of these two techniques is scale and time: only a small number of proteins can be measured requiring the period of a day or so. These blotting techniques have been miniaturized, made massively parallel, and semi-automated, so that $O(10^5)$ to $O(10^6)$ experiments can be conducted at a time. In DNA microarrays single stranded fragments of DNA are affixed to a substrate (called probes) in a grid and washed with a solution containing fluorescently tagged fragments of DNA (called targets). The concentration of DNA labeled fragments affects the likelihood of hybridizing to the probes. The intensities of each point on the grid are measured and result in a table of floating point numbers. It is from the intensity of labels that the levels of proteins are to be inferred. There are essentially two kinds of DNA microarrays: cDNA (spotted arrays) and high-density oligonucleotide arrays (oligos). In the former, fragments of a genome are used as probes. Oligos are synthesized sequences of nucleotides. cDNA arrays allow for matching against the genome, and Oligos for particular sequences of interest. Because the company Affemetrix developed the oligos, these are often referred to as Affy chips (or Affy arrays). The data produced from arrays is a very large set of intensities of electromagnetic radiation. Each intensity is associated with a two-dimensional location on the chip is called a spot. Microarrays are noisy, low resolution, and inconsistent; however, as the technology matures, there have been marked improvements. The data must be heavily pre-processed before analysis. This includes correcting for experimental design, biological factors, and specific mechanical idiosyncrasies themselves. One of the most significant pre-processing steps is called "normalization" which is an attempt to make different microarray data comparable. Currently, a consensus on how to achieve normalization does not exist, and a number of approaches can be taken. Extensive libraries exist in **R** (http://www.r-project.org) a feely available computing environment for statistical analysis; in particular, the OLIN [2] and Bioconductor packages [4] include normalization and dye correction. The main objective in microarray anaylsis is discovery patterns and outliers. Patterns are, crudely, sets of gene products that possess some discernable functional relationship. Typically, the relationship is between two expressions and linearity is examined. In particular, Pearson's correlation is often used to gauge the linearity of genes. Pearson's correction denoted $\rho(\cdot,\cdot)$ is a real-valued measurement on the interval $[-1,1]$ over two sets of data, X,Y. The score $|\rho(X, Y)| \approx 1$ if there is either a positive or negative unity if a strong linear relationship exists, tending toward zero otherwise. A zero value for Pearson's only indicates that linearity does not exist. Database practitioners should realize the microarray is significant when it can be thoroughly studied with extensive biological annotations – it is much more than a table of spots.

Key Applications

There are key applications for both bioinformatics and database. To give some indication of the amount of interest in the area, the number of publications found in PubMed (http://www.pubmed.gov) by searching with terms "`microarray`" and "`2007`" yields well over 10,000 entries (executed 01/20/2008). For bioinformatics, microarrays promise to yield cell states that can help determine function, disease states (as mentioned previously), guide areas of discovery (e.g., drugs). From a database perspective, there is an incredible wealth of data that needs to be managed. However, the empirical and complex nature of the processes underlying the microarray belie its apparent simplicity – usually rendered pictorially as an attractive rectangle grid of colored circular sports that range from green to yellow to red. Although no ANSI standard exists for microarrays, like much of bioinformatics there are different popular standards vying for dominance. Of these, the most well-known is MIAME (the minimum information about a microarray experiment) that specifies elements of experiments. Since this specification is at least recognized in name, it will briefly highlight its components: (i) Array information including platform (spotted, etc.), size and number of spots, protocols; (ii) Reporter information (sequences on the slide itself); (iii) Gene information; (iv) Information about control array control elements. Often cluster analysis is done on microarrays, rows are gene products and columns are experiment conditions. The clustering results in a tree (dendogram) that depicts the most similar genes on the set of conditions. A formal language for accessing, managing, creating these large data sets does not exist.

Queries associated with arrays vary with the intent of the user. This is significant because a good number of these queries rely on data completely external to the system. For example, a typical query might be, "What are the sequence annotations of gene g_1, g_2, g_3?" For this query, the system must link to sequence annotation databases to retrieve the information. The challenge is that there are (again) no official standards and that the data, contained in flat files or even XML, must be parsed to extract the meaningful information desired. To answer the growing needs to understand a group was formed near 2000 called the Microarray and Gene Expression Database (http://www.mged.org). The Microarray and Gene Expression Data (MGED) Society is a global consortium of scientists who are striving to provide some coherence in how to make data exchange easier. The scope of MGED includes other genome-wide data and so, provides additional information particular to data like binding. Although the MGED is working to establish standards for management and so forth, it is unclear how widespread the recognition and adoption is. As mentioned with the example query, one unusual aspect of managing gene expression data is associating it with other data housed and managed in other systems. The MGED provides a few standards: MIAME, MAGE-TAB, MAGE-ML, MGED, Ontology; it also provides information about the current status of these representations.

One of the most significant elements of database design for array databases is the ability to exchange and retrieve "foreign" data – data housed in different forms in different repositories likely due to the nature of the biological questions being asked. To this end, MAGE and MAGE-ML, are means of facilitating data exchange, the latter XML in spirit. MAGE is more popular and does associate with the MIAME standard, but the associations are not one-to-one. One significant difference between MIAME and MAGE is the latter provides elements of provenance and security, while MIAME has no mechanism at all.

ArrayExpress, a public European repository for array data, is housed at the European Bioinformatics Institute (EBI) and seems to be aiming more toward a data warehousing approach, archiving data, but allowing limited keyword searches, etc. accession number or author.

A significant challenge to management of array data is the dynamic nature of information. Since array data maps back to genomes, as genome drafts are updated, array data must reflect these changes. There is genomic draft versioning to help remap gene products to the updated genomic locations. To give an idea of the complexity, often drafts result in genes being split, coalesced, removed, or changed in length. This directly affects the interpretation of the results of array.

Semantics of terms in array database are, as described above, often imprecise. One approach that biologists have begun adopting is the use of ontologies. The most well known example in biology is the Gene Ontology [3] (GO) (*http://www.geneontology.org/*). By fixing a common vocabulary and set of relationships GO has become a common tool in analysis.

Future Directions

Microarrays are only one of many so-called high-throughput technologies that produce enormous amounts of data – these can easily range in size to terabytes. Many problems biologists have been able to effectively solve on small scales, do not scale with the data. There is much work to be done in how to analyze such a large and growing corpus of data. Another aspect is how to integrate the different types of high-throughput. Systems biology is a recent discipline that attempts to semantically merge disparate types of data to form global perspectives that no one piece of data would contain. One of the standard structures used in microarrays is the directed graph. Again, polynomial complexity algorithms become infeasible with such a large amount of data. Bayesian Belief Nets have recently become popular in analyzing these large graphs (or networks).

Data Sets

There are public data sets available through the internet. Some of the better known include:

Advanced transaction models; Extended transaction models

Definition

ACID (Atomicity, Consistency, Isolation, and Durability) is a set of properties that guarantee the reliability of database transactions [2]. ACID properties were initially developed with traditional, business-oriented applications (e.g., banking) in mind. Hence, they do not fully support the functional and performance requirements of advanced database applications such as computer-aided design, computer-aided manufacturing, office automation, network management, multidatabases, and mobile databases. For instance, transactions in computer-aided design applications are generally of long duration and preserving the traditional ACID properties in such transactions would require locking resources for long periods of time. This has lead to the generalization of ACID properties as Recovery, Consistency, Visibility, and Permanence. The aim of such generalization is to relax some of the constraints and restrictions imposed by the ACID properties. For example, visibility relaxes the isolation property by enabling the sharing of partial results and therefore promoting cooperation among concurrent transactions. Hence, the more generalized ACID properties are, the more flexible the corresponding transaction model will be.

Key Points

ACID is an important concept of database theory. It defines four properties that traditional database transactions must display: Atomicity, Consistency, Isolation, and Durability. *Atomicity* states that transactions must follow an "all or nothing" rule. Either all of the changes made by a transaction occur, or none of them do. The two-phase commit protocol (2PC) is generally used in distributed databases to ensure that each participant in a transaction agrees on whether or not the transaction should be committed. *Consistency* means that transactions always operate on a consistent view of the database and leave the database in a consistent state. A database is said to be consistent as long as it conforms to a set of invariants, called *integrity constraints*. *Isolation* gives the illusion that each transaction is executed alone. It ensures that the effects of a transaction are invisible to other concurrent transactions until that transaction is committed. Concurrency control protocol are generally implemented in database systems to preserve this property. *Durability* states that once a transaction is committed, its effects are guaranteed to persist even in the event of subsequent failures. This is usually achieved using database backups and transaction logs.

The limitations inherent to the original ACID properties and the peculiarities of advanced database applications has lead to the generalization of ACID properties Recovery, Consistency, Visibility and Permanence. *Recovery* refers to the ability to take the database to a state that is considered correct in case of failure. *Consistency* refers to the correctness of the state of the database that a committed transaction produces. *Visibility* refers to the ability of one transaction to see the results of another running transaction.

Permanence refers to the ability of a transaction to record its results in the database. The flexibility of a transaction model depends on the way ACID properties are generalized. An extensive coverage of advanced transaction models is presented in [1]. *Sagas*, *Nested Transactions*, and *Flex* are representative examples of models that generalize ACID properties while *ACTA* is an example of a formal framework to express these models and reason about them.

A *Saga* is a chain of transactions that is itself atomic. Isolation is relaxed at the level of a Saga and visibility is permitted at the component transaction boundaries. A saga itself is atomic but because of the relaxed visibility, it supports semantic consistency. That is, each transaction in the chain is assumed to have a semantic inverse, or compensation, transaction associated with it. If one of the transactions in the saga fails, the transactions are rolled back in the reverse order of their execution. Committed transactions are rolled back by executing their corresponding compensation transactions.

Nesting allows concurrency within a transaction and provides fine-grained and hierarchical control for failure handling. The original nested transaction model, which supports only closed sub-transactions, was extended to include open sub-transactions. Closed sub-transactions may not support consistency and durability. A closed sub-transaction commits its results to its parent. These partial results are externalized only after the top (root) transaction commits, thus ensuring atomicity and isolation of the whole transaction. Because of its relaxed visibility, open sub-transactions directly externalize their results and expose them to other transactions.

The *Flex Transaction Model* has been proposed to generalize ACID properties in multidatabase systems. It relaxes the atomicity and isolation properties of nested transactions to provide users increased flexibility in specifying their transactions. A Flex transaction may proceed and commit even if some of its sub-transactions fail. It also allows the specification of dependencies on sub-transactions as internal or external dependencies. Internal dependencies define the execution order of sub-transactions, while external dependencies define the dependency of a sub-transaction execution on events (such as the start/end execution times) that do not belong to the transaction. The Flex model also enables users to control the isolation granularity of a transaction through the use of compensating sub-transactions.

ACTA is a framework that facilitates the formal description of properties of extended transaction models. It defines constructs that facilitate the synthesis of extended transaction models by tailoring/combining existing models or starting from first principles. Different notions are introduced in ACTA to enable the generalization of ACID properties from different perspectives. For instance, the notion of delegation allows transactions to selectively abort some of the operations it has performed and yet commit.

Generalized Search Tree

Joseph M. Hellerstein
University of California-Berkeley, Berkeley, CA, USA

GiST; GIST

Definition

The Generalized Search Tree (GiST) is an extensible, disk-based index structure for large data sets, enabling the easy design and implementation of domain-specific index structures. The GiST provides a general-purpose implementation of many of the difficult systems issues inherent in indexing (data storage and access, search, concurrency and recovery), with a compact extensibility interface sufficient for the specification of the domain-specific, algorithmic aspects of indexing (clustering of data into pages, labeling of subtrees, and prioritization of the search frontier).

Historical Background

A key research challenge in database systems in the 1980s and 1990s was to support an *extensible* set of abstract data types, beyond the alphanumeric types typically used in business data processing. One critical component of database extensibility is the ability to easily add new *access methods* customized to specific data types and query operators. Ideally, extensibility interfaces should enable the programmer extending the DBMS to focus on their domain expertise (e.g., geographic information, bioinformatics, etc.), and not have to reason about database systems issues like storage, buffering, query optimization, concurrency or recovery.

The Postgres system provided one of the first truly extensible access method interfaces, which allows new access methods to be registered with a query planner and executor. However, this interface leaves the implementation of data storage, concurrency and recovery in the hands of the extension programmer, which makes the task of writing a new access method extremely difficult, and results in inelegant software that replicates complex functionality across different index implementations.

The GiST design was intended to take care of as many generic database systems issues as possible, while still enabling a wide range of indexes to be easily written within its framework. At heart, the GiST is a generalization of the B+-tree, and one of its contributions is to demonstrate the degree to which many subsequent index inventions are specific variations of the basic B+-tree ideas.

In principle, the GiST can be used for any indexing *workload*, as defined by a family of query predicates over a particular data domain. This raises theoretical questions of both lower and upper bounds: which workloads are efficiently indexable, and how close to optimal is the performance of a particular index design on a given workload? The first of these questions inspired the *Theory of Indexability*; the latter led to a set of empirical performance metrics, which have been embodied in the *Access Method DeBugger (amdb)* toolkit.

Foundations

Like the B+-tree, the GiST is a height-balanced tree of variable fan out, with data stored at the leaves, and *search keys* associated with pointers in the internal nodes. The GiST search keys are the center of its extensibility API: a new index is implemented via a new search key class and associated methods. Search keys are parameterized by four user-defined methods:

1. The `consistent` method of a search key *k* takes a query predicate *p*, and returns *false* if it is not possible for *k* and *p* to describe the same data items. The index search algorithm only traverses a subtree if the consistent method returns true for the search keys above it.
2. The `union` method takes a set of search keys from a child node, and produces a single search key to be placed in the parent. This is used to update search keys whenever the contents of the tree change.
3. The `penalty` method of a search key takes a new data item to be inserted, and returns a cost for the insertion of that item into the subtree labeled by that search key. This guides the index insertion algorithm's descent to a leaf, affecting the clustering of data in the tree.
4. The `pickSplit` method takes a set of search keys, and partitions them into two subsets; this is used for choosing how to split an overflowing page during insertion into the tree. This method also affects the clustering of data in the tree.

In its original conception, the GiST was designed to support selection predicates, via search keys forming a set-containment hierarchy. Subsequently, it was observed that the GiST can naturally support richer queries, including near-neighbor search, as well as statistical methods for approximate query answering that treat the search keys as a multi-resolution synopsis of the data.

Key Applications

GiST has been implemented in a number of database systems and projects, most notably in the Informix Universal Server, and the open-source PostgreSQL system, both of which implement the full GiST concurrency and recovery algorithms.

Currently, GiST serves as the default framework for spatial and text indexing in PostgreSQL, via extensions corresponding to R-trees for spatial data, and Russian-Doll (RD) Trees for text data. The open-source

PostGIS Geographic Information System relies upon the PostgreSQL GiST implementation for its spatial indexing.

In addition to their widespread use for spatial and text workloads, GiST-based indexes have been used for applications in image retrieval, astronomy data, and genomic data.

Genetic Algorithms

Colin R. Reeves
Coventry University, Coventry, UK

Synonyms

Evolutionary algorithms; Evolutionary computation

Definition

A genetic algorithm (GA) is one of a number of heuristic techniques that attempt to find high-quality solutions to large and complex optimization problems. The term *evolutionary algorithm* is sometimes used synonymously, but is generally used to denote a rather wider class of heuristics. All such algorithms use the notion of a sequence of cycles that employ mutation of, and subsequent selection from, a population of candidate solutions. While these features are also found in a GA, its most distinctive characteristic is the use of *recombination* (or *crossover*) to generate new candidate solutions. A secondary idea found in many, but not all GAs, is the existence of an encoding function that maps the original optimization problem into a space that is hoped to be more congenial to the application of the GA operators.

Historical Background

The term *genetic algorithm* was first used by John Holland, whose book [8], first published in 1975, was instrumental in creating what is now a flourishing field of research and application that goes much wider than the original GA. The area covers topics such as evolution strategies (ES), evolutionary programming (EP), artificial life (AL), classifier systems (CS), genetic programming (GP), and now the concept of evolvable hardware. These related fields of research are often grouped under the heading of *evolutionary computation* or *evolutionary algorithms* (EAs).

While Holland's influence in the development of the topic has been immense, from an historical perspective it is clear that several other scientists with different backgrounds were also involved in proposing and implementing similar ideas. In the 1960s in Germany, Rechenberg and Schwefel developed the idea of the *Evolutionsstrategie* (in English, *evolution strategy*), while – also in the 1960s – Lawrence Fogel and others in the USA implemented a similar idea that they called *evolutionary programming*. What these proposals had in common was their use of the ideas of mutation and selection that lie at the center of the neo-Darwinian theory of evolution. Relatively little attention was given to the use of recombination – the idea later placed at the heart of GAs by Holland. However, although some promising results were obtained, as an area of research the topic of evolutionary computing did not really catch fire. There may be many reasons for this, but the most obvious one is that the techniques tended to be computationally expensive – unless the applications were trivial – and far beyond the capabilities of the computers of the day. Nevertheless, the work of these early explorers is fascinating to read in the light of our current knowledge. David Fogel (son of one of these pioneers) has tracked down and collected some of this work [6].

The last 30 years has seen an explosion of interest in GAs and their applications, and there is now enormous literature on variations of the basic algorithm and developments in application areas. De Jong [4] – another early pioneer, particularly in relation to the GA's utility as an optimizer – has recently surveyed the most important developments from a unified perspective.

Theoretical analysis of GAs, and of EAs in general, has lagged far behind the development of novel practical applications. Holland's original work gave an account based on his idea of a *schema* that raised hopes that the GA's power was significantly greater than that of other heuristics. Sadly, these hopes have not been realized, and the rise of 'No-Free-Lunch' arguments [13] has put paid to the idea of some universal optimization algorithm that outperforms all others. In the case of GAs, Holland's schema-based theory has proved much less relevant than early accounts suggested. Several other theoretical approaches have been tried, with some success in accounting for large-scale GA behaviour, but something truly comprehensive is still awaited. Reeves and Rowe [10] provide the most recent description of the state of GA theory.

Foundations

Optimization problems arise in many forms, but the most obvious dichotomy is between continuous and discrete (or combinatorial) optimization. While GAs have been used successfully for continuous problems, the evolution strategy approach – although employing similar principles – is on the whole better suited to continuous problems. What is usually in mind for the application of a GA is the following:

Given a discrete search space $\mathcal{V}$, and a function

$$g : \mathcal{V} \mapsto \mathbb{R},$$

find

$$\arg \min_{v \in \mathcal{V}} g.$$

From a mathematical perspective, the decision variables of this problem are encoded as strings or vectors where each component is a symbol from an alphabet $\mathcal{A}$. These strings are then concatenated to provide a *chromosome*. That is, the vector v is represented by a string x of symbols drawn from $\mathcal{A}$, using a mapping

$$c : \mathcal{A}^{\ell} \mapsto \mathcal{V}.$$

where ℓ, the length of the string, depends on the dimensions of both $\mathcal{V}$ and $\mathcal{A}$. The elements of the string correspond to "genes", and the values those genes can take to "alleles". The position of a gene in the string is its "locus". The encoding function c is often designated as the *genotype–phenotype mapping*. The space $\mathcal{A}^{\ell}$ – or, quite often, some subspace $\mathcal{X}$ of it – is known as the genotype space, while the space $\mathcal{V}$, representing the original definition of the problem, is the phenotype space.

Thus the optimization problem becomes one of finding

$$\min_{x \in \mathcal{X}} g(\boldsymbol{x}),$$

where (with a slight abuse of notation)

$$g(\boldsymbol{x}) = g(c(\boldsymbol{x})).$$

In practice the distinction between genotype and phenotype is often blurred, and $g(\boldsymbol{v})$ or $g(\boldsymbol{x})$ is used according to context. Finally, a monotonic transformation of g

is often used to provide what is usually termed a *fitness function*, which can be regarded as

$$f : \mathcal{X} \mapsto \mathbb{R}^{+},$$

so that fitness is always a positive value. It should also be noted that the genotype search space $\mathcal{X} \subseteq \mathcal{A}^{\ell}$, which implies that some strings may represent invalid solutions to the original problem. This can be a source of difficulty for GAs, since GA operators may generate new strings in $\mathcal{A}^{\ell}$ that are not in $\mathcal{X}$. The choice of encoding is usually dictated by the type of problem that is being investigated. Examples and further details on such matters can be found in standard references such as [4] or [10].

With this background in mind, a basic version of a GA can now be presented as in Fig. 1.

Initial populations are usually generated randomly, although there are many variations that incorporate some aspects of problem-specific knowledge. Given a population, the next step is to choose parent chromosomes for reproduction. This is generally carried out by some means of *fitness-proportional* selection. Implementations of this idea vary widely: roulette-wheel, rank-based and tournament selection schemes are all popular and have associated advantages and disadvantages.

Reproduction takes place using crossover and mutation. Having selected parents in some way, they must be recombined – the process called *crossover*. This is simply a matter of replacing some of the alleles in one parent by alleles of the corresponding genes of the other. Suppose there are two strings ***a*** and ***b***, consisting of seven symbols, i.e.,

$$(a_1, a_2, a_3, a_4, a_5, a_6, a_7) \quad \text{and} \quad (b_1, b_2, b_3, b_4, b_5, b_6, b_7),$$

each representing a possible solution to a problem. To implement *one-point* crossover a *crossover point* is chosen at random from the numbers 1,...,6, and a new solution produced by combining the pieces of the original "parents". For instance, if the crossover point was 2, then the "offspring" solutions would be

$$(a_1, a_2, b_3, b_4, b_5, b_6, b_7) \quad \text{and} \quad (b_1, b_2, a_3, a_4, a_5, a_6, a_7).$$

Many other forms of crossover have been invented, with varying degrees of success.

The concept of mutation is even simpler than crossover: a gene (or subset of genes) is chosen randomly and the allele value of the chosen genes is changed. This can easily be represented as a bit-string mask such as

```
0100010
```

generated using a Bernoulli distribution – i.e., at each locus there is a small probability μ of a mutation occurring (indicated in the mask by a `1`). The above example would thus imply that the second and sixth genes are assigned new allele values.

Finally, a new population has to be selected from the joint set of old and newly generated members. Again there are many ways of carrying this out. At the extremes, there are the generational and steady-state approaches. In the first of these, the old population is completely replaced by the new. In the second, a single new candidate is generated, and some member of the old population (often the least fit one) is displaced by it. Again, many other techniques have been tried.

This is an extremely condensed overview of the possibilities available for implementing a GA. A more comprehensive picture of some of the most popular ideas, and a discussion of their effects on GA performance, can be found in [4] or [10].

```
Choose an initial population of chromosomes;
while termination condition not satisfied do
    repeat
        if crossover condition satisfied then
        {select parent chromosomes;
        choose crossover parameters;
        perform crossover;}
        if mutation condition satisfied then
        {select chromosome(s) for mutation;
        choose mutation points;
        perform mutation;}
        evaluate fitness of offspring
    until suffcient offspring created;
    select new population;
endwhile
```

Genetic Algorithms. Figure 1. A genetic algorithm template. This is a fairly general formulation, accommodating many different forms of selection, crossover and mutation. It assumes user-specified conditions under which crossover and mutation are performed, a new population is created, and whereby the whole process is terminated.

Key Applications

The number of NP-hard combinatorial optimization problems continues to grow, and heuristic methods offer the only realistic route to high-quality solutions. The use of GAs is thus motivated by the existence of computational complexity in many aspects of technological development. In the area of database systems, there were early applications to problems of database design [3] and query optimization [11]. Other areas of interest include data clustering methods [7] and data partitioning [2,1]. Genetic algorithms have also been used for rule discovery in data mining applications, seminal work in this area being reported in [5]. Data reduction by means of instance selection using GAs for other techniques such as decision trees, neural nets or nearest neighbour methods has also been reported [9]. Also, several companies claim – without revealing very many details – to use GAs in spam detection software. A recent published example of such work is [12].

Experimental Results

Given the lack of authoritative theoretical models of GAs, assessment of their performance in any individual case is necessarily experimental. Standard methods of evaluation include the *best-so-far curve* – a time series plot of the fitness of the best solution found so far (y-axis) against the number of generations or the number of individuals generated. This is sometimes called the *offline performance* measure, in contrast to the *online performance* measure, which is a time series plot of current (average) population fitness.

Another aspect of experimental evaluation is assessment of convergence – or equivalently, of population diversity. This can be assessed simply by plotting a time series of the coefficient of variation of the current population fitnesses, or more expensively, by means of a locus-wise count of allele percentages in successive populations.

Since GAs are stochastic algorithms, it is obvious that results will differ from one run of the algorithm to the next. In any experimental work it is essential to apply the algorithm several times in order to have some confidence that the results obtained are not freakishly good (or bad).

Geographical Information Retrieval

Christopher B. Jones[1], Ross S. Purves[2]
[1]Cardiff University, Cardiff, UK
[2]University of Zurich, Zurich, Switzerland

Definition

The provision of facilities to retrieve and relevance rank documents or other resources from an unstructured or partially structured collection on the basis of queries specifying both theme and geographic scope.

Historical Background

Geographical information associates things and events with locations. Since everything one does and everything that happens on Earth happens somewhere, there is a vast amount of information that can be regarded as geographical in some sense. This information is represented within a variety of media, including digital and analogue versions of text documents, images, videos and maps, as well as the structured spatial databases that are employed within most geographical information systems (GIS). In text documents the association with location is often qualitative with place names and natural language terminology (such as in, at, and near) that provide spatial context. This is in contrast to the use in GIS of, for example, digital topographic datasets in which location is described quantitatively with numerical coordinates. Over the past few decades, information technology for accessing geographical information has focused on the latter, quantitative representation of geographic space that characterizes GIS. It is only in recent years that much attention has been paid to the development of computer systems to retrieve geographically-specific information from the relatively unstructured but immense resource of digital documents, many of which can be found on the worldwide web (e.g., [7,9,11]).

Because of the importance of geographical context, it is not surprising that requirements for information on the web often have a geographical focus (it has been estimated that between 13–15% of web queries submitted to traditional search engines contain a place name) [6,12]. It is this need for public access to geographical information on the web that has been a major motivation for the growth of the academic field of geographical information retrieval (GIR).

Much current research in GIR can be regarded as an extension of the field of information retrieval (IR). The products of work in IR have provided the foundation for current search engine technology, with its focus on access to primarily textual documents that are relevant to user queries taking the form of a phrase or set of key words. This latter type of query is in contrast to the more formal approach common in spatial databases, where georeferenced data objects are retrieved from structured tables in response to queries that can stipulate precise spatial constraints. IR methods usually identify documents that contain query terms and rank the retrieved documents using statistical methods that are intended to highlight the most relevant to the user's needs. For some forms of geographical search, particularly when looking for common resources within relatively large geographic extents (e.g., hotels in London), this approach can work well but it is fraught with limitations.

From the user's perspective these limitations can be manifested in a failure to distinguish between different instances of the same place name, a lack of ability to deal with spatial qualifiers such as near or north, a lack of methods to rank and explore results with respect to their spatial relevance and the non-retrieval of resources which are spatially relevant but use a place name different from that specified in the query. GIR is therefore concerned with improving the quality of geographically-specific information retrieval with a focus on access to unstructured documents such as those found on the web. There are several types of functionality that are distinctive to GIR and which constitute significant challenges. These include:

- Detecting geographical references in the form of place names and associated spatial natural language qualifiers within text documents and in user queries.
- Disambiguating place names to determine which particular instance of a name is intended.
- Geometric interpretation of the meaning of vague place names, such as the "Midlands," and of vague spatial language such as "near".
- Indexing documents with respect to their geographic context as well as their non-spatial thematic content.
- Ranking the relevance of documents with respect to geography as well as theme.
- Developing effective user interfaces that help users to formulate effective queries and identify relevant results.
- Developing methods to evaluate the success of GIR.

The following sections elaborate upon these issues.

Foundations

Detecting Geographic References

Place names (or toponyms) can be used to refer to places on Earth, but they also occur frequently within the names of organizations and as part of people's names. It is also the case that place names may be used *metonymically*, for example to refer to administrative entities as in "talks with Washington." The process of geo-parsing is concerned with analyzing text to identify the presence of place names and other spatial language and distinguish the genuine geographical occurrences of place name usage from those where they are being used to refer to some other entity. This process is often treated as an extension of Named Entity Recognition that is a standard part of linguistic analysis in natural language processing (NLP). Various techniques can be employed to identify a place name, including the use of rule-based approaches and machine learning. In order to recognize that a word is a potential place name, it is common practice to employ a list of known place names as is found in a gazetteer. Within gazetteers, each name is usually accompanied by at least one parent region, a classification for the place and a coordinate-based footprint providing a quantitative location.

Disambiguating Place Names

Once it has been established that a place name is being used in a geographic sense, the problem remains of uniquely determining the place to which the name refers. Note that the combination of detecting place names and disambiguating them is referred to as geo-parsing. There are many names that are shared between different places. For example there are over 70 "Springfields" in the US. When humans read a document with a place name in it, they will tend to resolve ambiguity using knowledge gained from contextual clues within the document. Automatic resolution of geographic scope, and hence disambiguation of place names, attempts to mimic the methods humans use, for example by considering together all of the place names in the document. If a place name occurs in association with a set of other place names, several of which refer to neighboring places or are instances of places within the same parent region, then that provides evidence to distinguish which meaning is implied. Equally if the text mentions a parent or child region of an instance of a particular name, then that can help to determine the sense that is intended [14].

Vague Geographic Terminology

Many of the place names that users employ when searching on the web are of an informal or vernacular nature, often without precise boundaries. Examples include the Pennines and the Borders in the UK, the south of France, the Swiss Mittelland and the midwest in the US. Existing geographical search facilities make use of gazetteers that are based largely on the administrative names of places and which do not, in general, include any representations of vernacular names. There have been a few studies of methods of determining what may be a fuzzy extent for such places (e.g., [8]) but there is still much to be done. Recently, web mining methods have been used to determine associations between a vernacular place name and the names of other places within it or in the vicinity [4]. Spatial extent can then be modeled using, for example density surfaces, or Delaunay triangulation based methods [2].

The spatial language (such as near, close, between and north of) that accompanies place name terminology can be as vague as some of the place names. Being able to interpret such terms will help in analyzing the geographic context of documents and in interpreting user queries that employ vague spatial language. There have been previous studies of the meaning of natural language qualitative spatial relations, while [13] show how nearness can be interpreted quantitatively by analyzing the use of phrases such as "walking distance" in combination with knowledge of the coordinates of the places that are referred to.

Spatial and Textual Indexing

When web documents have been categorized according to their geographical context they must be indexed in a way that enables them to be found quickly in response to user queries. Techniques for indexing documents according to the words that they contain are well established. Typically an inverted file of documents is created in which each word is associated with a list of the documents that contain the word. This text index can be combined with a spatial index that records which documents relate to particular regions of space. Building a spatial index of documents can be done if each document has one or more document footprints that represent the regions of geographic space to which the document refers. Each document footprint may correspond to the spatial extent of a geographic reference that occurs in the document. If there are many such references an effort may be made to establish the main geographic foci of the document as represented by a smaller number of footprints [1,14]. These footprints can then be indexed in the same way that any other piece of geometry would be indexed in a conventional GIS. A challenge remains, however, to find efficient ways to combine text and spatial indexes (see [15] for a summary of some approaches to spatio-textual indexing).

Retrieval of relevant documents requires matching the query specification to the characteristics of the indexed documents. As mentioned above, in conventional web search engines this starts by finding those documents that contain the query terms, before ranking the resulting documents. For geographical search, there is a need to match the geographical component of the query with the geographical context of the documents as represented by the document footprints. GIR queries can be characterized as a triplet of <theme> <relationship> <location> composed of a topic of interest in combination with a place name qualified by a spatial preposition such as near, in, or north of. The combination of place name (after disambiguation) and spatial preposition can be used to generate a query footprint representing, for example, the interpretation of an expression such as "near Bristol." This query footprint can then be used to access the relevant part of the spatial index and hence find document footprints that intersect the query footprint. The retrieved documents will then be the members of this latter set of geographically relevant documents that also contain the thematic (text) query terms in the query.

Geographical Relevance Ranking

Having found a set of potentially relevant documents they should then be ranked by some measures of their estimated degree of relevance to the query. Relevance with respect to the thematic part of the query and the retrieved documents can be represented by a score that takes into account factors such as the frequency of occurrence of query terms within retrieved documents as a function of the overall frequency of query terms within the whole collection. The spatial score can be some measure of the geometric match between the query footprint and the document footprints. These two scores can then be combined to find an overall relevance. [16] has described some methods for doing this in which the text and spatial scores are normalized to values between 0 and 1 before calculating their distance from an ideal combined score in the two-dimensional space of text and spatial scores.

User Interfaces

Retrieval of documents using GIR also provides a variety of research challenges in the development of user interfaces. Query formulation generally requires, as indicated above, specification of a triplet of <theme> <spatial relationship> <location>. This can easily be facilitated by a simple structured interface, but this assumes sufficient geographic knowledge to specify relevant place names. Other approaches to query formulation allow users to sketch a region of interest on a map, and enter a related concept within a textbox [11]. This approach presupposes that users are interested in a spatial relationship representing containment, but to date very little progress has been made in developing map-based interfaces that allow users the option of graphically specifying other spatial relationships.

The results of a query to a GIR system can be treated in an identical manner to those of a traditional search engine, and simply displayed as a ranked list. In practice, the nature of geographic search and the pervasiveness of map-based web services means that the overlaying of results on a map has become a natural and expected visualization mechanism. Several challenges exist in displaying the results of GIR searches through a map interface. Many relevant documents may have the same geographic footprint, and techniques are required to allow the aggregation of these relevant documents, while summarizing or filtering duplicate content. Equally, document footprints often have scopes which are not sensibly represented at all scales as a point (e.g., London) and methods are required to allow users to explore documents with extensive geographic scopes in meaningful ways. Finally, there is much room for techniques from the Geovisualization community to be applied in exploring the typically large sets of documents that are returned by GIR.

User Studies and Evaluation

In developing GIR techniques, it is very important to take cognizance of user needs and to develop techniques to evaluate the quality of approaches to GIR. With respect to user needs, work is required to analyze where gaps exist in current approaches and to analyze query logs, firstly to identify the types of geographic search users undertake, and secondly to assess where users fail or have difficulty in search [6,12].

Evaluation is a key part of IR. In general, evaluation strategies within IR either take the form of system-focused or user-centered studies [5]. The former are based around the use of test collections, the measuring of the relevance of documents to specific queries and the calculation of standard IR measures such as precision and recall for a variety of systems and settings. Such methods require substantial resources to implement, particularly since relevance judgments must be performed manually and the numbers of judgments required are large. Within IR, the long-running TREC experiments have provided a mechanism for the pooling of resources to the mutual benefit of the research community. In GIR, GeoCLEF [3] has gone some way towards addressing this need by mounting a campaign to compare performance of a range of approaches to GIR across a set of multilingual queries performed on document collections based on newspaper articles. However, there is much room for further research on relevance judgment and measures for GIR. Current techniques are based on a single dimension of relevance using standard IR measures, which in general do not take account of the G (geography) in GIR [10]. To date, very little user-centered evaluation has been performed in GIR.

Key Applications

Geographical information retrieval is applicable in all areas where there is a need to specify geographical constraints when searching for information in document collections such as those found in digital libraries and on the World Wide Web. This applies in particular to spatially-aware (or geographical) search engines.

Geographic Information System

Michael F. Goodchild
University of California-Santa Barbara, Santa Barbara, CA, USA

Synonyms

Geospatial information system; Spatial information system

Definition

A geographic information system (GIS) is a computer application designed to perform a wide range of operations on geographic information. Geographic information is defined as information about locations on or near the surface of the Earth, and may be organized in a variety of ways. Thus a GIS includes functions to input, store, visualize, export, and analyze such information. Commercial off-the-shelf GIS software is today capable of virtually any conceivable operation on geographic information, and capable of recognizing hundreds of different formats. GISs are used in a wide range of applications, from the management of the distributed assets of utility companies to emergency response. Their scientific applications are found in any discipline that deals with phenomena distributed over the surface of the Earth, from ecology to criminology. Increasingly GIS technology is encountered by ordinary citizens, in the form of map-making sites based on Google Maps, wayfinding sites such as MapQuest, and hotel-finding sites such as Expedia.

A wide range of introductory textbooks on GIS are available with various levels of sophistication, covering the fundamentals of representation, analysis, and application. Clarke [2] provides a general introduction; Longley et al. [4] give a somewhat more advanced and comprehensive perspective; and Worboys and Duckham [6] provide a computational viewpoint.

Historical Background

GIS has several roots, and today's technology represents a convergence among several independent developments. In the mid 1960s, the Government of Canada developed the Canada Geographic Information System (CGIS), the first to use the term GIS, as a means of generating products from the Canada Land Inventory. CGIS implemented a very small set of functions, including map overlay and area calculation, and in its initial form included no capabilities for map output, yet it solved many fundamental problems. Another set of developments centered around the desire to automate the process of making paper maps, and yet another was stimulated by the need to manage complex sets of data in support of transportation planning and census data collection. By the late 1970s, the commonalities in these various threads had been recognized, and the first commercial software products began to emerge. Foresman [3] provides a comprehensive history of GIS.

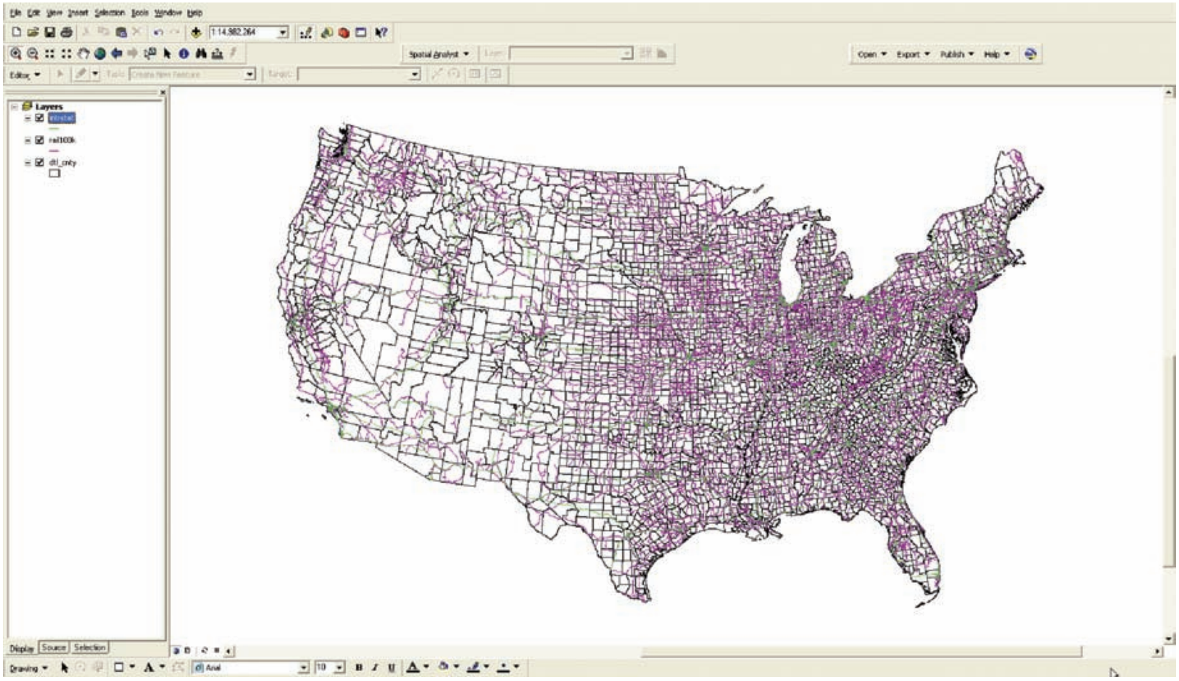
The early efforts to develop GIS were based on idiosyncratic data models and formats. By the late 1970s, the value of relational databases had been recognized, and GIS developers had begun to represent complex geographic features as interrelated collections of elements. A map of counties and their attributes, for example, could be represented as tables of nodes, edges, and faces; and the same approach could be used to represent a road network or a map of land cover types. Nevertheless, early relational database software was not easily adapted to the storage of the variable numbers of vertices needed to represent each edge, and so a hybrid approach had to be adopted in which some information was stored in a relational database and the remainder in a unique, proprietary structure. By the late 1980s, major problems of lack of interoperability began to impact the industry and led to the formation of the Open Geospatial Consortium.

By the 1990s, GIS designers had begun to adopt object-oriented database principles [1], and database technology and computing power had advanced to the point where hybrid architectures were no longer necessary. Greater flexibility in data modeling had opened the possibility of applying GIS tools to phenomena that were never traditionally associated with maps, such as events, transactions, movements and flows, and dynamic phenomena in general. GIS is no longer seen as a container of maps, but as an engine for the representation and analysis of spatio-temporal phenomena. The only limitation is that the information they contain be tied to specified locations on or near the surface of the Earth.

Figure 1 shows a screen shot of a typical application of a contemporary GIS, in this case ESRI's ArcMap.

Foundations

Two fundamentally distinct ways of conceptualizing spatial variation are recognized in GIS. In the discrete-object view, the Earth's surface is analogous to an empty table-top, on which are distributed a countable collection of features. The features may overlap, but between them is emptiness. The features might be represented as points, lines, or areas; and in some cases the third spatial dimension will be important and features may be represented as volumes. In the continuous-field view variation over the Earth's surface is described by a series of functions f of location $\mathbf{x}$, where f may be a measure, as in the case of elevation or temperature, or a class or name, as in the case of maps of soils or counties.



Geographic Information System. Figure 1. Screen shot of ESRI's ArcMap GIS. Three layers are displayed, as listed in the upper left: the county boundaries of the US (black), the railroads (blue), and the interstate highway network (green). Pull-down menus and toolbars provide access to a wide array of manipulation and analysis functions, and many more are available as third-party extensions. The display uses the Lambert Conformal Conic projection.

Location **x** may have two or three spatial dimensions, and may also include time in the case of dynamic phenomena. Phenomena distributed over networks, such as vehicle densities or pavement quality, can be conceptualized as fields distributed over a one-dimensional space that is in turn embedded in two- or three-dimensional space.

These conceptualizations can be implemented in GIS in two ways, as raster or vector structures. In a raster structure the set of possible locations is finite, being defined by a grid that is normally rectangular (though more complex grid geometries are needed when the Earth's curvature is important). In a vector structure, every feature is located using an appropriate number of coordinates. Areas and lines are normally represented as ordered sets of coordinates connected by straight lines, and known as polygons and polylines, respectively. These methods are straightforward in the case of discrete objects, but the representation of continuous fields requires another step of discretization, with six commonly used alternatives in the case of two-dimensional variation: (i) a set of irregularly spaced sample points, as used for example in capturing and representing weather observations; (ii) a set of regularly spaced sample points, as used in representing terrain; (iii) representation of the isolines of the field, as used in contour maps; (iv) a triangular mesh, with linear variation within the triangles and continuity of value across triangle edges; (v) a set of rectangular raster cells, as used in capturing and representing images; and (vi) a set of irregularly shaped, non-overlapping, and space-exhausting areas represented as polygons, as used in mapping land cover types or aggregated census data.

Whether raster or vector, any GIS data set must be referenced to the Earth's surface using some form of coordinate system. In the case of raster data this is usually achieved by registering the corner points of the raster; while in the case of vector data every feature is independently positioned in the coordinate system. Many alternative coordinate systems exist, including latitude and longitude plus numerous systems based on projections of the Earth's curved surface onto a plane. Some have been officially adopted by countries, such as the UK's National Grid, while others have been adopted by international agreement through agencies such as NATO, or by individual states in the case of the US State Plane Coordinate system. Unfortunately this leads to complexity and lack of interoperability, and any GIS must offer a comprehensive set of functions for managing coordinate systems. Moreover, the definitions of latitude and longitude are not entirely standard, being dependent on the mathematical figure adopted to represent the shape of the Earth, otherwise known as the datum, which adds another dimension of complexity. One approach to dealing with interoperability has been through the development of metadata standards, or standardized descriptions of data sets that include specification of such properties as coordinate systems. Metadata are now widely used by portals, libraries, and warehouses of geographic data that offer massive information resources to users over the Internet.

A GIS database is normally conceptualized as a collection of layers, each registered to the Earth's surface. A layer may contain the representation of a field, such as a map of land cover type, or it may contain a collection of discrete objects, such as buildings. This layer-based view of the world is often used as an icon, since it is so fundamental to GIS, and has appeared on the cover of more than one textbook. Raster-based layers will likely describe the geographic variation of only a single property, such as county name or land cover type, and because this property will exist for every cell and will have only a single recorded value per cell there is clearly a natural affinity between raster layers and continuous-field conceptualizations. Vector-based layers on the other hand may represent either collections of discrete objects with any number of associated attributes, or the variation of a single property conceptualized as a continuous field. Unfortunately today's GIS designs do not recognize the field/object distinction, with the result that no automatic procedures exist to avoid violating the constraints that apply in the field case. For example, a GIS will treat a set of digitized isolines representing a field as if they were discrete, independent polyline objects, and will not object if a user attempts to edit them in such a way as to make two isolines cross.

Many GIS applications employ some form of tiling, in which the geographic area covered by the database is divided into smaller units, often in the interests of computational efficiency. Tiles correspond to the map sheets of cartography, and are often defined on a rectangular basis. In some cases they may be evident to the user, who must develop explicit strategies for handling queries or analyses that involve multiple tiles; in other cases the tiling scheme may be transparent. In addition, a GIS will employ one or more systems of indexing, again in the interests of computational efficiency. Van Oosterom [5] provides a comprehensive survey of spatial database indexing options.

GIS implementations vary from the stand-alone desktop system designed to support the work of a single user, to departmental solutions that integrate the work of several people around a common database, to enterprise-wide solutions that organize the entire operation of a company or agency around its GIS. Increasingly, GIS functions are available on-line from servers, either based on data held at the server, or on data supplied by the user. For example, many Web sites now offer the GIS function of geocoding, which takes a list of postal addresses as input and returns their corresponding geographic coordinates.

A wide range of GIS software products are available to match these various implementation strategies, ranging from versions for hand-held devices through desktop systems to server-side GIS. The use of component-based software architectures has allowed vendors to build different products from the same collection of discrete elements. The trend in recent years has been away from the single-user desktop to integrated client-server architectures, and increasing reliance on data downloaded from Internet portals. Open-source GIS is growing steadily in popularity, and a number of low-cost options have recently appeared to challenge the marketplace dominance of the industry leaders, ESRI and Intergraph. Idrisi, originating from Clark University, continues to provide a software option with very strong support for decision making. Niche products also exist, particularly in transportation where the products of Caliper offer some powerful capabilities, and products from developing countries, particularly China, are increasingly competitive.

Key Applications

As noted above, the earliest applications of GIS were in isolated domains: land resource management; automated cartography; and transportation. By the late 1970s a broader vision of GIS had emerged as a general-purpose software application that could be used to solve a vast range of problems, all dealing in one way or another with the surface and near-surface of the Earth. Nevertheless, the first software products that emerged in the early 1980s found their most important applications in resource management, and were heavily adopted by forest-management companies and agencies, where they were used for compiling inventories, planning harvesting, and management of road access.

This viewpoint largely ignores the role of the military in GIS development, however. By the late 1950s the U.S. was heavily engaged in classified programs aimed at acquiring imagery from space, and in developing the systems needed to assemble, interpret, and analyze their products. Civilian satellites were first deployed in the early 1970s, and led quickly to a generation of GIS software, largely raster-based, that found useful applications in agriculture. Today the military and intelligence agencies are among the heaviest users of GIS, and many weapons systems and warfighting strategies depend on ready access to current, digital geographic information.

One of the most successful areas of GIS application has been in facilities management, and more generally in the management of distributed assets. Public and private utilities, planning departments of governments, transportation agencies, and managers of complex facilities such as university campuses will all use GIS routinely to inventory assets, manage and schedule maintenance, and address problems. Investments by individual companies may run to the millions of dollars, and involve hundreds of GIS workstations.

Of rapidly growing importance are GIS applications that impact the daily lives of the general public. These include route guidance, provided perhaps by an in-vehicle navigation system or by a Web service, and map-based services such as Zillow that provide current information on property values. The general public is increasingly familiar with GIS data sources, including remote sensing, and with concepts such as geo-tagging that permit information in sources such as Wikipedia to be georeferenced and thus linked to maps. The term neogeography is being used to describe such novel applications of GIS.

Future Directions

The days when GIS was an exotic computer application familiar only to a small elite, and accessible only after extensive training, are long gone; today virtually everyone with access to the Internet is familiar with at least some of its capabilities. The meaning of the term itself has become confused: some would reserve it exclusively for the single-user desktop application, while others would extend it to cover what is now a vast array of activities, for which the adjective geospatial has emerged recently as an alternative umbrella term. In discussing future directions, then, it is possible to take either the first, somewhat narrow perspective, or the second broader one.

From the narrow perspective, GIS software will continue to evolve, particularly in the direction of greater support for dynamics. Some application areas are currently in their infancy, and will likely grow in importance in the next few years. They include human health, the understanding of disease transmission and diffusion, and the assessment of health service outcomes; and business, whose mantra "location, location, location" feeds directly into GIS applications. Related areas of logistics, real estate, and insurance are also ripe for greater use of GIS.

A rich research agenda has evolved over the past decade, and will likely produce results that will in turn impact future generations of GIS software. The University Consortium for Geographic Information Science has taken the lead in this context, with short- and long-term agendas that address topics ranging from spatial cognition (How can GIS interfaces be made easier to use?) to the social impacts of GIS technology (Who gains, who loses?). The topic of uncertainty remains a thorny issue, with much useful research completed on the sources and management of uncertainty in GIS but little adoption in mainstream software. As a result, the user is left with little choice but to accept the results of GIS analysis at face value, while knowing that the data on which they were based is inevitably imperfect and uncertain.

From the broader perspective, GIS functions will continue to become more available in Web services. In the past year a very interesting series of developments have occurred that are enabling citizens to create their own geographic information, and to integrate and publish it on the Internet. Sites such as OpenStreetMap are enabling communities to create their own maps; Wikimapia is collecting descriptions of features on the Earth's surface from vast numbers of volunteers; and Flickr is assembling a vast collection of geo-referenced photographs. This process of volunteering geographic information is having a profound impact on citizens' knowledge of the planet, and on their engagement with geography and GIS.

Geography Markup Language

Jayant Sharma, John Herring
Oracle Corporation, Nashua, NH, USA

Synonyms

ISO 19136; Geographic information; Geography markup language

Definition

Geography Markup Language (GML) (http://www.opengis.net/gml/) is an XML vocabulary that can be used as the basis for the modeling, transfer, communication, or storage of geographic feature information. It is defined and maintained by members of the Open Geospatial Consortium (OGC), a voluntary consensus standards organization that develops standards for geospatial information handling and location based services. It has been accepted as one of and harmonized with the standards of ISO TC 211: Geographic information (http://www.isotc211.org/). The official copies of all versions of the GML specification and related OGC standards can be found at http://www.opengeospatial.org/standards/. The most recent version of GML, version 3.2.1, is identical with ISO 19136 (http://www.isotc211.org/Outreach/Overview/Factsheet_19136.pdf).

The primary purpose and rationale for GML, as described by the OGC, is to provide an open, vendor-neutral format for the definition of geographical entities used by applications, in various domains, for geospatial information processing and exchange. The enhanced ability of organizations to, efficiently and effectively, re-use, share, integrate, and consequently extract more value from, their extremely valuable geospatial information across operational units and processes is one immediate benefit of using GML.

Historical Background

GML (version 1.0) was first submitted to the OpenGIS Consortium, now Open Geospatial Consortium in 1999, as a "request for comment" (RFC) by authors from CubeWerx, Compusult, Galdos Systems, MapInfo, and Oracle. It was accepted by OGC and published in May 2000. GML 2, the first widely accepted version, was published in February 2001. GML 2.1 is still commonly used today.

GML 3.1 was published by OGC in February 2004, and submitted to ISO TC 211: Geographic Information, for consideration as an ISO standard. This would make it acceptable under the laws of some countries as the basis for national standards. It has since been accepted and ISO 19136 (GML, version 3.2.1), became an International Standard in 2007.

Foundations

GML is based on a feature and property model. Any complete GML file contains a collection of features, and each feature contains a collection of properties, and each property contains its value, which may either be direct (lexically contained within the property as an XML sub element) or indirect (pointed to by the property using an xlink).

Features represent real-world entities, such as roads or parks. Some real-world entities are composed of other entities and hence are represented as collections of features. For example, a city may be represented as a collection of roads, parks, land parcels etc.

Features have properties that have a name and type. For example, a road has a name (i.e., a property called "name") and its value is of type "String." Features may also have named geometry-valued properties. For example, a road might have a geometry property named "centerLineOf" that is of type "Linestring."

GML implements a subset of the ISO 19107 standard geometry model that defines the primitive geometry types and their hierarchy. GML 2 was concerned with simple features that only have a simple two-dimensional geometry property. GML 3 addresses requirements of applications that need to model more complex geographic phenomena that are dynamic (e.g., coverages or sensors), and have non-linear (e.g., circular or parametric arcs) or 3-D (cubes, prisms) geometry, 2-D topology, or temporal properties. To be useful, such feature models must include spatial and temporal reference systems, units of measure, metadata, and default styling (or portrayal) information.

Base and Application Schema

In order to enable an open, interoperable, vendor-neutral means of modeling and exchanging geographic information, GML includes types for features, geometry, topology, coordinate reference systems, grids, measures, observations, and temporal reference system/values.

Feature types form the basic logical construct and all other types are used to express property values for features. Geometry types are used to describe the basic spatial attributes of a feature. Topology types can be used to describe the spatial relations between those geometries. Coordinate and coordinate reference systems describe the manner in which point locations are described for geometry (and related purposes). Grids are commonly used for "image-like" raster structures for distributing measurements across space. Measure and observation types are used for describing measurable attributes and their units. Temporal values and their reference systems are used for expression of time.

Applications define and describe a "feature schema" as defined in ISO 19109: Rules for application schema. These schemata control the types of features that can actually be stored in a GML file. Each schema uses the basic GML structure as defined above and created "feature types" which determine the name of the feature types and which properties a particular feature type must (mandatory) or may (optional) contain, and with what cardinality (maximum and minimum occurrence). Because these application schemata are restricted by ISO 19109 and by the syntax of XML schema, they are single classification objects as is common in most programming languages.

Profiles

GML is quite comprehensive and consequently complex, even its early versions. To compensate for this for particular information communities (informal groups of users with similar data content needs), "profiles" are often defined as subset of the full base schema for use within their applications.

One profile is the "point profile" which simply describes the way geographic point location can be expressed. It is used as the basis for geographic extension of other standards that only require a geographic point as a location reference and hence do not use, or require, the GML feature and geometry model.

The most common profile is the one used for another OGC standard, Simple Feature Access that includes a data architecture volume (http://www.opengeospatial.org/standards/sfa). It was defined first in 1999, and became an ISO standard soon thereafter. The GML simple features profile was developed to support another OGC specification, namely, the OpenGIS Web Feature Service (WFS) Implementation Specification. The primary purpose is to define a useful subset of GML that (i) "lowered the implementation bar," and (ii) supported the Simple Features for SQL (SF-SQL) geometry model and hence the WFS specification. So this profile "prescribes the encoding of GML application schemas in sufficient detail that client applications do not need to deal with the entire scope of XML-Schema and GML but only need to understand a restricted subset of both specifications in order to be able to interpret schema documents generated or referenced by servers offering data encoded in GML." As a consequence, this document is just 49 pages long compared to over 800-page length of the full GML specification.

Other relevant profiles are the common CRS, and common dictionary profiles. These define encodings of commonly used coordinate reference systems and conversions, and simple dictionaries respectively.

Key Applications

The WFS (Web Feature Service) implementation specification defines an interface for retrieving or updating, geographical features encoded in GML, using HTTP.

RSS (real simple syndication, http://www.rssboard.org/rss-specification) is a news feed mechanism for the web and GeoRSS (http://www.rssboard.org/rss-specification) uses the geometry of the simple feature profile to geographically locate the information in the news. See http://www.georss.org/gml.html for some examples of GML usage in GeoRSS.

JPEG2000 (http://www.jpeg.org/jpeg2000/) is a digital image format that allows "XML" data to be stored with the image data. GML is the preferred format for geographic information and the combination of image and geographic information allows JPEG2000 to be used for geographically referencible images such as satellite and aerial imagery.

CityGML (http://www.citygml.org/) is an application schema for GML that integrates building information, at various levels of detail, into 3-D city and landscape models. The basic concept is to create a full 3-D model capable of supporting a wide variety of applications associated to such fields as environment, telecommunications, security, navigation and others requiring highly accurate and detailed building and landscape models. Some examples of GML as used in CityGML are at http://www.citygmlwiki.org/index.php/Examples_and_WFSs. A free viewer for CityGML can be found at http://www.3dgeo.de/citygml.aspx.

The IETF (Internet Engineering Task Force – http://www.ietf.org/) has several "rfc" specifications that use GML for location information. In particular, *IETF RFC 4119 – A Presence-based GEOPRIV Location Object Format and IETF RFC 3863 – Presence Information Data Format (PIDF)*. Each uses a profile of GML for location information.

Schemas for GML

All versions of GML have their schemas posted for public use in some subdirectory of http://schemas.opengis.net/gml/. For example http://schemas.opengis.net/gml/3.2.1/contains the schema for the latest version of GML version 3.2.1 [5], which is the same as ISO 19136.

Examples

Some fairly simple examples of GML can be found in the Wikipedia article located at http://en.wikipedia.org/wiki/Geography_Markup_Language.

Geometric Stream Mining

CECILIA M. PROCOPIUC
AT&T Labs, Florham Park, NJ, USA

Definition

Let $P = \{p_1, p_2, ...\}$ be a stream of points in the metric space (X, L_q). Usually, $X = \mathbb{R}^d$ or $X = \{1, ..., U\}^d$ (discrete case), and $L_q = L_2$ is the Euclidean distance. The set P is called a *spatial data stream*. Geometric stream mining algorithms compute the (approximate) answer to a geometric question over the subset of P seen so far. For example, the *diameter* problem asks to maintain the pair of points that are farthest away in the current stream. A more comprehensive list of problems is presented later.

Historical Background

Geometric algorithms in the offline setting have been extensively studied over the past decades. Their applications encompass many fields, such as image processing, robotics, data mining, or VLSI design. For an introduction to computational geometry, refer to the book [8]. On the other hand, research on spatial data streams is a recent development. Shortly after the first results on numeric data streams appeared, a slew of papers argued that in many applications numeric streams exist in metric spaces, and that the capabilities of such systems can be expanded by taking into account the underlying metric, and by supporting geometric queries. Queries can be similar to offline databases (e.g., range queries), but they can also be about the shape and extent of the stream (e.g., diameter). Most examples of spatial streams come from sensor networks, traffic monitoring, and satellite data, all of which have location information.

Foundations

Stream Models

Online algorithms come in two flavors. In the first model, points can only be inserted in the stream. In the second, both insertions and deletions are permitted. The latter case is usually referred to as the *turnstile* or *dynamic* model. Allowing deletions introduces distinct challenges. Frahling et al. [5] proved that certain computations over a dynamic stream from $\{1, ..., U\}^d$ require $\Omega(U^d)$ space in any deterministic approach, but only $O(d \log U)$ space if randomization is allowed. This contrasts with the insertions-only case, for which there are deterministic space-efficient methods.

Further classification of stream models depends on whether the metric space X is continuous or discrete. In the following, *data stream* refers to insertions-only streams from a continuous metric space, unless stated otherwise.

Classes of Problems

Some geometric stream problems are closely related, i.e., they can be solved by the same methods. Such a classification is presented below. The details of the techniques are deferred to the next subsection.

Range Counting and Robust Statistics *Range counting* asks for the number of points that lie inside an arbitrary axis-parallel hyper-rectangle. The query hyper-rectangle is not known a priori. The *Tukey depth* of a point p is the minimum proportion of points among all the half-spaces that contain p (the larger the depth, the more "central" the point). The *simplicial depth* of p is the proportion of simplices that contain p, among all simplices that are convex hulls of $d + 1$ data points. These problems can be approximated using a so-called *ε-approximation* of the data.

Extent Measures The *diameter* of a point set is the maximum distance between two points in the set. The convex hull is the smallest convex region that contains the set. The *width* is the minimum distance between two parallel hyper-planes so that the set lies between them. The *minimum enclosing cylinder, respectively sphere* is the cylinder, respectively sphere, of minimum radius containing the points. The *minimum cylindrical, respectively spherical, shell* is the region of minimum width between two concentric cylinders, respectively spheres, that contains the points. These problems can be approximated by computing appropriate *ε-kernels*. More efficient methods exist for the diameter and convex hull, but they do not extend to the other problems.

Geometric Graphs Many graph problems have a natural equivalent when the graph is embedded in a metric space, and the distance between points is given by that metric. Such problems include the *minimum weight spanning tree*, *minimum match*, and *TSP*. In the online version, the solution cannot be stored explicitly, so only the cost is computed. A general technique is to reduce the problems to vector computations over streams, and use existing algorithms from that area. Another approach is to maintain appropriate ε-coresets.

Nearest Neighbor and Skyline The classical nearest neighbor problem asks for the data point closest to a query point. This cannot be computed in sub-linear space, as any data point can be the answer to some query. Thus, several modifications have been proposed for streams. Korn et al. [7] studied *reverse nearest neighbors*, in which the data set is known a priori, and the stream consists of query points. However, some data points may be inactive at times, and the query is only with respect to active points. An indexing structure is pre-computed on the data points (in one dimension, this involves sorting the points and putting a geometric grid between each pair of consecutive points). A different framework is studied by Böhm et al. Queries and points have time spans in which they are active, and the k-nearest neighbors are computed from among the active data points during the query's entire span. This can be reduced to the *skyline* problem, defined as follows. The skyline of a dataset with respect to a fixed quadrant contains those points p_i for which the quadrant translated with the origin in p_i has no other points. For example, for the lower right quadrant, p_i is in the skyline if all points whose x-coordinate is larger than p_i also have larger y-coordinate. For nearest neighbors, the data stream is transformed into new coordinates, with the x-axis being expiration time, and the y-axis being the distance to the query. Then the nearest neighbors are the points on the skyline. The skyline can be maintained exactly, but may have $\Omega(n)$ complexity. The authors propose heuristics for maintaining approximate skylines in that case.

General Techniques

Most geometric problems cannot be solved exactly in sublinear space, so approximate solutions are sought. Three techniques for designing approximation algorithms for spatial data streams are presented below.

1. Merge and Reduce A popular approach in geometric algorithms is to compute a "sketch" of the dataset, so that the optimal solution can be approximated by a computation over the sketch. The sketch is a small subset of the input, whose size usually depends only on the approximation error. Given its space efficiency, this approach is a good candidate for stream algorithms. To maintain a sketch online, the stream is divided into substreams, and a sketch is independently computed for each substream. As more points arrive, the algorithm merges older sketches and replaces them by a smaller sketch.

Figure 1 illustrates this process when the stream is divided based on the *logarithmic method*: Let n denote the number of points seen so far. Let $0 \leq i_1 < i_2 < \ldots i_k \leq \log n$ be the 1-bits in the binary representation of n, i.e., $n = 2^{i_k} + \ldots + 2^{i_2} + 2^{i_1}$. Divide the stream into disjoint substreams of consecutive points $P_{i_k}, \ldots, P_{i_1}$, such that P_{i_j} arrives before $P_{i_{j-1}}$ for all $2 \leq j \leq k$, and $|P_{i_j}| = 2^{i_j}$. When a new point arrives, assign it to P_0. If $|P_0| = 1$, i.e., P_0 was empty before, return. Otherwise, $|P_0| = 2$ violates the cardinality condition. Merge P_0 into P_1, and set $P_0 = \emptyset$. Continue the process until all sets have the correct cardinality (if necessary, create a new set $P_{i_{k+1}}$).

Since P_{i_j} cannot be stored exactly, its sketch S_{i_j} is stored instead. Merging two substreams is simulated by merging their sketches – this is the *merge step*. \To maintain the space bound, a sketch of the merged sketches is computed – the *reduce step*. Finally, a sketch S of the whole stream is computed as a sketch of all S_{i_j}, and the original optimization problem is solved over S. To guarantee correctness, sketches must observe two key properties:

1. If S_1, S_2 are sketches of P_1, P_2, then $S_1 \cup S_2$ is a sketch for $P_1 \cup P_2$ (correctness of merge step).
2. If S is a sketch of P and T is a sketch of S, then T is also a sketch of P, possibly with larger error (correctness of reduce step).

Let σ be the size of one sketch; σ is independent of n, but depends on ε. Then the overall space is $O(\sigma \log n)$. However, errors usually increase during the reduce step. To guarantee that the final sketch has error at most ε, a smaller error ε_i is used for each S_i. This increases the space by logarithmic factors. A recent result replaces the logarithmic method by a geometric strategy, eliminating all $\log n$ factors.

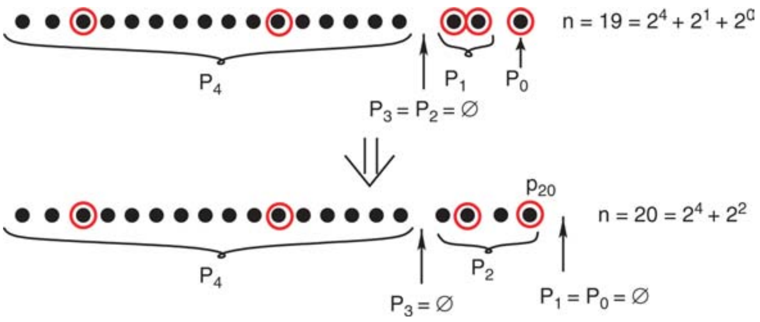
Two types of sketches apply to a wide range of problems. The first, called ε-approximations, was defined by Vapnik and Chervonenkis, in the context of set systems with finite VC dimension. For an introduction to this theory see, e.g., the book. Some classes of set systems to which the theory applies are specified below. The second type of sketches, called ε-coresets, were first introduced by Agarwal et al. and have emerged as a powerful tool in geometric approximation [1].

ε-approximations: A subset $S \subseteq P$ is an ε-approximation of P if for any *range* R from a fixed family of ranges of bounded VC-dimension

$$\frac{|R \cap S|}{|S|} = \frac{|R \cap P|}{|P|} \pm \varepsilon.$$

Examples of families of ranges of bounded VC-dimension include the set of all hyper-rectangles, and the set of half-spaces. Thus, a range counting query can be answered as follows. Let Q be the query hyper-rectangle and S be the current ε-approximation of the stream P. Then the number of points inside Q is approximated by $|Q \cap S| \cdot \frac{|P|}{|S|}$, and the error is $\pm\, \varepsilon |P|$.

Any set system of bounded VC-dimension admits an ε-approximation of size $O(\varepsilon^{-2} \log(\varepsilon^{-1}))$. Matousek designed a deterministic offline algorithm for computing such an ε-approximation. The algorithm was extended to the online setting by Bagchi et al. [5] using the logarithmic method as above.



Geometric Stream Mining. Figure 1. Merge and reduce via logarithmic method: A sketch of size at most two (*circled points*) is stored for each P_i. When p_{20} arrives, the sketch of P_2 is computed from p_{20} and the previous sketches of P_0,P_1.

ε-coresets and ε-kernels: Let $\mu : 2^X \rightarrow \mathbb{R}^+ \cup \{0\}$ be the measure to be optimized. For example, $\mu(P)$ can be the width, or the cost of the minimum weight spanning tree of P. Assume that μ is monotone, i.e., for any $P_1 \subseteq P_2$, $\mu(P_1) \leq \mu(P_2)$. A subset $S \subseteq P$ is an ε-coreset of P if

$$(1-\varepsilon)\mu(P) \leq \mu(S).$$

Many geometric problems have ε-coresets of small size, i.e., $|S| = 1/\varepsilon^{O(1)}$.

The related notion of ε-kernels provides a blueprint for computing coresets for several measures. For any unit vector $v \in \mathbb{R}^d$, let $\mu_v(P)$ denote the *directional width* of P along v. Formally, $\mu_v(P) = max_{p\in P}\langle p, u\rangle - min_{p\in P}\langle p, u\rangle$, where $\langle \cdot,\cdot \rangle$ is the inner product. See Fig. 2a. A subset $S \subseteq P$ is an ε-kernel of P if it simultaneously ε-approximates all directional widths, i.e., for all unit vectors v,

$$(1-\varepsilon)\mu_\upsilon(P) \leq \mu_\upsilon(S).$$

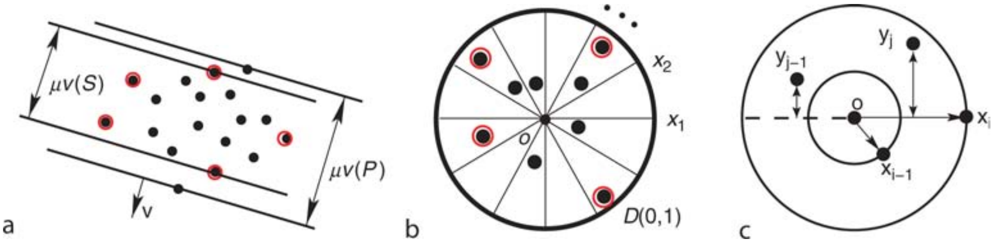
Figure 2b illustrates the offline algorithm by Agarwal et al. [1] for computing an ε-kernel in two dimensions. The algorithm assumes that all points of P lie inside the unit disk centered at the origin $\mathcal{D}(o, 1)$. It also assumes that P is "fat," i.e., there exists a constant $0 < \alpha < 1$ such that $\mu_\upsilon(P) \geq \alpha diam\ (P)$ for any direction v. Both conditions are enforced by applying an affine transform. The algorithm pre-defines a set of directions $\overrightarrow{ox_1},\ldots,\overrightarrow{ox_r}$ and computes the extremal points in each direction. Let $S \subseteq P$ be the set of at most $2r$ extremal points. The authors show that one can choose $r = O(1/\sqrt{\varepsilon})$ directions, so that S is an ε-kernel. For the d-dimensional case, $r = O(\varepsilon^{-(d-1)/2})$.

Maintaining extremal points along a fixed set of directions extends to the online setting. However, computing the affine transform that insures that P is fat requires first scanning the whole set. Thus, the logarithmic method is used for the online version. Different affine transforms are applied to different substreams.

A significant improvement is due to Chan [3], who eliminates the $\log n$ factors from the space bound. He partitions the data stream based on significant changes in the "shape" of the current substream, rather than its number of points. As before, a different affine transform applies to each substream, but the transform can be computed from the first three substream points.

In two dimensions, he uses the following affine transform. For any set P, let $o \in P$ be a fixed point, and let $x, y \in P$ such that $||op|| \leq 2||ox||$ and $d(p, ox) \leq 2d(y, ox)$ for all $p \in P$. Translate P to make o the origin. Rotate and scale P so that $x = (1/2, 0)$. Map each $(a,b) \in P$ to $(a, b/2d(y, ox))$. Let τ be the resulting transform. Then $\tau(P)$ is fat and $\tau(P) \subseteq \mathcal{D}(o, 1)$.

Let o be the first point in the stream; see Fig. 2c. Then o is assigned to all substreams (which are no longer disjoint). Divide the stream into sequences called *epochs*. An epoch E_i starts with a stream point x_i, and contains any subsequent point p so that $||op|| \leq 2||ox_i||$. Once a point q arrives so that $||oq|| > 2||ox_i||$, epoch E_{i+1} starts with $x_{i+1} = q$. Each epoch E_i is further divided into *subepochs* as follows. The jth subepoch $E_{i,j}$ which started with point $y_j \in E_i$ contains all subsequent points $p \in E_i$ for which $d(p, ox_i) \leq 2d(y_j, ox_i)$. When a point q arrives so that $d(q, ox_i) > 2d(y_j, ox_i)$, and q does not start a new epoch, then subepoch $E_{i,j+1}$ starts with $y_{j+1} = q$. A substream is a subepoch $E_{i,j}$, plus o and the point x_i that starts epoch E_i. An affine transform as above is computed at the beginning of each $E_{i,j}$, using points o, x_i and y_j.



Geometric Stream Mining. Figure 2. Computing an ε-kernel: (a) an ε-kernel S (circled points) approximates the directional width for all directions υ; (b) offline algorithm: kernel = extreme points along fixed directions (circled points); (c) online algorithm: x_{i-1}, x_i start epochs $i-1$, resp. i, where $d(o, x_i) > 2d(o, x_{i-1})$; y_{j-1}, y_j start subepochs $j-1$, resp. j, inside epoch i, where $d(y_j, ox_i) > 2d(y_{j-1}, ox_i)$.

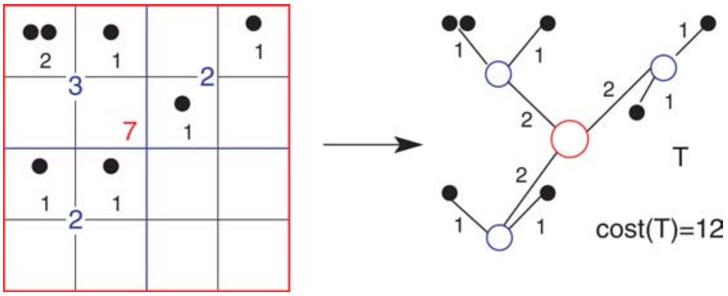
The number of subepochs can be $\Omega(n)$. However, Chan proves that it is sufficient to maintain kernels only for the most recent $\log(1/\varepsilon)$ epochs. Older epochs are so close to o that they can be represented by only two points. A similar argument applies to sub-epochs. The overall space is $O((1/\sqrt{\varepsilon})\log^2(1/\varepsilon))$, which was recently improved to $O(1/\sqrt{\varepsilon})$. In higher dimensions, a slightly different algorithm requires $O([(1/\varepsilon)\log(1/\varepsilon)]^{d-1})$ space.

2. Reduction to Vector Problems This technique has been applied to dynamic spatial streams, as the previous approach cannot handle deletions. The method was introduced by Indyk [6] and was used to approximate several geometric graph problems. It assumes a discrete space $\{1,\ldots,U\}^d$ and imposes a hierarchical decomposition on it. Statistics on the number of points in each cell is maintained under both insertion and deletion, using previous results from numerical data streams.

Figure 3 illustrates the method in two dimensions. The space decomposition consists of $k = \log U$ nested square grids $G_0,\ldots,G_k$ with side lengths $2^0,\ldots,2^k$, randomly shifted along each axis. This decomposition induces a tree structure, where a cell of G_i has at most four children corresponding to the non-empty cells of G_{i-1} contained in it. Data points are stored in leaves. The edge between a cell of G_i and its child from G_{i-1} has weight 2^{i-1}. Conceptually, the graph problem is solved on this tree, where the distance function is the shortest path. Indyk proves that, for randomly shifted grids, the expected cost of the tree solution is within $O(\log U)$ from the cost of the optimal solution. An $O(1)$ approximation of the tree solution can be computed by only maintaining statistics on the number of points in each non-empty cell. For the minimum spanning tree problem, the optimal solution on the induced tree is the tree itself, whose weight is $\sum_{i=0}^{k-1} 2^i n_i$, where n_i is the number of non-empty cells of G_i. Thus, for each i, it is sufficient to estimate the 0-norm of the vector defined over the cells of G_i under increment and decrement operations (i.e., when $p \in P$ is inserted, the counter of the cell containing p in G_i is increased by 1, and when p is deleted, the counter is decreased by 1). Thus, the original problem is reduced to a vector problem over data streams, which has already been studied. Other geometric graph problems can similarly be reduced to estimating vector norms of streams.

3. Random Sampling Several offline algorithms have a single-pass flavor and could work online, except that they need to select random samples from the data. If one can maintain random samples over a stream, then the algorithms extend online. When the stream is insertions-only, a random sample can be maintained via the reservoir sampling technique by Vitter [9]: Select the ith stream point p_i with probability r/i, where r is the size of the sample. If p_i is selected, it replaces a previous sample point, chosen uniformly at random.

For dynamic discrete streams, Cormode et al. [4] proposed a more general technique (a similar approach was independently designed by Frahling et al. [5]). The stream points are hashed to levels, such that the likelihood of being hashed to level l decreases exponentially in l. More exactly, if h is a universal hash function and $x \in \{1,\ldots,U\}$ is the stream point, then x is assigned to the level l for which $2C^{l+1}U \leq h(x) < 2C^lU$ ($0 < C < 1$ is a constant). Hence, there are $O(\log U)$ levels. Each level l has two counters $sum[l]$ and $count[l]$, initialized to zero, as well as a collision detection structure. If x is assigned to level l, then



Geometric Stream Mining. Figure 3. Cell count statistics (e.g., how many are non-zero) lead to approximate solution. Points can be inserted and deleted multiple times.

for each insertion of x, $sum[l] \leftarrow sum[l] + x$ and $count[l] \leftarrow count[l] + 1$; and for each deletion of x, $sum[l] \leftarrow sum[l] - x$ and $count[l] \leftarrow count[l] - 1$. If $count[l] > 0$ and there is only one point assigned to level l (as determined by the collision detection structure), then $sum[l]/count[l]$ is chosen in the random sample (note that $sum[l]/count[l] = x$, where x is the point assigned to l). The authors prove that there is a constant probability of finding such a level l, and that each point present in the stream has equal probability of being assigned to l. (A point is present in the stream if it has been inserted more times than it has been deleted.) To choose a random sample of size r, $O(r)$ independent copies of this structure are maintained.

Since a random sample of size $O(1/\varepsilon^2 \log(1/\varepsilon))$ is an ε-approximation with high probability, this provides a different method for maintaining ε-approximations. Frahling et al. [5] used the technique for the minimum spanning tree problem, improving the $O(\log U)$-approximation to $(1 + \varepsilon)$-approximation.

Key Applications

Most streaming applications whose data are embedded in a metric space require some analysis of the "geometry" of the stream. Three main areas, to which the above algorithms apply, are mentioned below.

Sensor networks Basic analysis of such systems computes information about the shape and extent of some sensor-covered area. For example, a system of sensors that monitor air quality can track the spread of a chemical spill, by maintaining the convex hull of the sensors that signal. In other applications, such as herd monitoring, the sensors are mobile, and the application tracks the distribution and density of the herd. In this case, it is useful to answer range counting and statistics queries.

Fixed wireless telephony This is an application of reverse nearest neighbor searching. Fixed wireless base stations are installed so that residential customers connect to the closest one that can handle the traffic. To optimize the performance, stations may be turned on or off depending on the stream of calls. To insure service quality, the system monitors station loads, as well as the maximum distance between a customer and the nearest station.

Mobile networks Such networks have a dynamic topology, in which connections between nodes appear and disappear based on their relative location. In this case, maintaining information on the network topology requires solving geometric graph problems.

GEO-RBAC Model

YUE ZHANG, JAMES B. D. JOSHI
University of Pittsburgh, Pittsburgh, PA, USA

Synonyms

LoT-RBAC

Definition

The central idea of the GEO-RBAC model is the role schema, and instances of roles, as defined below [1]:

- Role Schema: *A Role Schema is a tuple <r, ext, loc, m_{loc}>, where r is the name of the role, ext is the feature type of the role extent, loc is the feature type of the logical positions and mloc is the mapping function that maps a real position into a logical position of type loc.*
- Role Instance: *Given a role schema r_s, an instance r_i of r_s is a pair of <r, e> where r = r_s.r and e∈F, such that FT_Type (e) = r_s.ext.*

The notion of permissions, users, sessions, permission-role assignment and user-role assignment in the GEO-RBAC are similar to those in the RBAC model. The role enabling status in GEO-RBAC depends on whether the user's physical location maps the logical location specified in the role schema, as defined below:

- Enabled Roles: *Enabled session roles are defined as the function: EnabledSessionRoles: SES × RPOS→2^{RI} such that EnabledSessionRoles (s, rp) = {<r, e>∈R_I | <r, e>∈SessionRoles (s), lpos = SchemaOf(<r, e>).mloc(rp), Contrains (LocObj(e), LocObj (lpos))* = TRUE}

Finally, the control of the authorization in GEO-RBAC is defined as follows [1]:

- Authorization control function: An access request is a tuple *ar* = <*s, rp, p, o*>, where *s* is the session of the user, *rp* is the real positions of the user, *p* is permission requested, and *o* is the object of the permission. *ar* can be satisfied at position *rp* if

$$(p,o) \in \bigcup_{y \in EnabledSessionRoles(S,rp)} I\_PrmsAssignment^*(y)$$

where *I_PrmsAssignment** (*y*) represents those permissions that are directly assigned to role instance *y* or assigned to the role schema corresponding to *y*.

Key Points

The widespread deployment of location-based services and mobile applications, as well as the increased concerns for the management and sharing of geographical information in strategic applications like environmental protection and homeland security have resulted in a strong demand for fine-grained location based access control models and mechanisms. Efforts have been expended to extend existing RBAC models to develop fine-grained specification and enforcement framework for location based access control requirements.

The GEO-RBAC model, proposed by Bertino et al. [1], supports location constraints to address such location based access control needs. GEO_RBAC is based on the notion of *spatial role* that is a geographically bounded organizational function. The boundary of a role is defined as a geographical feature, such as a road, city, or hospital, and specifies the spatial extent in which the user has to be located in order to use the role. The location constraints and the authorization are integrated through enabled roles. If the user is located inside the spatial boundary of the role that has been selected (activated) during the session, the role is said to be enabled. The user can acquire all the permissions that are assigned to the enabled roles from all the roles available in his/her sessions.

As RBAC, GEO-RBAC encompasses a family of models. Core GEO-RBAC includes the basic concepts of the model, thus the notion of spatial role, role schema, real/logical position, and activated/enabled role. Hierarchical GEO-RBAC extends the conventional hierarchical RBAC model by introducing two distinct hierarchies – one over role schemas and one over role instances. Constrained GEO-RBAC supports the specification of separation of duty (SoD) constraints for spatial roles and role schemas. Since exclusive role constraints are important to support the definition and maintenance of access control policies in mobile contexts, SoD constraints are extended to account for different granularities (schema/instance level), dimension (spatial/non-spatial), and different verification time (static, dynamic at activation time, dynamic at enabling time).

Another model that addresses location based access in conjunction with temporal constraint is the Location and time-based RBAC (LoT-RBAC) model.

Georeferencing

Jordan T. Hastings, Linda L. Hill
Department of Geography, University of California-Santa Barbara, Santa Barbara, CA, USA

Synonyms

Geospatial referencing; Spatial referencing

Definition

Georeferencing is the name given to the process of geospatially referencing data and information objects – datasets, text documents, maps, photographs and imagery, etc. – to their proper locations on Earth. The vast majority of such objects derive from measurements and observations phenomena that are inherently georeferenceable, because humans are largely confined in their activities to the near-surface of the Earth and "Almost everything that happens, happens somewhere" [3].

Georeferencing can be accomplished in two main ways [2]: formally, by assigning geospatial coordinates directly to data and information objects; and informally, by relating such objects to one or more pre-existing ones for which georeferences have already been established. In everyday life, the latter approach predominates, using the mechanism of *place*. A geographic place is a real-world location, perhaps vague, with a recognizable name and type, and optionally other attributes, e.g., "Northern California," Golden Gate Park. A *gazetteer* is a dictionary of such places, which is essential for translating back and forth between informal and formal georeferences.

Numerous problems and subtleties attend the formal, or direct, georeferencing process. The Earth is not a sphere, in fact, but a lumpy body that is cannot be exactly described geometrically. Indeed, multiple definitions exist for the fundamental geospatial coordinates – longitude, latitude, and surface elevation – all of which depend on a definition of the Earth's center. Map projections further confound matters. No projection of the globe onto a flat sheet, to create a map, can simultaneously preserve both area and shape, even locally; thus, all projections introduce distortions, which can be severe. In addition, most projections involve transcendental mathematical functions, which are only approximated by computers.

Other problems apply to informal georeferencing using named places, e.g., "Fisherman's Wharf" or "5 miles south of San Francisco." Except for officially designated and defined administrative regions, geographic places are inherently subjective, based in geospatial cognition and mediated by linguistic, historical, and social conventions. Places are therefore approximate in location, shape and size, and further subject to various typing schemes. What are the distinctions among "metropolis," "city," and "town," for example; or between "lake" and "pond"? A single name may apply to many places – for example, there are many Lake Genevas in addition to the famous water body in Switzerland; some are lakes, in fact, others are cities. Also, a single place can have multiple names and types – for example, New York City is colloquially known as "The Big Apple."

Historical Background

Geospatial referencing originated in marine navigation, where it is essentially a 2-D exercise, using knowledge of celestial mechanics and time. Latitude can be determined from a sighting of the sun at local noon, knowing the day of the year. Determining longitude requires a reliable shipboard time-of-day clock [5] as well. Positional accuracies on the order of kilometers, i.e., within range of sight, are typical.

On land, longitude and latitude are relatively unimportant in people's everyday affairs, supplanted by linear measurements of distance and direction along constrained routes, e.g., riverways and roadways. Even these measurements are subordinate in many cases to the observation of salient places, also known as landmarks, along the routes: topographic features, human settlements, water bodies, etc. Again, relatively low-technology tools suffice: a wheel to measure distance, a compass to indicate direction, and optionally a barometer to estimate elevation. Positional accuracies on the order of ∼100 m are suitable for most purposes.

In space, the position of every satellite must be meticulously tracked. A constellation of ∼30 satellites has been deployed specifically as a global positioning system (GPS). Several of these satellites are visible from most points on Earth at all times, although the particular satellites come and go throughout the day. GPS satellites continuously broadcast their positions on special radio frequencies. A companion GPS receiver on Earth that picks up the signal from three or more of these satellites can back-calculate its own horizontal position by trilateralization (a variant of triangulation); with four or more satellites, vertical position can be determined as well. From multiple "fixes" on position over time, the GPS receiver also can work out its speed and direction of movement, if any. Overall, this system provides positional accuracies of ~5 m horizontally and ~20 m vertically, which is more than sufficient for most georeferencing purposes.

Foundations

Technical Background

The Earth is a globe, but only approximately spherical, with an equatorial radius of 6,378,137.0 m and a polar radius of 6,356,752.3 m, by modern measurement (WGS84). This ellipsoidal description is also approximate, as the Northern hemisphere is squatter than the Southern hemisphere; in addition, both hemispheres are incised by oceans and elevated by continents. The exact 3-D "figure" of the Earth defies analytic mathematical description, in fact. For precise geodetic work, affecting rocket and satellite trajectories among other things, a gridded model of the Earth's shape is used. However, for most mapping applications, an ellipsoidal approximation is satisfactory [1].

A *datum* is a set of parameters that define an approximate figure for the Earth, typically as an ellipsoid. The horizontal datum defines longitude and latitude with regard to this figure, and the vertical datum defines elevation in relation to an average sea level on it. Until the satellite era, the Clarke 1866 datum was sufficient and stable; since then a progression of datums (Table 1) have been adopted. A *map projection* depicts the globular figure of the Earth on a flat sheet of paper. In the projection process, lines of longitude and latitude (circles on the Earth) become other shapes on paper; inevitably, distortions are introduced. For example, the well known Mercator projection (Figure 1) depicts both longitudes and latitudes as straight lines, resulting in extreme distortion at the poles. No projection preserves both shape and area throughout the map, and many projections preserve neither (but still are useful).

Digital geospatial data representations are numerous. Three well established categories of such representation are: *vectors*, discrete shapes, applying to object-like phenomena; *rasters*, regular grids, best suited to field-like phenomena; and TINS (triangulated irregular networks), for 2½-D surfaces. Vector data further subdivides into points, lines, and polygons. With the exception of points and the simplest polygons – triangles and rectangles – none of these representations fits easily into a single relational database table; rather, table(s) containing open-ended "blob" (binary large object) structures, or a group of tables, are frequently used. A wide variety of proprietary structures exist for geospatial data transcribed to files. The Geographic Markup Language (GML) [4] is an application of XML designed to remedy this complexity by encoding

Georeferencing. Table 1. Selected world datums

Name	Semi-major axis (m)	Semi-minor axis (m)	Flattening ratio
Clarke 1866 (NAD27)	6378206.4	6356583.8	294.979
GCS 80 (NAD83)	6378137.0	6356752.3	298.257
WGS 84[a]	6378137.0	6356752.3	298.257
GCS 87 (Europe)	6378388.0	6356911.9	297.000

[a] Differs imperceptibly from GCS80, for most purposes

both vectors and rasters (but not TINS), including their associated attributes, in a portable text format.

Georeferencing Techniques

Georeferencing spans a variety of techniques, determined in part by the content and format of the underlying data and information objects. Some objects must be formally georeferenced with longitude and latitude coordinates. Aerial photographs and satellite imagery, for example, are usually located and oriented geospatially by the coordinates of their center and/or corner points. By contrast, text documents are typically georeferenced either by assigned geographic subject headings or by place names (in titles, indexes, and the text itself). Subsequently, using a gazetteer, these informal place references can be translated to coordinates. Hardcopy maps usually can be georeferenced in both ways, because they are drawn in a coordinate framework and also have place names embedded in titles, marginalia, map features, etc. Tabular materials represent another special case, because they can contain both place names and coordinates explicitly. Photographs, works of art, biological specimens, and other such objects are most often georeferenced informally in accompanying notes, although some digital cameras are now equipped with GPS and capable of recording formal coordinates directly with the image.

Following is a synopsis of common georeferencing techniques.

Datasets Scientific and technical data are frequently presented in tables, recorded in spreadsheets or databases. Such tables may include georeferences as coordinates, place names, or both. For statistical data, place codes may appear in lieu of place names for administrative or other formally defined areas, such as census tracts or postal zips. Data in tables may be georeferenced formally, informally using gazetteers, or both.

Documents Textual materials commonly contain geospatial references as place names, which may serve to locate the subject matter more or less precisely, viz. "Washington Mall" versus "apex of Washington Monument". Place names also may appear adjectively ("Washington Redskins' stadium"), prepositionally ("suburbs of Washington"), or they may be the subject itself ("Washington, DC"). A single text document may contain many place names, some relevant to the subject matter, some not, viz. "unlike its neighboring states of Maryland and Virginia, Washington, DC is a federal district". A technique called geoparsing is used to recognize salient place references in text documents and to associate coordinates with them via gazetteers.

Maps Maps are, by definition, depictions of geospatial phenomena in a coordinate framework, i.e., graphical displays of geospatial data. A significant portion of the geography curriculum at all levels concerns locating coordinate pairs on maps and conversely extracting the coordinate locations of mapped points. Linear and areal features are typically represented by sequences of points, which can be intricate. A GIS (below) is, to first approximation, a map in digital form. Map content is inherently georeferenced, but the maps themselves often require external, informal georeferencing.

Photographs It is useful to distinguish between photographs taken *in* the environment – "snapshots" – and photographs taken *of* the environment, typically from an aerial platform such as an airplane. The former may be georeferenced, either formally or informally, as objects at mapped points; the later cover a quasi-rectangular area on a map, indicated by a sequence of points. With aerial photographs, comes the additional issue of othro-rectification: removing the dilation or "bloom" in portions of the photograph except at the single point (if any) focused straight down.

Imagery Satellite imagery is an electronic rather than film product – so-called "digital numbers" (DNs), representing the brightness of a scene in a gridded pattern of picture elements (pixels). Images are taken from sufficient distance above the Earth that dilation issues are small, but not negligible. The satellite's orbit coupled with the Earth's rotation typically results in an image swath that tracks diagonally across the land surface, producing trapezoidal pixels. For ease of use, the trapezoids are usually interpolated back to square pixels during post-processing of the satellite data, in conjunction with ortho-rectification. Georeferencing then proceeds as for aerial photographs.

Key Applications

Georeferencing makes data and information objects more useful for many purposes. In a geographic information system (GIS), for example, vector objects, raster fields and imagery are presented in layers. When such layers are georegistered to a common standard, their content appears superimposed – as on an electronic light table. Users are frequently surprised by even slight mis-registrations of the layers. Hence, the intrinsic accuracy of geospatial measurements relating to the layers also must be considered.

Geographic information retrieval (GIR) is an extension of textual information retrieval (IR) that compares coordinate-based queries to georeferenced data and information objects to find the best matches. In a geospatially-enabled digital library, for example, the query "find information about Washington, DC" can be translated into coordinates for the area, from which a wide variety of materials can be retrieved, including satellite images, maps, and books. The spatial matching operations usually include containment, overlap, and proximity within a specified distance. As with GIS, issues of georeferencing accuracy as well as intrinsic errors must be considered.

A third, hybrid application, is geospatial modeling and analysis, in which GIS layers, are manipulated numerically to yield additional insights and results. When the physical laws governing the behavior of environmental phenomena are known, or hypothesized, these also can be integrated with the GIS layers to produce diagnostic and forecast models of environmental behavior. The purpose of such models, beyond scientific curiosity, is usually to inform political policy and decision-making.

Geospatial Metadata

Bugra Gedik
IBM T.J. Watson Research Center, Hawthorne, NY, USA

Synonyms

Geographical metadata

Definition

Geospatial metadata are a type of metadata used to describe geospatial data. Data described by geospatial metadata relates to objects that have an explicit or implicit geographic extent or position on the surface of the Globe. Geospatial metadata can be used to create metadata catalogues or directories that describe geographic features of data stored in any environment, ranging from data stored in geographic information systems (GIS) to simple documents, datasets, images, or even services. Geospatial metadata captures the basic characteristics of geospatial data and represents the what, the when, the where, and the who of the geospatial data. A typical geospatial metadata record includes catalog elements such as title, abstract, and publication data; geographic elements such as geographic extent and projection information; and database elements such as attribute label definitions and attribute domain values.

Historical Background

The interest in geospatial metadata grew steadily over the 1980s and 1990s, and as a result several national and international organizations, as well as communities of practice, started to develop their own formats and conventions for collecting and organizing geospatial metadata. For instance, United States National

Aeronautics and Space Administration's (NASA) Directory Interchange Format (DIF) [2] was developed in 1987, and formally approved for adoption in 1988. A similar geospatial metadata development effort was undertaken by the United States Federal Geographic Data Committee (FGDC) throughout 1992 to 1994 [5], which led to FGDC's release of Content Standard for Digital Geospatial Metadata (CSDGM) standard in 1998 [3]. Similarly, in 1996 Australia and New Zealand Land Information Council (ANZLIC) released its metadata guidelines [1]. The emerging need for consolidating various formats and standards developed by different communities of practice was addressed by ISO/TC 211 over the years 1999 to 2002. Consequently, ISO 19115 standard was released in 2003 under the title "Geographic Information – Metadata." Following the release of the ISO 19115 standard, national and international organizations, as well as communities of practice have started the process of fitting their previously adopted metadata standards as profiles or recommended subsets of the ISO 19115 standard, via formal extensions to it. The increasing popularity and adoption of the Extensible Markup Language (XML) for sharing data across different information systems over the Internet led to the development of mechanisms for exchanging geographic metadata on the Web during the 1990s. Consequently, the Geography Markup Language (GML), an XML grammar for expressing geospatial features and metadata, was released in 2004 by the Open Geospatial Consortium (OGC). With the growth of the Semantic Web in the 2000s, several organizations have started to develop ontologies for representing semantic geospatial metadata. Some examples include the Hydrology and Administrative Geography ontologies [4] developed by the Ordnance Survey in the United Kingdom.

Foundations

Digital geospatial data are often used to create a model of the real world geographical objects for use in computer analysis and digital display of geospatial information. Hence, it is an abstraction of the real world geographical objects that are being described. This abstraction often involves various approximations, simplifications, and exclusions. Given that this digital representation is seldom perfect or complete, the assumptions and limitations affecting its accuracy must be fully documented to ensure that such data are not misused. Geospatial metadata allows a data producer to describe a geospatial dataset fully, so that the users can understand the assumptions and limitations associated with the dataset and evaluate its applicability for their intended use. In summary, geospatial metadata provides data producers with appropriate information to characterize their geospatial data, facilitates the organization and management of geospatial data, enables users to apply geospatial data in the most efficient way by knowing its basic characteristics, facilitates data discovery, retrieval and reuse, and enables users to determine whether geospatial data at hand will be of use to them.

Geospatial metadata consists of a schema required for describing geographic information and services. It provides information about the identification, quality, spatial and temporal extent, spatial reference, and distribution of geospatial data. The set of geospatial metadata elements is often large and typically only a subset of the full number of elements is used. For instance, ISO 19115 standard includes a list of core metadata elements – a minimum set of basic elements required to identify a dataset for cataloging purposes. These core metadata elements answer the following questions:

- Does a dataset on a specific topic exist? ("what" aspect)
- For a specific place? ("where" aspect)
- For a specific date or period? ("when" aspect)
- With a point of contact to learn more about the dataset? ("who" aspect)

GML: The Geography Markup Language

The Geography Markup Language (GML) is an XML grammar used to express geospatial features. GML serves as a modeling language for geographic systems as well as an open interchange format for geographic transactions on the Internet. Originally developed by the Open Geospatial Consortium (OGC), it is later adopted as ISO 19136 standard in 2007.

Geospatial Metadata Catalog

A geospatial metadata catalog is a collection of geospatial metadata entries that are managed together. A geospatial metadata catalog is often accompanied by a catalog service, which responds to requests for metadata in the catalog and help browse or search geospatial data described by the collection of geospatial metadata managed in the catalog. In summary, the main goal of a geospatial catalog is to support a wide range of users in discovering relevant geospatial information from heterogeneous and distributed repositories of geospatial data.

Geo-Targeted Web Search

Torsten Suel
Yahoo! Research, Sunnyvale, CA, USA

Synonyms

Geographic web search; Local web search

Definition

Geo-Targeted Web Search (Geo Search) describes a set of techniques used in web search engines that aim to return more relevant results to users by exploiting geographic knowledge. Most commonly, a Geo Search Engine (a search engine using Geo Search) tries to infer a geographic area of interest for a user query by considering the query itself, the current location of the user, or the search history of the user. The Geo Search Engine then tries to return documents that are relevant to the query search terms and that also match the geographic area of interest of the query, as determined through analysis of the web page itself, any geographic meta tags (geo tags), link or site structure, or other data. As an example, a Geo Search Engine may return to a mobile user a list of restaurants close to the user's current location given a query "restaurants." Or a user may explicitly ask for information about tourism attractions in Florida, by adding a keyword such as "florida" or pointing to a map. Geo Search techniques can be integrated into standard broad-based or specialized search engines, or deployed as separate search facilities with special interfaces that allow more convenient query input or result display.

Historical Background

Geo Search developed over the last decade as a response to several challenges faced by search engines. First, given the size of the web, there are often too many potentially relevant results, and geography can provide a natural way of filtering such results for those the user really wants. Second, much of commerce is still local in nature, and Geo Web Search can provide a platform for supporting local advertising models on the web. Third, it was found that treating geographic terms in queries just as normal terms does not give the best possible results, and that some amount of geographic domain knowledge should be added to engines to improve results. For example, by simply matching on the term "manhattan" in a query, one might miss out on results referring to New York in general or to a particular neighborhood in Manhattan, or results about Brooklyn that are close enough to be of interest. As a result, there have been significant efforts by major search engine companies and start-ups to develop Geo Search Engines, and there has also been increasing interest in the academic community.

Even before the emergence of the web, researchers in Information Retrieval studied how to exploit geographic information embedded in text documents for better text search and analysis; see Larson [10] for earlier work and Jones and Purves [8] for a recent overview of the slightly more general area of *Geographic Information Retrieval* (GIR). This article focuses on geographic web search technology, which currently dominates the area of GIR in terms of number of users and total economic investments, but there are of course important applications outside the web domain. Initial work on Geo Search on the web appears in [5,6,13], and in recent years a significant amount of research has addressed this new challenge. A lot of the work has studied the problem of reliably identifying geographic references in documents in the presence of noise and ambiguity [1,11–13]; for example, many common place names (e.g., Washington) can also refer to persons, hotels, or other entities, while others can refer to several different places (e.g., Paris, Texas vs. Paris, France). Recent work has also focused on indexing and query processing techniques for Geo Search [2,15,17], and on analyzing and studying user queries in order to better understand the types of geographic search needs that real users have [7,9,14,16].

Foundations

This discussion begins with an outline of the main tasks in Geo Search. As in conventional web search engines, these tasks can be divided into four groups: (i) data acquisition (i.e., web crawling), (ii) preprocessing and data analysis, (iii) index building, and (iv) processing of user queries using these index structures. Geo Search engines that are limited to a particular geographic area need to be able to efficiently crawl sites and documents related to this area; this problem is called *geo crawling*. In the preprocessing phase, the collection has to be analyzed to extract geographic information that can be used for indexing. This can include, e.g., complete addresses, phone numbers, town names, or informal references (such as "big apple" for New York). The output of this phase may be either sets of geographic terms, or sets of points, polygons, or other geometric objects. During index building, additional index structures may have to be built, e.g., spatial index structures for the geometric objects obtained from the previous phase. Finally, during query processing, queries and their contexts are analyzed to determine if the user might be interested in a particular geographic area, and then the index structures is used to find relevant documents.

Geo Parsing and Geo Coding

A significant amount of work has focused on (ii), the analysis of documents for geographic information [1,11–13]. In particular, *geo parsing* is the process of identifying likely geographic references (such as town names, addresses, etc.) in the document text or meta data. Most commonly, this is performed by matching terms in the documents with databases of geographic names (gazetteers) obtained from outside sources, such as the GNIS database made available by the US Geological Survey for the US. If databases of business listings (yellow pages) are available, these can also be used to extract additional geographic references. In addition, techniques for named entity recognition can be applied. When databases of geographic names are available, the problem may appear simple but is in fact not so. Consider the many ways in which city or state names may appear as part of names of persons, businesses, foods, or many other items. Moreover, Washington can be a city or a state, LA can refer to Los Angeles or Louisiana, and there are dozens of towns named Lexington. These problems are referred to as geo/non-geo ambiguity and geo/geo ambiguity, respectively. In addition, it can be desirable to also detect informal place names (e.g., "big apple" for New York).

An alternative proposal is to introduce *geo tags* that allow authors to attach appropriate geographic terms or coordinates to pages [3] or other objects such as images or business listings or reviews, or allow communities of users to supply tags. This avoids many of the challenges of automatic extraction, but potential problems are lack of participation and possible manipulation.

Once the geographic terms have been extracted, there are two main approaches for further processing. One approach performs *geo coding* to map the geographic references into longitude-latitude coordinates, and then uses spatial or geometric algorithms and data structures for further processing. Alternatively, the geographic terms can be kept in textual form and related to a geographic ontology, in the simplest case just a hierarchical grouping of geographic terms representing simple spatial facts (e.g., that San Jose is in Santa Clara County which is in California), that is used for subsequent processing.

The geo coding approach is now discussed in more detail. In this step, the goal is to infer for each document its *geographic focus* [13], which is the area that the document relates to. The estimate of this area will be stored as a spatial data structure called the document's *footprint*. To compute the footprint of a document, any references to countries, cities, counties, or maybe businesses in the document are first translated into coordinates, using coordinate data available as part of many gazetteers. The output is a set of points, rectangles, polygons, or other spatial objects, possibly with appropriate weights or amplitudes. For example, a business may be mapped to a precise coordinate, while a city could be modeled by a circle or rectangle with some diameter, or a polygon approximating city boundaries. Weights might model the importance of a geographic term in the document or the extraction confidence for this term. In general, the geographic footprint of a document might assign an amplitude to every location on a map, with a value of zero for areas that are not relevant to the document, and very high values for areas that are referenced multiple times in the document. Efficient processing will usually require approximation of this data by a small number of polygons or bounding rectangles.

Note that both geo parsing and geo coding could potentially be improved by using site and link structure [12,13], such that pages with ambiguous or missing geographic references are analyzed using information on neighboring pages. It may also be useful to assign footprints on a per-site basis. Finally, note that the geographic focus of a page is related but not identical to the *geographic scope* introduced in [5], which is the geographic area of the readership addressed by a page. For example, a page about travel to Paris in a local newspaper or site in Seattle might have a geographic focus around Paris, but a geographic scope around Seattle.

Indexing and Query Execution

After analyzing the documents for geographic references, it is necessary to build appropriate index structures that allow efficient query processing. Recall that in the analysis phase there were two main approaches, one that keeps extracted geographic references as terms that can be related to some spatial ontology or other knowledge base, and one that translates the extracted geographic terms into a spatial footprint structure based on polygons or rectangles. The former approach then uses textual index structures and techniques such as query expansion on the geographic terms in the user's query [4] in order to find the best results.

Lot of recent work, e.g., [2,15,17], follows the latter approach, which is now discussed in more detail. Assume that a query to a geo search engine consists of two parts, a set of terms as in a standard engine, and a *query footprint* in the same basic format as the document footprints. Such a query footprint could be obtained from the user in a number of ways, e.g., by having the user input a geographic term or point and click in a map, or by using the user's current location or past queries to derive a likely area of interest. Then a possible definition of query processing in geo search engines is as follows:

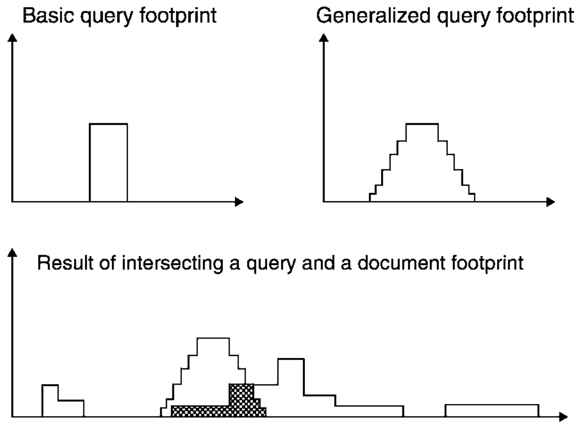
Definition: Given a collection of documents, each consisting of a document footprint and a set of terms, and a query consisting of a query footprint and a set of terms, the top-k query processing problem in geographic search engines is to return k documents such that:

- The footprint of each returned document has a nonempty intersection with the query footprint, i.e., there exists a location where both footprints are non-zero.
- Each returned document contains all terms in the query, or alternatively satisfies some weaker Boolean filter on the query terms (e.g., an OR).
- The returned documents are the k highest scoring documents according to a ranking function of the form $h(s_t,s_g)$ where s_t is a term-based score computed on the query and document terms, s_g is a geographic score obtained from the query and document footprints, and h is a monotone function for aggregating the two scores.

Some of the above assumptions can be relaxed, for example by allowing s_t to also contain scores based on link analysis or page visit frequency. One interesting choice for s_g is a dot product over all locations of the two footprints (or a corresponding integral in the continuous case). As shown in Fig. 1, by properly preprocessing the footprints it is possible to achieve objectives such as scoring documents higher if they are closer to the center of the query footprint or if they overlap with locations that are of particular interest to the user.

Thus, for fast query processing, it is necessary to have index structures that support execution of the spatial and textual filtering conditions, and an efficient way to score the remaining documents. In typical web collections, the textual data to be indexed is larger than the extracted spatial data, and thus efficient text index structures, such as inverted lists, are crucial. The size of the spatial data depends on the format used for the footprints. If the average footprint consists only of a few bounding rectangles, then this data may be only a few percent of the text data and thus may fit in main memory. If a footprint contains a more precise representation involving polygons or amplitudes, then the spatial data may only be moderately smaller than the text data.

In any case, to perform query processing, both textual and spatial index structures are required, and the challenge is to integrate these efficiently. A number of algorithms for this problem were first proposed in [15]. Two recent optimized approaches [2,17]



Basic query footprint
Generalized query footprint
Result of intersecting a query and a document footprint

Geo-Targeted Web Search. Figure 1. [12] An illustration of query and document footprints in a single spatial dimension. The top shows a query footprint with a distance threshold (*left*), and a footprint for a query that gives a lower score for documents that are farther away from the center (*right*). The bottom shows an intersection between the query footprint and a document footprint.

address this issue by combining inverted indexes with spatial structures such as R*-trees and space-filling curves. The approach in [17] assumes that each footprint is a set of rectangles; this results in a fairly small amount of spatial data and very fast query processing as most spatial data will be in memory. Work in [2] assumes that footprints are approximated by a set of bounding rectangles that is used during the filtering phase, but that a more precise representation of the footprints is also stored and must be fetched in order to compute precise values for s_g. The precise footprints are treated as binary objects (BLOBs) whose detailed structure is not important as long as a score can be computed from them; they might for example contain amplitudes or additional context about the geographic terms that were parsed from the documents. Compared to [17], this approach results in more spatial data that needs to be accessed, and thus more disk transfers, but it is more general in terms of the types of ranking functions that can be supported. However, it is not clear to what degree this generality is actually needed, and the approach in [17] may suffice in many practical scenarios.

Geographic Search Queries

In order to provide useful geographic search services, it is necessary to study how users search on the web. Several recent studies have looked at how to automatically identify queries that have a geographic intent and could thus benefit from geographic search technology [7,9,16]. Automatic identification allows a proper query footprint to be assigned to such queries. It may also allow better processing of queries that have no explicit geographic terms. For example, when searching from mobile devices or sometimes also from desktops, users may prefer results close to their current location without explicitly specifying so. Other researchers have studied the basic properties of such queries [14]. It is estimated that about 10% to 15% of queries submitted to standard search engines contain geographic terms. Work in [9] looks at how users modify the geographic terms in query sessions in order to get better results.

Key Applications

All the major search engine companies have developed and deployed geographic search technology as part of their offerings. In particular, these engines provide local search options that allow users to search for businesses and organizations using keywords, geographic terms, and map-based interfaces. In addition, geographic search technology is also used in their standard web search engines to provide better results for queries that are likely to have a geographic intent. Closely related and of particular commercial interest to the search engines are techniques for local advertising on the web.

Other applications on the web are in the automatic compilation of local information for city or neighborhood portals, and in providing better interfaces and search for real estate, car trading, or classified sites where users tend to search in a certain geographic area. Finally, although this discussion has focused on the case of the web, Geographic Information Retrieval has many applications on other textual collections where geographic search, browsing, and analysis are useful.

Future Directions

There is continuing research on many aspects of geographic web search, which is still in its infancy. This includes work on better extraction of geographic terms from documents and queries using techniques from Natural Language Processing and Information Retrieval. Ideally, techniques should be general enough to be applicable across languages, and it would be desirable to also identify implicit geographic intent in queries and informal place names.

Further studies of search logs and user behavior are needed to better understand user intentions and search strategies, particularly for queries that go beyond the types of searches for local businesses that are already handled fairly well by current local search services. Growing interest in technologies for local advertising on the web is also expected.

An intriguing future direction in geographic search involves online virtual worlds, such as Second Life as well as models of the real world such as Google Earth. As such models become more popular and users become more comfortable in navigating them, significant textual content is expected to migrate to or be mapped into these spaces, resulting in yet unexplored research problems related to geographic web search.

Geometric mean average precision

Definition

The Geometric Mean Average Precision (GMAP) is the geometric mean of the average precision values for an information retrieval system over a set of *n* query topics. GMAP is expressed as follows (from [1]):

$$\mathrm{GMAP} = \sqrt[n]{\prod_n AP_n}$$

where *AP* represents the Average Precision value for a given topic from the evaluation set of *n* topics. Please refer to the entry on *Average Precision* for the complete definition of *AP*. An alternate calculation method expresses GMAP as an arithmetic mean of logs (also from [1]):

$$\mathrm{GMAP} = \exp \frac{1}{n} \sum_n \log AP_n$$

Key Points

The Geometric Mean Average Precision evaluation metric was first introduced in the Robust track at the 2004 NIST Text Retrieval Conference (TREC). A stated goal of the robust track was to examine and evaluate information retrieval systems with a view towards achieving consistently good performance over all query topics in the evaluation set. The geometric mean was considered for this purpose because it tends to better illustrate large relative improvements in the scores of poorly performing topics between a set of runs while suppressing the effect of minor fluctuations in the scores for topics that achieve good performance. By contrast, the traditional Mean Average Precision metric, which uses the arithmetic mean of average precision scores, gives equal weight to absolute changes in per-topic scores, regardless of the relative size of the change.

As an example, consider a run with five topics, each having the following Average Precision Scores:

	Topic #1	Topic #2	Topic #3	Topic #4	Topic #5
Run 1 AP	0.05	0.10	0.50	0.50	0.75
Run 2 AP	0.10	0.30	0.45	0.45	0.60

In this example, Run 1 and Run 2 have the same Mean Average Precision (0.38), whereas Run 1 has a GMAP of ∼0.25 and Run 2 has a GMAP of ∼0.33. If the evaluator is interested in a measure of consistency and collective performance across all topics, GMAP is a good choice for the evaluation metric.

Definition

Grammar inference is the task of learning grammars or languages from training data. It is a type of inductive inference, the name given to learning techniques that try to guess general rules from examples.

The basic problem is to find a grammar consistent with a training set of positive examples. Usually, the target language is infinite, while the training set is finite. Some work assumes that both positive and negative examples are available, but this is not true in most real applications. Sometimes probability information is attached to each example. In this case, it is possible to learn a probability distribution for the strings in the language in addition to the grammar. This is sometimes called *stochastic* grammar inference.

A grammar inference algorithm must target a particular grammar representation. More expressive representations are more difficult and expensive to learn. For example, context-free grammars are more expressive than regular languages, but much harder to learn. The target representation for stochastic grammar inference can be viewed as separate structure and probability components. The structure component is a standard grammar. The probability component defines the probabilities associated with individual strings. One way to define this association is to assign a probability to every production of the grammar, or for regular grammars, to every transition of the finite automaton. The probability of a string is then the product of the production or transition probabilities used in its generation.

As with all learning problems, a solution is not necessarily acceptable just because it is consistent with the training set. Infinitely many grammars are consistent with any finite sample. Inference must construct a possible grammar, and also choose from among the possibilities. Usually the grammar must generalize outside the available examples in some useful way. What is useful varies with the application. Some applications require a result that a human can interpret. Others require a grammar that assigns accurate probability predictions to strings.

Historical Background

Grammar inference has been studied by researchers in many fields including information theory, formal languages, automata theory, language acquisition, computational linguistics, machine learning, pattern recognition, computational learning theory, neural networks, and data compression. Several conferences and workshops focus specifically on the subject. One example is the International Colloquium on Grammatical Inference (ICGI) which has been held in 1993, 1994, 1996, and every 2 years through 2006 so far. There have also been associated language learning competitions such as the Abbadingo competition which focused on learning deterministic finite automata and the Omphalos competition that focused on learning context free languages.

The first studies of grammar inference date back to the 1960s. One formalization is called *language identification in the limit* [7]. This assumes two sets of strings: $R+$ is the set of positive examples, and $R-$ is the set of negative examples. A language is said to be *identifiable in the limit* if it can be learned by *some method* for *sufficiently large* $R+$ and $R-$. Put another way, adding new examples to $R+$ and $R-$ must only produce a finite number of changes to the hypothesized model.

There are two decidability results in this formalization. The first is negative and says that no infinite language can be identified in the limit from only positive examples. This is intuitively a consequence of over-generalization since adding more positive examples can never imply that a string mistakenly included in the model should subsequently be removed. In fact, a consistent generalization of any set of positive examples is a language containing all finite strings constructed from the alphabet.

The second decidability result is positive and states that any member of an enumerable class of recursive languages (context-sensitive and below) is identifiable in the limit given both positive and negative data. However, this result says nothing about how large a sample is needed and therefore has limited application. Even if negative examples are available, which is often not the case, the learning problem may be intractable. For example, finding the smallest finite automaton compatible with given positive and negative example sets is NP-hard [3,8]. A polynomial time algorithm can construct a *non-minimal* solution to this problem in the limit [11]. However, the problem remains that there is no bound on the size of the required training data.

Within the standard Chomsky hierarchy from automata theory [10], grammar inference research has focused mainly on regular and context free grammars. Restricted grammars, referred to as *characterizable subclasses*, are also commonly targeted. For example, *k*-reversible languages [4], generalize from 0-reversible languages which are those generated by finite automata that remain deterministic if all of their arcs are reversed. The main justification for using restricted language classes is to reduce the time complexity of the inference process. The defining restrictions are not themselves relevant to real applications.

Much work has been done on stochastic grammar inference because of its applicability to real applications. Early work in information theory used probability information to discover rules. Shannon proposed that language learning can be seen as a problem of estimating probabilities of sequences of n-grams as n approaches infinity. Well known techniques such as the Baum-Welch algorithm [5] for learning hidden Markov models can be considered stochastic grammar inference since hidden Markov models are equivalent to stochastic finite automata. Many learning algorithms for data compression and neural networks perform stochastic grammar inference, although not always using representations that map to standard grammars.

Foundations

A common grammar inference paradigm starts with a model constructed to accept the finite language composed of exactly the strings in the training set. The inference process then transforms this *de-facto* model by applying generalization operations. This is analogous to a natural learning process that starts with a complete memory of specific examples and then combines groups of similar examples into general rules.

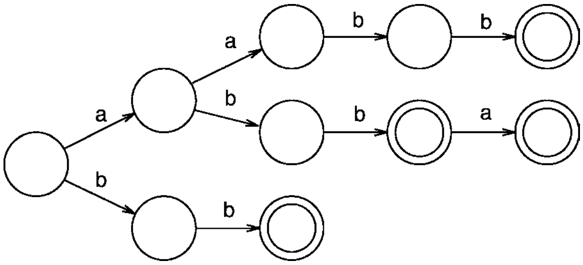
The form of the de-facto model depends on the target representation. The training set {*abb*, *bb*, *aabb*, *abba*}, for example, can be represented by the de-facto grammar in Fig. 1, the de-facto stochastic finite automaton in Fig. 2, or by appropriately chosen models in other representations.

Generalization operations can usually be viewed as merging sub-components of the model. Finite automata, for example, are generalized by merging states, thus creating new loops or paths. Grammars are generalized by merging productions. This expands the language so that it includes new strings with characteristics similar to existing strings. Operations that arbitrarily expand the language (e.g., by adding symbols to the alphabet or adding strings that have nothing in common with any of the training examples) are also possible, but not generally useful.

While the paradigm of moving from specific to more general models is common, the opposite strategy is also possible. This involves starting with a completely general model and then modifying it to describe specific rules or patterns. This is done in the previous example by starting with the finite automaton having a single state and transitions back to that state on input of *a* and *b*. If it is then observed that *b*s always occur in pairs, then a new state can be split off to express this rule.

$$\begin{array}{lcl} S & \rightarrow & abb \\ S & \rightarrow & bb \\ S & \rightarrow & aabb \\ S & \rightarrow & abba \end{array}$$

Grammar Inference. Figure 1. A de-facto grammar.



Grammar Inference. Figure 2. A de-facto stochastic finite automaton.

Generalization from a specific model and specialization from a general model are two paradigms for moving through the infinite space of all languages consistent with a given training set. Also needed is a specific control strategy that defines the order of generalization or specialization operations and when the process terminates. If a metric is available for evaluating intermediate results, then the task can be seen as a search problem, and many well known control strategies such as greedy search are applicable. However, many grammar inference algorithms are not explicitly formulated in this way. Instead, they choose the control strategy, the movement operations, or the representation in some way that is computationally convenient. The use of characterizable subclasses mentioned above is one example of this.

Stochastic grammar inference works with training data that can be viewed as a statistical sample of an unknown distribution. This means that candidate models can be evaluated in a relatively objective manner using either statistical tests or metrics based on information theory. In particular, it is possible to evaluate strings that are generated by the model but are not present in the training data. Probability information thus makes up for the lack of negative examples. Such unseen strings must be assigned low enough probability to fit the assumption that the training set is a random sample of the language generated by the model. Consider the training set $T = \{(a, 20), (aa, 10), (aaa, 5)\}$ consisting of three (*string*, *frequency*) pairs for a total frequency of 35. One possible model is $\{a^n | p(a^n) = 0.5^n\}$ which assigns a total probability of 0.125 to strings of four or more *a*s even though no such strings are present in the sample. A simple statistical test can verify that since T contains only 35 strings it could in fact have realistically been generated by the model. For example, a χ^2 test shows that the chance of getting T or any less likely sample from the model is somewhere between 0.20 and 0.50 – probably not unlikely enough to conclude that the model is a bad one. For the set $T' = \{(a, 200), (aa, 100), (aaa, 50)\}$, on the other hand, the probability is less than one in a thousand. The reason is that a random sample of 350 strings from the model should have included at least a few longer strings such as *aaaa* or *aaaaa*. Alternative evaluation criteria can be based on things other than strict probability of occurrence. Other approaches include Bayesian comparison to prior probability distributions [14] and divergence comparisons based on information theory [12].

Key Applications

The traditional application domain of grammar inference has been syntactic pattern recognition. This assumes that pattern classes can be represented by grammar models, and it is useful to learn these models automatically. Other application areas include speech and natural language processing, optical character recognition, information retrieval, gene analysis, sequence prediction, and cryptography.

In the database context, most recent work on selectivity estimation for query optimization in XML databases can be classified as stochastic grammar inference. Grammar inference also applies to data mining and knowledge discovery. Stochastic grammar inference is a key part of many compression techniques where better models directly correspond to better compression ratios.

For structured document collections, grammars are a natural representation to use as a database schema. This is also true of semi-structured and XML databases. Grammar inference is applicable to such data if it has no explicitly-created schema and there has been some work on grammar inference in this context. Fankhauser and Xu [6] describe a system that learns a grammar for use in automatic markup. Shafer [13] describes a C++ library, the GB (Grammar Builder) Engine which produces a grammar by generalizing examples marked up in an SGML-style. Work by Ahonen et al. [1,2] uses a more classical grammatical inference approach based on a characterizable subclass of regular languages that they call $(k-h)$ contextual languages. Goldman and Widom [9] describe the use of automatically constructed DataGuides for browsing database structure and formulating queries. Young-Lai and Tompa [15] look at applying stochastic grammar inference to the problem.

Definition

Graph theory: A set of nodes (also called **points** or **vertices**) connected by links called **lines** or **edges** or **arcs**. In an **undirected graph**, a line from point ***A*** to point ***B*** is considered to be the same thing as a line from point ***B*** to point ***A***. In a **directed graph**, the two directions are counted as being distinct **arcs** or **directed edges**.

Mathematics: A diagram exhibiting a relationship, often functional, between two or more sets of numbers as a set of points having coordinates determined by the relationship. Also called a plot.

Computer science: A data structure representing relationships or connections in lists, trees, and networks.

Data visualization: Any pictorial device such as a point graph, surface graph or symbol graph used to display numerical relationships. Also called a chart because graphs constitute one of the major categories of charts. Graphs combine two or more straight or circular axes, utilizing one or more quantitative scales. Straight axes are typically drawn perpendicular to each other, sharing a common origin. The most notable exceptions are triangular graphs, nomographs, and parallel coordinates.

Triangular (Trilinear) Graphs place the axes either along the sides or the along the angle bisectors of an equilateral triangle.

Nomographs (Nomograms) arrange the axes in such a way that a straight index line connecting known values on two axes passes through the solution value on another axis. The most common nomographs consist of three parallel axes, some place the axes at an angle to each other, others employ one or more curved axes.

Circular axes are based on polar coordinates, using angle or radius or both to represent values.

Key Points

Because graphs can be powerful tools to reveal the structure of data they are the preferred method to visualize data in science and technology, particularly as a tool for exploratory data analysis.

The use of graphical images to show data has evolved during the past 250 years, reaching unprecedented popularity with computer supported methods. The basic ideas behind good graphical design, however, transcend technology as they follow principles dictated by the human visual system.

W.S. Cleveland [1] has studied methods and basic principles that must be observed if a data analyst wants to realize a graph's potential for visualization. A classic on issues of graphical practice, including a theoretical approach to data graphics has been published by E.R. Tufte [3]. R.L. Harris [2] has assembled a comprehensive overview of different graphs by organizing them categorically according to their type of configuration (e.g., line graph, contour graph), area of application (e.g., technical, business), type of data plotted (e.g., original data, derived data), number of axes, and by purpose (e.g., analysis, monitoring, presentation).

Graphs are not only used to visualize data, they also serve as a tool for data acquisition and storage carried out by mechanical plotting devices or, in the form of nomograms, function as calculating devices, usually designed to perform a specific calculation.

Synonyms

Graph theory; Graph data structure; Graph database

Definition

In mathematics and computer science, graphs are mathematical structures used to model pairwise relations between objects from a certain collection. As a data structure, a "graph" is a set of vertices or "nodes" and a set of edges that connect pairs of vertices.

Historical Background

Graph data management has been studied for nearly two decades. A recent survey [1] states "Graph db-models are applied in areas where information about data interconnectivity or topology is more important, or as important, as the data itself. In these applications, the data and relations among the data, are usually at the same level…. It allows for a more natural modeling of data" and "Queries can refer directly to this graph structure. Associated with graphs are specific graph operations in the query language algebra, such as finding shortest paths, determining certain subgraphs, and so forth." One of the earliest applications of graph data models in science was the study of road networks [9]. While the development of medical terminologies started in the 1980s, the need to study the problem of medical terminology as a graph database came about in the early 1990s. Ellis [4] was one of the early attempts to model nomenclature such as SNOMED and the Unified Medical Language System (UMLS) as graphs.

Foundations

Graphs in Science

Many scientific disciplines deal with data that are structured like graphs. In chemistry, molecules can be considered as graphs whose nodes are atoms and edges are atomic bonds. In ecosystem studies, food webs are graphs where the nodes represent organisms and the edges are directed, representing predatory relationship. In infectious disease epidemiology, the contact network is an undirected graph, where the nodes are people affected by the disease, and an edge is created between pairs of people who came in contact with each other, and possibly caused the infection. In each application the properties of the graph are a little different. The nodes and edges may have additional attributes. The edges may have weights on them. The graph may be acyclic or have cycles. The graph may have a regular structure or may be more random in nature. Despite these difference, in all of these cases, the scientific pursuit involves some kind of network (i.e., graph-based) analysis. In the ecosystem example above, scientists analyze the structure of the graph (e.g., strongly connected components, weighted path lengths) as well as the values of node attributes (e.g., estimates of nutrients) [5].

Graph data management becomes important for science when (i) the problem domain has a very large graph and complex structural properties of this graph need to be extracted or computed by searching for structural patterns over the graph, or (ii) the problem domain has a large collection of graphs, each of which is not necessarily large. The fist situation occurs in the case of large protein networks in biology, where queries may correspond to extracting neighborhoods around nodes that satisfy properties given by the conditions of the query. The second situation occurs in the case of a library of chemical structures, from which one may want to find frequently occurring subgraphs from among a set of graphs that satisfy some query conditions. The data management needs and solutions for these two categories of problems are generally different.

Data Management for Large Graphs

Perhaps the most significant development in graph data management for the large graph case has been done in the context of biological networks, which are graphs where the nodes represent different kinds of biological molecules and edges represent observed or computed relationships between molecule pairs. In some cases, the graphs also include ontologies, which are graphs of standard terms and inter-term relationships. The simplest graph database represents a graph where nodes and edges have labels, and is implemented in a relational database system, and has a node table and an edge table over which graph operations are performed. There are three broad classes of operations that are performed in most common science applications.

1. *Relational Queries on the attributes of Nodes and Edges*: In general, the nodes and edges for the graphs are "thick," that is, they have attributes that are spread into one or more relational tables that can be joined with the basic node and edge tables. A typical query against the graph will have two kinds of conditions – those that are on the connectivity structure of the graph, and those that are standard relational queries on the attributes of the nodes and edges.
2. *Substructure Exploration, Extraction and Transformation*: These operations probe into the connectivity structure of the graph. A basic operation is to extract the k-neighborhood of a node, where the node is selected by some other query condition. Another basic operation is to find the shortest path(s) between two nodes. The query becomes much more complex if all paths between two nodes are desired – for a heavily interconnected graph (i.e., a graph with a small diameter) it may return the entire graph. Even if the graph is not heavily interconnected, the number of paths between two nodes is exponential in the number of edges. In practice, many scientific graph management systems do not allow an all-paths operation. A more complex operation seeks to extract a subgraph that satisfies certain conditions. The PQL system [10] allows queries of the form:

   ```
   SELECT A[−2], A[−*]B
   FROM A, B
   WHERE  A[−<  5]B  AND  A  ISA
   'enzyme' AND
   B.name = 'Propane-1,2-diol'
   ```

   The query returns a 2-neighborhood of a graph around node A and all (denoted by −*) the paths between A and B, where A and B are nodes that satisfy the graph pattern specified by WHERE condition. The WHERE condition looks for all B's having a specific name, and all A's that are within five edges away from the B's, and at the same time have an edge labeled ISA with the term "enzyme." In the industry, the Life Sciences Division of IBM has created a graph extension of DB2, which allows similar operations, and further allows construction and merging of new graphs. Eckman and Brown [3] provides a detailed overview of the system as applied to the life science domain. The graph transformation operation is used in applications like the food web [5], where a graph like a binary food web graph is converted into an aggregate graph called the trophic food web, where nodes having similar properties are collapsed into aggregate nodes and edges between individual nodes are also aggregated into composite edges between the corresponding aggregate nodes.
3. *Computation of Structural Properties*: A different class of operations focuses on computing aggregate graph properties like the number of cliques or strong components in the graph, as well as node properties like betweenness centrality (see http://en.wikipedia.org/wiki/Centrality for a definition and other similar measures). Epidemiological studies like [2] first compute the largest connected component and then determine nodes having the highest centrality values. Applications like molecular structure analysis [6] identify operations like maximal clique operations over Cartesian products of graphs. While graph matching and searching techniques have started using structural properties of graphs, relatively little work has been done in using data management techniques to facilitate these computations.

Data Management for Large Collections of Graphs

In the case where a science application uses a large collection of graphs, most of the data management issues center around finding common substructures, structurally similar graphs and ways to index graph collections to improve retrieval efficiency. A specific class of techniques focuses on mining graph collections to find frequently occurring substructures for chemical data.

Some Data Management Techniques

- A class of techniques called *descriptor spaces* use the idea of keyword-based text retrieval and adapt it for graphs. If the graph is conceived as a document, a keyword is a characteristic substructure of the graph. Chains of a certain length, cycles up to a certain size and number, tree-like branching fragments etc. are commonly used as descriptors. Wale and Karypis [12] computes acyclic portions of the graph as descriptors for chemical compounds. Once these descriptors are collected, graphs are represented in a vector space where the dimensions of the space are formed by these extracted graph fragments. Given a query graph, a suitable similarity function is used to find a ranked list of similar graphs. A common similarity function is the radial basis function (see http://en.wikipedia.org/wiki/Radial_basis_function for a definition).
- A class of techniques has also been developed to rank matching graphs that are returned from any graph query. One basis of ranking graphs is by the frequency of their occurrence in a collection. A different way, often valued more in biological sciences, is by assigning a statistical significance to each returned graph, and ranking results on the significance value. In systems biology, such techniques have been developed for path ranking [8] and graph ranking [11]. However, the algorithms are not very efficient especially for large graphs. A more efficient graph ranking technique based on statistical significance has been developed for the frequent subgraph problem in [7].

Key Applications

Road networks, biological pathways, social networks, transportation and communication networks.

Graph Database

Peter T. Wood
Birkbeck, University of London, London, UK

Synonyms

Network database; Link database; Semi-structured database

Definition

A graph database is a database whose data model conforms to some form of graph (or network or link) structure. The graph data model usually consists of nodes (or vertices) and (directed) edges (or arcs or links), where the nodes represent concepts (or objects) and the edges represent relationships (or connections) between these concepts (objects). Therefore the nodes are typically labeled with the names of concepts or objects, while the edges are labeled with types of relationships. More elaborate labeling might involve sets of attribute-value pairs being associated with nodes and/or edges. In addition, more complex structures, such as nested graphs or hypergraphs, may also be permitted. On the other hand, the graph model may be restricted to allow only certain types of graph structures, for example, only acyclic graphs or those that have a distinguished root node.

Similar to relational databases, users can query the graph database with a high-level query language. However, such query languages are usually designed in such a way as to make it easy to ask about paths through the graph (or routes through the network) of unspecified length.

Historical Background

Connections between graph structures and databases existed from the earliest data models developed in the 1960s and 1970s. For example, the hierarchical data model viewed data as comprising tree structures, while the network data model viewed data as consisting of linked structures. The entity-relationship model also defines what is essentially a graph-based structure. However, none of these would really be considered as a graph database.

The notion of a graph database evolved from the recognition that, in a number of applications, a *single* relationship type connecting instances of a single concept may itself form a graph structure. Examples include the link structure in hypertext documents, road connections in geographical databases, and, more recently, various pathways in biological databases. In all of these applications, useful queries need to be able to ask about paths through the database, where the length of the required paths is not necessarily predetermined or known beforehand by the user. Such capabilities were not available in the data models mentioned above, nor in the relational model as originally defined.

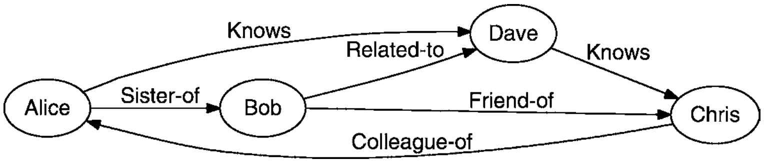
A further requirement of most data models is that data conforms strictly to the structural requirements of the model. Applications in heterogenous data integration and data on the web needed more flexibility, giving rise to the notion of semi-structured data [1] which also conformed to a graph model. Appropriate data models and query languages for graph databases and their applications were investigated mostly in the 1980s and 1990s, with interest having been renewed recently in the context of the semantic web and social networks.

Foundations

A graph database typically comprises a set of graphs. Each graph in the database consists of a set of nodes *N* and a set of edges *E*, with each edge in *E* connecting a pair of nodes in *N*. The edges may be directed or undirected. In the case of the former, an edge is an ordered pair of nodes; in the case of the latter, it is an unordered pair of nodes. Both nodes and edges may have labels associated with them. This is usually done by two functions, one mapping nodes to labels and the other mapping edges to labels. The labels may be simple values, tuples of values, sets of values, and so on.

A very simple example of a directed graph is shown in Fig. 1. Here the node labels denote names of people and the edge labels denote relationships between people, so this graph could represent a tiny fragment of a simple social network. Note that the graph is *cyclic*; for example, Dave knows Chris who is a colleague of Alice who knows Dave.

Given a graph of data like that in Fig. 1, various queries about the data may be relevant. These might be conventional queries such as to find the pairs of people who know each other (Alice knows Dave, and Dave knows Chris), or to find the people who are sisters of friends of Chris (Alice). However, "schema-level"queries may also be needed, for example to find the relationships in which Alice is involved, or to find in what way(s) Alice and Chris are related. Users might also be interested in nodes in the graph that are connected by paths whose lengths are not known a-priori, such as people connected by any sequence of "knows" relationships or any sequence of either "knows" or "friend-of" relationships. In general, users may want to specify a pattern that should be matched by the sequence of edge labels on paths in which they are interested. One way of specifying such a pattern is by using *regular expressions* over the alphabet of edge labels [9]. So for example, the regular expression (know|friend-of)$^+$ specifies sequences of one or more occurrences of edges labeled with either "knows"



Graph Database. Figure 1. A simple example of a graph.

or "friend-of." The use of regular expressions for querying path information has been studied extensively in the area of semi-structured data [1]. XPath, a language for selecting nodes from XML documents, provides a limited form of path pattern specification for querying XML documents, which are essentially trees rather than graphs.

Depending of the application area for which a graph database is being used, there are many other forms of query that may be useful. Examples include shortest path queries (e.g., find the shortest or quickest route from one node to another), subgraph isomorphism queries (the query is viewed as a subgraph whose matches against a graph in the database are to be found), approximate graph matching (where the query may not match a subgraph exactly), finding complete subgraphs (where every node is connected to every other node), queries involving counting the indegree and outdegree of nodes (the number of incoming and outgoing edges, respectively, perhaps to see how "well-connected" a node is), finding the largest common subgraph among a number of graphs, or locating the least common ancestor of two or more nodes (usually in trees).

Unlike in a conventional database, the data in Fig. 1 does not have an explicit *schema* describing it. This lack of explicit *schema* is one of the characteristics of what has been termed semi-structured data [1]. In fact, some schema information is given by the edge labels, so the data are in some sense *self-describing*. However, there is no requirement that the data conform to a set of constraints as usually defined in a schema. Such constraints might assign types to nodes, state what edge labels are permitted, and limit the types of nodes that are permitted to participate in each relationship. Another graph-based model that does not require a schema is RDF (Resource Description Framework), one of the languages proposed for the semantic web. Nevertheless, researchers have defined various forms of schemas for graph databases [3], and RDF does have an associated schema language, although this is used for inference of derived information rather than for validation of RDF graphs.

As in conventional databases, one of the principal concerns in a graph database system is the efficient evaluation of queries. This gives rise to the study of query optimization [5,6] and appropriate index structures for graph data [10,15]. Both of these topics have been studied more extensively in the context of tree-structured XML data.

Some applications require graph structures that are more elaborate than the simple version of nodes and edges described above. For example, hypergraphs, where edges comprise sets of nodes rather than pairs of nodes, have been used to model hypertext [14]. Alternatively, the hypernode model [12] considers nodes that can themselves comprise graphs, thereby providing a useful abstraction mechanism. A different approach to abstraction is provided by so-called blobs that can appear in the hygraphs of the Hy$^+$ system [4]. These blobs comprise sets of nodes and share some similarities with the blobs defined in higraphs [8]. Graphs have also been used as models for object-oriented databases [7].

Key Applications

There are a large number of potential application areas for graph databases. These include hypertext [14] and the Web, discovery of semantic associations in national security (or criminal investigation) applications [13] (also called link analysis), chemical structure modeling, geographic information systems, bibliographic citation analysis, taxonomy and partonomy representation, data provenance graphs, and the semantic web, e.g., RDF [2]. In biology alone [11], there are numerous applications including metabolic pathways, signaling pathways, gene regulatory networks, gene clusterings, and protein interaction networks.

Graph Management in the Life Sciences

Ulf Leser, Silke Trißl
Humboldt University of Berlin, Berlin, Germany

Definition

Graphs play an increasingly important role in many research areas in the life sciences. Especially in systems biology, graphs are used to model the complex temporal and spatial relationships between entities within an organism. For example, graphs are used to model signaling pathways, where nodes are proteins and edges represent the flow of information between proteins. The flow represents physical modifications of the participating proteins, such as the addition or removal of certain chemical groups. Since proteins are often involved in various signaling pathways, one can model the complete signaling management inside a cell as a graph consisting of tens of thousands of nodes and many more edges. However, graphs are also used in less obvious areas. Biological *ontologies* are cycle-free graphs of biological concepts connected by specialization relationships; they are called thesauri in information retrieval. Phylogenetic networks are formed by species and their evolutionary relationships.

Biological graphs are the subject of various types of analyses. *Graph querying* searches for all occurrences of a given (sub-) graph pattern inside a large graph, for instance to find common motifs of gene regulation. *Graph mining* aims at detecting significant patterns inside one or more graphs, for instance finding all graph patterns that are more frequent than expected by chance. *Graph clustering* tries to find dense subgraphs, which potentially can be associated with stable multi-protein complexes.

Formally, a graph G is composed of nodes V and edges E with E $\subseteq$ V×V. Nodes usually represent biological or chemical entities, and edges represent specific types of relationships between those entities. Depending on the application, edges may be directed or undirected, labeled or unlabeled, and weighted or unweighted.

Historical Background

For a long time, graphs have been used in the life sciences only for describing the two- or three-dimensional structure of complex molecules, especially of proteins. In such graphs, nodes represent atoms and edges represent bonds between atoms. However, with the recent massive increase in data production on all levels (including DNA sequences, protein structures, gene expression levels etc.), many more applications of graphs have been suggested. The most prominent types of graphs that emerged are: (i) networks of interacting proteins, (ii) networks of gene regulation, (iii) networks of signal transduction, and (iv) metabolic networks.

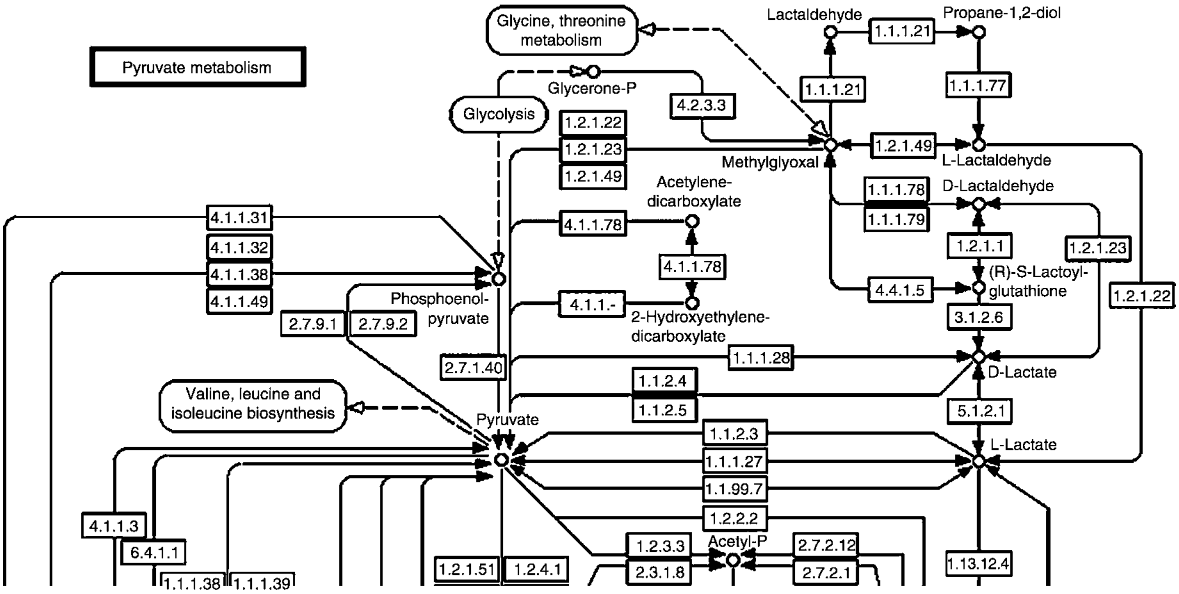
The study of such networks has flourished with the advent of high-throughput techniques to detect the different "types" of edges. The most important ones are the Yeast 2-Hybrid technique for detecting physical interactions between proteins and the co-immunoprecipitation technique for detecting regulation events. The study of the complex interplay of all components inside a cell and across cell boundaries is one of the main goals of modern systems biology. Today, the largest graphs available based on experimental evidence contain in the order of ~15,000 proteins and ~100,000 edges. When predicted information is taken into account, the resulting graphs are much larger, with up to one million nodes and five million edges.

Systems for storing biological networks and their experimental evidence were first developed around 2000, with the notable exception of the KEGG database (first published in 1997) and the EcoCyc system (first published in 1994). With more and more networks being available, various approaches emerged to analyze the information contained in those graphs, for instance to predict further edges based on graphs from evolutionary closely related species, or to predict the function of a protein from its neighbors in a protein-protein interaction network. Only very recently, there have been proposals for developing specific data management solutions that take into account the intrinsic nature of biological graphs.

Foundations

Types and Models of Graphs

The most prominent types of graphs in the life sciences are (i) Networks of physically interacting proteins: Here, nodes represent proteins and edges represent a physical interaction between two proteins. Edges are directed or undirected and may be labeled with the type of the interaction and the evidence for the biological truth of the interaction; (ii) Networks of gene regulation: Nodes represent genes or transcription factors (TF), and edges represent the influence of transcription factors on gene expression. Since transcription factors are also produced by gene expression, TFs also influence the regulation of other TFs. Edges are directed and labeled to reflect a positive or a negative influence; (iii) Signal transduction: Nodes represent proteins or other molecules and edges model the flow of information. Edges are directed and may be labeled; (iv) Metabolic networks (see Fig. 1): Nodes represent arbitrary molecules and edges represent a chemical reaction between the connected molecules catalyzed by enzymes. Edges are labeled and directed



Graph Management in the Life Sciences. Figure 1. Fraction of the Pyruvate Metabolism as represented in the KEGG Database.

or, as many reactions are reversible, bidirectional. In any real system, nodes usually have a wealth of information attached, such name(s), sequences, structures, functions, or experimental values, e.g., values from microarray experiments.

Properties of Biological Networks

A human cell is estimated to contain approximately 20,000 genes that are translated in up to 150,000 different proteins. The same number can also be estimated for other mammals, such as mouse, rat, or chimp. Metabolic networks currently contain up to 20,000 nodes and 40,000 edges, depending on the organism (for bacteria, the networks are much smaller). In contrast, cross-species protein-protein interaction networks currently contain up to 1,000,000 nodes and, depending on the method used to infer the interactions, many more edges.

Biological networks exhibit a specific structure, which is shared by other complex systems, such as the Internet or social networks. Biological networks are scale-free, i.e., the degree distribution follows a power-law. In *scale-free graphs* many nodes have only few edges. These nodes are connected by some nodes that have many edges, called hubs. Scale-free networks can be grown in computer simulations using the so-called preferential attachment, which reflects the evolution of existing biological networks. Preferential attachment means that graphs are grown incrementally. One starts with a small number of nodes and incrementally adds new nodes, which are attached to existing ones, preferably to nodes that are already well connected [1].

Graph Databases

Graph databases in the life sciences can be divided into different categories. First, there are databases about metabolic pathways. The best known sources are KEGG, aMAZE, Reactome, and BioCyc, which contain information added manually by biological experts. For example the reference pathway in KEGG currently (as of 2007) contains 20,000 nodes and 40,000 edges. Secondly, there exist various protein-protein interaction databases, e.g., DIP, MINT, STRING, or PubGene. While the first two databases only accept entries for which strong evidence has been published, STRING also accept entries from less reliable high-throughput experiments. STRING and PubGene also automatically mine the scientific literature for interactions and include those into the database. Therefore the size of the data sets as well as the data quality varies to a great degree.

To exchange data between different databases several standards were established. The “Systems Biology Markup Language” (SBML) and the “BioPAX Data Exchange format” were both designed for the exchange of data in systems biology and especially for biological networks. The "Proteomics Standards Initiative Molecular Interaction XML format" (PSI MI) targets only protein-protein interaction data. For a comparison of the different format standards see [11].

Graph Query Languages

Query languages for graphs are based on the description of properties of subgraphs. Evaluating a graph query on a graph means to find all subgraphs having the specified properties. Numerous different properties may be used, which require the existence of nodes with certain attributes, edges with specific labels, or the existence of paths of various shapes connecting nodes.

The specific difficulty in developing graph query languages is the required support for path queries, i.e., queries over sequences of connected nodes. An exemplary query posed on a biological network might be "Give me all enzymes that affect a compound called glucose in less than five steps and which are also associated with the enzyme 1.6.3.1 in an arbitrary number of steps." Such queries can be solved by either traversing the graph at query time, or by using special graph indexing structures, such as the 2-Hop-Cover. In general, indexing graphs is much harder than indexing trees. Even when graph queries contain no transitive predicates their evaluation is equivalent to solving the subgraph isomorphism problem, which is NP-complete. However, as nodes in biological graphs usually have unique labels, evaluation of queries in real applications is often much less complex.

Examples of graph query languages in biology are the pathway query language [5] and the language described in [2]. Both approaches are implemented on top of a relational database management system.

Graph Mining

The need to analyze graph data has lead to the development of various tools and algorithms that solve specific problems on graphs, of which three are particularly important. (i) Finding cliques or densely connected clusters (quasi-cliques) in a graph of protein-protein interactions is important to identify molecular complexes, which are groups of proteins that together perform a biological function. Jeong and colleagues present different algorithms, for instance based on supermagnetic clustering or a Monto Carlo optimization algorithm [10]; (ii) Subgraphs that are present in the PPI networks of various species (conserved subgraphs) are important evidence towards the evolutionary importance of subnetworks. Algorithms either find perfectly conserved subgraphs or allow insertions and deletions of nodes or edges. One approach based on path alignment is presented in [8]; (iii) Frequent subgraphs in biological networks are believed to hint "building blocks" of the molecular machinery of a cell. A subgraph of a graph is called frequent when it appears more often than expected. An efficient algorithm based on random sampling of isomorphic subgraphs is presented in [14].

Key Applications

Graph-Based Function Prediction

The computer-driven prediction of the biological function of a given protein is a long-standing goal of bioinformatics research, which, until recently, was mostly based on finding similarities between the sequences of different genes or proteins. The possibility to analyze the proteins with which a protein interacts in a cell has added a powerful new source of evidence for function prediction. It has, for instance, been shown that proteins in densely connected regions of a protein-protein-interaction network very often share the same biological function. Furthermore, the fact that two proteins interact with the same other proteins increases the likelihood that these two proteins share a biological function. This interaction can happen within a species, or can be transferred from orthologous (i.e., highly similar) proteins in other species. A survey on those methods has appeared in [8].

Managing Biological Ontologies

Biological ontologies are structured sets of concepts. Usually, concepts have a name, a textual description, and are related to each other through ISA (generalization/specialization) or PART-OF relationships. Prominent examples are the Gene Ontology (for describing the function and location of genes) and the Mammalian Phenotype Ontology (for describing phenotypes of mammalians). Naturally, an ontology may be seen as a graph, where the concepts are nodes and the relationships are edges. Ontologies form trees or directed acyclic graphs. Therefore, many approaches to the management, analysis, and visualization of ontologies use a graph-based framework. For instance, the semantic similarity between two concepts is often computed by finding the least common ancestor of the two concepts in the ontology [6]. In the same spirit, the semantic similarity between two genes based on all their assigned concepts may be computed by comparing the two subgraphs formed by the concepts of the genes and their ancestors in the ontology. Such techniques are often used to score the functional coherence of groups of genes, for instance, whose gene expression react in a similar way under external stimulus.

Management of Phylogenetic Trees

Phylogenetic trees are used to describe the relationship between different species. The trees may be rooted or not and usually are unweighted. Leaf nodes represent different species and inner nodes stand for common, often unknown ancestors. Phylogenetic trees are constructed using one or more common features from the species, usually a gene whose genetic sequence varies slightly in different species. Since there are various algorithms for constructing phylogenetic trees using different features, very often contradicting trees emerge. Recently, tree banks have been proposed as special applications for managing and searching phylogenetic trees. A particular problem is to find for a given query tree those trees in a database of phylogenetic trees that are most similar to the query. This requires a tree distance measure and a search procedure (see for instance, [13]).

It is more and more acknowledged that trees are inappropriate for modeling certain effects in evolution, such as plant hybridization or horizontal gene transfer. This results in efforts to develop algorithms for the inference of phylogenetic networks, i.e., graphs where one species can have two or more ancestors. An interesting method based on a Maximum Parsymony approach to network reconstruction is presented in [3].

Visualization of Biological Networks

Visualization tools for biological networks must address several issues. First of all, they must be able to display the graph using suitable layout algorithms. In addition, these tools must provide visualization of attached information, e.g., name of a node, its cellular location, or results of high-throughput experiments. Several tools were specifically developed for this purpose. A well known tool is Cytoscape, a Java-based open source tool that can display large networks and can be extended using plug-ins. Further tools are Pathway Tools, Pathway Studio, or Ospey, which both also allow various kinds of network analysis. For a review on visualization tools for biological networks see [12].

Future Directions

Systems biology will be a major research area in the life sciences in the coming years. Since it focuses on the interplay of chemical entities in cells, it builds on graphs in a very fundamental manner. Therefore, the importance of graphs in the life sciences is expected to grow further in the near future. This will also bring a steep increase in the size of graphs under study, as more and more experimental data become available. Since, for many applications also the inclusion of predicted edges perfectly makes sense, already now graphs may contain up to several hundreds of thousands of edges. It is therefore foreseeable that studies that address interaction data from many species will have to cope with millions of objects in the near future.

Technically, relational databases nowadays build the backbone of most graph management systems. However, a graph may also be modeled using the *Resource Description Framework* (RDF), an underlying technology of the *Semantic Web*. Therefore, query languages for RDF might be a natural choice for also analyzing biological graphs. However, the current proposals lack the advanced graph search features required in the life sciences. The development of new graph query languages, possibly including certain types of simple graph analysis predicates, will remain an important topic.

Graph Mining on Streams

Andrew McGregor
Microsoft Research, Silicon Valley, Mountain View, CA, USA

Synonyms

Graph streams; Semi-streaming model

Definition

Consider a data stream $A = \langle a_1, a_2,\ldots,a_m\rangle$ where each data item $a_k \in [n] \times [n]$. Such a stream naturally defines an undirected, unweighted graph $G = (V, E)$ where

$$V = \{v_1,\ldots,v_n\} and$$
$$E = \{(v_i, v_j) : a_k = (i,j) \text{ for some } k \in [m]\}.$$

Graph mining on streams is concerned with estimating properties of G, or finding patterns within G, given the usual constraints of the data-stream model, i.e., sequential access to A and limited memory. However, there are the following common variants.

Multi-Pass Models: It is common in graph mining to consider algorithms that may take more than one pass over the stream. There has also been work in the *W-Stream* model in which the algorithm is allowed to write to the stream during each pass [9]. These *annotations* can then be utilized by the algorithm during successive passes and it can be shown that this gives sufficient power to the model for PRAM algorithms to be simulated [8]. The *Stream-Sort* model goes one step further and allows *sorting passes* in which the data stream is sorted according to a key encoded by the annotations [1].

Weighted, Dynamic, or Directed Graphs: For many problems it is implicitly assumed that the elements a_k are distinct. When the data items are not distinct, the stream naturally defines a multi-graph, i.e., an edge (v_i, v_j) has multiplicity equal to $|\{k : a_k = (i, j)\}|$. In such a model it would be natural to consider the deletion of edges but this has not been explored thoroughly. Finally, the definition can be generalized to define weighted graphs where a third component of the data item, $a_k \in [n] \times [n] \times \mathbb{R}^+$, would indicate a weight $w_{(u,v)}$ associated with the edge (u,v), or directed graphs.

Adjacency and Incidence Orderings: In some applications it is reasonable to assume that all edges incident on the same node arrive consecutively. This assumption defines the *incidence model*. In the *adjacency model* no such assumption is made.

Historical Background

Graph problems were considered by Henzinger et al. [15] in one of the earliest papers on the data-stream model. Their work considered a variety of problems including pointer jumping problems based on the degrees of various nodes in a directed layered graph. Unfortunately, many of the results showed that a large amount of space is required for these types of problems. Subsequent early work considered counting the number of triangles in a graph [2] and estimating common neighborhoods [3]. Again, a large component of these results were negative. It seemed that more "complicated" computation was not possible in this model using only a small amount of space.

It seems that most graph algorithms need to access the data in a very adaptive fashion. Since the entire graph can not be stored, emulating a traditional algorithm may necessitate an excessive number of passes over the data. This has motivated various specific stream models tailored to processing graphs, including the *Semi-Streaming*, *W-Stream*, and *Sort-Stream* models. The semi-streaming model is characterized by an $O(n$ polylog $n)$ space restriction, i.e., space proportional to the number of nodes rather than the number of edges. For dense graphs this represents considerably less space than that required to store the entire graph. This restriction was identified as an apparent "sweet-spot" for graph streaming in a survey article by Muthukrishnan [17] and was first explored by Feigenbaum et al. [13]. The W-Stream and Stream-Sort models, described earlier, were introduced by Demetrescu et al. [9] and Aggarwal et al. [1] respectively.

Foundations

This section discusses the main upper and lower bounds known for solving graph problems in the data-stream model. The focus is on results for the standard data-stream model (including the Semi-Streaming space restriction) but note that some of the below problems, including testing connectivity, computing shortest paths, and constructing minimum spanning trees, have been considered in the W-Stream and Stream-Sort models [1,9].

Connectivity and Minimum Spanning Trees: Determining whether a graph is connected is a fundamental problem. It can be solved in the semi-streaming model and it can be shown that any one-pass algorithm requires $\Omega(n)$ space [15]. More generally, connectivity is a *balanced property* where a graph property $\mathcal{P}$ is *balanced* if there exists a constant $c > 0$ such that for all sufficiently large n, there exists a graph $G = (V, E)$ with $|V| = n$ and $u \in V$ such that:

$$\min\{|\{v : (V, E \cup \{(u,v)\}) \text{ has } \mathcal{P}\}|,\\ |\{v : (V, E \cup \{(u,v)\}) \text{ has} \neg \mathcal{P}\}|\} \geq cn.$$

It was shown that all balanced properties require $\Omega(n)$ space [12]. This was part of the justification for the semi-streaming space restriction. However, many problems become feasible with $O(n$ polylog $n)$ space such as testing planarity and determining whether a graph is bipartite. Testing higher degrees of vertex-connectivity has also been considered in the semi-streaming model. The below table summarizes the start of the art results for determining if a graph is k-connected, i.e., whether k vertices need to be removed in order to disconnect the graph:

k	Passes	Time (per-edge)	Ref.
1,2,3	1	$O(\alpha(n))$	[12]
4	1	$O(\log n)$	[12]
k	1	$O(k^2 n)$	[18]
k	$k + 1$	$O(k + \alpha(n))$	[18]

where $\alpha(n)$ is the inverse Ackermann function. Lower bounds have also been investigated for k-edge and k-vertex connectivity [15]. Other related results include a semi-streaming, one-pass algorithm for constructing the minimum spanning tree with $O(\log n)$ processing-time per edge.

Distances and Spanners: An undirected graph $G = (V, E)$ naturally defines a distance function $d_G : V \times V \rightarrow \mathbb{R}$ where $d_G(u, v)$ is the length of the shortest path in G between u and v. The diameter of G is the length of the longest shortest path, i.e.,

$$\mathrm{Diam}(G) = \max_{u,v \in V} d_G(u,v),$$

and the girth of G is the length of the shortest cycle in G, i.e.,

$$\mathrm{Girth}(G) = \min_{(u,v)\in E} [w_{(u,v)} + d_{G\backslash(u,v)}(u,v)].$$

To date, most of the algorithms for approximating quantities related to distance are based on constructing sparse *spanners*, where a subgraph $H = (V, E')$ is an (α, β)-spanner of $G = (V, E)$ if, for any vertices $x, y \in V$,

$$d_G(x,y) \le d_H(x,y) \le \alpha \cdot d_G(x,y) + \beta.$$

Note that constructing an $(\alpha, 0)$-spanner H for an unweighted graph also gives an indication of the girth of the original graph. In particular, if $H \neq G$ then $\mathrm{Girth}(G) \le \alpha + 1$ because there exists $(u, v) \in E(G)\backslash E(H)$ and this must satisfy $d_{G\backslash(u,v)}(u,v) \le \alpha$ if H is an $(\alpha, 0)$-spanner.

The first spanner constructions in the data-stream model were presented in [12,13]. The state of the art construction is due to Elkin [10] who presented a randomized, single-pass algorithm that constructs a $(2t - 1,0)$-spanner for an unweighted graph in $O((t \log n)^{1-1/t} n^{1+1/t})$ space (with probability $1 - 1/n^{\Omega(1)}$). The algorithm processes each edge (u, v) in $O(1)$ expected time and $O(\log d_{u,v}/\log \log d_{u,v})$ worst-case time where $d_{u,v}$ is the sum of the degrees of u and v. The algorithm can be generalized to weighted graphs by rounding edge weights to powers of $(1 + \varepsilon)$, constructing spanners for each edge set with the same weight, and taking the union of these spanners. This adds a factor of $O(\varepsilon^{-1} \log \omega)$ (where ω is the ratio between the biggest and smallest weights) in the space and time complexity and adds a factor of $(1 + \varepsilon)$ in the approximation factor of a distance. Elkin and Zhang [11] present various algorithms for constructing (α, β)-spanners.

If only a specific distance, $d_G(u, v)$, needs to be approximated then it may appear that constructing a spanner for the entire graph is excessive. However, this is not the case. In particular, it can be shown that any single-pass algorithm that approximates the (weighted) graph distance between two given nodes up to a factor t with probability at least 3/4 requires $\Omega(n^{1+1/t})$ space [13]. Furthermore, this bound also applies even with the promise $d_G(u,v) = \mathrm{Diam}(G)$. Consequently approximation via spanners is at most a factor 2 from optimal.

Counting Triangles: As was noted earlier, approximating the number of triangles in an undirected graph was one of the earliest problems considered in the data-stream model [2]. The number of triangles is related to the clustering and transitivity coefficients of the graph. The state of the art [4] are one-pass, randomized algorithms that estimate the number of triangles up to a multiplicative factor or $(1 + \varepsilon)$ with probability at least $1 - \delta$ using space:

Model	Space
Adjacency	$O(\varepsilon^{-2}(1 + T_1/T_3 + T_2/T_3) \log\delta^{-1})$
Incidence	$O(\varepsilon^{-2}(1 + T_2/T_3) \log\delta^{-1} \log n)$

where T_i is the number of node triples upon which the induced sub-graph has exactly i edges. While both of these space bounds can be large (e.g., for dense graphs with few triangles) this compares favorably to the

$$O(\epsilon^{-2}(1 + T_0/T_3 + T_1/T_3 + T_2/T_3) \log \delta^{-1})$$

space required by the naive algorithm that randomly samples node-triples and computes the fraction that are triangles. It can also be shown that any p-pass algorithm determining if the number of triangles is non-zero requires $\Omega(p^{-1}n^2)$ space [2]. There has also been work on estimating the count of larger cycles or cliques. However, it can be shown using results in extremal graph theory and a reduction from the set-disjointness communication problem that any p-pass algorithm that determines if $\mathrm{Girth}(G) \ge g$ requires $\Omega(p^{-1}(n/g)^{1+4/(3g-4)})$ space [13].

A related problem is that of estimating *path aggregates*. Define P_k to be the number of pairs of vertices that are joined by a simple path of length k. For a graph with r connected components, it is possible to approximate P_2 in one pass and $O(\varepsilon^{-2} m(m - r)^{-1/4} \log\delta^{-1})$ space even if edges may be deleted [14]. A space lower bound of $\Omega(\sqrt{m})$ is also known.

BFS trees: A common subroutine in many traditional graph algorithms is that of constructing a breadth-first-search (BFS) tree. Unfortunately it can be shown that computing the first l layers of a breadth-first-tree from a prescribed node requires either $\lceil (l - 1)/2 \rceil$ passes or $\Omega(n^{1+1/l})$ of space [13].

Matchings: Given a graph $G = (V, E)$, the *Maximum Cardinality Matching* (MCM) problem is to find the largest set of edges such that no two adjacent edges are selected. More generally, for an edge-weighted graph, the *Maximum Weighted Matching* (MWM) problem is to find the set of edges whose total weight is maximized subject to the condition that no two adjacent edges are selected. The following semi-streaming algorithms are known for these problems:

Weighted	Passes	Approximation Ratio	Ref.
No	1	0.5	[13]
No	$O_\varepsilon(1)$	$1 - \varepsilon$	[16]
Yes	1	0.179	[19]
Yes	$O_\varepsilon(1)$	$0.5 - \varepsilon$	[16]

The first of the above algorithms is based on a simple greedy approach, i.e., the algorithm always maintains a matching and adds the latest edge if it is not adjacent to a currently stored edge. The third and fourth algorithms are variants on this basic idea. The second algorithm is based on finding augmenting paths for a currently stored matching, i.e., odd length paths with every second edge in the currently stored matching. For each augmenting path found it is possible to increase the size of the currently stored matching by one. It can be shown that if there are only a relatively small number of $O(\varepsilon^{-1})$-length augmenting paths then the current matching is already a good approximation. Alternatively, if there are many short augmenting paths then it is possible to find a constant fraction using a randomized approach.

Degree Distributions and Random Walks: Given a stream of edges with possible duplicates, a natural question that arises is to estimate properties of the underlying graph. Work has been done on estimating the frequency moments, heavy hitter, and range sums of the degrees of this underlying graph [6]. For example, if d_v is the degree of v in the underlying graph then it is possible to approximate $M_2 := \sum_v {d_v}^2$ in one pass and $O(\epsilon^{-4}\sqrt{n}\log n)$ space. Note that many of these problem are solvable using standard techniques if there are no duplicates in the stream of edges. A related problem is to estimate the entropy of a random walk on an undirected, unweighted graph. Here the graph stream is an observation of a random walk whose states are nodes of the graph. There exists a single-pass $O(\varepsilon^{-4}\ \log^2 n\ \log^2 \delta^{-1})$ space algorithm that estimates the entropy of the walk [5]. These algorithms use a combination of algorithms for counting distinct items and the AMS sampling technique. The problem of actually constructing random walks has also been considered [7]. This has applications to estimating the page-rank vector, mixing time and conductance of graphs.

Key Applications

Massive graphs arise naturally in many real world scenarios. Two examples are the *call-graph* and the *web-graph*. In the call-graph, nodes represent telephone numbers and edges correspond to calls placed during some time interval. In the web-graph, nodes represent web pages, and the edges correspond to hyper-links between pages. When processing these graphs it is often appropriate to use the data-stream model. For example, the graph may be revealed by a web-crawler or the graph may be stored on external memory devices and being able to process the edges in an arbitrary order improves I/O efficiency. One of the major drawbacks of traditional graph algorithms, when applied to massive graphs such as the web, is their need to have random access to the edge set. Massive graphs also arise in structured data mining, where the relationships among the data items in the data set are represented as graphs, and social networks.

Future Directions

There are numerous specific open problems that arise from the existing work on graph streams. For example, one could attempt to improve the approximation factors of the known approximate matching algorithms or the space required to approximate M_2. Another idea is to explore distance approximation in multiple passes. While computing exact distance may require many passes this does not preclude the possibility of better approximation with a few additional passes.

Other more general ideas include investigating graph problems in the *probabilistic data-stream model* or the *random-order data-stream model*. In the probabilistic data-stream model, a probability p_e would be assigned to each edge e. The goal of an algorithm would be to estimate the probability that the random graph generated has a certain property given that each edge is present independently with probability p_e. In the random-order data-stream model the assumption, as the name suggests, is that the edges arrive in random order. The goal is to design algorithms that estimate some property with high probability where the probability is defined over both the coin flips of the algorithm and the ordering of the stream.

Workflow on grid

Definition

Built on Internet and World Wide Web, the Grid is a new class of infrastructure which supports coordinated resource sharing and problem solving in dynamic, multi-institutional virtual organizations [6,7]. In a grid architecture, a grid workflow management system is a type of user-level grid middleware. It aims to support large-scale sophisticated scientific and business processes in a variety of complex e-science and e-business applications [7,10,12,15]. Such sophisticated processes are modeled or redesigned as grid workflow specifications at build-time stage by some modeling languages such as Grid Workflow Execution Language (GWEL), Abstract Grid Workflow Language (AGWL), and Martlet [4,5,9]. The specifications normally contain a large number of computation, data and/or transaction intensive activities [1,2,12]. Then, at run-time instantiation stage, grid workflow instances are created [4]. Finally, at run-time execution stage, grid workflow instances are executed by facilitating the super computing and data sharing capability of underlying grid infrastructure to complete the computation, data and/or transaction intensive activities [8,11].

Historical Background

Workflow research can be traced back to mid 1980s. In 1993, the WfMC (Workflow Management Coalition) was founded to promote the research and development of workflow technologies such as workflow reference model [13]. WfMC mainly focuses on business workflows, i.e., workflows in business applications. According to WfMC, workflow is defined as the computerized facilitation or automation of a business process, in whole or part [13].

Grid research can be traced back to mid 1990s. It aims to support the sharing of large-scale distributed and heterogeneous resources in a full and negotiable fashion. Resource providers and consumers can dynamically negotiate the sharing mode and extent. For example, they can share resources in client/server mode at one time, but then change to peer-to-peer fashion at another time [7].

With intensive research poured into grid, around the year 2000 the term grid workflow came into picture. Its basic idea is to execute large-scale complex workflows on grid by facilitating the grid's powerful computing and resource sharing capability. The main motivation for grid workflow is that many grid applications such as climate modeling and disaster recovery simulation often require the creation of a collaborative workflow management system as part of their sophisticated problem solving processes so that scientists and business people who lack the low-level expertise can still utilize the current generation of grid toolkits, such as GT4 (Globus Toolkits), Gridbus, and SwinGrid [7,14,15].

Foundations

Traditionally in the business workflow domain, a business workflow is more about logic between activities rather than computation, data or transaction intensive. As a result, there is a very modest level data transfer between activities. However, a grid workflow is often computation, data or transaction intensive. Hence, the key scientific fundamentals in grid workflow area are how to accommodate huge amount of data transfer, computation and transaction processing, and how to schedule and map to the computation capable resources in the underlying grid infrastructure [4,14]. Research and development are ongoing to tackle the key fundamentals [10,11,14,15].

Key Applications

Grid workflow aims to support large-scale sophisticated scientific and business processes in a variety of complex e-science and e-business applications. Typically, such e-science applications are data and computation intensive such as climate modeling, disaster recovery simulation, earth observation data processing, and high energy physics. Such e-business applications are often transaction intensive such as bank, stock modeling, and insurance processing [7,10,12,14,15].

Future Directions

Since in a business workflow, there is a very modest level data transfer between activities, the interaction between activities is normally performed via a centralized workflow engine. However, a grid workflow is normally computation, data and/or transaction intensive. There is often huge amount of data transfer and processing between activities. Therefore, it is inefficient or even congests the centralized workflow engine if the interaction between activities is performed via the centralized engine. As such, the interaction with data transfer should be decentralized. Peer-to-peer processing becomes an ideal alternative. At the same time, the centralized monitoring and management are still necessary. Thus, in overall terms, a promising future direction can be peer-to-peer based interaction with huge amount of data transfer between activities plus centralized monitoring and management with modest information interaction between activities and the centralized engine [4,14]. In this direction, many issues need to be investigated such as global monitoring of distributed peers, workflow scheduling and modeling in support of data, computation and/or transaction intensity.

Experimental Results

The overall architecture of a grid workflow management system can be depicted in Fig. 1. Currently, many grid workflow management systems such as SwinDeW-G, Kepler, Taverna, Triana, Gridbus Workflow, and Pegasus have been developed to experimentally perform the execution of grid workflows [10,11,14,15]. Among them, SwinDeW-G (Swinburne Decentralised Workflow for Grid) as depicted in Fig. 2 is a peer-to-peer based grid workflow management system which naturally matches to the feature of computation, data and/or transaction intensity [3,14]. a grid workflow is executed by different peers that are distributed in the underlying grid infrastructure. Different peers communicate with each other directly in a peer-to-peer fashion. Kepler supports fault tolerance and p2p or centralised data transfer [10]. Taverna uses centralised approach to support data transfer and retry for fault tolerance [11]. Triana uses p2p for data transfer [15]. Gridbus Workflow also uses a centralised approach for data transfer. Pegasus supports the mapping from abstract workflow specification to specific grid resources for workflow execution [15]. There are more grid workflow management systems which can be referred to [15]. In general, many experimental practices and implementations of grid workflow management are being widely conducted.

Definition

The Grid File is a *multidimensional indexing* scheme capable to efficiently index database records in a symmetrical manner, i.e., by avoiding the distinction between primary and secondary keys. The structure is dynamic and adapts gracefully to its contents under insertions and deletions. A single record retrieval costs two disk accesses at most (upper bound), whereas range queries and partial match queries are also executed efficiently. The Grid File can be thought of as a generalization of dynamic hashing (e.g., *extendible hashing*) in multiple dimensions.

Historical Background

Until the 1980s many file structures for the processing of single attribute queries have been proposed, i.e., queries on the primary key or any secondary key for which a corresponding index has been built. Multi-attribute queries are the ones where the user seeks objects that satisfy constraints (such as equality or range) on several attributes. Such queries can be executed by accessing all the corresponding indices (if they exist) and combine the partial results, or resort to sequential scanning.

To speed up the processing of multiple attribute queries, a better solution is to create an index that leads the search directly to the objects of interest. Such an index can be designed if a data record with k attributes is envisioned as a point in a k-dimensional space. A multi-attribute range query would then be a hyper-rectangle in this k-dimensional space and the answer to it would be all points inside this rectangle. Access methods that can handle multidimensional points are called *Point Access Methods* (PAMs). In 1975, Bentley proposed such a basic PAM, which is called the k-dimensional tree or k-d tree [2]. The Grid File is yet another structure designed to handle similar cases, proposed by Nievergelt, Hinterberger, and Sevcik in 1984 [10]. Since then, several variations have been proposed in the literature in an effort to optimize its space and time performance behavior.

Foundations

The Grid File can be viewed as an access method comprising of two separate parts: (i) the *directory*, and (ii) the *linear scales*. To illustrate this, assume that an index is to be constructed on the *Employee* file using two attributes, say *salary* and *dept* (extension to more dimensions is straightforward). The Grid File imposes a grid on the two-dimensional attribute space. Each cell in this grid corresponds to one data page. The data points that "fall" inside a given cell are stored in the cell's corresponding page. Each cell must thus store a pointer to its corresponding page. This information is stored in the Grid File's *directory*. However, cells that are empty do not use a page. Rather, two or more cells can share a page (i.e., point to the same page). The grid adapts to the data density by introducing more divisions in areas where there are more points.

The information of how each dimension is divided (and thus how data values are assigned to cells) is kept through *linear scales*. There is one linear scale per dimension (indexed attribute). Each linear scale is a one-dimensional array that divides the values on a particular dimension in such a way that records (points) are uniformly distributed across cells. An example of a Grid File on the "Dept" and "Salary" attributes appears in Fig. 1.

Searching for a record with given attribute values involves two operations: (i) the Grid File's directory is searched to locate the cell that the record is hosted in, (ii) the cell's pointer is followed to access the corresponding data page (say *A*), and (iii) the record is searched only in data page *A*. If the record is found in *A* then the search terminates successfully, otherwise the search for the specific record is unsuccessful (i.e., the record does not exist). The Grid File can also address multi-dimensional *range queries* by selecting the appropriate cells from each dimension's linear scale. For example, such a query may ask for all employee records with the *salary* attribute ranging between 10K and 40K and the *dept* attribute ranging between 2 and 6. Again, the first step examines the directory and determines the cells that are intersected by the query range in both attributes, then the corresponding pointers to data pages are collected and finally the data pages are examined for relevant records. The accessed cells may also contain some records outside the query range. These records are eliminated from further consideration and they are not returned as part of the query answer.

Inserting a new record in this method is straightforward. First, the two linear scales are searched so as to map the record's *salary* and *dept* attribute values in each dimension. This mapping provides a cell in the directory. This cell is then accessed and using its pointer, the appropriate page, say *A*, for the new record is found. If this page has enough space to accommodate the new record, the insertion process is complete. Otherwise, a new page *B* is allocated. If page *A* was pointed to by more than one cell, the pointers of these cells are rearranged such that some will point to page *A* and some to page *B* (and the records of page *A* are redistributed accordingly between *A* and *B*). If page *A* was pointed by a single cell and overflows, a reorganization of the Grid File is needed. This reorganization will expand the directory and the scales by introducing a new column (or row) of cells.

In the sequel, the insertion process is illustrated by an example given in Fig. 2 White dots correspond to existing records, whereas black dots are used to indicate new records being inserted to the Grid File. Assume that each data page can host at most three records. Practically, this number is larger in real applications and depends on the size of the data page and the number of attributes. Assume that initially the Grid File is empty (does not contain any records). The first three records can be easily accommodated in the single data page *A*pointed by the single cell of the directory (corresponding to the whole data space), as illustrated in Fig. 2(a). The next inserted record is *d*. However, the new record cannot be hosted by data page *A* because its capacity is exceeded. Therefore, another data page *B* is allocated and records are distributed to the two data pages as it is shown in Fig. 2 (b). The next two insertions for records *e* and *f* do not cause any reorganization since the new records can be easily accommodated in the corresponding data pages pointed by the cells, as illustrated in Fig. 2(c). Finally, the insertion of record *g* causes an overflow in data page *A*. The corresponding cell is split again using the other attribute and one more data page is allocated and records are distributed accordingly. The final shape of the Grid File is given in Fig. 2(d).

Grid File (and Family). Figure 1. A Grid File.

Deletions are also supported, but they are handled differently. Initially, the deleted record is located using the directory and the corresponding data page is determined. If the record is found, it is deleted from the data page. Instead of overflowing, data page deletions may cause the underutilization effect, which means that several data pages may contain too few records. Therefore, appropriate merging operations are required to maintain the storage utilization of the Grid File at an acceptable level. For a detailed description of the methods used for merging as well as for splitting, the reader is directed to [10].

The Grid File has a set of nice properties: (i) it is based on simple mechanisms for insertion, deletion, and search; (ii) it guarantees only two disk accesses for exact match queries (one for the directory and one for the data page); and, (iii) it treats all indexed attributes symmetrically which leads to simple directory management policies. However, it has a set of serious disadvantages such as: (i) it introduces a space overhead for the directory, which can be large for high-dimensional spaces, (ii) it has an extra update overhead, since reorganization affects many cells and not only the cell with the overflowing page; and, (iii) it suffers from performance degradation if the attributes are correlated, since the uniform scheme for performing splits is not adequate to guarantee performance efficiency.

Toward improving the behavior of the Grid File several research efforts have been performed. Some of these efforts are highlighted in the following lines. One of the first variations, the BANG File, has been proposed by Freeston [4]. The BANG File is based on a self-balanced tree-based directory, which better reflects changes of the data distribution. To achieve better storage utilization the Twin Grid File has been proposed by Hulflesz, Six, and Widmayer in [5]. The new scheme is as efficient as the original Grid File during range query processing but shows significant improvements regarding storage utilization. Blanken et al. proposed the Generalized Grid File [3], which offers fast access for single attribute queries. The Multilevel Grid File [12] is another research effort to improve the performance of the original structure for exact-match, partial-match, and range queries. This new scheme uses multiple grid levels and succeeds in better directory management and more efficient query processing than the original structure.

In addition to the variations proposed in the literature, there are efforts to use the Grid File in a parallel environment, toward more efficient data management. In [13] the authors study the problem of partitioning a Grid File to multiple disk devices toward more efficient search. When a data page split is performed, the new data page is carefully allocated to a disk. Since disks can be accessed in parallel, several data pages can be read simultaneously during range query processing, offering significant performance improvements in comparison to a single-disk system. More complex queries on Grid Files, like *spatial joins*, have been also parallelized [6] toward reduced query response times. A different approach has been followed by [7]. The authors have proposed a method to load a Grid File in parallel. The data file is initially partitioned to the available processors using dynamic programing and sampling, and then each processor builds its own part of the Grid File.

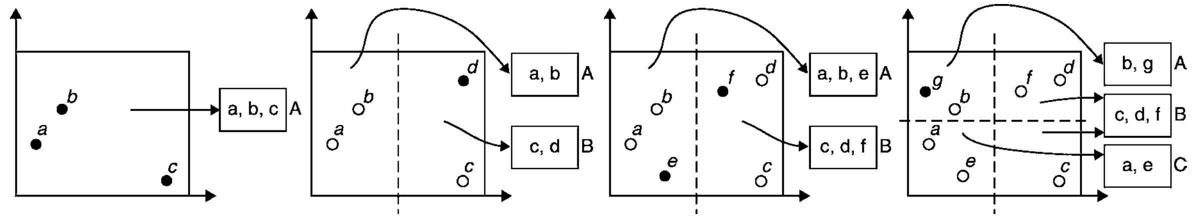
Key Applications

Spatial Databases

In Spatial Databases it is commonly required to join spatial data sets or perform nearest neighbor searches. Several algorithms have been proposed for such operations by adopting the Grid File as the underlying access method [1].

Data Mining

The Grid File can also be used for clustering data sets to identify correlation characteristics of the underlying value space. This stems from its ability to group



Grid File (and Family). Figure 2. Insertions in the Grid File.

patterns into blocks and cluster them with respect to the blocks by a topological neighbor search algorithm [11].

Data Warehouses

The Grid File can be used for efficient data cube storage in warehouses [9].

Future Directions

The Grid File has eventually emerged as a popular theoretical access method. However, although it has been widely honored in theory, in practice it has not been used by the database industry.

Experimental Results

A detailed performance evaluation of the Grid File can be found in [10], where the authors offer a detailed experimental section studying the properties of the structure regarding capacity of data pages, directory size, and evaluation of splitting and merging policies. Moreover, interesting experimental results can be found in [5,3], which compare the original Grid File with the corresponding variation proposed in each work.

GUIs for Web Data Extraction

CAI-NICOLAS ZIEGLER
Siemens AG, Munich, Germany

Synonyms

Visual web data extraction; Wrapper generator GUIs; Visual web information extraction

Definition

While content management systems (CMS) are geared towards *adding* presentational information to relational and structured data from database systems, thus dynamically generating HTML documents, the goal of GUIs for Web data extraction is diametrically opposed: The commonly semi-automatic Web data extraction tools intend to *remove* all presentational information from Web pages, so that only pure structured content remains. The extraction process itself does not address single documents, but template types, such as the product page of an online retailer or the news page template of an online journal. That is, for each template type, one set of extraction rules is generated. These extraction rules are defined in a graphical manner, by selecting the pieces of information that are relevant and by assigning labels to them. To this end, GUIs are used that largely resemble Web browsers, extended by user actions for highlighting and assigning appropriate labels. For instance, for a book seller's product page, such labels were "author," "publisher," "price," or "number of pages."

The learned extraction rules for one document template, called "wrapper" [5], are then applied to those documents that have been generated based on the template type at hand. Referring to the book seller's example, one could now extract structured relational information for each book published on the online retailer's website (see Fig. 1).

Historical Background

GUIs for Web data extraction are advanced variants of wrapper induction systems [5]. Being graphics-oriented, these follow-ups add to the state of art by making the extraction process more user-friendly and easier to manage, saving time and making Web data extraction accessible to a broad range of non-experts as well.

Early Web data extraction systems have been implemented by writing small programs in scripting languages like Perl. These programs, termed screen scrapers, contained manually defined extraction rules that focused on structural communalities of information types to be extracted from the documents, e.g., price, title, and publisher. The huge disadvantage was that people had to look at the very HTML code of documents, comparing several instances of the document template used and trying to figure out which sequences of HTML documents and/or textual content remained static and which appeared dynamic.

The tedious nature of screen scraping favored the naissance of wrapper induction systems. These applications did not require the human to manually write extraction rules, but to label a number of documents and have machines inductively learn the extraction rules. Early seminal systems include Kushmerick's wrapper generator [5], Stalker [6,7], and RoadRunner [4]. The latter system takes HTML documents that have been generated using the same template as input

GUIs for Web Data Extraction. Figure 1. Web data wrappers extract relevant information from Web documents and store the labeled results into data structures, such as XML documents.

and infers a most specific grammar that subsumes the variety of all of them.

At the same time, early GUI-based extraction systems have begun to evolve. NoDoSe [1] extracts information from plain string sources and provides a user interface for instance labeling. Kushmerick proposed Wien [1], a visual support tool, as an extension to his early wrapper system. Wien receives a set of training pages where the user can label relevant information and learn a wrapper.

The shift from research towards commercial tools became manifest with the advent of Lixto [2], which started off as an academic project and transformed into a commercial product soon after. (See *http://www.lixto.com* for details). The early Lixto system allowed the user to mark relevant, information-bearing passages in a browser-like window, assign labels to these passages, e.g., "price," "manufacturer," etc., test the wrappers on unseen data, and modify the learned extraction rules. Lixto incorporated a system for inductive extraction rule learning based on the ELOG [3] language, which bears traits of both PROLOG and XPATH (see Fig. 2). The extracted and labeled result was written to an XML document.

Complex enterprise-scale commercial solutions have evolved since then, boasting graphical user interfaces that allow for recording HTML form inputs and interaction events in a macro-like fashion, handling dynamic and AJAX-enhanced documents, and creating complex processing and wrapping workflows.

Foundations

With the advent of graphical user interfaces for Web data extraction, the focus of supervised wrapper generation has greatly changed from one relying on inductive machine learning techniques to one that intends to offer the non-expert user a broad range of easy-to-use actions that allow him to specify what he intends to extract in a comfortable and 100% WYSIWYG fashion. The goal is not so much the use of intelligent techniques for the generalization and conjunction of extraction patterns as much more to cover the full content extraction and publication process, by means of an end-to-end lifecycle approach. This includes the easy interfacing to databases for the parameterization of wrapper input data and output storage, the availability of APIs and Web service interfaces in order to embed the extraction process as yet another component or service of a larger Web application infrastructure, as well as the ability to design wrappers that can be re-used as subordinate components in other wrappers.

At the time of this writing, the major vendors of commercial state-of-the-art GUIs for Web data extraction are Kapow (*http://www.kapow.com*), Lixto (*http://www.lixto.com*), Denodo (*http://www.denodo.com*), and Twinsoft (*http://www.twinsoft.fr*). All products offered exhibit a similar look and feel, with an HTML browser window being the central component that all other dialogues and tool frames are clustered around (see Fig. 3).

Typically, the user can indicate regions that contain relevant information by highlighting the respective region with his mouse. Moreover, most GUIs offer the possibility to navigate, in another window, the DOM tree of the HTML document at hand and select the nodes that match the demanded criteria. Next, the user can assign labels to these selected information regions and thus generate extraction rules based on path expressions. Some tools, such as Lixto Visual Developer, attempt to generalize the matching extraction paths in an intelligent fashion, assuming wildcards for appropriate location steps so as to avoid over-fitting [3]. In order to handle Dynamic HTML and cascading stylesheets (CSS), most graphical

extraction systems have a built-in JavaScript interpretation engine. Debugging capabilities are also state-of-the-art, allowing the user to step through the entire extraction process, from the wrapper's entering of the website to the eventual extraction and storage.

Commercial products for Web data extraction have matured over the years and have become user-friendly and extremely powerful tools. From a scientific perspective, though, there is little new technology to discover.

Key Applications

The number of applications for wrapper generation GUIs is rife and extends to all areas where information extraction on the Web is put to use. Integration of Web data is surely the most important application scenario and heavily advertised by solution vendors. However, instead of referring to "integration," the synonymous term "mashup" is used, which hints at the deliberate placement of such tools into the Web 2.0 universe. For instance, the GUIs could be used to create extraction wrappers for news articles from various sources, which are then presented in one page. Another mashup application scenario is the creation of value-added services that exploit heterogeneous information sources: For instance, the implementation of a travel service that acts as meta search engine for other travel search engines, integrates their results into a single list, and enriches each entry by resorting to another wrapper which obtains information for the destination country at hand from encyclopedic websites such as Wikipedia (*http://www.wikipedia.com*).

Definition

A hash function is a well-defined deterministic algorithm that takes as input data of arbitrary length and produces a short fixed-length digital representation of the data, or a digest, as its output. The output of a hash function can serve the role of a digital "fingerprint" of the input data, as an important design property of hash functions is that of collision resilience: two hashes produced on different inputs are very unlikely to result in the same value. Furthermore, given a hash function output, it is normally infeasible to find a (previously unseen) input that matches that output (this property is called preimage resistance).

Key Points

Hash functions have many uses, and in cryptography they are widely used because of their collusion resistance and preimage resistance properties. In particular, hash functions are used to verify integrity of messages and can be used to construct *message authentication codes*. They are also used in many cryptographic protocols and to construct cryptographic primitives (e.g., to construct symmetric encryption schemes and in digital signatures) [4].

The two most commonly used hash functions are MD5 [3] and SHA-1 [1], but a variety of other algorithms is also available. Both MD5 and SHA-1, however, should be used with caution because a recent development of attacks indicate that MD5 is too weak to meet the necessary cryptographic properties and it may become possible to also attack SHA-1 in the near future. SHA-2 [2] is a collection of new hash functions from the SHA family (such as SHA-256, SHA-224, SHA-384, and SHA-512) which were designed by the National Security Agency (NSA) to be a new standard.

Hash join

Definition

The hash join is a common join algorithm in database systems using hashing. The join predicate needs to be an equality join predicate. The classic algorithm consists of two phases: the "build" phase and the "probe" phase. In the "build" phase, the algorithm builds a hash table on the smaller relation, say *R*, by applying a hash function to the join attribute of each tuple. In the "probe" phase, the algorithm probes the hash table using tuples of the larger relation, say *S*, to find matches.

Key Points

The classic algorithm is simple, but it requires that the smaller join relation fits into memory. If there is no enough memory to hold all the tuples in *R*, an additional "partition" phase is required. There are several variants of the classic hash join algorithm. They differ in terms of utilizing memory and handling overflow.

Grace Hash Join The idea behind grace hash join is to hash partition both relations on the join attribute, using the *same* hash function. As the result, each relation is hashed into *k* partitions, and these partitions are written to disk. The key observation is that *R* tuples in partition *i* can join only with *S* tuples in the same partition *i*. If any given partition of *R* can be hold in memory, the algorithm can read in and build a hash table on the partition of *R*, and then probe the hash table using tuples of the corresponding partition of *S* for matches.

If one or more of the partitions still does not fit into the available memory (for instance, due to data skewness), the algorithm is recursively applied. An additional orthogonal hash function is chosen to hash the large partition into sub-partitions, which are then processed as before.

Hybrid Hash Join The hybrid hash join algorithm is a refinement of the grace hash join algorithm which takes advantage of more available memory. To partition *R* (*S*) into *k* partitions, the grace hash join uses one input buffer for reading in the relation and *k* output buffers, one for each partitions.

```
Algorithm 1: Grace Hash Join: R $\bowtie_{r=s}$ S
// partition R into k partitions
foreach R ∈ R do
  read R and add it to buffer page $h_1$ (R);
  flush the page to disk if full;
end
// partition S into k partitions
foreach S ∈ S do
  read S and add it to buffer page $h_1$ (S);
  flush the page to disk if full;
end
// "build" and "probe" phases
for $i \leftarrow 1$ to $k$ do
  foreach R ∈ partition $R_i$ do
    read R and insert into the hash table using $h_2$ (R);
  end
  foreach S ∈ partition $S_i$ do
    read S and probe the hash table using $h_2$(S);
    for matching R tuples, add {R , S} to result;
  end
  clear the hash table and release the memory;
end
```

Suppose there are enough extra memory to hold an in-memory hash table for one partition, say the first partition, of *R*, the hybrid hash join does not write the partition to disk. Instead, it builds an in-memory hash table for the first partition of *R* during the "partition" phase. Similarly, when partitioning *S*, for the tuples in the first partition of *S*, the algorithm directly probes the in-memory hash table and writes out the results. At the end of the "partition" phase, the algorithm completes the join between the first partitions of *R* and *S* while partitioning the two relations. The algorithm then joins the remaining partitions as the grace hash join algorithm does.

Compared with the grace hash join algorithm, the hybrid hash join algorithm avoids writing the first partitions of *R* and *S* to disk during the "partition" phase and reading them in again during the "build" and the "probe" phases.

Definition

Consider a relation *R* with some attribute *A* taking values over domain *D*. A *membership* (or *equality*) *query* retrieves all tuples in *R* with $A = x$ $(x \in D)$. To enable fast processing of such equality selection queries, an access method that can group records by their value on attribute *A* is needed. A hash-based scheme maps the search-key values on a collection of buckets. The bucket to which a value is assigned (mapped) is determined by a function, called the *hashing function*.

Key Points

A major performance goal of a database management system is to minimize the number of I/O's (i.e., blocks or pages transferred) between the disk and main memory when answering a query. To achieve such fast access, additional data structures called access methods (or indices) are designed per database file. There are two fundamental access methods, namely tree-based and hash-based indexing. They differ on the kind of queries that they can efficiently address.

Hash-based indexing does not maintain any ordering among the indexed values; rather it is based on mapping the search-key values on a collection of buckets. Therefore it can only address *equality* (or *membership*) queries. Tree-based indices maintain order and can thus also address range queries.

In database management systems hashing is implemented on disk-resident data (also termed as *external hashing*). Here instead of a slot the scheme uses a *bucket* which is typically the size of a page (or a fixed number of pages) and can thus hold many records. Consider a hashing scheme using *M* buckets. Assume a page can store *B* values. A *hashing function h* is a function that maps *D* to *M* (one example of such function is $h(x) = x \ modM$). To insert a record with search-key x $(x \in D)$, the hashing function $h(x)$ is computed which gives the bucket to store that record. In *static* external hashing, if this bucket has space the record is simply added. If *B* values have already been hashed on this bucket, an *overflow* occurs. An extra page is added (and chained to this bucket) and the new record is stored there.

Given that the number of possible values in domain *D* is typically much larger than *M*, different values can be hashed on the same bucket. Nevertheless, a given hashing function will always hash a given value on the same bucket. Searching for record(s) with a given search-key y (also called *hash-key*) is simple. The hashing function is computed on the *y* and *h(y)* will be the bucket accessed. The record(s) with the requested value will either be found on this bucket or there is no such record in the file. No other buckets need to be searched. Note that searching a hash-based scheme avoids the tree navigation that a tree-index implies. Rather, a hashing function is computed (in main memory) and the only I/O is for bringing in main memory the page(s) of a given bucket.

In static external hashing, the number of buckets is pre-allocated and does not change whether the file is small or large. In contrast, *dynamic* hashing schemes (like *extensible* and *linear* hashing) use a number of buckets that increases/decreases as the size of the indexed file changes by record insertions/deletions.

The cost for updating and querying a hash-based hashing scheme is constant in the expected case (but can be linear in the worst case, for example when most records are mapped to one bucket creating a long overflow chain of pages); its space requirements are linear to the size of the indexed file.

Another hashing related scheme is the Bloom filter, a space-efficient probabilistic data-structure that drastically reducing space by allowing false positives (but not false negatives). For multi-attribute search, the Grid-File has been proposed, which can be considered as an extension of hashing into many dimensions.

Hierarchial Clustering

Maria Halkidi
University of Piraeus, Piraeus, Greece

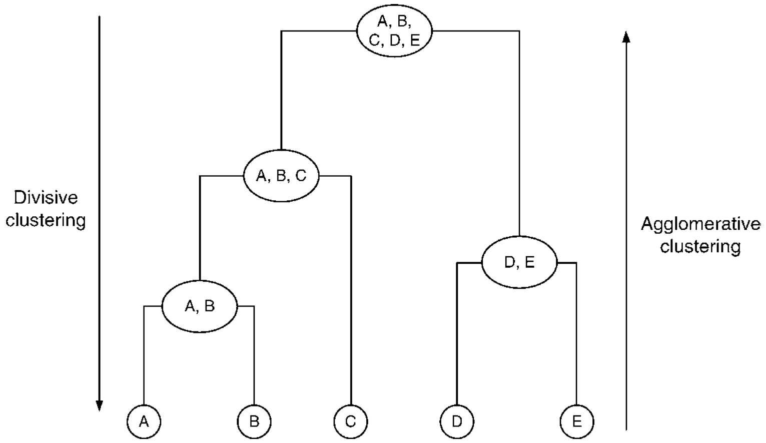
Definition

A *hierarchical clustering* method generates a sequence of partitions of data objects. It proceeds successively by either merging smaller clusters into larger ones, or by splitting larger clusters. The result of the algorithm is a tree of clusters, called dendrogram (see Fig. 1), which shows how the clusters are related. By cutting the dendrogram at a desired level, a clustering of the data items into disjointed groups is obtained.

Historical Background

Hierarchical clustering is one of the main methods used in data mining to partition a data collection. A number of hierarchical clustering algorithms [3] have been developed to deal with various types of data and application requirements. According to the method that the algorithms produce clusters, can be classified into the following categories:

1. *Agglomerative hierarchical clustering.* The algorithms of this category follow a bottom-up strategy and they produce sequence of data clusterings by decreasing number of clusters at each step (resulting in a different tree level). The algorithm starts by considering each data object as a separate cluster. Then, at each step it selects to merge the pair of two closest clusters defining thus a new clustering. To find the similarity of two clusters, one of the following criteria is typically used: *the minimum, the maximum,* or *the average distance* between objects of the two clusters. The merging procedure proceeds iteratively until all objects are in a single cluster or a termination condition is satisfied.
2. *Divisive hierarchical clustering.* These algorithms produce a sequence of clusterings increasing the number of clusters at each step. Contrary to the agglomerative, the divisive algorithms produce at each step a clustering from the previous one by splitting a cluster into two. The algorithm starts with all objects in a single cluster. Then it iteratively subdivides the clusters into smaller ones, until each object forms a separate cluster or a cetrain termination condition is satisfied.



Hierarchial Clustering. Figure 1. Dendogram.

One of the drawbacks of pure hierarchical clustering methods is their inability to perform adjustment when a merge or split decision has been executed. Once a group (cluster) of data is merged or split, the clustering process at the next step will operate on the newly generated clusters. Thus the quality of hierarchical clustering depends on the selection of merge or split point. To tackle this problem the recent studies have focused on the integration of hierarchical agglomerative with multiple phase clustering techniques and relocation methods.

Foundations

This section provides an overview of the main algorithms that are representatives of hierarchical clustering method.

BIRCH [6] uses a hierarchical data structure called CF-tree for partitioning the incoming data objects in an incremental and dynamic way. CF-tree is a height-balanced tree, which stores the clustering features. A clustering feature (CF) is a structure that summarizes statistics for the given sub-clusters. Considering a set $X = \{X_1, \ldots, X_N\}$ of d-dimensional data objects assigned into a sub-cluster C_i, the CF of C_i is defined as $CF = \{N, LS, SS\}$, where $LS = \sum_{i=1}^{N} X_i$ is the linear sum on N objects and $SS = \sum_{i=1}^{N} X_i^2$ is the square sum of data objects.

The BIRCH algorithm is based on two parameters: *branching factor B* and *threshold T*, which refer to the diameter of a cluster (the diameter (or radius) of each cluster must be less than T). It consists of two phases:

1. Scan of the data collection to *build an initial in-memory CF tree*. It can be viewed as a multilevel compression of data that tries to preserve the inherent clustering structure of the data.
2. Application of a clustering algorithm to *cluster the leaf nodes of the CF tree.*

BIRCH adopts an incremental clustering method since the CF tree is built dynamically as new objects are inserted. It can typically find a good clustering with a single scan of the data and improve the quality further with a few additional scans. Thus using a multi-phase clustering BIRCH tries to produce the best clusters with the available resources. However, BIRCH does not always correspond to a natural cluster (as a user may consider it), since each node in CF-tree can hold a limited number of entries due to its size. Also it uses the notion of radius or diameter to control the boundaries of a cluster and thus it tends to favor spherical clusters. Moreover, it is order-sensitive as it may generate different clusters for different orders of the same input data. The computational complexity of BIRCH to cluster a set of n objects is $O(n)$.

CURE [1] is a hierarchical clustering algorithm that combines centroid-based and representative object based approaches. CURE represents each cluster by a certain number of objects that are generated by selecting well-scattered points and then shrinking them toward the cluster center by a specified fraction α. These representative points try to capture the natural schema and the geometry of a cluster. Additionally, moving the dispersed points toward the cluster center by a certain factor (further reffered to as α) the algorithm aims to remove the noise and eliminate the influence of outliers. Significant movements of outliers will eliminate the possibility of merging inappropriate clusters. A high value of α shrinks the representatives closer to the cluster center and thus it favors more compact clusters. On the other hand, a small value of α shrinks more slowly the representatives favoring elongated clusters. Thus CURE efficiently achieves to identify arbitrarily shaped clusters (i.e., non spherical) and it is robust to the presence of outliers.

CURE scales for large databases using a combination of random sampling and partition clustering. The data that are used as input to the algorithm, can be a sample randomly selected from the original data set. The selected data sample is partitioned into a certain number of partitions and then each of the defined partitions is partially clustered. A clustering step follows that aims to generate a hierarchy of partial clusters. The clustering starts considering each data object of input (partial clusters) as a separate cluster and then it iteratively merges the nearest pairs of clusters. The distance between two clusters is defined as the distance between their closest representatives. Thus only the representative points of clusters are used to measure the distance between them. Then the representative points falling in each of the newly defined clusters are moved toward the center of clusters by a shrinking factor α.

The time complexity of CURE is $O(n^2 \, log \, n)$ (where n is the number of data objects to be clustered), while it reduces to $O(n^2)$ in case of low-dimensional data.

ROCK [2], is a robust hierarchical clustering algorithm for Boolean and categorical data. It introduces two new concepts: (i) the *neighbors of a point* and (ii) *links*. The clustering algorithm is based on these concepts to measure the similarity/proximity between a pair of data points. Given a user-defined threshold $\theta \in [0,1]$, a pair of points p_i, p_j are defined to be neighbors if $sim(p_i, p_j) \geq \theta$. Also the term $link(p_i, p_j)$ is defined to be the number of common neighbors between p_i and p_j. The ROCK algorithm exploits the concept of *links* to make decisions about the clusters that will be merged at each step. The similarity between a pair of clusters (C_i, C_j) is measured based on the number of points from C_i and C_j that have neighbors in common. For a pair of clusters C_i and C_j, the algorithm measure the number of cross links between the clusters, that is, $\sum_{pk \in C_i \text{ and } pl \in C_j} links(p_k, p_l)$. Then the *goodness measure* for merging clusters C_i, C_j is defined as follows:

$$goodness(C_i, C_j) = \frac{link(C_i, C_j)}{(n_i + n_j)^{1+2f(\theta)} - n_i^{1+2f(\theta)} - n_j^{1+2f(\theta)}}$$

Then, at a given step, the algorithm selects to merge the pair of clusters for which the goodness measure is maximum.

CHAMELEON [4] is a clustering algorithm that explores characteristics of dynamic modeling in hierarchical clustering. It is an agglomerative hierarchical algorithm that measures the similarity of two clusters based on a dynamic model. Specifically, it defines the clusters in the data set by using a two-phase algorithm. During the first phase, CHAMELEON uses a graph-clustering algorithm to partition a data set into a large number of relatively small sub-clusters. During the second phase, it uses an agglomerative hierarchical clustering algorithm to find the clusters by repeatedly combining together these sub-clusters. The similarity between clusters is determined by looking at their relative *inter-connectivity* and *relative closeness*. The representation of the data objects is based on the widely used k-nearest neighbor graph approach. The vertices of the graph represents data objects, and there is an edge between two vertices if data object corresponding to one of the nodes is among the k-most similar data objects of the other node. Then the algorithm finds the initial sub-clusters using a graph-partitioning algorithm in order to partition the k-nearest neighbor graph of the considered data set into a large number of partitions. During the next phase CHAMELEON switches to an agglomerative hierarchical clustering that combines together these small sub-clusters. It measures the similarity between each pair of considered clusters based on their *relative inter-connectivity* and *closeness of the sub-clusters*:

1. The *relative interconnectivity* between a pair of clusters C_i and C_j is their absolute interconnectivity normalized with respect to their internal interconnectivities. It is given by

$$RI(C_i, C_j) = \frac{\left| EC_{\{C_i, C_j\}} \right|}{\frac{1}{2}(|EC_{C_i}| + |EC_{C_i}|)}$$

   where $EC_{\{C_i,C_j\}}$ is defined as the sum of weights of the edges that connect vertices in C_i to vertices in C_j and EC_{C_i} is defined as the weighted sum of the edges that partition the graph into two roughly equal parts.
2. The relative closeness between a pair of clusters C_i and C_j is the absolute closeness normalized with respect to the internal closeness of the two clusters:

$$RC(C_i, C_j) = \frac{\overline{S}_{EC_{\{C_i,C_j\}}}}{\frac{|C_i|}{|C_i|+|C_j|}\overline{S}_{EC_{C_i}} + \frac{|C_j|}{|C_i|+|C_j|}\overline{S}_{EC_{C_j}}}$$

   where $\overline{S}_{EC_{\{C_i,C_j\}}}$ is defined as the average weight of the edges that connect vertices in C_i to vertices in C_j, and $\overline{S}_{EC_{C_i}}$ is the average weight of edges that partition the graph into two roughly equal parts.

According to the above definition CHAMELEON makes merging decisions. Those pairs of clusters whose relative inter-connectivity and closeness are above some user-specified threshold are merged. CHAMELEON has been proved to be more powerful at discovering arbitrarily shaped clusters than CURE. However, the processing cost for high dimensional data may require quadratic time to the number of processed objects ($O(n^2)$).

The most recent clustering algorithm that combines characteristics of hierarchical clustering and graph-theory is C^2P [5]. It exploits index structures, and the processing of the *Closest-Pair* queries in spatial databases. The algorithm considers that the data points can be organized in an R-tree data structure to facilitate the searching of the nearest representative point. Then the Closest-Pair Query (CPQ) is used to find the closest pair of points from two datasets indexed with two R-tree data structures.

The C^2P algorithm consists of two main phases. The first phase (Phase I) organizes a set of objects into a number of sub-clusters, which are an effective representation of the final clusters. The *Self Semi-Closest-Pair* Query (Self-Semi-CPQ) is used to find pairs of objects (p, p') that belong to a data set S such as $dist(p, p') = min_{\forall x \in S}\{dist(p, x)\}$. The algorithm uses a graph representation that organizes the proximity information computed by the CPQ. Using the Depth-First Search the algorithm can efficiently find the *c* connected components of the graph, which also comprises the sub-clusters of the data set. All objects that belong to the same connected component can be considered as a sub-cluster. When the number of defined sub-clusters, is equal to the required number of sub-clusters the Phase I terminates. Otherwise, the algorithm finds the center of each sub-cluster to represent it. Then the previously described procedure is iteratively applied to the set of *c* cluster centers until the required number of sub-clusters is defined. The second phase is a specialization of the first phase using a different cluster representation so as to produce the finer final clustering. The second phase (Phase II) has as input the centers of sub-clusters defined in Phase I. At each iteration of Phase II, Self-CPQ finds the closest pair of clusters by finding the closest pair among their representatives. Then these two clusters are merged and the *r* data objects, among all the objects of the merged clusters, that are closest to the cluster center are selected as representatives of the new cluster. Using multi-representatives instead of the center, C^2P can effectively capture the shape and size of the clusters. The procedure terminates when the required number of clusters is reached. The above description shows that Phase II operates in a fashion analogous to a hierarchical agglomerative clustering algorithm.

The C^2P algorithm is shown to scale well to large databases. Its time complexity for a dataset with *n* objects is $O(n \log n)$.

Key Applications

Hierarchical clustering has applications in various fields of real world. In biology, it can be used to define taxonomies, categorize genes with similar functionality and gain insights into structures inherent in populations. Clustering may help to automate the process of analyzing and understanding spatial data. It is used to identify and extract interesting characteristics and patterns that may exist in large spatial databases. Also hierarchical clustering is used to discover significant groups of documents on the Web's huge collection of semi-structured documents. This classification of Web documents assists in information discovery.

IMS data model

Definition

The hierarchical data model is based on a view of the application domain (i.e., the *world*) as a hierarchical arrangement of concepts where some concepts exist on their own while the others depend on the former. According to this conceptual model, data are organized into records that are recursively composed of other records. Though this paradigm is fairly common in data structures, the term hierarchical model most generally refers to the *IMS model*, a proprietary DBMS developed by IBM from the sixties that is still widely used.

The IMS model organizes data in tree structures of records augmented with additional links that compensate for the weaknesses of this base model. Data processing itself is hierarchical, starting from the root of a record tree then parsing the dependent records in depth-first, left-to-right, traversal order.

Historical Background

In 1966, IBM started the development of ICS (Information Control System), a data management software for, and with the collaboration of, American Rockwell, then in charge of building the Apollo spacecraft which was to send men on the moon. IBM commercialized ICS in 1969 under the name IMS (Information Management System) [1].

The first version offered storage and processing facilities for data records organized in trees and linearized according to the depth-first traversal order. The data could be stored on tapes and on disks and were processed sequentially. Thanks to the addressability of magnetic discs, IMS was later given direct access (through hashing and B-tree techniques) to root records and therefore was able to support transaction processing.

At that time, tree structures were strictly independent and not connected, a fact that led to much redundancy (a record cannot be stored in two different trees without duplication). IBM then introduced logical relationship types which explicitly linked records from different tree structures. A record could then be shared by several trees.

Later on, IMS was added secondary indexes that provided direct access to non-root records. IMS is now a complex and powerful data management and data communication environment mostly used by data-intensive batch and On-Line Transaction Processing (OLTP) applications.

Though System 2000 (SAS Institute), XML document structures (DTD and XML Schema) and standard file structures can legitimately claim to belong to the hierarchical family, the presentation will focus on the IMS model. Data description and manipulation languages, API and implementation techniques will not be addressed in this chapter. They can be found in references [2, 4–6].

Foundations

Due to historical reasons, in particular the incremental development of IMS, the description of its data structures is generally intricate. In this entry, they will be described by way of a simpler approach based on graph theory. Of course, some very specific details will be ignored.

Graphs and Hierarchies

This section relates database schemas with various kinds of graphs. Due to the limited scope of this chapter, only an intuitive view of the equivalence principles will be developed. Is-a hierarchies, in particular, will be ignored.

Preliminary Definitions

A database schema can be seen as a *multigraph*, whose nodes denote entity types and whose labeled edges represent binary relationship types (*rel-types* for short). This applies to any Entity-relationship schema, provided n-ary rel-types have been replaced by relationship entity types through some kind of *reification* transformation (such as T1 in Fig. 1). In this graph, edges are given a pictorial representation that specifies the functional dependencies that hold in the rel-type according to the usual arrow convention. A single arrow denotes a N:1 rel-type, a double arrow a 1:1 rel-type and a plain edge a N:N rel-type. N:1 and 1:1 rel-types are called *functional* as well as the edges that represent them.

A *hierarchical graph* is a binary graph such that (i) the edges are functional and (ii) the edges define a partial order on the nodes. In practical words, there is no chain of successive N:1 edges the starting and arrival nodes of which are the same node (in short, *no circuit*). Considering a directed edge drawn from *B* (the *many* side) to *A* (the *one* side), *A* is called a *parent* of *B* while *B* is a *child* of *A*. *A* is called a *k-node* if it is the child of *k* parents. A graph is a *n-hierarchy* if none of its nodes has more than n parents. A 0-node is a *root* of its hierarchy. A hierarchy comprises at least one root. A node that is not a parent is a leaf node. A *1-hierarchy* is a set of trees, that is, a forest.

Properties of Hierarchies

1. *Any multigraph can be losslessly transformed into a hierarchy.* Three patterns can prevent an arbitrary schema from defining a hierarchy, namely complex rel-types (n-ary, with attributes), N:N rel-types

and rel-types that form a circuit. N-ary and N:N rel-types can be processed by transformations T1 and T2 respectively (Fig. 1). Any functional rel-type of a circuit transformed through T3 or T4 (Fig. 1) destroys this circuit. All these entity-generating transformations have been proved to preserve the semantics of the schema [3]. A large number of hierarchies can be derived from a definite multigraph.

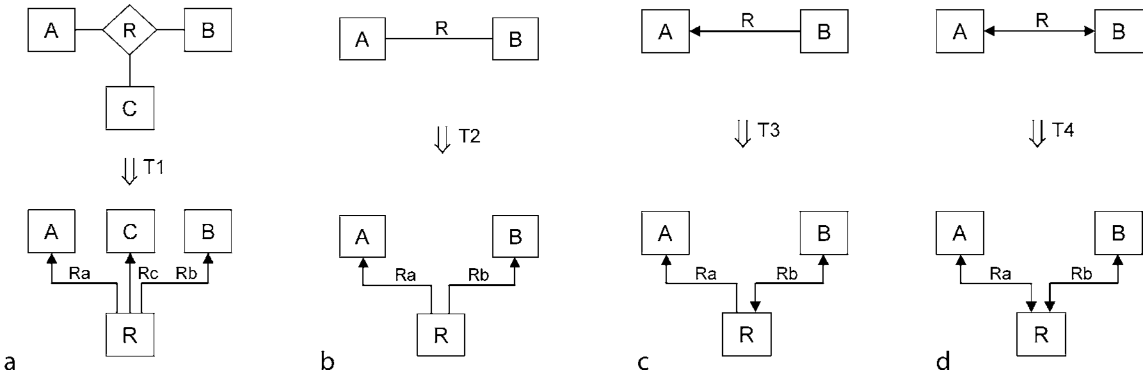
2. *Any hierarchy can be losslessly transformed into a 2-hierarchy.* Transformation T3 shows that *B*, which is the child of *A* in the source schema looses its parent (which becomes its "spouse") in the target schema. A similar transformation exists for 1:1 rel-types (T4). Iteratively applying this transformation produces an equivalent 2-hierarchy from an arbitrary hierarchy (Fig. 2). This process is not unique, so that many 2-hierarchies can be derived from a given hierarchy.
3. *Any 2-hierarchy can be built by superimposing two forests on the same set of nodes.* For each child node of a 2-hierarchy *H* with two parents, one of the parental edges is colored in black and the other one in gray. Each of the remaining edges is arbitrarily colored in black or in gray. The set of nodes together with black (resp. gray) edges form the black (resp. gray) subgraph(s). Each of them is a forest and their union is *H*. There are many ways to color the edges of a given 2-hierarchy (Fig. 3).
4. *Any arbitrary Entity-relationship schema is equivalent to the superimposition of two forests.* Properties 1 and 2 show that any Entity-relationship schema is equivalent to a 2-hierarchy, which in turn can be decomposed into two forests.

IMS Data Structures

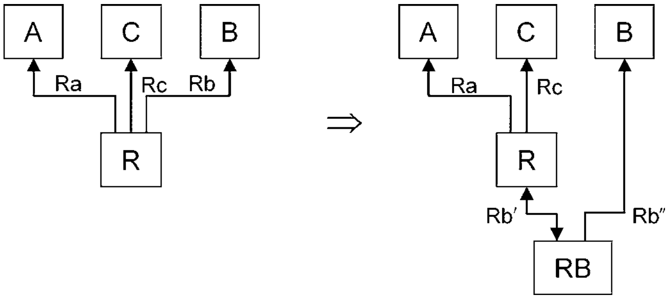
IMS is by far the most popular DBMS based on the hierarchical data model. This section describes its main data structures.

The IMS Global Schema

The global schema of an IMS database can be modeled by a 2-hierarchy formed by two distinct forests. The nodes represent *segment types* (the IMS name for record types) and the edges N:1 *parent-child rel-types*. The black rel-types are called *physical rel-types* and the



Hierarchical Data Model. Figure 1. Transforming arbitrary relationship types into functional relationship types.



Hierarchical Data Model. Figure 2. Reduction of a *n*-hierarchy to a *n-1*-hierarchy by application of transformation T3.

gray ones *logical rel-types* (this naming is purely historical and bears little meaning at this level). According to the *color* of the rel-type that links them, two segment types will be called respectively physical/logical child and physical/logical parent. A rel-type bears no name. If two rel-types link the same pair of segment types, one of them is physical and the other one is logical. IMS schemas use graphical conventions that are close to those of Figs. 1–3 but their edges have no arrow heads (Fig. 4).

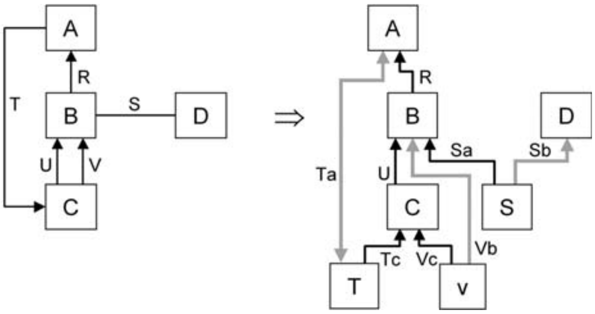
IMS imposes additional constraints of this double tree structure:

1. a logical child must be a physical child; therefore a root segment type cannot be a logical child;
2. a logical child cannot be a logical parent;
3. a logical child cannot have a physical child that is also a logical child.

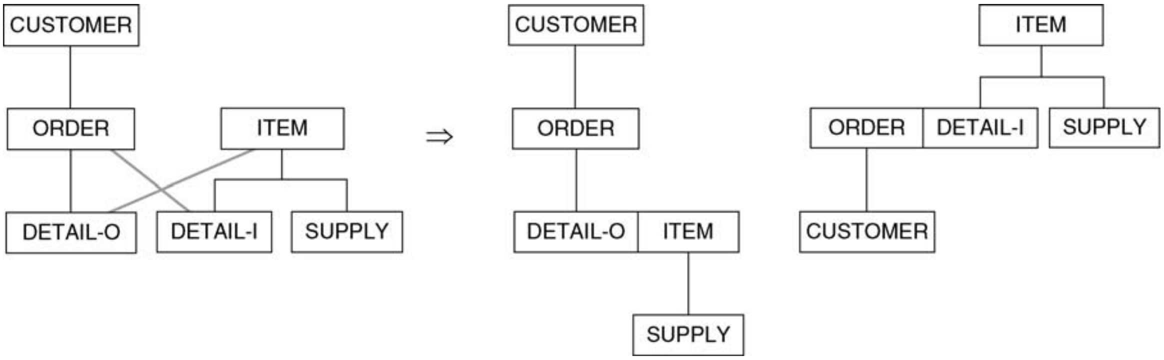
As a consequence, many logical children are leaf physical segment types (Fig. 3 – right).

A segment type has a name and a length. It is made up of fields. A field is an untyped byte string with which a name, a starting position and a length are associated. Some parts of the segment type may be left undefined, while some fields may overlap, which is a way of describing compound fields. In summary, a segment type comprises single-valued mandatory fields that can be atomic or compound.

Now only the physical (black) rel-types are considered. Each 0-node denotes a *physical root segment type*. Each physical root segment type, together with all the segment types to which it is directly or transitively connected through a physical rel-type, form a *physical database*. A root segment followed by all its direct and indirect child segments, in the depth-first order traversal (or preorder), is a *physical record* of this database. A physical database contains a sequence of physical records. One of the fields of the root segment type is the *sequence field* or *key*. No two records can have the same key value and the records are sorted on this key. Direct access is allowed to a record based on its key value. A field of a dependent segment type can also be declared a key. In this case, and unless otherwise stated, the children segments of a definite



Hierarchical Data Model. Figure 3. Any multigraph is equivalent to the superimposition of two forests.



Hierarchical Data Model. Figure 4. Two examples of logical database schemas.

parent have distinct values of their key. The key value of a segment prefixed by the concatenated key of its parent forms its *concatenated key*. The latter identifies this segment in the physical database. The implicit goal of a physical database is twofold:

- historically, a physical record collects all the data that are needed by an application program (process-oriented approach);
- according to the modern way of perceiving a database, a physical record collects the proper data of a major entity of the application domain, independent of the programs that will use it (domain-oriented approach).

An *IMS database* comprises one or several physical databases together with all their logical rel-types. Logical rel-types can be defined between two segment types pertaining to one or two physical databases.

The IMS Logical Database

A *logical database* is a virtual tree data structure derived from an IMS global database schema and tailored to the specific needs of an application program. Its role is similar to that of CODASYL subschemas and of relational views. The main derivation rules are the following:

1. the logical database schema *L* comprises a connected subset of the physical database schema *PH*;
2. the root of *L* is the root of *PH* (secondary indexes allow more flexible structures);
3. the logical parent *P* of a logical child *C* of *L* can be concatenated with *C*, giving fictitious segment type *CP*;
4. all or some of the direct and transitive physical children of *P* can be attached to *CP*;
5. all or some of the direct and transitive physical parents of *P* can be attached to *CP* as fictitious children.

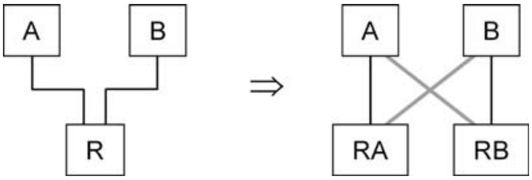
Fig. 4 shows some examples of logical database schemas derived from the same IMS database.

Additional Constructs

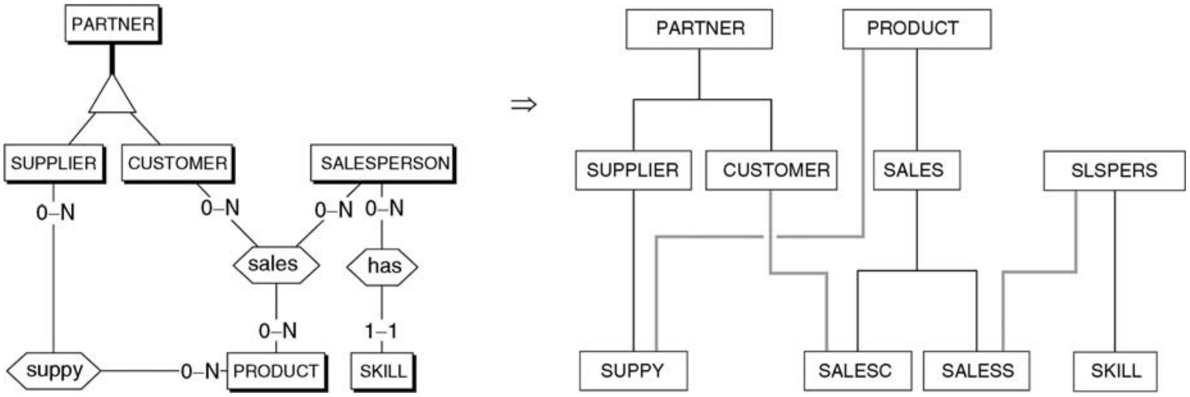
Several other concepts are part of the IMS model and are devoted large sections in usual IMS presentations. They have not been included in the preceding sections inasmuch as they do not contribute to the understanding of the data model but rather appear, according to today's conceptual standards, as minor idiosyncrasies. Two of them are briefly described, namely *segment pairing* and *secondary indexes.*

Segment pairing. Consider the hierarchical schema fragment of Fig. 5 (left), in which *relationship* segment type *R* materializes a N:N link between *A* and *B*. Though this pattern is intuitive from the conceptual and physical points of view, it violates the spirit of tree structures that underlies the hierarchical model of IMS: for bidirectional access, both *A* and *B* must have a normal (physical) child of their own. So, each of them is given a physical child, namely *RA* and *RB*, and it is linked to the other parent through a logical (gray) rel-type. However, since *RA* and *RB* are just clones of each other, they are declared *paired* (Fig. 5 – right). Physically, this pattern can be implemented according to two techniques: with a single child segment type (virtual pairing) or with two redundant child segment types whose contents are synchronized automatically (physical pairing).

Secondary indexes. Physical (or logical) records can be directly accessed through indexing techniques applied to the root sequence field. A secondary index allows additional access based on other fields of the root segment type or access to non root segment types. It is implemented as a special-purpose physical database, the *index database*, made up of one segment type (the *pointer* segment type), that collects all the values of the key fields together with the addresses of the segments that include these values. In fact, this technique is based on two segment types in the indexed database. The indexed values are extracted from the *source segment type* while the access is performed on the *target segment type*. These segment types are generally the same but the former can be the child of the latter. For instance, a secondary index can allow access to *CUSTOMER* segments that have at least one *ORDER* child segment with a given date of order. In addition, a logical database can be built on an index database in such a way



Hierarchical Data Model. Figure 5. Normalization of a *relationship segment type* according to the IMS model.



Hierarchical Data Model. Figure 6. Partial translation of a representative Entity-relationship schema (left) into a hierarchical schema (right).

that its logical root segment type is any, possibly non-root, segment type of the indexed database.

Entity-Relationship to Hierarchical Mapping

As shown above, an Entity-relationship schema can always be translated into an equivalent 2-hierarchy, a structure that is close to the IMS data model. The translation is mostly based on a unique technique, that is, the transformation of a rel-type into a relationship entity type together with two or several functional rel-types. The procedure of deriving an IMS database schema from an Entity-relationship schema can be sketched as follows.

1. Each entity type is represented by a segment type, each attribute by a field and each functional rel-type by a parent-child rel-type (still *uncolored*).
2. A non functional rel-type is transformed into a segment type by techniques T1 and T2.
3. Is-a hierarchies are best transformed through the *one segment type per entity type* technique; subtypes are represented by physical children of their super-type segment type.
4. A circuit is opened by the transformation of one of its links by technique T3 and T4.
5. 1:1 rel-types are implemented as standard 1:N rel-types and controlled by the application programs.
6. The schema is then transformed into a 2-hierarchy by the technique illustrated in Fig. 3. When a segment type has two parents, two techniques can be used. The first one consists in marking one rel-type as *logical.* The second one applies transformations T3 or T4. The latter will be preferred when IMS structural rules concerning logical rel-types are violated or to make the schema more balanced (rel-type *RA* of the schema of Fig. 3 could be processed in the same way as *RB*).

Figure 6 illustrates some of these principles. The IMS global schema comprises three physical databases and three logical relationship types. For readability, segment pairing, according to which each logical child is duplicated as a dependent of its respective logical parent, is not shown.

Key Applications

IMS is a major legacy technology in which many large corporate databases are still implemented. It is mainly used for stable, slowly evolving, batch and OLTP applications, notably in banking companies. The complexity of the hierarchical model and its lack of flexibility in evolving domains make IMS technology less attractive for decisional applications, such as data warehouses.

Hierarchical data summarization

Definition

Given a set of records data summaries on different attributes are frequently produced in data management systems. Commonly used examples are the number of records that fall into a set of ranges of an attribute or the minimum values in these ranges. To improve the efficiency in accessing summaries at different resolutions or due to a direct need for investigating a hierarchy that is inherent to the data type, such as dates, hierarchical versions of data summaries can be used. A data structure or algorithm is labelled as hierarchical if that structure or algorithm uses the concept of subcomponents to systematically obtain conceptually larger components. The method of obtaining a larger component is regularly induced by the user's understanding of the domain, such as dates in a year, as well as the fact that hierarchies can also be created automatically by a set of rules embedded into the system. Thus, rules used in a data structure's creation, e.g., B+-trees, are also considered as a means for hierarchical data summarization. In fact, different variants of popular data structures are used in hierarchical data summarization. Various algorithms for data reduction and aggregation have also adopted hierarchical processing techniques.

Historical Background

From a data structures point of view, foundations of hierarchical data summarization (HDS) techniques can be found in indexing literature for databases. Although many of the indexing techniques, e.g., B+-trees, are used for efficiently selecting records stored on a disk, they can also be considered as hierarchical summaries on large amounts of data. For multidimensional and spatial data, indices such as R-trees and quadtrees can be used for HDS.

Today, many versions of popular indexing techniques that directly target retrieval of summary information exist. Some indices are also used in query optimization due to their HDS capabilities, e.g., using a space decomposition one can guess the number of records in a certain region of data before a join operation can take place. More recently, spatial indexing techniques, for example quadtrees, were developed for distributed settings such as sensor networks for HDS.

Historically, histograms are the most basic structures that could be used for data summarization. They are frequently utilized in query optimization decisions. They are also used in data warehousing. Hierarchical versions of histograms were recently built and are of interest for HDS.

From an algorithmic point of view, techniques such as wavelet transformations, sketches, and data clustering with aggregation, when run in a hierarchical fashion, can be considered as HDS techniques. These techniques are extensively deployed in data management as well as in other fields of computer science over many years.

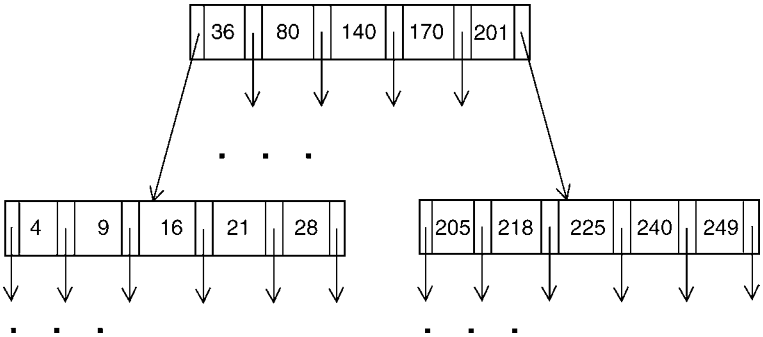
In recent years, for distributed data processing, variants of known algorithms have become popular in HDS. For example, researchers have introduced data aggregation techniques on sensor networks that can be considered as HDS techniques that rely on sketches. In this context, random-tree-based data aggregation algorithms in sensor networks can also be considered as basic HDS techniques. All of these different roots and aspects of hierarchical data summarization are visited in this article.

Foundations

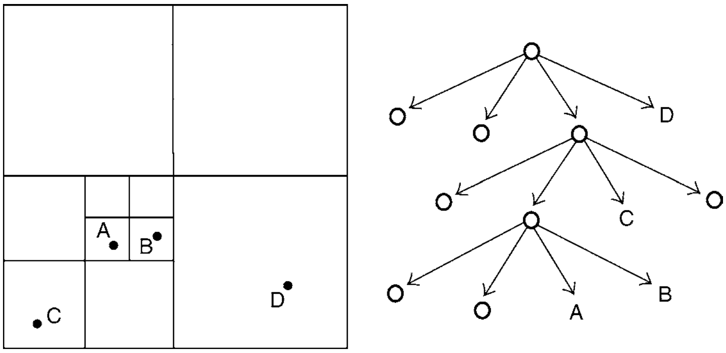
B+-trees are frequently used in databases. A B+-tree is given in Fig. 1 (only some parts of the tree are shown to simplify the presentation). B+-trees are hierarchical structures where internal nodes store keys and the leaf nodes contain the records attached to these keys. Due to their high fanout they are commonly shallow as well as balanced, i.e., in comparison to binary trees. They are used for efficient selection of a range of records from disks. The lowest level contains links between neighboring nodes to allow for sequential access to consecutive data items.

The B+-tree and related data structures can be considered as basic means of keeping hierarchical summary information. Given a fanout for a B+-tree, upper levels of the tree can be easily used for approximate HDS. One can refer to these levels to find the approximate number of items in a range. To make this HDS method more accurate, extra information should be maintained within the tree structure. For example, counts can be kept with each link in this hierarchy [10]. This requires extra space and maintenance costs as each count needs to be stored and updated with insertion and deletion operations. This can cause problems if many levels and nodes need to be maintained per update operation and if updates occur frequently for a given tree. If small errors in counters are tolerated then these overheads can be significantly reduced [3]. Counts form only one form of data summaries. Thus, the idea of counts is extended to other types of data summaries in [4,9].

For a set of queries and objects in space, such as range queries and a set of waterways in a country, spatial data structures can be used to efficiently store the data and answer queries on this data. For example, quadtrees are well-known, space-partitioning based structures. They are used with many different types of spatial data and thus many quadtree variants can be found in the literature. For example, a PR quadtree is given in Fig. 2. In this example, the space is recursively divided into four quadrants until a single data item is left in each quadrant. In Fig. 2, the space partitioning is shown (on the left) with its mapping tree structure (on the right). The positions of all the data items are also stored in the structure (not shown in the figure). Another related space partitioning method is the k-d tree. For k-d trees different dimensions of the



Hierarchical Data Summarization. Figure 1. An example B+-tree.



Hierarchical Data Summarization. Figure 2. An example quadtree with point objects.

underlying space is partitioned in turns at different levels of the tree. (Note that some of these methods are better named as tries, however, due to historical reasons, they are referred to as trees.)

If spatial objects are grouped together using bounding boxes and then a hierarchy of these bounding boxes are created, one can obtain an index called the R-tree. R-trees also have many variants. In comparison to quadtrees, they are commonly more balanced indexing schemes. However, many variants suffer from the fact that multiple bounding boxes, defining the tree nodes, can overlap in space. This nature of R-trees can reduce the pruning capability of this structure as a query may have to investigate multiple branches for the same space. Although disjoint-bounding-box based versions of R-trees exist, these variants could partition the data items into multiple boxes. There are many other spatial indices that are not presented in this article for the brevity of the presentation. The techniques mentioned are used to present HDS methods based on spatial indexing.

Similar to the case in B+-trees, spatial indices can also be viewed as HDS techniques. Moreover, data summaries can be explicitly maintained with these spatial data structures. This information can then be used for query processing, e.g., aggregate queries. Recently, spatial indexing is used in distributed settings for data summarization. For example, [7] introduces fractional cascading in sensor networks. In this approach, each sensor maintains detailed readings that it has obtained as well as data from its nearby neighbors. Information regarding other sensors are not kept as accurately. The space of sensors is partitioned using a distributed quadtree that is overlayed onto the sensor network. The partitioning is done in a similar manner to the PR quadtree example in Fig. 2. With increasing distance to the rest of the sensors in the network (i.e., to faraway quadrants) the amount of data collected from them drops with a function, e.g., a logarithmic function. This paradigm utilized the fact that data and queries in sensor networks are spatially and temporally correlated. Thus, this structure can be used to efficiently serve routing requests using locally summarized data as well as to answer queries. The distributed structure can be seen as a multi-rooted HDS technique as each sensor uses the same summarization scheme independently.

Similar to fractional cascading, [6] introduces the DIMENSIONS system that uses a pyramid-based space decomposition to aggregate and summarize data in a sensor network. Each quadrant finds a "local" leader node for building a distributed pyramid of nodes with their data. Other similar systems are DIM and DIFS systems [8,11] that use spatial indices on sensor networks for processing selection queries as well as resorting to summaries for user interest elimination. In [8] a k-d tree based structure is introduced while [11] introduces a multi-rooted quadtree type for avoiding bottlenecks from having a single root node.

Indices such as quadtrees and R-trees are also utilized in query optimization (e.g., [1]). As they represent summary information about the space they cover, they can easily be used in estimating the runtime costs of a query before it is executed.

In comparison to sophisticated indexing methods, a simple technique for summarizing data is the histogram. Histograms have long been employed in query optimization as they are compact and easy to maintain. With the emergence of data warehousing and On-line Analytical Processing (OLAP) technologies, they have also become crucial components from a new angle in data management. For data sets that explicitly contain hierarchies, e.g., years-months-weeks, histograms can easily be used.

From a processing cost estimation and query optimization point of view, Bruno et al. [5] introduced the concept of nested buckets with histograms. This can be seen as the first form of HDS using histograms. Later, Reiss et al. [14] built on this concept for distributed settings for bandwidth usage reduction. Reiss et al. present hierarchical histograms for aggregate query processing on identification data, i.e., RFIDs.

From an algorithmic point of view many methods that have long been used in approximating and summarizing data can be considered as hierarchical approaches to summarization. For example, wavelet transformations are well-established techniques in signal processing that can be used and considered as HDS methods. The following considers wavelets in the context of spatial data to give a simple example.

A three dimensional (3D) object in space can be approximated using a triangular mesh. One can use different sets of triangles, i.e., small or large, to give a more or less detailed approximation of the surface of the 3D object. Thus, an object can be represented in different resolutions using different meshes. If these meshes are related to each other geometrically, one can easily progressively update the details for this object on demand. Therefore, if M^I denotes a triangular mesh at resolution I, one can then represent an object as a series of meshes, M^0, M^1,...,M^J, where, M^0 is the base mesh and M^J is the final mesh. Figure 3a shows a triangular mesh with one triangle, M^0, (1,2,3), for a 2D object. The triangle is the coarse approximation for the surface of the given circle.

Consider a simple transformation. To obtain a higher resolution approximation of the given surface in the figure, the triangle (1,2,3) is divided into four sub-faces by introducing new vertices (4′,5′,6′), Fig. 3b. The new set of vertices are now displaced to make the mesh better fit to the surface of the circle. The new, finer resolution mesh M^1, is shown in Fig. 3c. This operation can be done recursively and can be represented with a simple transformation function. The coefficients that represent the difference between M^0 and M^1 are $d_4{}^0$, $d_5{}^0$, and $d_6{}^0$. In this simple wavelet transformation, for example, the wavelet coefficient $d_4{}^0$ is obtained by $v_4^1 - \frac{v_1^0+v_2^0}{2} = v_4^1 - v_{4'}^1$. Thus, the wavelet-based decomposition of a mesh M^J produces a base mesh M^0 and the sets, $\{W_0, W_1, \ldots, W_{J-1}\}$, of coefficients. From an HDS point of view, the recursive execution of the above mentioned method can be seen as a hierarchical summarization of a detailed polygonal representation of a complex data set. Various further HDS methods can be derived using the base concept of wavelets. For example, recently, [2] uses wavelets with R-trees to progressively retrieve and refine spatial data from a remote database.

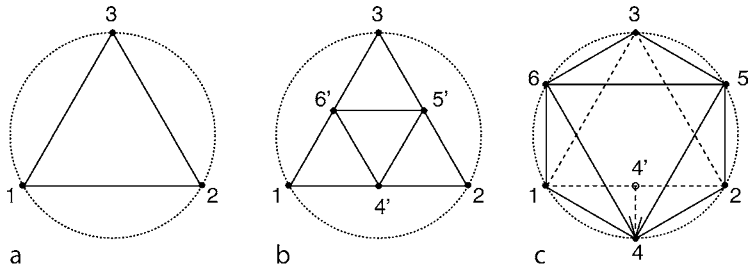
With the emergence of distributed systems such as sensor networks, aggregate query processing itself can now also be considered as a HDS technique. For example, to process an aggregate query in sensor networks, [12] uses a random-tree with in-network aggregation. Each node in this tree can compute an aggregate from its sub-trees, such as a minimum, and then pass this information to the higher-levels of the tree along the data collection path. The base-station, root, can then present a summary of the sensor data to the user.

Random-trees, however, are not robust. A single failure can cause significant problems (especially when a node that is close to the root fails). To address these problems, researchers have been working on multi-path data aggregation methods. In this scheme, multiple reports, due to the wireless coverage advantage in sensor networks, can be sent through different routes for increasing the robustness of the data collection method. However, this can cause deviations in certain aggregation operations, e.g., counts, as the same data is incorporated to the result multiple times. In [13], Nath et al. introduce a sketch theory-based HDS method to address this issue. They map aggregate functions, e.g., counts, to a set of order and duplicate insensitive synopsis generation and fusion functions.

Data clustering forms another area of research that, when applied using data aggregates and hierarchies, can be considered as a source of HDS techniques. For example, [15] introduces the STING system which uses a hierarchy of cells that contain aggregate information about the individual data items. Thus, for many query types, they can resort to these cells, rather than items, to answer queries efficiently. For queries that cannot be answered using summary data, individual data items can still be used as a backup strategy.

Key Applications

Key applications of HDS techniques are aggregate query processing and query optimization. If many queries are interested in retrieving summary data, e.g., aggregate queries, then maintaining a hierarchical summary would be efficient. For example, for data warehousing applications with hierarchical data, the benefits for maintaining a hierarchical summary could be significant. Data summaries have also long been used in query optimization. For example, an optimizer can use HDS techniques for selectivity estimation on attributes.



Hierarchical Data Summarization. Figure 3. A wavelet-based approximation.

Future Directions

There is a significant amount of activity in using data summaries in distributed settings and especially in sensor networks. In addition, with the emerging research directions in location-based services and VANETs, readers may expect to see the use of spatial HDS techniques more frequently. In distributed settings, bandwidth savings on the communication optimization front using HDS could be significant.

Hierarchical Heavy Hitter Mining on Streams

FLIP R. KORN
AT&T Labs–Research, Florham Park, NJ, USA

Synonyms

HHH

Definition

Given a multiset S of N elements from a hierarchical domain D and a count thres hold $\phi \in (0,1)$, Hierarchical Heavy Hitters (HHH) summarize the distribution of S projected along the hierarchy of D as a set of prefixes $P \subseteq D$, and are defined inductively as the nodes in the hierarchy such that their "HHH count" exceeds φN, where the HHH count is the sum of all descendant nodes having no HHH ancestors. The approximate HHH problem over a data stream of elements e is defined with an additional error parameter $\varepsilon \in (0,\phi)$, where a set of prefixes $P \subseteq D$ and estimates of their associated frequencies, with accuracy bounds on the frequency of each $p \in P$, f_{min} and f_{max}, is output with $f_{min}(p) \leq f^*(p) \leq f_{max}(p)$ such that $f^*(p)$ is the true frequency of p in S (i.e., $f^*(p) = \sum_{e \preceq p} f(e)$) and $f_{max}(p) - f_{min}(p) \leq \varepsilon N$. Additionally, there is a coverage guarantee that, for all prefixes $q \notin P$, $\phi N > \sum f(e) : (e \preceq q) \wedge (e \not\preceq P)$, with $\preceq$ denoting prefix containment and $(e \preceq P)$ denoting $(\exists p \in P : e \preceq p)$. Algorithms for maintaining HHHs on data streams aim to minimize space usage as well as update time and possibly query reporting time, while maintaining these accuracy and coverage guarantees.

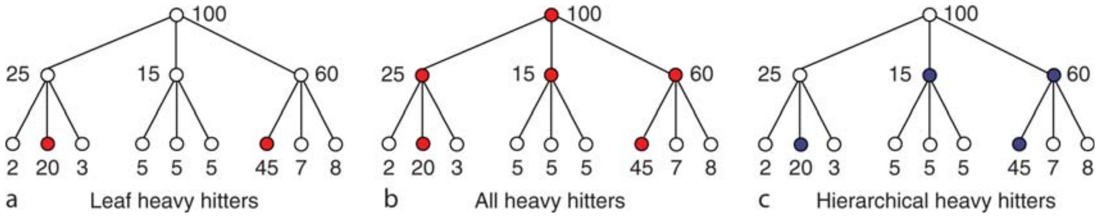
Historical Background

The Hierarchical Heavy Hitters problem was defined in [2] for one-dimensional hierarchical domains, and algorithms for finding online HHHs were given. The multi-dimensional version of the problem was defined and studied in [3,5]. HHHs extend the concept of Heavy Hitters (frequent items), which are all items with frequency at least ϕN, to hierarchical domains; the problem of finding Heavy Hitters on data streams was studied in [6,10,11].

Foundations

Figure 1 shows an example distribution of $N = 100$ items over a simple hierarchy in one dimension, with the counts for each internal node representing the total number of items at leaves of the corresponding subtree. Figure 1a shows that setting $\phi = 0.1$ yields two heavy hitters, that is, items with frequency above 10. However, this does not adequately cover the full distribution, and so one seeks a definition which also considers heavy hitters at points in the hierarchy other than the leaves. A natural approach is to apply the heavy hitters definition at each level of generalization: at the leaves, but also for each internal node. The effect of this definition is shown in Fig. 1b. But this fails to convey the complexity of the distribution: is a node marked as significant merely because it contains a child which is significant, or because the aggregation of its children makes it significant? This leads to the definition of HHHs given a fraction ϕ: find nodes in the hierarchy such that their HHH count exceeds ϕN, where the HHH count is the sum of all descendant nodes which have no HHH ancestors. This is best seen through an example, as shown in Fig. 1c. Observe that the node with total count 25 is not an HHH, since its HHH count is only 5 (less than the threshold of 10): the child node with count 20 is an HHH, and so does not contribute. But the node with total count 60 is an HHH, since its HHH count is 15. Thus the set of HHHs forms a superset of the heavy hitters consisting of only data stream elements, but a subset of the heavy hitters over all prefixes of all elements in the data stream.

One approach to computing HHHs extends the `LossyCounting` algorithm for frequency estimates on streams proposed in [10], which involves maintaining a set of samples from the input stream and associating a small amount of auxiliary information with each sampled item e used for determining the lower- and upper-bounds on the frequency of e. The space usage of `LossyCounting` is $O(\frac{1}{\epsilon}\log(\epsilon N))$, where N is the length of the stream (Better asymptotic space bounds for the heavy hitter problem were obtained in [12], but it was reported in [10] that `LossyCounting` often



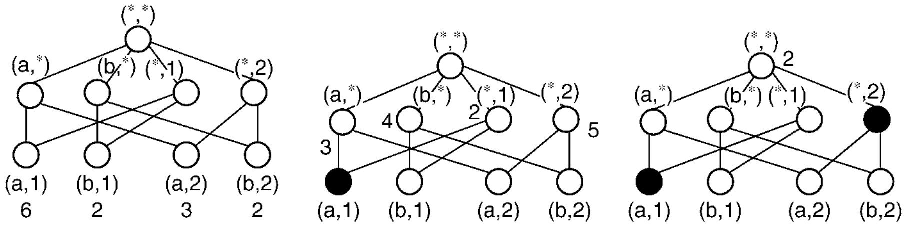
Hierarchical Heavy Hitter Mining on Streams. Figure 1. Illustration of HHH concept ($N = 100$, $\phi = 0.1$).

uses less space in practice). Online algorithms for finding HHHs similarly sample the input stream, but maintain a trie data structure T consisting of a set of tuples which correspond to samples from the input stream and their prefix relationships. There are two classes of these algorithms, which are described as follows.

Using the "Full Ancestry" strategy for finding HHHs, the data structure tracks information about a set of nodes that vary over time, but which always form a subtree of the full hierarchy. It enforces the property that if information about a node in the hierarchy is stored, then all of its ancestors are also stored. When a new node is inserted, information stored by its ancestors is used to give more accurate information about the possible frequency count of the node. This has the twin benefits of yielding more accurate answers and keeping fewer nodes in the data structure (since one can more quickly determine if a node cannot be frequent and so does not need to be stored). Thus, it can be shown that the algorithm requirements are no worse than that required for find heavy hitters at all prefix lengths of maximum length h, which is $O(\frac{h}{\epsilon}\log(\epsilon N))$ based on LossyCounting.

Observe that the previous strategy can be wasteful of space, since it retains all ancestors of the fringe nodes, even when these have low (even zero) count. In the "Partial Ancestry" strategy, such low count nodes can be removed from the data structure, thus potentially using less space. Thus, it is no longer the case that every prefix that is stored has all its ancestors stored as well. Frequency bounds are obtained from the closest existing ancestor of the newly inserted element. While this strategy does not come with space and time guarantees, its performance can be superior to the Full Ancestry strategy in practice [2].

The *Multi-Dimensional Hierarchical Heavy* Hitters problem is to find all items whose count exceeds a given fraction, ϕ, of the total count of all items, after discounting the appropriate descendants that are themselves HHHs. This still needs further refinement, since in this setting nodes can have multiple parents (i.e., the prefix containment forms a lattice rather than a tree), so it is not immediately clear how to compute the count of items at various nodes. In the one-dimensional HHH problem, the semantics of what to do with the count of a single element when it was rolled up was clear: simply add the count of the rolled up element to that of its (unique) parent. In the d-dimensional case, adding the count of the rolled up element to all its d parents runs the risk of overcounting. This can be rectified via careful bookkeeping, as illustrated in the example in Fig. 2. Consider a two-dimensional domain, where the first attribute can take on values a and b, and the second 1 and 2. Figure 2a shows a distribution where $(a, 1)$ has count 6, $(a, 2)$ has count 3, $(b, 1)$ has count 2, and $(b, 2)$ has count 2. Moving up the hierarchy on one or other of the dimensions yields internal nodes: $(a, *)$ covers both $(a, 1)$ and $(a, 2)$ and has count 9; $(*, 2)$ covers both $(a, 2)$ and $(b, 2)$, and has count 5. Setting $\phi = 0.35$ means that a count of 5 or higher suffices, thus there is only one Heavy Hitter over the leaves of the domain, as shown in Fig. 2b. In the multi-dimensional case, since one input item may contribute to multiple ancestors becoming HHHs, each node therefore counts the contributions of all its non-HHH descendants. Figure 2c shows the result on the example: the node $(*, 2)$ becomes an HHH, since it covers a count of 5. $(*, 1)$ is not an HHH, because the count of its non-HHH descendants is only 2. Note that the root node is not a HHH since, after subtracting off the contributions from $(a, 1)$ and $(*, 2)$, its remaining count is only 2. Online algorithms for finding multi-dimensional HHHs in data streams were first proposed and



a Frequency distribution with $N = 13$ b Heavy hitters with $\phi = 0.35$ c HHHs under overlap rule

Hierarchical Heavy Hitter Mining on Streams. Figure 2. Illustration of HHH in two dimensions.

analyzed in [3]; a complete analyis of space and time requirements can be found in [5].

Note that the bounds on the frequency estimates given by online HHH algorithms are for the total frequencies, not the (discounted) HHH counts. By appropriate rescaling of ε, one could find the discounted counts accurately; however, this comes at a high price for the required space, multiplying by a factor proportional to the largest possible number of HHH descendants. It is shown in [9] that such a factor is essentially unavoidable: any approximation guarantee on discounted counts of ϕ-HHHs requires $\Omega(1/\phi^{d+1})$ space. Hence, only guarantees on the total frequencies, not HHH counts, are provided by online algorithms.

Related follow-up work considered the problem of HHH detection without compensating for the count of HHH descendants [13]. The problem therefore simplifies to finding all nodes in the lattice whose count is above the threshold, that is, the heavy hitters over all prefixes. In [1], a sketch-based approach was considered for finding one-dimensional HHHs requiring $O(\frac{h}{\epsilon}\ln(1/\delta))$ space and $O(h\ln(1/\delta))$ time per update.

Key Applications

Hierarchical heavy hitters were implicitly studied in [7,8], to find patterns of traffic (offline) over a multi-dimensional hierarchy of source and destination ports and addresses in what the authors call "compressed traffic clusters." Online HHHs were used for real-time anomaly detection on IP data streams, again based on source and destination ports and addresses in [13]. A DDos detection system based on HHHs was proposed in [12].

Experimental Results

Experiments reported in [5], based on an implementation of HHHs as a User Defined Aggregate Function (UDAF) in the Gigascope data stream system (See [4] for a description of Gigascope UDAFs), show that the proposed online algorithms yielded outputs that were very similar to their offline counterparts and significantly better than that of heavy hitters on all prefixes. The algorithms also require an order of magnitude less space usage while giving competitive performance compared with the heavy hitters approach. The Partial Ancestry strategy is better when space usage is of importance whereas the Full Ancestry strategy is better when update time and output size is more crucial.

Hierarchy

Torben Bach Pedersen
Aalborg University, Aalborg, Denmark

Definition

A *hierarchy* is a structure specifying the containment relationships of a number of *values* (or *nodes* or *elements*). A hierarchy has a single *root* (or *top* or *ALL*) value. A value in a hierarchy may be linked to one or more *children* and a non-top value is linked to one or more *parents*. The links between values thus specify the containment structure. Hierarchies are essential for specifying *dimensions* in multidimensional *cubes*.

Key Points

The notion of a dimension is an essential and distinguishing concept for multidimensional cubes. Dimensions are used for two purposes: the *selection* of data and the *grouping* of data at a desired level of detail. As an example, a three-dimensional cube for capturing product sales may have a Product dimension, a Time dimension, and a Store dimension. The Product dimension captures information about the product sold, such as textual description, color, weight, etc., as well as groupings of products (product groups, product families, departments, etc.). The root value, representing "All products" then has store departments such as "Food" and "Electronics" as children, "Food" has product families such as "Dairy," "Meat," etc., as children and so on.

A hierarchy is typically organized into a number of *levels*, each of which represents a level of detail that is of interest to the analyses to be performed. In the example above, the levels could be ALL Products, Departments, Product Families, Product Groups and Products. The instances of the dimension, e.g., "Food" are typically called *dimension values*. Each such value then belongs to a particular level. The hierarchy is used intensively, e.g., when performing *On-Line Analytical Processing (OLAP)*. Here, data is explored by either moving up in the hierarchy to get a better overview (*rollup*) or moving down in the hierarchy to get more details (*drilldown*).

In some cases, it is advantageous for a dimension to have *multiple hierarchies* defined on it. For example, a Time dimension may have hierarchies for both *Fiscal Year* and *Calendar Year* defined on it. Multiple hierarchies share one or more common lowest level(s), e.g., Day and Month, and then group these into multiple levels higher up, e.g., Fiscal Quarter and Calendar Quarter to allow for easy reference to several ways of grouping. Most multidimensional models allow multiple hierarchies. A dimension hierarchy is defined in the metadata of the cube, or the metadata of the multidimensional database, if dimensions can be shared.

Most models require dimension hierarchies to form *balanced trees*. This means that the dimension hierarchy must have uniform height everywhere, e.g., all departments, even small ones, must be subdivided into Product families (and so on, all the way down to Products). If the hierarchy is not balanced like this, it is referred to as a *non-onto* or *unbalanced* hierarchy [2,3]. Additionally, direct links between dimension values can only go between immediate parent-child levels, and not jump two or more levels. For example, all cities are first grouped into states and then into countries, so cities cannot be grouped directly under countries (as is the case in Denmark which has no states). If such non-immediate links occur in the hierarchy, it is called a *non-covering* or *ragged* hierarchy [2,3], Finally, each non-top value has precisely one parent, e.g., a product must belong to exactly one product group. This may not always be desirable, e.g., it would be natural to put skimmed milk into both the "Diet" and "Dairy" product groups. If the hierarchies do not form balanced trees, this affects the so-called *summarizability* of the data, which means that special care must be taken to obtain correct aggregation results [1].

Indexing for similarity search

Definition

The term High Dimensional Indexing [6,9] subsumes all techniques for indexing vector spaces addressing problems which are specific in the context of high dimensional data spaces, and all optimization techniques to improve index structures, and the algorithms for various variants of similarity search (nearest neighbor, reverse nearest neighbor queries, range queries, similarity joins etc.) for high dimensional spaces. The well-known Curse of Dimensionality leads to a worsening of the index selectivity with increasing dimensionality of the data space, an effect which already starts at dimensions of 10–15, also depending on the size of the database and the data distribution (clustering, attribute dependencies). During query processing, large parts of conventional hierarchical indexes (e.g., R-tree) need to be randomly accessed, which is by a factor of up to 20 more expensive than sequential reading operations. Therefore, specialized indexing techniques for high dimensional spaces include e.g., ideas to scale up sequential scans, hybrid approaches combining elements of hierarchical and scan-based indexes, dimensionality reduction and data compression.

Historical Background

One of the first indexing techniques which is nowadays wide spread in commercial databases is the B-tree. One dimensional data items, so-called keys, are stored in a hierarchical balanced search tree. Since the height of a B-tree is bounded above by $O(\log N)$, the index provides retrieval in logarithmic time complexity. Approaches to extend the B-tree to higher dimensions include the R-tree [12], which has been originally designed for two dimensional spatial objects (polygons). The R-tree consists of two types of nodes: directory and data pages. The directory pages contain rectangles (or hyper-rectangles for higher dimensional data) which are the minimum bounding rectangles (MBR) for the underlaying sub-trees, all the way down to the data pages at the leaves. The hyper-rectangles may overlap, and also the directory does not need to cover the whole data space. This implies that the search is not guaranteed to be restricted to one single path from the root to a leave as in the B-tree. However, since the R-tree is a balanced search tree and algorithms for tree construction and restructuring are designed to minimize overlap, search operations on low dimensional data can be performed in almost logarithmic time. Various variants of the R-tree, such as the R*-tree have been proposed.

Foundations

The central problem of similarity search in high dimensional spaces is the deterioration of the index selectivity with increasing dimensionality of the data space, an effect which is essentially inherent to any kind of index structure. Conventional hierarchical index structures achieve impressive performance gains over sequential scan on low to medium dimensional data by excluding large parts of the data contained in sub-trees which do not need to be visited. Special properties of high dimensional spaces, often subsumed by the term Curse of Dimensionality cause that conventional hierarchical indexes break down in performance on high dimensional data. With increasing dimensionality, more points are situated at the boundaries of the data space and the distances between points assimilate. During retrieval, large parts of the index have to be accessed. In the extreme case of very high dimensionality ($d \rightarrow \infty$) it is therefore obvious that no indexing technique is able to outperform the simplest processing technique for similarity queries, the sequential scan. This fact has been discussed in the context of cost models and of various indexing methods [3,7,19] and has also solicited a scientific discussion of the usefulness of similarity queries per se [6]. However, when, and to which extent the dimensionality curse occurs, depends on the size of the database and various other parameters such as the statistical distribution of the data, correlations between the single attributes (i.e., whether the complete data space is covered or the data reside in an arbitrarily complex subspace), and clustering (i.e., if there are clearly distinguishable groups of similar objects in the database). Many indexing methods can be successfully applied in moderately high dimensions, and many dedicated indexing methods are able to index data spaces of a dimensionality which is considerably higher than expected. In order to achieve the goal of efficiently indexing (moderately) high dimensional spaces, the well-known proposals to high-dimensional indexing all apply a combination of tricks which can be categorized into the following classes:

1. Dimensionality reduction
2. Data compression
3. Optimized i/o schedules (page size optimization and fast index scan)
4. Hierarchy flattening
5. Optimizing of the shape of page regions
6. Clustering

In the following, the most relevant approaches to High Dimensional Indexing are described in chronological order.

TV-Tree

High dimensional real data often exhibits a much lower intrinsic dimensionality. In this case, principal component analysis leads to a few highly loaded components almost totally covering the variance in the data. The TV-tree [16] exploits the fact that those top ranked components are highly selective dimensions for similarity search, whereas the remaining dimensions are of minor importance. Therefore, only the most selective components are used for pruning during query processing. Since irrelevant sub-trees should be excluded as early as possible, these components, called *active dimensions* are placed at the topmost levels of the index. A region of the TV-tree is described by a sphere in the active dimensions. The remaining dimensions may be active at lower levels of the index or not selective enough for query processing. The authors report a good speed-up in comparison with the R*-tree if the data can be effectively reduced by PCA, Fourier transform etc. On uniform or other real data not amenable to PCA, the X-tree outperforms the TV-tree.

The main contribution to High Dimensional Indexing is the implicit dimensionality reduction. Depending on the depth of the tree, only the first few dimensions are considered in the directory structure. Further, in these considered dimensions, the pages are approximated by bounding spheres which are more suitable for Euclidean queries.

SS-Tree

The SS-tree [20] also uses spheres instead of bounding rectangles as page regions. For efficiency, the spheres are not minimum bounding spheres. Rather, the centroid of the stored points is used as center for the sphere and the radius is chosen such that all objects are included. The region description consists of the centroid and the radius and thus allows efficient pruning. The SS-tree is suitable for all kinds of data distributions and outperforms the R*-tree by a factor of 2, which is mainly due to the fact that spherical page regions are, as mentioned, more suitable to support Euclidean queries. In addition, the algorithms for tree construction and maintenance are highly efficient and also very effective for low to medium dimensional data. On high dimensional data, the SS-tree encounters similar problems as the R-tree family. Compared to the minimum bounding rectangles (MBR) of R-trees, spherical page regions are even more difficult to split in an overlap-free way. This problem is tackled by the SR-tree [15] which uses a combination of a rectangle and a sphere as page region.

X-Tree

In contrast to the TV-tree and the SS-tree, the X-tree [5] is a high-dimensional index structure which is more closely related to the R-tree, and, in particular, to the R*-tree. It is the first technique which introduces the ideas of flattening the hierarchies of the directory and of enlarging the sizes of directory pages, but in contrast to the techniques described in the next section, this idea was not inspired by a cost analysis but simply from the observation that it can be difficult to split directory nodes (particularly of the higher directory levels) in an overlap-free way. The regions of the child nodes of such directory nodes are axis-parallel rectangles, which have, themselves, been created in a recursive process of splitting. Typically, only the first split in the split history of the child nodes is a good split decision for the parent node. Therefore, each directory node stores this split history of its children and, thus, tries to imitate the splits of its children. If this imitation would result in an unbalanced tree, the split is avoided and, instead, a so-called supernode is created, i.e., a node with an enlarged size and capacity.

Cost Model Based Optimization Techniques

In [3,7], a cost model for vector space index structures with particular emphasis on high dimensional spaces was proposed. The main idea is to estimate the average size of a page region and of a query and to form the Minkowski sum of these two geometric objetcs which has been shown to be a measure of the probability of a page access. To take effects in high-dimensional spaces into account, two concepts were additionally included into the cost model, *the boundary effect* and *the fractal dimension*. The boundary effect means that for high-dimensional spaces typically large parts of a query sphere and of the Minkowski sum are outside the covered data space. The fractal dimension covers the sparsity of the data space. Typically, a high dimensional space is not uniformly and independently in all dimensions covered by data objects. Rather, some of the attributes are dependent on each other, and, therefore, only subspaces of lower dimensionality (not necessarily linear subspaces) are populated. The intrinsic dimensionality of the data can be formalized by the fractal dimension.

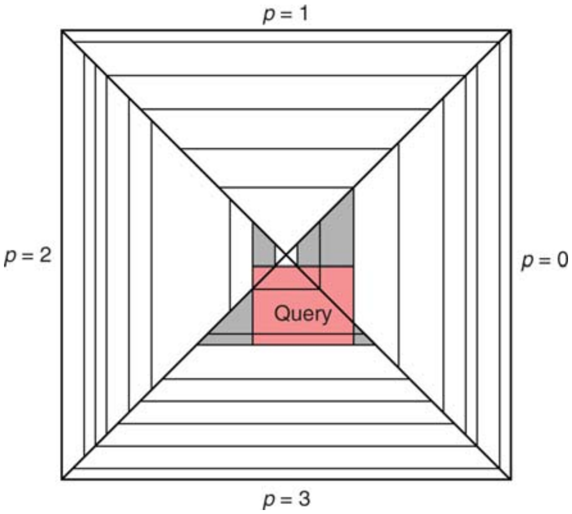
It is important to optimize various parameters of an index using a cost model in order to make it competitive. For instance, in [8], it was proposed to optimize the page size of data pages of the index according to the cost model. To do this automatically is particularly important because data sets with a large intrinsic dimensionality cause scanning of large parts of the index. If small page sizes (such as 4 KB) are used in this case, the random accesses cause a large I/O load, and an unoptimized index is much slower than sequential data processing. In contrast, if the intrinsic dimensionality is small, then large page sizes lead to unnecessarily large reading operations. Carefully optimized page sizes outperform sequential scanning and non-optimized indexes for most of the data sets and tie with the competitors in the worst case. The dynamic page size optimization allows the automatic adaptation of the page size even if the data distribution of the data set changes over time. Moreover, it is possible to use different page sizes for different parts of the index structure, if the index stores groups of data with different characteristics.

Another example of the successful application of a cost model is tree striping [4], where the data objects are vertically decomposed into sub-vectors which are stored in separate search trees. The dimensionality of the sub-vectors (and, inversely, the number of index structures to store them) is an optimization task which is important, because the unnecessary decomposition in too many, small sub-vectors causes a large overhead in the final merging of the results, whereas no decomposition or an insufficient decomposition the query processing inside a single index is too expensive due to the curse of dimensionality. Again, a cost model can decide an optimal dimensionality.

Pyramid Technique

The Pyramid Technique [1] is a *one-dimensional embedding technique*, that means, it transforms the high-dimensional objects into a single-dimensional space which can be efficiently indexed using B-trees, for instance. In contrast to most previous embedding techniques which are based on space-filling curves, the Pyramid Technique does not rely on a *recursive* schema of space partitioning. In contrast, the data space is partitioned into $2 \cdot d$ hyper-pyramids which share the origin of the data space (which can be chosen as the center point of the data set) as top point and have each an individual $(d - 1)$-dimensional basis area (cf. the four pyramids in Fig. 1 $p = 0..3$). The pyramids are systematically numbered which forms the first part of the embedding key (a natural number p). The second part is the distance (with respect to the maximum metric) from the origin (a positive real number r). The embedding key can be formed as an ordered pair $k = (p, r)$, or, equivalently, if the maximum of all r-values (r_{max}) is known, one single embedding key

$k' = r_{max} \cdot p + r$ can be formed. In both cases, a d-dimensional range query can be translated into a set of search intervals on the search keys. The number of intervals is at most $2 \cdot d$ because the query object can at most have one intersection with each of the pyramids. Since nearest neighbor queries can be transformed into range queries (which requires a set of at most two one-dimensional ranking processes per pyramid) it is also possible to evaluate nearest neighbor queries. The Pyramid Technique is in general not limited to a particular metric, but the schema of space partitioning makes it particularly suited for queries using the maximum metric. The Pyramid Technique has inspired a number of other techniques such as the Onion Technique [10] or Concentric Hyperspaces [11] and many others which focus on different metrics including the Euclidean metric.



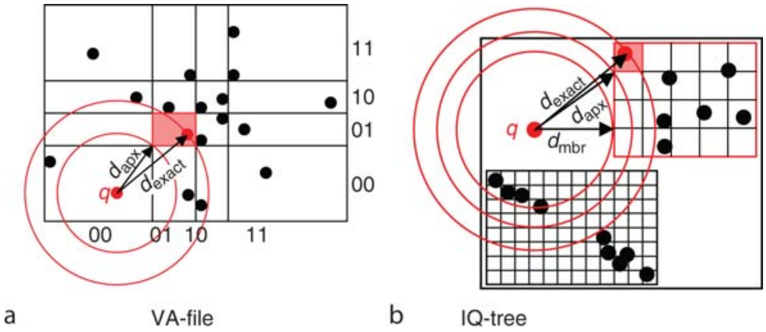
High Dimensional Indexing. Figure 1. Pyramid technique.

VA-File

As an alternative to tree based indexing techniques, the VA-file (Vector Approximation File [6]) has been designed to speed up the linear scan. The basic idea is to store compact approximations of the high dimensional feature vectors in the so-called *approximation file* which is small enough to enable a fast linear scan during query processing. The approximations are derived by dividing each dimension of the data space into equally populated intervals. Thus, the data space is divided into hyper-rectangular cells. Each cell is allocated by a bit string composed of a fixed number of bits per dimension. As approximation for all contained points, this bit string is stored in the approximation file. The principle of vector quantization is visualized in Fig. 2a. In this example, two bits are assigned to each dimension. While the approximation file is scanned, upper and lower bounds on the distances from the query to the approximations d_{apx} are derived and refined. As a result, only very few approximations have to be further checked for answer candidates, which requires random accesses. Extensions to the VA-file e.g., include the parallel VA-file [18] originally designed for parallel nearest neighbor search in large image collections and the kernel-VA-file [13] for complex, kernel supported distance metrics. Due to global quantization, the VA-file is especially suitable for uniformly distributed data. For clustered data, hierarchical techniques show superior performance.

IQ-Tree

With the IQ-tree [2], the idea of quantizing the data using a grid has been integrated into a hierarchical indexing method. In the IQ-tree, every data page has two versions, one which contains the data points in a compressed way, and one which contains the exact



High Dimensional Indexing. Figure 2. Schematic view of vector quantization.

information. In contrast to the VA-file, each page is quantized independently, and this independent quantization gives the structure its name. The quantization grid is not based on quantiles but is a regular grid partition of the rectangular page region. In the IQ-tree, it was shown that quantiles are not necessary because the page regions already serve a sufficient adaptation to the actual data distribution, and storing individual quantiles for each page would result in a prohibitive storage overhead. In contrast to the VA-file, the resolution of the grid is not determined experimentally but dynamically optimized using a cost model. In the IQ-tree, the actual directory is non-hierarchic and contains only one level. Taken together, the IQ-tree consists of three levels, the directory level, the compressed data level and the uncompressed data level. The vector quantization principle is illustrated in Fig. 2b. When considering a query object q and an arbitrary database object, there are two lower bounding approximations of the exact distance d_{exact}, the distance to the minimum bounding rectangle d_{mbr} which can be determined from the directory and the distance to the grid cell (d_{apx}) which can be derived from the compressed data level.

Apart from the idea of independent quantization, the IQ tree contains the idea of the Fast Index Scan (FIS). After scanning of the directory, it can be decided for every page, whether it is certainly needed, certainly excluded, or has some probability to be needed for a given nearest neighbor query. The probability can again be estimated using a cost model. From this probability, a query processing algorithm can derive optimal schedules of pages, i.e., pages which have neighboring disk addresses, can be called in together in a single I/O operation if they have both high probabilities. Depending on data and query characteristics, the pages of the compressed data level can either be accessed by random accesses or in a more sequential style. Another related approach, also designed to allow a flexible adaptation of the height of the directory to the current data distribution is the A-tree [17].

iDistance

iDistance [21] combines a one-dimensional embedding technique with clustering. The embedding is obtained by expressing the similarity ratios in high dimensional space in terms of distances to reference points which can be stored in a single dimensional index. More precisely, the data space is first split into partitions. As a second step, a reference point is selected for each partition. For all data objects the distances to their reference points are stored in a B^+-tree. The performance of the index strongly depends on an appropriate partitioning and on the strategy how to select the reference points. In the original paper, the authors proposed two variants of partitioning: The straightforward approach of equal data space partitioning is especially suitable for uniformly distributed data. For clustered data the partitions can be determined by an arbitrary clustering algorithm, a simple sampling based method is proposed in the paper. Often it is favorable to select the centroid of a partition as reference point, however selecting an edge point may help to reduce overlap.

The most important strategies to cope with the problems of high dimensional spaces can be subsumed by clustering and mapping to one dimensional space. During query processing, the maximum distance between the query point and the points contained in each partition is used for pruning. The single dimensional space of distances can be very efficiently searched supported by the B^+-tree. However, in high dimensional data, the distances to reference points are often not selective and there are no clusters in the full dimensional space such that large parts of the index need to be accessed. But many real world data sets exhibit more selective subspaces. Therefore in [14] a subspace clustering step to identify local correlations in the data is applied before indexing.

Key Applications

High dimensional indexing is important for similarity search systems in various application areas such as multimedia, CAD, systems biology, medical image analysis, time sequence analysis and many others. Complex objects are typically transformed into vectors of a high-dimensional space (feature vectors), and the similarity search thereby translates into a range or nearest neighbor query on the feature vectors. High-dimensional feature vectors are also required for more advanced data analysis tasks such as cluster analysis or classification.

Histogram

Qing Zhang
CSIRO ICT Centre, Herston, QLD, Australia

Definition

Given a relation R and an attribute X of R, the domain D of X is the set of all possible values of X, and a finite set $V(\subseteq D)$ denotes the distinct values of X in an instance r of R. Let V be ordered, that is: $V = \{v_i : 1 \leq i \leq n\}$, where $v_i < v_j$ if $i < j$. The instance r of R restricted to X is denoted by T, and can be represented as: $T = \{(v_1, f_1), \cdots (v_n, f_n)\}$. In T, each v_i is distinct and is called a *value* of T; and f_i is the occurrence of v_i in T and is called the *frequency* of v_i, T is called the *data distribution*. A *histogram* on data distribution T is constructed by the following two steps.

1. Partitioning the values of T into $\beta(\geq 1)$ disjoint intervals (called buckets) – $\{B_i : 1 \leq i \leq \beta\}$, such that each value in B_i is smaller than that in B_j if $i < j$.

2. Approximately representing the frequencies and values in each bucket.

Key Points

Histogram, as a summarization of the data distribution, has been successfully used by the query optimizer in RDBMS for the past few decades. Due to its simplicity and straightforwardness, it is also the most popular data reduction technique for approximately processing range aggregates. However, to find a good histogram, which occupies a reasonable small storage space yet can provide accurate approximations, is not an easy work. The key issues in constructing a histogram are: (i) how to partition the original data into buckets, and (ii) how to approximate the original data in each bucket.

Since a histogram only occupies limited storage space in the system catalog, partition methods study how to effectively partition the original data distribution, under a fixed bucket number, to construct a histogram with good performance. Different partition strategies can greatly influence the histogram's performance. Four basic partition methods, based on different partition goals, are: *Equi-width, Equi-sum, Maxdiff, V-optimal* [3]. Empirical results indicate that in most applications, Maxdiff and V-optimal outperform Equi-width and Equi-sum. V-optimal usually leads to more accurate approximation than Maxdiff does. However, the time complexity on constructing a V-optimal histogram seriously impedes its further application.

Techniques on approximately representing the values and frequencies in each histogram bucket usually adopt the *uniform spread* and *average* frequency assumptions. That is distinct values in a same bucket are assumed to evenly span the bucket and every value has a same frequency, the average frequency of the bucket. More accurate approximation techniques on the values and frequencies have also been proposed in recent years, such as *curve-fitting histogram* [2] and *4-level tree index* [1].

There exist other types of histograms in the literature, such as spatio-temporal histogram, multi-dimensional histogram, etc.

Piecewise-constant approximations

Definition

A B-bucket histogram of length N is a partition of the set $[0,N)$ of N integers into intervals $[b_0,b_1) \cup [b_1,b_2) \cup ... \cup [b_{B-1},b_B)$, where $b_0 = 0$ and $b_B = N$, together with a collection of B heights h_j, for $0 \le j < B$, one for each bucket. On point query i, the histogram answer is h_j, where j is the index of the interval (or "bucket") containing i; that is, the unique j with $b_j \le i < b_{j+1}$. In vector notation, χ_S is the vector that is 1 on the set S and zero elsewhere and the answer vector of a histogram is $\vec{H} = \sum_{0\le j<B} h_j \chi_{[b_j,b_{j+1})}$.

A histogram, $\vec{H}$, is often used to approximate some other function, $\vec{A}$, on $[0,N)$. In building a B-bucket histogram, it is desirable to choose $B - 1$ boundaries b_j and B heights h_j that tend to minimize some distance, e.g., the sum square error $\left\|\vec{A} - \vec{H}\right\|^2 = \sum_i |\vec{A}[i] - \vec{H}[i]|^2$.

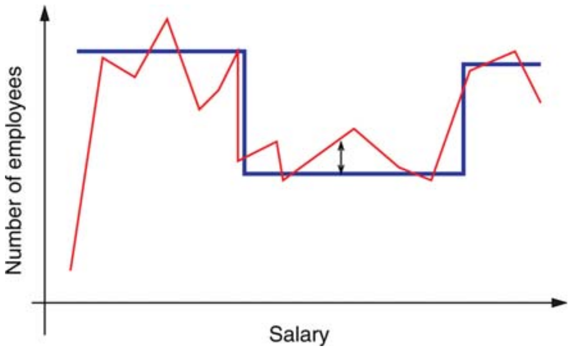
The function $\vec{A}$ may be presented in a stream in one of several ways. In many of these cases, it is infeasible to produce a best histogram; instead, algorithms trade off the representational accuracy of the histogram, the time to process stream items, and the space used.

Historical Background

Fix a universe $[0,N) = \{0,1,2,...,N - 1\}$ of N item types, e.g., salaries. The goal is to summarize a vector $\vec{A} = \langle \vec{A}[0], \vec{A}[1],..., \vec{A}[N-1] \rangle$ over $[0,N)$, in which $\vec{A}[i]$ represents, e.g., the number of employees earning salary *i*. To summarize $\vec{A}$ by a histogram, partition the interval of indices (salaries) into *B* subintervals and represent $\vec{A}$ on interval *j* as a single number, h_j, according to some specification. For example, h_j might be the total number $\vec{A}[b_j,b_{j+1})$ of items in the range (the total number of employees whose salary *i* falls in the range $[b_j,b_{j+1})$). Alternatively, h_j might be the normalized expression $\frac{\vec{A}[b_j,b_{j+1})}{b_{j+1}-b_j}$ (the *average height* of $\vec{A}$), which conveys the same information but is more natural below to analyze, because the average height is the optimal value of h_j from the perspective of sum-square-error; it will be the focus of this article. See Fig. 1.

Classical histograms include equi-width histograms, in which the *j*th boundary b_j, for $0 \le j \le B$, is fixed to be (the integer nearest to) jN/B. In many circumstances, average height of all buckets can be found efficiently and straightforwardly when the bucket boundaries are fixed in advance.

Letting the bucket boundaries vary, however, can lead to more accurate histograms. This generalization can be handled [5] by dynamic programming when time and space polynomial in *N* is allowed; i.e., for non-streaming data. For each $j \le N$ and each $k \le B$, find the best *k*-bucket histogram on $[0,j)$; this clearly suffices to find the best *B*-bucket histogram on $[0,N)$. Observe that the best *k*-bucket histogram on $[0,j)$ consists of a $(k-1)$-bucket histogram on $[0,i)$ for some $i < j$ followed by a single bucket $[i,j)$ with height $\frac{\vec{A}[i,j)}{j-i}$; this naturally leads to an algorithm that uses time $O(N^2B)$, assuming one can find $\vec{A}[i,j)$ in constant time. The latter task may be accomplished by computing, in time and space $O(N)$ during preprocessing, the *prefix array* $\vec{P}$ for $\vec{A}$ defined by $\vec{P}[0] = 0$ and $\vec{P}[j] = \vec{P}[j-1] + \vec{A}[j-1]$ for $j > 0$. Thus $\vec{P}[j] = \vec{A}[0,j) = \vec{A}[0] + \vec{A}[1] + \ldots + \vec{A}[j-1]$ so that $\vec{A}[i,j) = \vec{P}[j] - \vec{P}[i]$ can be computed in constant time.



Histograms on Streams. Figure 1. A histogram of three buckets for a frequency vector of data (jagged polygon). Often the goal is to minimize the sum of square between the data vector and histogram by choosing the bucket boundaries and heights for the histogram.

Many variations of histograms are possible, including equi-depth histograms, also known as quantile summaries, in which bucket boundaries are fixed so that the total number of items in each bucket is equal. For example, a 4-bucket equi-depth histogram has boundaries at the 25th, 50th, and 75th percentiles. Neither quantiles nor other variations will be discussed further in this article.

A fuller history of histogram research is available [4].

Foundations

There are several ways in which a data vector $\vec{A}$ can be presented in a stream; this article discusses two. In the *ordered aggregate* (or *time-series*) presentation, the algorithm receives $\vec{A}[0],\vec{A}[1],\vec{A}[2],\ldots$, in order. In the *turnstile* (or *dynamic*) presentation, $\vec{A}$ is implicit and initially zero. The algorithm receives update commands of the form (i, u), whose semantics is "add u to $\vec{A}[i]$." In general, the update u may be negative or positive. More efficient algorithms are possible if it is known that the updates are positive (or merely that each $\vec{A}[i]$ is never negative); that will not be discussed further here.

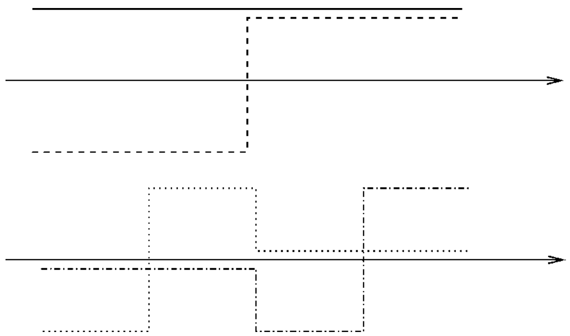
A class of algorithms for building near-optimal histograms relies on the theory of *Haar wavelets*. Assume *N* is a power of 2 (which can be achieved, without loss of generality, by padding $\vec{A}$ implicitly with trailing zeros). A Haar wavelet is either the constant vector $\phi = N^{-1/2}\chi_{[0,N)}$ or a vector of the form

$$\psi_{j,k}(i) = \begin{cases} -\sqrt{2^j/N}, & kN2^{-(j+1)} \le \\ & i < (k+1)N2^{-(j+1)}; \\ +\sqrt{2^j/N}, & (k+1)N2^{-(j+1)} \le \\ & i < (k+2)N2^{-(j+1)}, \end{cases}$$

where $0 \le j < \log_2(N)$ and $0 \le k < 2^j$ are integers. That is, for some scale *j*, divide $[0,N)$ into 2^j subintervals of length $N2^{-j}$. Then $\psi_{j,k}$ takes the value $-\sqrt{2^j/N}$ on the left half of the *k*th interval and takes the value $+\sqrt{2^j/N}$ on the right half. See Fig. 2.

One also writes ψ_ℓ to index all the $\psi_{j,k}$ and ϕ by a single index. A partial Haar wavelet representation is $\Sigma_{\ell\in\Lambda}\langle\vec{A}\psi_\ell\rangle\psi_\ell$, where $\langle.,.\rangle$ denotes the dot product and Λ is a subset of $[0, N)$.

In many streaming situations, it is not possible to find the best *B*-bucket histogram $\vec{H}_{\text{opt}}$ for $\vec{A}$. Instead,



Histograms on Streams. Figure 2. The four coarsest Haar wavelets ϕ,$\psi_{0,0}$,$\psi_{1,0}$, and $\psi_{0,1}$ with normalization modified for visibility.

the goal will be to find a near-best histogram, $\|\vec{H}-\vec{A}\| \le (1+\varepsilon)\|\vec{H}_{\text{opt}}-\vec{A}\|$, where ε is a user-supplied accuracy parameter.

A class of algorithms for building near-optimal histograms efficiently from streaming data proceeds as follows.

1. Find the largest B_1 Haar wavelet terms, where $B_1 \le (B log(N)/\varepsilon)^{O(1)}$. Let $\vec{R}$ be the resulting vector. That is, let Λ_1 be a set of size B_1 consisting of the ℓ's that maximize $|\langle\vec{A},\psi_\ell\rangle|$ and let $\vec{R}$ be $\sum_{\ell\in\Lambda_1} c_\ell\psi_\ell$, where c_ℓ is $\langle\vec{A},\psi_\ell\rangle$ or a close enough approximation. How to find $\vec{R}$ depends on the way that $\vec{A}$ is presented. The representation $\vec{R}$ must be constructible with little space and little per-item time, so that its construction fits within the constraints of a streaming algorithm. Furthermore, a description of $\vec{R}$ has size $|\vec{R}|$ that is small enough so that polynomial time in $|\vec{R}|$ is also within the constraints of a streaming algorithm for the overall problem.
2. Let $\vec{H}_{rob} = \sum_{\ell\in\Lambda_2} c_\ell\psi_\ell$, where Λ_2 is a subset of Λ_1, chosen so that either $\|\vec{R}-\vec{H}_{\text{rob}}\|$ cannot be significantly improved by enlarging Λ_2 within Λ_1 by $\Theta(B\ log(N))$ wavelet terms (if there is such a set Λ_2) or $\Lambda_2=\Lambda_1$ (otherwise). This is done greedily. Let Λ_2 be initially empty. Let Λ^* be the set of $\Theta(B\ log(N))$ indices $\ell \in \Lambda_2 \setminus \Lambda_1$ with maximal $|c_\ell|$; if $\|\Sigma_{\ell\in\Lambda_2\cup\Lambda^*} c_\ell\psi_\ell - \vec{R}\|$ is significantly less than $\|\sum_{\ell\in\Lambda_2} c_\ell\psi_\ell - \vec{R}\|$, then put $\Lambda_2 \leftarrow \Lambda_2 \cup \Lambda^*$ and repeat; otherwise, halt and return the current Λ_2.
3. Let $\vec{H}$ be the best B-bucket histogram representation for $\vec{H}_{\text{rob}}$. This can be done efficiently using dynamic programming, as above, noting that the boundaries of $\vec{H}$ will be among the boundaries of $\vec{H}_{\text{rob}}$. Output $\vec{H}$ as a near-best B-bucket histogram for $\vec{A}$.

In the case of time-series data, the wavelet coefficients can be found efficiently using a structure based on a binary tree in which each leaf corresponds to an input item $\vec{A}[i]$ and each internal node receives inputs denoted x and y from its children, outputs $y-x$ as a wavelet coefficient (up to normalization) and passes $x+y$ as an input to the node's parent. Note that, while reading $\vec{A}[i]$, the algorithm only needs to instantiate nodes on the path from the ith leaf to the root, for a total of $O(log(N))$ space. Each of $O(N)$ nodes performs $O(1)$ work, for a total of $O(N)$ time. The top B_1 wavelet coefficients can be collected from the tree's output stream in time $O(N)$. It follows that the above algorithm, on time-series data, takes total time $c_1N + (B\log(N)/\epsilon)^{c_2}$ and space $(B\log(N)/\epsilon)^{c_3}$, for constants c_1,c_2, and c_3. Using suitable buffering (without significantly increasing the space requirements), the per-item time is $O(1)$.

In the case of dynamic data, updates to $\vec{A}$ positions are transformed into updates to wavelet coefficients of $\vec{A}$ and the large wavelet coefficients are tracked using a sketch-based structure. An update (i,u), with semantics "add u to $\vec{A}[i]$," is regarded for analysis as the vector $u\delta_i$ that takes the value u at position i and zero elsewhere. Using the tree structure of wavelets, it can be shown that, for all i, $\delta_i = \sum_{\ell\in\Lambda_i}\langle\delta_i,\psi_\ell\rangle\psi_\ell$, where Λ_i has size $O(log(N))$ and can be constructed quickly from i. Given update (u,i) to $\vec{A}$, the algorithm quickly forms updates $(u\langle\delta_i,\psi_\ell\rangle,\ell)$ to the vector $\hat{\vec{A}}$ of wavelet coefficients for each $\ell \in \Lambda_i$. This algorithm uses a synopsis data structure, called an "L^2 count sketch," parametrized by N and η, that efficiently supports the following operations on an unordered set S of size N:

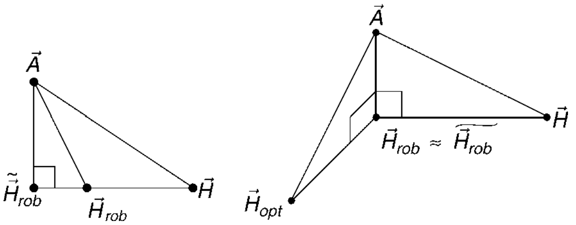
1. UPDATES of the form "add x to a count $\mathbf{C}[i]$ for item $i \in S$."
2. Unparametrized "FIND" queries. The answer is a list containing all j where $C[j]^2 \ge \eta\Sigma_i C[i]^2$.
3. "COUNT" queries about item i, for which the answer is $\tilde{C}[i]$ such that $\left|\tilde{C}[i]-C[i]\right|^2 \le \eta\|C\|^2$.

There are randomized implementations of L^2 count sketches [1,2] that need space $(log(N)/\eta)^{O(1)}$ and time $(log(N)/\eta)^{O(1)}$ for either query. Such an L^2 count sketch with appropriate η at least $(Blog(N)/\varepsilon)^{-O(1)}$ suffices to track the large wavelet terms needed for our algorithm. With appropriate implementations, the algorithm will take space and per-item time $(Blog(N)/\varepsilon)^{O(1)}$, including time to build the histogram completely after each update. (The algorithm depends on a randomized data structure. There is also a cost factor of $O(log\,(1/\delta))$ to achieve success probability $1 - \delta$.)

Correctness of the algorithm depends on which of the two conditions is in force when constructing $\vec{H}_{\mathrm{rob}}$. If $\vec{H}_{\mathrm{rob}} = \vec{R}$, then one can show that the wavelet coefficient magnitudes of $\vec{A}$ decay essentially exponentially. It follows that $\vec{H}_{\mathrm{rob}}$ is a very good approximation to $\vec{A}$, say, $\|\vec{H}_{rob} - A\| \leq \frac{\epsilon}{2}\|\vec{H}_{opt} - A\|$, where $\vec{H}_{\mathrm{opt}}$ is the optimal B-bucket histogram for $\vec{A}$. In that case, since $\vec{H}$ is the optimal B-bucket histogram for $\vec{H}_{\mathrm{rob}}$,

$$\begin{aligned}\|\vec{H} - \vec{A}\| &\leq \|\vec{H} - \vec{H}_{rob}\| + \|\vec{H}_{rob} - \vec{A}\|\\ &\leq \|\vec{H}_{opt} - \vec{H}_{rob}\| + \|\vec{H}_{rob} - \vec{A}\|\\ &\leq \|\vec{H}_{opt} - \vec{A}\| + 2\|\vec{H}_{rob} - \vec{A}\|\\ &\leq (1+\epsilon)\|\vec{H}_{opt} - \vec{A}\|.\end{aligned}$$

Otherwise, if $\vec{H}_{\mathrm{rob}} \neq \vec{R}$, it follows that $\vec{H}_{\mathrm{rob}}$ can not be much improved as an approximation to $\vec{R}$ whence it cannot be much improved as an approximation to $\vec{A}$ by refinements of $B - 1$ more bucket boundaries and bucket heights that are optimal or close enough to optimal so that the effect of approximation of bucket heights can be ignored. In particular, the best linear combination of $\vec{H}_{\mathrm{rob}}$ and any B-bucket histogram is a refinement of $\vec{H}_{\mathrm{rob}}$ by at most $B - 1$ boundaries and so is not much of an improvement over $\vec{H}_{\mathrm{rob}}$. Thus, as in Fig. 3, there are two (near-) right angles at $\vec{H}_{\mathrm{rob}}$ and so $\|\vec{H} - \vec{A}\|$ is (nearly) no worse than $\|\vec{H}_{\mathrm{opt}} - \vec{A}\|$, i.e., $\|\vec{H} - \vec{A}\| \leq (1+\in)\|\vec{H}_{\mathrm{opt}} - \vec{A}\|$, as desired.



Histograms on Streams. Figure 3. Illustration of histograms in correctness discussion. On the left, $\tilde{\vec{H}}_{\mathrm{rob}}$ is the best histogram for $\vec{A}$ in the linear span of $\vec{H}_{\mathrm{rob}}$ and $\vec{H}$; there is a right angle as indicated. On the right, since $\vec{H}_{\mathrm{rob}} \approx \tilde{\vec{H}}_{\mathrm{rob}}$, there are two near right angles at $\vec{H}_{\mathrm{rob}}$. Since $\vec{H}$ is no farther from $\vec{H}_{\mathrm{rob}}$ than $\vec{H}_{\mathrm{opt}}$ is, it follows that $\vec{H}$ is almost as close to $\vec{A}$ as $\vec{H}_{\mathrm{opt}}$ is. (Because the angles at $\vec{H}_{\mathrm{rob}}$ are not quite right angles, it does not follow that $\|\vec{A} - \vec{H}\| \leq \|\vec{A} - \vec{H}_{\mathrm{opt}}\|$, only that $\|\vec{A} - \vec{H}\| \leq (1+\in)\|\vec{A} - \vec{H}_{\mathrm{opt}}\|$.)

Key Applications

Histograms on streaming data can be used for selectivity estimation as part of query execution optimization. They can also be used at the user level, e.g., for visualization of data. Many of the techniques developed for stream processing also support the processing of distributed databases.

Definition

The *history* of an "object" of the real world or of a database is the temporal representation of that object. Depending on the specific object, one can have *attribute histories, entity histories, relationship histories, schema histories, transaction histories*, etc.

Key Points

"History" is a general concept, intended in the sense of "train of events connected with a person or thing."

In the realm of temporal databases, the concept of history is intended to include multiple time dimensions as well as multiple data models. Thus one can have, e.g., valid-time histories, transaction-time histories, and bitemporal histories. Also multi-dimensional histories can be defined from mono-dimensional ones (e.g., a bitemporal history can be seen as the transaction-time history of a valid-time history).

The term "history," defined formally or informally, has been used in many temporal database papers, also to explain other terms. For instance, salary history, object history, and transaction history are all expressions used in this respect.

Although "history" usually has to do with past events, its use for the future—as introduced by, e.g., prophecies, science fiction, and scientific forecasts—does not seem to present comprehension difficulties (The adjective "historical" seems more problematic for some). Talking about future history requires the same extension of meaning as required by talking about future data.

The synonym "temporal value" appears less general than "history," since it applies when "history" specializes into attribute history (value history), and it suggests a single value rather than a succession of values across time. The concept of a history is a slightly more general than the concept of a time sequence. Therefore the definition of "history" does not prevent defining "time sequence."

Since "history" in itself implies the idea of time, the use of "history" does not require further qualifications as is needed in the case of "sequence" or "series." In particular, "history" lends itself well to be used as modifier, even though "time sequence" is an alternative consolidated term.

Homomorphic Encryption

NINGHUI LI
Purdue University, West Lafayette, IN, USA

Definition

Homomorphic encryption is a form of public-key encryption where one can perform a specific algebraic operation on the plaintext by performing a (possibly different) algebraic operation on the ciphertext. For example, knowing only $C_1 = \varepsilon(x)$ and $C_2 = \varepsilon(y)$, but not x, y, one may be able to get $\varepsilon(x + y)$ by calculating $C_1 \times C_2$. A homomorphic encryption scheme allows a third party to operate on encrypted values without knowing the plaintext.

Key Points

Depending on the intended application, the homomorphic property can be seen as a positive or negative attribute of the cryptosystem. Homomorphic encryption schemes are malleable by design. On the other hand, homomorphic encryption algorithms have found applications in a number of cryptographic problems, e.g., for secure voting and private information retrieval. Some encryption schemes that have the homomorphic property are given below.

RSA

If the public key is n, e, then the encryption of a message x is given by $\varepsilon(x) = x^e \bmod n$. The homomorphic property is property is as follows.

$$\begin{aligned}\varepsilon(x_1) \cdot \varepsilon(x_2) &= x_1^e x_2^e \bmod n \\ &= (x_1 x_2)^e \bmod n \\ &= \varepsilon(x_1 \cdot x_2 \bmod n)\end{aligned}$$

El Gamal

If the public key is p, g, $h = g^a$, and a is the secret key, then the encryption of a message x is $\varepsilon(x) = (g^r, x \cdot h^r)$. The homomorphic property is property is as follows.

$$\begin{aligned}\varepsilon(x_1) \cdot \varepsilon(x_2) &= (g^{r_1}, x_1 \cdot h^{r_1})(g^{r_2}, x_2 \cdot h^{r_2}) \\ &= (g^{r_1+r_2}, (x_1 \cdot x_2) h^{r_1+r_2}) \\ &= \varepsilon(x_1 \cdot x_2 \bmod p)\end{aligned}$$

Goldwasser-Micali

If the public key is the modulus n, and x is a quadratic non-residue modulo n, then the encryption of a bit b is $\varepsilon(b) = r^2 x^b \bmod n$. The homomorphic property is property is as follows.

$$\begin{aligned}\varepsilon(b_1) \cdot \varepsilon(b_2) &= r_1^2 x^{b_1} r_2^2 x^{b_2} = (r_1 r_2)^2 x^{b_1+b_2} \\ &= \varepsilon(b_1 \oplus b_2)\end{aligned}$$

where $\bigoplus$ denotes addition modulo 2 (i.e., exclusive-or).

Paillier

If the public key is the modulus n and the base g, then the encryption of a message x is $\varepsilon(x) = g^x r^n \bmod n^2$. The homomorphic property is property is as follows.

$$\begin{aligned}\varepsilon(x_1) \cdot \varepsilon(x_2) &= (g^{x_1} r_1^n)(g^{x_2} r_2^n) = g^{x_1+x_2}(r_1 r_2)^n \\ &= \varepsilon(x_1 + x_2 \bmod n)\end{aligned}$$

Horizontal Fragmentation

▶ Distributed Database Design

Horizontally Partitioned Data

Murat Kantarcioglu
University of Texas at Dallas, Dallas, TX, USA

Synonyms

Homogeneously distributed data

Definition

Data is said to be horizontally partitioned when several organizations own the same set of attributes for different sets of entities. More formally, horizontal partitioning of data can be defined as follows: given a dataset $DB = (E, I)$ (e.g., hospital discharge data for state of Texas) where E is the set of entities about whom the information is collected (e.g., the set of patients) and I is the set of attributes that is collected about entities (e.g., set of features collected about patients), DB is said to be horizontally partitioned among k sites where each site owns $DB_i = (E_i, I_i)$, $1 \leq i \leq k$ if $E = E_1 \cup E_2 ... \cup E_k$, $E_i \cap E_j = \emptyset$, $1 \leq i \neq j \leq \mathbf{k}$ and $I = I_1 = I_2 ... = I_n$. In relational terms, with horizontal partitioning, the relation to be mined is the union of the relations at the sites.

Historical Background

Cheap data storage and abundant network capacity have revolutionized data collection and data dissemination. At the same time, advances in data mining have made it possible to learn previously unknown and interesting knowledge from the collected data [4]. These developments have caused serious concerns related to privacy implications of data mining. Especially, privacy issues related to sharing data for data mining raised significant concerns [2]. To address these privacy issues for the horizontally partitioned data case, two different solution ideas were initially proposed. In [1], perturbation-based techniques were proposed to build decision trees in a privacy preserving way. In perturbation based techniques data noise is added to the data before it is revealed to the data miner to protect individual values. In [10], the secure multi-party computation based approach was proposed to build decision trees. The definition of privacy followed in this line of research is conceptually simple: anything learned during the data mining process must be derivable given one's own data and the final result. Following these initial works, many different privacy-preserving data mining algorithms have been proposed including association rule mining [10], naive bayes classification [6], k-NN Classification [7], support vector machine classification [11], and k-means and EM clustering [5,9].

Foundations

Most of the work in privacy preserving data mining on horizontally partitioned data deals with the privacy issues that arise in data collection and data sharing for data mining. Due to privacy concerns, individuals and organizations may not be willing to share their data. For example, individuals may not be willing to tell their incomes or companies may not be willing to reveal statistics related to their core businesses. Fortunately, in many cases, the information aggregated over many individuals may not be considered a privacy problem, and it can be assumed that the data mining result itself is not a privacy violation. Therefore the main goal is to learn the data mining results by disclosing as little as possible about the data sources. Two different solution ideas have been suggested for addressing this privacy challenge. One idea is to apply data perturbation techniques to privacy-sensitive data before data mining (e.g., [1]). The other solution idea is to use cryptographic techniques to learn only the final data mining result without revealing anything under some cryptographic assumptions (e.g., [10]).

Key Applications

Since the horizontally partitioned data model assumes that different sites collect the same set of information about different entities, the solution techniques developed could be applied for any application that satisfies this assumption. For example, it could be applied for building fraud detection models using the data that is collected by different credit card companies related to the credit card transactions of different individuals.

The health-care industry provides one of the key application areas for the methods developed for horizontally partitioned data. For example, suppose the Centers for Disease Control (CDC), a public agency, would like to mine health records to try to find ways to reduce the proliferation of antibiotic resistant bacteria. Insurance companies have data on patient diseases and prescriptions. CDC may try to mine association rules of the form $X \Rightarrow Y$ such that the $Pr(X\&Y)$ and $Pr(Y|X)$ are above thresholds. Mining this data for association rules would allow the discovery of rules such as *Augmentin&Summer* ⇒ *Infection&Fall*, i.e., people taking Augmentin in the summer seem to have recurring infections.

The problem is that insurance companies will be concerned about sharing this data. Not only must the privacy of patient records be maintained, but insurers will be unwilling to release rules pertaining only to them. Imagine a rule indicating a high rate of complications with a particular medical procedure. If this rule doesn't hold globally, the insurer would like to know this; they can then try to pinpoint the problem with their policies and improve patient care. If the fact that the insurer's data supports this rule is revealed (say, under a Freedom of Information Act request to the CDC), the insurer could be exposed to significant public relations or liability problems. This potential risk could exceed their own perception of the benefit of participating in the CDC study. In many such cases, privacy preserving distributed data mining techniques could be used to learn the final data mining result without revealing anything other than the result itself.

Future Directions

Although the provably secure distributed data mining protocols that reveal nothing but the resulting data mining model. This work still leaves a privacy question open: Do the resulting data mining models inherently violate privacy? This question is important because the full impact of privacy-preserving data mining will only be realized when there are guarantees that the resulting models do not violate privacy as well. The long list of possible privacy violations due to data mining results given in [8] indicates that care must be taken in revealing data mining results. Recently, in [3], the authors gave a new decision tree learning algorithm which guarantees that the data mining result does not violate the k-anonymity of the individuals represented in the training data. Although current work in this area has made valuable contributions, more research is needed to understand the privacy implications of data mining results.

HCC; Human-centered multimedia; HCM

Definition

Human-centered computing (HCC) is an emerging, interdisciplinary academic field broadly concerned with computing and computational artifacts as they relate to the human condition.

HCC consists of a set of methodologies for designing, implementing, and deploying computing in any field that uses computing in any form. The definition of HCC is purposely broad, and this reflects the view that computing plays an active and crucial role in a huge number of human activities.

One important area of HCC is concerned with the design, implementation, and deployment of computing systems or devices *in everyday environments*. In such cases, it is desirable for HCC approaches to:

- Integrate input from different types of sensors and communicate through a combination of media as output.
- Act according to relevant social and cultural contexts.
- Be useful to diverse individuals.

In general, HCC methodologies guide the design of effective computer systems taking into account personal, social, and cultural aspects. The field of study, therefore, includes topics such as information design, human-information interaction, human-computer interaction, and human-human interaction. Additionally, it includes topics that are not directly related to interaction (algorithms, data collection and analysis, system design, etc.). Of particular interest in HCC is a critical analysis of the relationships between computing technology, society, and culture – so works in fields such as new media art also form part of HCC.

The distinction between computing and multimedia computing is blurry but in spite of this, the main human-centered activities in multimedia can be identified as follows [6]: media production, annotation, organization, archival, retrieval, sharing, analysis, and communication. The above activities can in turn be clustered into three large activity areas: production, analysis, and interaction.

Historical Background

Discussions about HCC have taken place over several years [5,7,16,20]. HCC draws from concepts and research in the humanities and social sciences (cognitive psychology, sociology, anthropology, philosophy, information sciences, and several others), as well as from established and emerging technical and interdisciplinary fields (HCI, computer-supported cooperative work (CSCW), user-centered design (UCD) [11], ubiquitous computing, artificial intelligence, new media art, etc.).

Although it is difficult to quantify the contributions of various fields to HCC, it is generally acknowledged that researchers and practitioners in HCI, UCD, and CSCW have made many important contributions to HCC.

User-centered design can be characterized as a multistage problem-solving process that requires designers not only to analyze and foresee how users are likely to use an interface but also to test the validity of their assumptions with regard to user behavior in the real world [15]. CSCW, on the other hand, combines the understanding of the way people work in groups with the enabling technologies of computer networking and associated hardware, software, services, and techniques [4].

While many of the topics covered by UCD and CSCW are relevant to HCC, the scope of Human-centered computing is much broader, covering more than the traditional areas of usability engineering, HCI, and human factors, which are primarily concerned with user interfaces or user interaction [8]. Compared to HCI, HCC has a twofold perspective [20]:

- HCC is "conceived as a theme that is important for all computer-related research, not as a field that overlaps or is a subdiscipline of computer science."
- HCC acknowledges that "computing connotes both concrete technologies (that facilitate various tasks) and a major social and economic force."

HCC is not to be confused with *human-based computation* [3], a technique also known as interactive evolutionary computation first developed in the early 1990s which puts the human at the center, but in a different way. In traditional computation, a human provides a formalized problem description to a computer and receives a solution to interpret. In human computation, the roles are reversed: the computer asks a person or a large number of people to solve a problem, then collects, interprets, and integrates their solutions. In other words, the computer "asks" the human to do the work it cannot do. This is done as a way to overcome technical difficulties: instead of trying to get computers to solve problems that are too complex, use human beings. In human computation the human helps the computer solve difficult problems. In HCC, the goal is to consider human abilities in creating, developing, and deploying systems or devices that use computing.

Although HCC and human-based computation approach computing from two different perspectives, they both try to maximize the synergy between human abilities and computing resources. Work in human computation can therefore be of significant importance to HCC. On one hand, data collected through human computation systems can be valuable for developing machine-learning models. On the other hand, it can help in better understanding of human behavior and abilities, again of direct use in HCC algorithm development and system design.

Foundations

A human-centered approach to multimedia starts with a deep understanding of human abilities and behavior in particular socio-cultural contexts. When human interaction is part of the computing process, HCM methodologies must consider how human beings understand and interpret multimedia signals at the perceptual, cognitive, and affective levels, and how they interact naturally – embedding the cultural and social contexts as well as personal factors such as emotion, attitude, and attention. The human-centered systems that humans directly interact with should be multimodal, processing inputs and outputs in a naturally rich communication channel; be proactive – understanding cultural and social contexts and responding accordingly; and be easily accessible outside the desktop to a wide range of users [6]. Because of this, HCM must consider work in fields such as neuroscience, psychology, cognitive science, and others. One of the key challenges, therefore, is incorporating what is known in those fields within computational frameworks that integrate different media.

Research on machine learning integrated with domain knowledge, data mining, sensor fusion, and multimodal interaction will play a key role [18]. Further research into quantifying human-related knowledge is necessary, which means developing new theories and mathematical models of multimedia integration at multiple levels.

Although many disciplines contribute to HCM (and implicitly HCC), the field is at an early stage so a research agenda will involve a non-exhaustive list of goals including the following:

- New human-centered methodologies for the design of models and algorithms and the development of diverse human-centered systems
- Focused research on the integration of multiple sensors, media, and human sciences that have people as the central point
- New interdisciplinary academic and industrial programs, initiatives, and meeting opportunities

- Discussions on the impact of computing technology that include the social, economic, and cultural contexts in which such technology is or might be deployed
- Research data that reflects human-centered approaches – for example, rich data collected from real multisensorial and culturally diverse social situations
- Common computing resources – for example, software tools and platforms
- Evaluation metrics for theories, design processes, implementations, and systems from a human-centered perspective
- Methodologies for privacy protection and the consideration of ethical and cultural issues

Clearly, an HCM and HCC research agenda should include a broad understanding and a multidisciplinary approach. This is of particular importance when considering computing in the context of developing regions [2].

Key Applications

The span of HCM application areas is very broad and as computing becomes more ubiquitous, practically every aspect of interaction with objects, and the environment, as well as human-human interaction (e.g., remote collaboration, etc.) will make use of HCM techniques. Several key application area descriptions follow:

Ambient Intelligence and Personal Spaces

Computing is being integrated with everyday objects in a variety of domains. This implies that the model of "user" in which a person sits in front of a "computer" is no longer the only model. Therefore, the actions or events to be recognized by the "interface" are not necessarily explicit commands and must respond to personal context in homes, offices, and other spaces, making ambient intelligence [1] a very important application area of HCM.

Public information kiosk applications [10] present many technical challenges in the design and implementation of natural multimodal interaction: kiosks are often intended to be used by a wide audience, thus there may be few assumptions about the types of users of the system. Thus, they present interesting opportunities for HCM approaches and must integrate context and socio-cultural considerations.

HCM also plays an important role in personal spaces (e.g., cars, office spaces, etc.). On one hand HCM techniques emphasize personalization, and on the other hand they emphasize natural interaction. Computing in vehicles, for example, can be used to monitor the driver [9] and to adjust conditions according to personal preferences. In addition, since the driver must focus on the driving task, traditional interfaces (e.g., GUIs) are not suitable, creating the need for natural, non-disruptive interaction techniques focused on maximizing human abilities while answering human needs in specific situations.

Ubiquitous Computing

One of the major challenges in ubiquitous computing is that while devices such as PDAs and mobile phones have become smaller and more powerful, there has been little progress in developing effective interfaces to access the increased computational and media resources they posses. Computing in ubiquitous devices constitute a very important area of opportunity for research in HCM: they create challenges in interaction for creation and access to content, as well as opportunities for contextual data collection and personalization.

Data Analysis and Data Interaction

HCM approaches can be used to process, analyze, and visualize various types of human-related data. The range of personal information collected in digital format is very wide, and can be used to support many human activities. Social networks, for example, have gained significant popularity and are based largely on connections of data about different individuals. HCM approaches to analyze and interact with data and information are crucial in such types of applications. Web search and recommender systems are two additional areas in which HCM techniques play a significant role because they can strongly impact not only the interaction aspects, but how the information is organized, indexed, and searched. Systems for analyzing, processing, and visualizing customer data for user modeling, profiling, and market segmentation can clearly have positive impacts in fields that use computing (e.g., marketing, advertising) to determine how and where products or services are provided.

Virtual Environments

Virtual and augmented reality have been very active research areas at the crossroads of computer graphics, computer vision, and human-computer interaction. One of the major difficulties of VR systems is the interaction component, and many researchers are currently exploring the use of interaction analysis techniques to enhance the user experience. One reason this is very attractive in VR environments is that it helps disambiguate communication between users and machines (in some cases virtual characters, the virtual environment, or even other users represented by virtual characters [14]). HCM techniques can be applied, however, to many aspects of VR environments: from the visual representation of characters and the environment, to the "physical" behavior of objects and how events and actions are perceived by human "users" of such systems.

Art

Perhaps one of the most exciting application areas of HCM is art, from interactive installation and interactive architecture to performance and audience participation. Multiple modalities (video, audio, pressure sensors) can be used to allow audience participation and influence a performance [19]. Mouth gestures can be interpreted [13] by a wearable camera pointing at the wearer's mouth to generate MIDI sounds (so a musician can play other instruments while generating sounds by moving his mouth). HCM technologies can also be used in museums to augment exhibitions [17] and in many other contexts.

Persons with Disabilities

Persons with disabilities can benefit greatly from HCM techniques [12] because the goal is specifically to enhance or complement person's abilities. Solutions for smart wheel-chair systems, for example, integrate different types of sensors and consider different kinds of interaction such as using only eye blinks and eyebrow movements for navigation.

Other Applications

Other applications include education, medicine, remote collaboration, entertainment, robotics, surveillance, or biometrics. HCM also plays an important role in safety-critical applications (e.g., medicine, military, etc.) and in situations in which a lot of information from multiple sources has to be viewed in short periods of time (e.g., crisis management).

Human-Computer Interaction

Alan Dix
Lancaster University, Lancaster, UK

Synonyms

HCI; Computer human interaction (CHI); Human interface; Interaction design; Human centered computing; User-centred design; Human factors; Man-machine interaction (obsolete)

Definition

Human–Computer Interaction (HCI) is the study of the way in which computer technology influences human work and activities. The term "computer technology" now-a-days includes most technology from obvious computers with screens and keyboards to mobile phones, household appliances, in-car navigation systems and even embedded sensors and actuators such as automatic lighting. HCI has an associated design discipline, sometimes called *Interaction Design* or *User-Centered Design*, focused on how to design computer technology so that it is as easy and pleasant to use as possible. A key aspect of the design discipline is the notion of "usability," which is often defined in terms of efficiency, effectiveness and satisfaction. However, equally or more important in systems designed for personal use, such as internet shopping, is the idea of user experience – the way people feel about the system as they use it.

Historical Background

The roots of HCI can be traced back to the innovative work of Douglas Englebart at the Augmented Research Center at Stanford in the early 1960s [4] and more pragmatic work of Brain Shackel in the late 1950s [8]. However, it was with the rise of personal computing in the early 1980s that the discipline took shape and got its name(s). Notable was the founding of IFIP Technical Committee 13 on Human-Computer Interaction in 1981 and the first international INTERACT Conference in 1984. Several major national conferences started around the same period ACM CHI in the US, the British HCI conference and Vienna HCI. At this stage the main academic roots were in psychology, computing and ergonomics with much of the early work founded on strong experimental methods.

As in so many areas of computing XEROX PARC played a key role in HCI, developing the WIMP (window-icon-menu-pointer) interface style that was eventually popularized in the Macintosh in 1984. In the second half of the 1980s a number of books were published that shaped the development of the field. In particular the *User-Centered System Design* collection in 1986 [6] set the ground for what would be the dominant view of HCI for many years with a strong focus on cognitive modeling and theoretical accounts of *direct manipulation*. As a contrast to this, Suchman's *Plans and Situated Actions* [12] drew on anthropological traditions and in particular *ethnography* and was formative in the fledgling area of *Computer Supported Collaborative Work* (*CSCW*).

Towards the end of the 1980s and early 1990s technological advances as much as methodological and theoretical factors had a large impact on HCI. The introduction of computer networks both within and between offices was one of the factors that fueled the growth of CSCW as it became possible to develop systems that enabled remote groups of workers to collaborate electronically. Increased graphics and computational capabilities also meant that for the first time it was possible to have high-quality *interactive* visualization of large data sets.

The importance of HCI as a discipline has grown gradually over the years as industry became aware of the importance of the usability of its products in a competitive environment. This has intensified since the late 1990s due to the world-wide web and consumer electronics such as mobile phones. As individual consumer choice took over from corporate IT decisions not only usability but also user experience have become key selling points.

With this growth the field has also spawned subfields such as web usability and mobile HCI, which can be confusing to someone new to the area. HCI has also drawn in fresh theoretical input, for example *Activity Theory* (see [1], chapter 11), as well as developing its own methods, for example ways of studying users in real-world contexts.

Foundations

As noted, HCI is both an academic discipline studying the way technology impacts human activity and also a design discipline aimed at designing that technology for maximum effectiveness. It draws on many results from other disciplines such as psychology and sociology, but also has its own methods and techniques.

Usability

Usability is one of the core issues in HCI. There are various definitions, most notably in ISO 9241–11 it is defined as: "The extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use."

The key terms in this definition are:

Effectiveness–Can the user achieve their goals with accuracy?
Efficiency –Can this be achieved with minimal resources: time, physical, and mental effort?
Satisfaction–Do users feel comfortable or happy in doing this?

For many years satisfaction has been largely ignored, but more recently affective issues such as motivation, trust, enjoyment, and engagement have become increasingly important.

The concept of usability is quite broad. At the lowest level there is the visual layout of information and controls on a screen or on a physical appliance and their immediate behavior. At a higher level one also has to take into account the whole social and organizational context: the people who will use the system being designed, their beliefs and values, the purpose and constraints of the design.

Observation and Empirical Data

Various techniques are used to observe or evaluate technology in use (see also [3] chapter 9 and [9] chapters 12–14). These techniques may be used purely for research, early in the design cycle in order to understand a situation, or later when an artifact has been reduced and one desires to evaluate it and identify any usability problems.

These evaluation or observation methods fall into two main types:

1. *Laboratory experiments* – where users perform a task or interact with an application under some level of controlled conditions
2. *Field studies* – where users are "in the wild"; that is in their workplace, outside, in their homes: wherever they would normally interact with the technology being studied or evaluated

Laboratory studies are often criticized for lack of *ecological validity*, that is that they are too far from the real context of use. To counter this laboratory studies are often performed in semi-realistic situations and a *usability laboratory* may include features such as a one-way mirror to enable unobtrusive observation.

Field studies may include a level of control, for example, giving two groups of people different versions of an interface, or may be more open, simply observing people doing their day-to-day work or activities.

Both types of empirical study can be performed with a closed agenda to evaluate or improve a proposed or existing design, but can also be used in a more open or exploratory way to explore a design idea or attempt to learn unexpected things about an area.

Design and Methodology

It often requires too much time or skill to apply fundamental knowledge to a new design. Instead good practice is often captured in design guidelines, principles or heuristics, for example providing immediate feedback for user actions. There are many collections of detailed guidelines for example the US Department of Health and Human Services *Research-Based Web Design and Usability Guidelines* runs to 18 chapters [13], but also there are shorter lists of more generic rules such as Ben Shneiderman's Eight Golden Rules of Interface Design [10]:

- Strive for consistency
- Enable frequent users to use shortcuts
- Offer informative feedback
- Design dialog to yield closure
- Offer simple error handling
- Permit easy reversal of actions
- Support internal locus of control
- Reduce short-term memory load

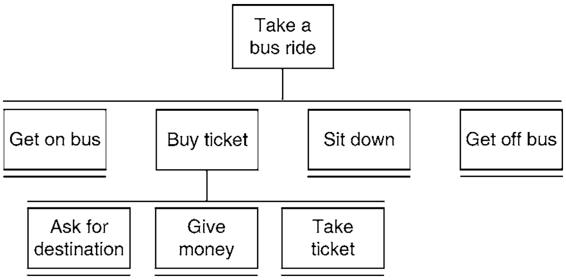
As important as design guidance are the design methods and processes. *User-centered design* refers to a number of practices that put the user first in thinking about the design of an application or product; this will typically involve some direct observation, interviewing of users or otherwise getting to know them. More radical are *participatory design* approaches where users are brought more deeply into the process acting as co-designers of the end product (see [7] Part VII).

Typically user-interface design processes are iterative involving some form of *prototype* or *storyboard* that enables users to see or experience early designs. This reflects the complexity of designing for real people and also the difficulty of even understanding what is wanted. Some level of iterative re-design is always required. However, this iterative design process typically needs a good start point so that more predictive and more iterative methods work together.

Representation and Analysis

Given the focus on users, HCI uses various forms of representation of users and their behavior. These may be informal such as personae or scenarios. A *persona* is a rich description of a real or fictitious user that can be used as a surrogate user in design. A *scenario* is a form of story describing a context in which a device or application is used and the way it gets used. These are both conveyed in text and pictures. More formal representations can also be used, for example, *hierarchical task analysis* (HTA, see [3] chapter 15) focuses on the decomposition of higher-level tasks (such as “take a bus ride” in Fig. 1) into lower evel tasks (such as “buy ticket”).

Various forms of representations are also used to describe the behavior of interactive systems themselves; that is how the system responds to user inputs, the responses it produces, and the internal states insofar as they may affect future user interaction. This is often called a *dialogue specification*. These sometimes take the form of fairly informal diagrams, for example showing a collection of web pages and their interconnections. However, more formal representations may be used, for example, using state-transition networks or Petri nets. The more formal representations can be analyzed to look for potential usability problems or even verified using forms of model checking to verify various forms of usability property. More commonly however, these are used to understand or communicate designs, or to specify them clearly for implementation.



Human-Computer Interaction. Figure 1. Example of an hierarchical task analysis (HTA).

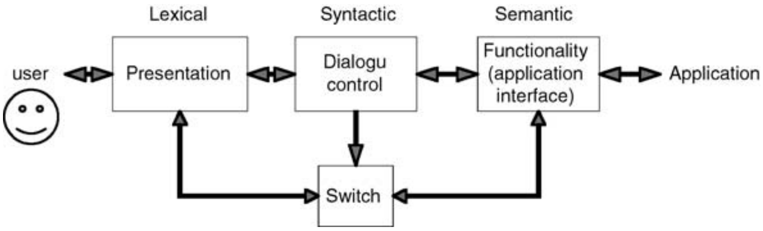
Implementation and User Interface Architecture

For the users of a system all that matters is its external behavior. However, in order to effectively construct such systems the internal structure or *software architecture* has to be in some way consonant with the external design (see also [3] chapter 8). The view that the user has of a system frequently cuts across what would be regarded as different functional areas, sometimes conflicting with what would otherwise be regarded as a suitable decomposition. It is also often desirable that more surface features of a user interface can be changed without a complete redesign of the entire system. Because of this, specific architectures have been developed that separate the parts that are closer to the user (e.g., choice of menu names or font color) from those about the underlying functionality. The most influential of these at a conceptual level and one of the earliest was the *Seeheim model*, which divided the system into presentation, dialogue and functionality (with some form of wrapper) (Fig. 2). At a practical level the *Model-View-Control* (MVC) model has been most widely adopted (for example in the *Java* Swing toolkit). This operates on the level of components or widgets (for example, the tree-view of a file system).

Key Applications

HCI is an issue whenever people use systems so the applications are very wide. Traditionally a substantial focus has been on office work where the desktop PC was the main computing device, although there has always been a strand focused on industrial interfaces and command and control situations (e.g., aircraft cockpits). As noted previously, domestic appliances and devices and systems for leisure and entertainment have become increasingly important.

Two of the biggest application areas over recent years have been in the web [2] and mobile computing [5]. However, these are really platforms and the range



Human-Computer Interaction. Figure 2. Seeheim model of user interface architecture.

applications supported on these have ranged from eCommerce to text messaging.

There has been some work focused specifically on user interfaces for databases to aid in areas such as query formulation or schema visualization. Related to this has been more recent work on usability issues for web search and user interfaces for various forms of ontologies and other semantic web structures. Applications in *information visualization* are also important allowing users to view structures including simple point data, hierarchies, trees, or geographic data [11].

Future Directions

The web will clearly be an important driver for some time to come. Whilst traditional web page usability has been well studied, the implications of *Web2.0* both as a social and a technological phenomenon are only just beginning to be understood. For example, users are increasingly making their own "mashups" and customizing shared web content, so that effectively they are taking on the role that used to be in the hands of developers – it is important that this does not become as confusing as cooking in someone else's kitchen! Developments in HCI aspects of mobile applications will continue to be important, especially as it is expected that mobile access to the Internet will outstrip desktop access in the next few years.

Looking slightly longer term, human aspects of *ubiquitous computing* are still only partially understood, but will be critical as homes, offices and public spaces become filled with sensors, points of interaction and numerous small and large screens. As these increasingly become wirelessly networked they will need to be designed in way that make their effects comprehensible and trustworthy.

In work environments technology is more stable and usability of desktop applications well understood. However, increasing availability of data and communications (e.g., email, instant messaging) is creating demands to manage large volumes of data. This may change the traditional desktop itself and is likely to involve more "intelligent" and often proactive applications, that will in turn need to be understood and controlled by their users.

Mobile and web applications are creating demands to re-target applications to multiple devices, and to share and mash-up data. For cost-effective construction and ease of maintenance it is likely that studies of user interface architecture, marginalized for a number of years, will become more important.

Web-based applications are leading to service-based solutions replacing many traditionally product-based ones. Greater choice and ease of movement between applications will demand changes in design practice away from "one size fits all" designs to more individual designs. This trend reflects similar diversification and shorter more dynamic product runs in traditional manufactured devices, which themselves are more likely to involve computation. This will clearly impact both design research and design practice.

Finally the demographics of computer and technology use is moving out from the relatively young and prosperous to include the increasingly older populations of developed countries, socially-deprived groups, and the growing markets of the developing world. While much of the understanding of human-computer interaction is universal, still many cultural and other assumptions are embedded in design practice and this will be an important issue for some years to come.

Hypertexts

Frank Wm. Tompa
University of Waterloo, Waterloo, ON, Canada

Synonyms

Hypermedia

Definition

A hypertext is a collection of interconnected documents or document fragments. The idea of computer-based hypertexts is rooted in Vannevar Bush's vision, as described in his 1945 *Atlantic Monthly* article "As We May Think," of a personal document collection with "a provision whereby any item may be caused at will to select immediately and automatically another." Authors who wish to emphasize the multimedia nature of constituent documents and fragments prefer to use the term hypermedia when describing hypertexts.

Key Points

The term *hypertext* was introduced in the early 1960s by Ted Nelson, who advocated the power of non-linearity in organizing thoughts and discourses. Simultaneously, Doug Englebart demonstrated a system for "augmenting human intellect" that included a facility to expose inline fragments of text in response to users' request for finer detail. These early ideas have evolved to form the basis of HTML (the Hypertext Markup Language) and the World Wide Web.

Hypertexts have been used extensively as features of reference texts, collaborative design documents, and bibliographic systems, and as a structure for creative writing. Links between document fragments are used to represent various rhetorical relationships (support, rebuttal, elaboration, motivation, consequence, etc.).

Systems to support hypertexts include editors, browsers, and visualizers.

Disk-based model

Definition

The I/O model of computation measures the efficiency of an algorithm by counting how many disk reads and writes it needs. It is widely applicable to the database environment, since most data is stored on disks and disk access typically dominates CPU time.

Key Points

For many computing-intensive applications, the appropriate model of computation is to measure CPU time. Yet in data-intensive applications, such as databases, it is more relevant to measure the number of disk I/Os [1]. This is termed the "I/O model of computation," or disk-based model. Nowadays, most hard drives use the seek-rotate-transfer protocol [2]. In order to transfer some data from disk to memory (so as the data can be processed by the CPU), or to transfer data back to disk, the hard drive needs first to spend some "seek time" to move the read/write head to the cylinder where the data is located at. Then the "rotational delay" is spent until the sector containing the data rotates to a position under the read/write head. Finally, time is spent to actually transfer the data from/to the CPU. Typically, seek time is longer than rotational delay, which is in turn longer than transfer time. Therefore reading a few bytes of data takes roughly as long as reading thousands of bytes. Due to this reason, data is stored on disks in units called blocks or pages. Every disk I/O corresponds to reading or writing one such page. Moreover, a random disk I/O costs more than a sequential access. This is because the access of multiple sequential pages on the disk does not involve major seek and rotational times (since in sequential access, a page is accessed after its neighbor page). Hence a more accurate I/O model should account for the difference between random and sequential I/O.

There are three ways to minimize the disk accesses in a database environment: (i) by buffering in main memory pages that have already been accessed (and thus future accesses can be served by a buffer access and not a disk access), (ii) by transferring a number of consecutive pages at once, called bucket, anticipating the next requests due to data locality, and, (iii) by using structures (indices) that organize the data into pages so as searching for a particular record takes few page accesses.

To exemplify the importance of the I/O computation in data structures, consider the following scenario. Assume an application (query) requests a record from a database file. If a balanced binary search tree is directly implemented on top of this file, to search for a record would need $O(\log_2 n)$ I/Os, where n is the number of records in the tree. For example, if n is a million records, this means about 20 I/Os. If instead, a disk optimized structure is used (like the B+-tree) the same search is much more efficient (in number of page I/Os). The B+-tree extends the binary tree, by expanding a node size. Every tree node corresponds to one disk page. If for simplicity, every index node as well as leaf node in the B+-tree contains 100 entries, a million records fits into a three-level B+-tree. Then to search for any record in the file, only three I/Os are needed, which is much faster than the 20 I/Os. Disk resident data structures are called paginated or disk-based or external.

Before a new page read is executed, the buffer manager is first examined for whether it already contains the requested page. For instance, if a page is read 100 times, only the first read triggers an actual disk read, while subsequence reads are serviced by returning the in-buffer page (and thus avoiding the cost of a page I/O). Of course the buffer has limited capacity and issues like page replacement policies play an important role.

Picture; Image; Representation

Definition

Originally, the Greek word *eikon* stood for an image, carrying some meaning as in typical portraits of sacred persons within the Orthodox Church. An operational definition of icon was given by Peirce [1] as *anything that stands for something else, to somebody, in some respect or capacity*. Being so general, it covers most customary practices, typically linking linguistic, pictorial (or even auditory) expressions to a *meaning* that needs to be *interpreted* by a human. In general discourse, an icon may imply an idol (as a pop star) or a symbol (the Rotary wheel worn on coat lapels) that represents a group of persons or a life style (the Nike symbol for sports). Within Human-Computer Interaction, the common understanding of an icon is to consider it as a visual metaphor representing a file, a directory, a window, an option or a program. Whenever a number of icons are presented together, this group is referred to as an icon bar, generally at the top of the page in most web browsers.

Key Points

The study of signs, a scientific discipline under the name of Semiotics, started from the work of two contemporary researchers: Ferdinand de Saussure (a linguist) [2] and Charles Sanders Peirce (a philosopher) [1]. De Saussure showed that language may be considered as a collection of *signs*, each one formed by a pair (a twofold nature) named signifier/signified, and only if both were present, the sign could be a valid indication of a meaning, otherwise the sign only represents itself. Peirce made a well known triangular classification (a threefold nature), where the sign stands in the center and the three vertices correspond to (i) the representation, (ii) the object (referent) and (iii) the interpretant (meaning) [3]. The main issue here is that the interpretation is subjective and dynamic, there is no unique meaning corresponding to a class of signs: the *icons*. Following Peirce's sign taxonomy, he indicated three possible sign classes: the *icon* (where a mental process is required to understand it), the index (having a causal relationship to its signified, like smoke for fire) and the *symbol* (having a totally arbitrary relationship, like a red cross for the corresponding, well known, international medical organization). The icon is wrongly considered to be similar to its signified; typically by looking at the icon one should infer information about its signified, yet this is not always the case, since different meanings may be attributed to the icon, depending on the observer. This fact provides a possible approach to ambiguity management in human-computer interfaces, by restricting the user model to a given class of users. The design of effective icons should be performed after an accurate study of the cultural background, age, and motivation of the potential users.

Iconic Displays

Georges Grinstein, Damon Andrew Berry
University of Massachusetts, Lowell, MA, USA

Synonyms

Icons; Glyphs; Iconographics

Definition

Iconic displays are visualizations that generalize traditional displays (especially scatterplots) where each record, instead of being drawn as a point, is represented by a more general primitive called an icon or glyph. The goals are to harness human perception, especially texture, and to display many more parameters. Whereas a pixel is driven by three data values from some color model (typically red, green, and blue) an icon is a geometric object driven by potentially many values, with some icons displaying over 30. Some icons are drawn using lines, some using colored areas, some move and vibrate, and some even have sound output. Some iconic displays drop the Cartesian base of the underlying display and use alternative layout techniques. However, in all of these, the key defining factor is the representation of a record in a visualization by a very general, most often geometric, primitive, with the goal of producing more perceptually-based displays.

Historical Background

The analysis of complex images is still performed largely by human visual means which is most highly effective in situations where the patterns of potential interest are directly visible. The most widely used technique for displaying multivariate data or multiparameter imagery is based on the representation of different parameters as points with two or three position coordinates and color based on a color model such as RGB (Red, Green, Blue) or HLS (Hue, Lightness, Saturation).

Such scatterplots employ simple graphic representations with attributes (retinal variables) characterized by Bertin [2] and Healy et al. [8]. The number of variables or parameters that can be displayed with such a two dimensional scatterplot is easily five using five degrees of freedom (x, y, shape, size, and color) and seven if one thinks of color as three separate variables (e.g., RGB).

But what if one wishes to go beyond five or seven variables? This was the motivation for the development of icons. By increasing the number of variables encoded with more complex representations, an arbitrary number of variables can be encoded. Examples include Chernoff faces [4], asymmetrical faces [5], star glyphs [3], the stick figure icons of Pickett et al. [1,7,13], color icons [11], moving icons [15], and moxels [19].

In addition to the different icons, there are a number of different algorithms for placing them on a two-dimensional plane. Ward presents an overview and taxonomy of such icon or glyph placement strategies [17].

Foundations

Perceptual Foundations

Gibson [6] developed an ecologically-based approach to perception, quite different from the then conventional approach. The human visual system is an ecologically evolved system still guiding the behavior of animals. Humans discriminate textures very effectively and use variations in visual texture as important sources of information in the detection and recognition of objects. Pickett [13] suggested that modern displays (visualizations) should be developed using this ecological spatiotemporal pattern recognition system of the human optical system. Further, experiments developed by Julesz, demonstrated that differences in textons (characteristic features of the surface) or their densities can be preattentively detected by the human visual system [9]. The work developed by Julesz shows that texture is a statistical property of textons. The perception and discrimination of textures seems to be based on the density (first order statistics) of textons.

In 1967, Jacques Bertin [2] in Sémiologie Graphique presented the fundamentals of information encoding via graphic representations as a semiology, a science dealing with sign-systems. His first key point is the strict separation of content (the information to encode) from the container (the properties of the graphic system). Bertin defined a graphical vocabulary consisting of three elements: marks, positional variables, and retinal variables. Marks are artifacts like points, lines, and areas. Positional variables are (usually) two planar dimensions. Retinal variables are encoded entities such as size, color, shape, orientation, texture, and value. These were extended by others to include temporal aspects with animation and work in three dimensions. Additional parameters such as shading, connectivity, labels, visibility, and tabularity were added. Extensions to the non-visual have also appeared such as the use of sound as a perceptual variable [16] as well as touch and smell.

In all of the above the goal is to develop perceptually salient displays.

Iconographics

Iconographics initially developed at the University of Massachusetts Lowell, harnesses texture perception to increase the dimensionality of the represented data visible in an image [13]. Each datum is represented by an icon whose visual features are controlled by the data. Two of the data variables control the position of each icon on the display surface. When icons are used to represent imagery data, the icon position simply corresponds to the pixel position. With sufficient density, the icons form a surface texture display, and structures in the data are revealed as streaks, gradients, or islands of contrasting texture.

Humans discriminate textures very effectively and use variations in visual texture as important sources of information in the detection and recognition of objects. Based on the early work of Pickett, Pickett and Grinstein [13] developed data representation techniques that engaged and harnessed the mechanisms of texture perception. Later, Levkowitz et al. [14] came back to color as a basis for integrating multiparameter images, but with a more sophisticated approach based textural representations.

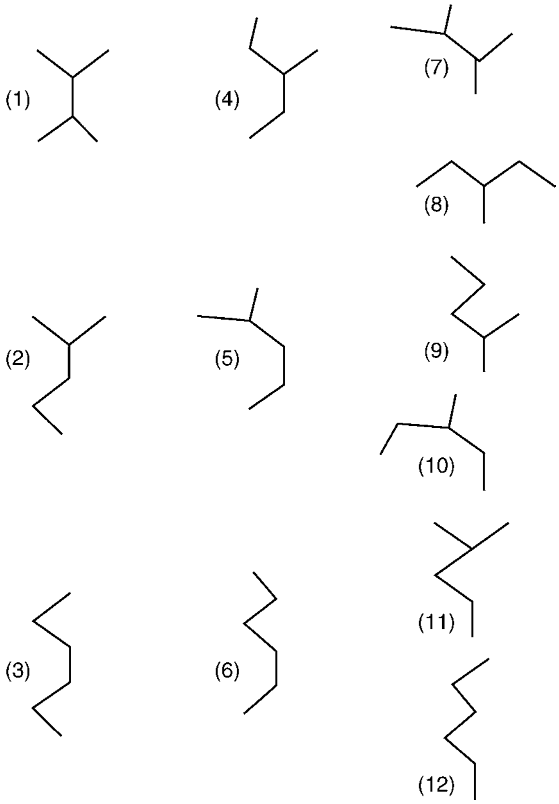
The iconographic technique extends the classic visualization approaches by representing each record of a multidimensional database as an icon whose features (such as color, geometry, and sound) are under the control of the various fields of the record. This technique allows the information content of the objects represented to have high dimensionality and allows for the fusion of multiple data sets (usually images) into a single integrated multi-modal display.

This is done through an icon which is an $m \times n$ box of screen pixels. A single pixel can be thought of as a 1×1 icon. Because an icon is a box of pixels, it can represent many more attributes (data parameters) than a single screen pixel. The increased per-element information content comes at the price of decreased screen resolution, a tradeoff that must be considered in the design of any iconographic display.

Stick Figure Icons

Figure 1 shows a typical stick-figure icon. The line segments are called the "limbs" of the icon. Each icon has a special limb, called the "body," which serves as a reference for the various geometric transformations that an icon can undergo. The first complete family of stick-figure icons had twelve members, each of which has up to five limbs connected in a unique configuration. The five-limbed icon [1] was designed to display multiparameter images on a single display in a way that would engage the vision system's ability to perceive textures.

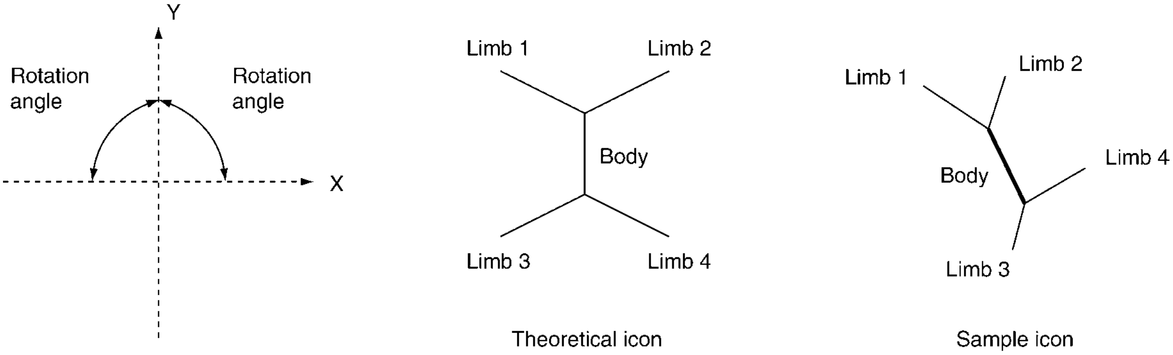
Each limb has at least three parameters that can be bound to data attributes: the angle, intensity, and length. The manner in which limbs are attached to the body or to each other defines the family of stick figure icons. Figure 2 shows one member of the family of stick figure icons. The figure shows the icon in its base



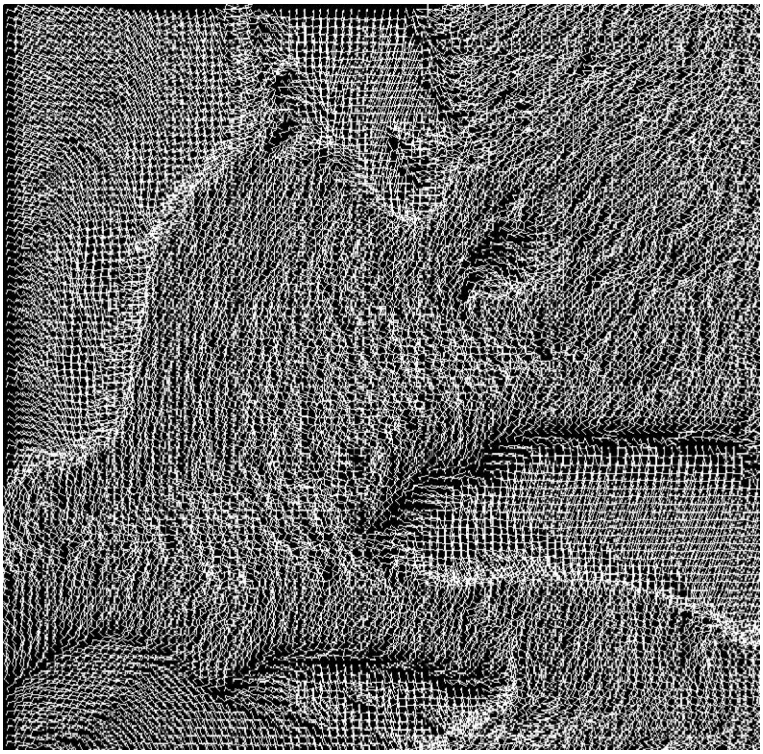
Iconic Displays. Figure 1. Family of stick figure icons.

configuration with no data mapped to any limb parameters and also a sample icon with data mapped to the limbs' parameters. The value of any variable is normalized into the unit interval [0,1]. The variable is mapped to a limb with the limb's reference angle or rotation angle determined from the normalized value (0 = 0°; 0.5 = 90°; 1.0 = 180°).

The general character of displays made with this icon can be seen in Fig. 3, one of Grinstein and Pickett's earliest displays, where they merged four grayscale images. The merged images are satellite images of a portion of the Great Lakes region (readers familiar with this area will immediately recognize Lakes Erie, Ontario, and Huron, as well as Georgian Bay and Lake Simcoe). Two of the images are from the infrared spectrum and two are from the visible spectrum. The goal is to show in one picture both the fine detail from the visible images and the heat signatures of the infrared images (here, the lakes are colder than the surrounding land). The mappings chosen produced an



Iconic Displays. Figure 2. One member of the stick-figure icon family.



Iconic Displays. Figure 3. Satellite image of the Great Lakes – line icon.

integrated display that shows the lakes as flat, concave features in relation to the rougher and predominantly convex land features. These three-dimensional effects are striking and highly effective.

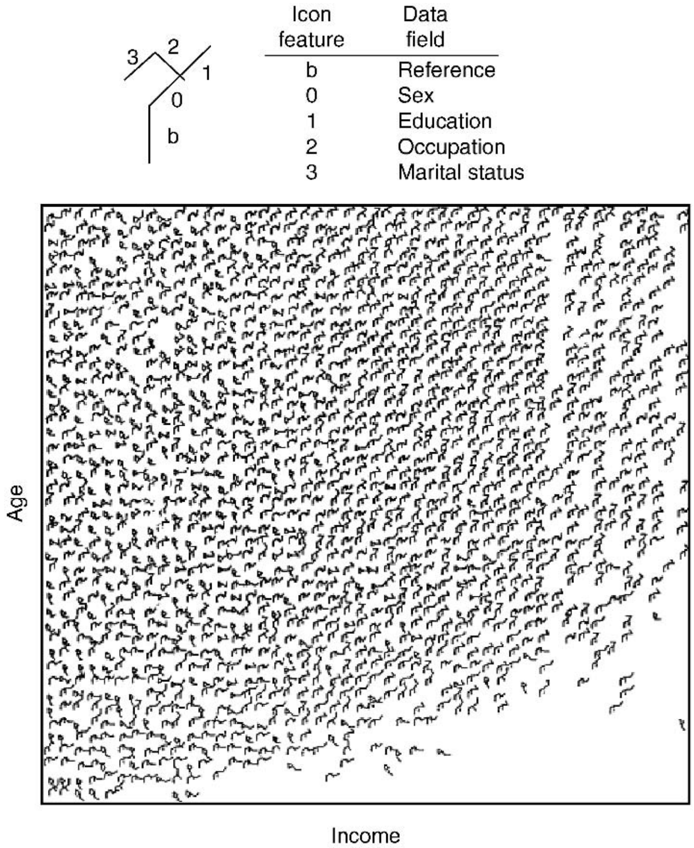
Figure 4 shows a scatterplot of a subset of the PUMS US Census data of engineers and technicians in New England, using the stick figure icon developed by Pickett and Grinstein in 1989. This icon encodes four variables (sex, education, occupation, and marital status). Each variable is mapped to a limb whose angles are determined by the value of the variable. Placing the icon on the scatterplot encodes two more variables (income and age). The result is an iconic display that encodes six variables.

Figure 5 represents some of the possible geometric layouts of icon number 4 from the stick figure family in Fig. 1 for various values of the variables. There are 16 possible configurations of the stick figure icon (Fig. 5), each corresponding to a particular geometric organization of the icon's limbs. Of particular interest are females with a high level of education since the icon forms a triangle, a highly perceptual object. For this data set (engineers and technicians in New England) almost all individuals have a high level of education. Since there are few women engineers and technicians with a low level of education one can state that all icons in Figure 3 having a triangle can be interpreted as female.

It is thus possible to get some insight into this subset. For example one can see the boundary between females and males; one can see that most female's salaries fall within the first third of the salary scale. Once can also quickly see outliers and trends in Fig. 4.

Color Icons

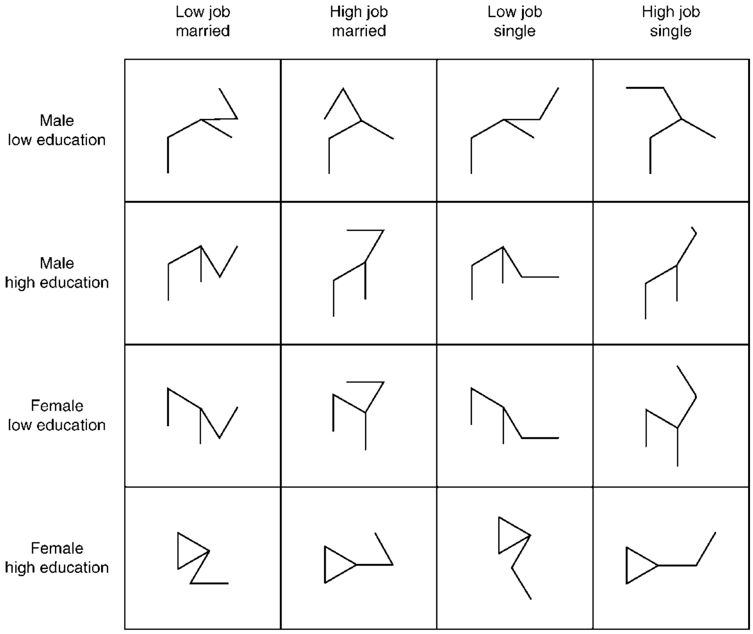
Applying the concepts learned with the stick-figure icon to color, Levkowitz developed a color icon [11]. In the color technique, a pixel in the input data is represented by an arbitrarily-sized *m* x *n* box of screen pixels. In the most frequently used version of the color



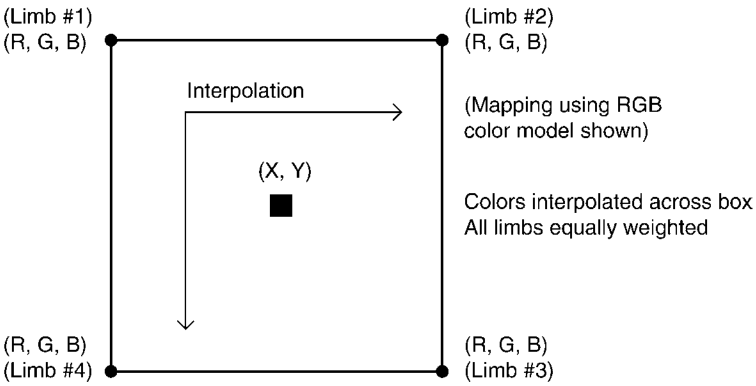
Iconic Displays. Figure 4. PUMS US Census data using a Picket icon.

icon, each of up to 12 data parameters is mapped to a color channel of the four corners of the icon box. Each data value determines the intensity of that color channel. The colors of the remaining pixels in the box are obtained by interpolation. The color icon is independent of color models and was tested with four color models: GLHS (Generalized Lightness, Hue, Saturation), RGB (Red, Green, Blue), Munsell Book of Color, or CIELUV (Commission on Illumination 1976 L*, u*, v*). The design of this icon is shown in Fig. 6. Figure 7 shows the color icon used to display several parameters of the FBI (Federal Bureau of Investigation) homicide database.

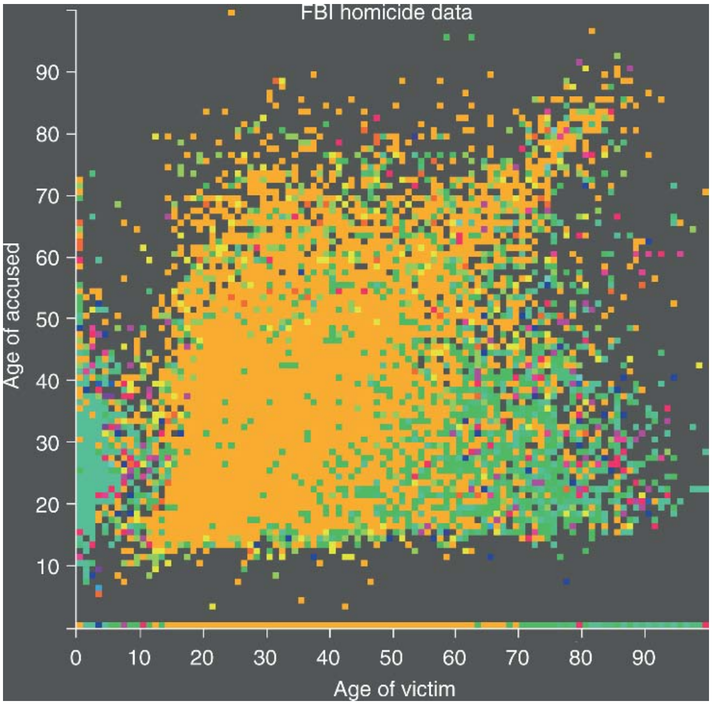
In Fig. 8, standout regions (which are common with other similar color icon displays of the same data set) can easily be identified. The first (labeled A), highlights very young victims with different attributes. The greenish color shows offenders whose homicides were family related. The second (labeled B) is the tail in the display which highlights spouses involved in the homicide. The final obvious pattern (labeled C) is that of zero-aged offenders, clearly produced by missing data.



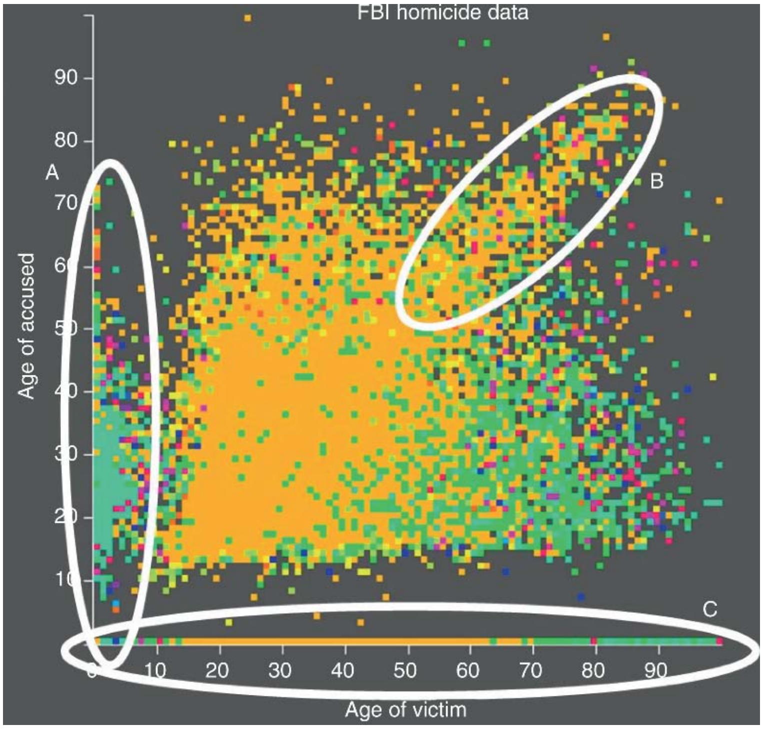
Iconic Displays. Figure 5. The stick figure icon's possible representation for various values of the parameters of a record from the Census data.



Iconic Displays. Figure 6. Design of color icon.



Iconic Displays. Figure 7. FBI homicide data using a color icon.



Iconic Displays. Figure 8. The same figure as in 7, but with three regions of interest.

Kinetic Displays and Moxels

Kinetic displays are extensions of the above icon displays in which motions of the graphical icon's limbs are used to represent attributes of the data, so the elements are in constant motion independent of user interactions. Example motions of data driven graphics include translations and rotations that produce visual vibrations and oscillations. Such kinetic displays are designed to capitalize on the human preattentive ability to perceive and understand motion.

The term "pixel" stands for "picture element;" similarly the term "moxel" stands for "moving element." Moxels are an extension of standard iconographic displays into three dimensional displays that incorporate motion coding of data dimensions.

The first such display was produced by Pinkney [15] with several interactions a "magnet" interaction; a "vibrating" interaction; a "comb" interaction; a "zoom" interaction; and a "pinwheel" interaction. In all of these interactions the mouse is used for specifying a region of interest. Interaction acts over all icons within the selected region. Users can select either a constant value or a variable (data attribute) to drive the interaction. Icons within the selected region are transformed in some way (depending on which interaction) that is proportional to the value driving the interaction. For example in the "magnet" interaction the mouse acts as a magnet repelling or attracting icons. Users can select if the magnet will affect the angle of the icons, the position of the icons, or both. The value associated with the interaction is used to determine the angular and positional response of the icon to the magnet, in the case of magnet interaction, lower values imply greater effect.

Yang et. al. [19] presented an information visualization system that links both static and kinetic visualizations. The images in Fig. 9 show a zoomed out view (left) and a zoomed in view (right) of a moxel visualization of the AVARIS (Airborne Visible/Infrared Imaging Spectrometer) dataset. These static images do not really do justice to the actual moving visualizations, where independent regions are clearly visible not only due to common textures, but due to coordinated movements as well.

Key Applications

Iconographic displays have become part of many different visualization efforts and environments. They have been used for both information visualization as well as scientific visualization in areas such as GIS (Geographic Information System) [20], physics [18], medicine [10], and computer network security [12].

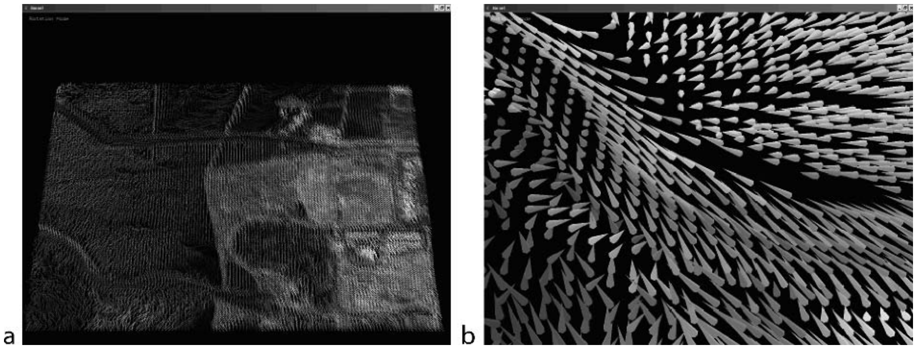
Data Sets

The PUMS US Census data used in Fig. 1 was from the 1980 census. Comparable data fro the last conducted US census may be found at: http://www.census.gov/main/www/pums.html.

The Great Lakes satellite image in Fig. 2 is based on data from the National Oceanic and Atmospheric Administration (NOAA) and is available from the National Geophysical Data Center (NGDC) at: http://www.ngdc.noaa.gov/dmsp/download.html.

The AVIRIS data used for the moxel visualizations in Fig. 9 is available at: http://aviris.jpl.nasa.gov/html/data.html.

The FBI Homicide Data visualized in Figs. 6 and 7 is available at: http://www.fbi.gov/ucr/ucr.htm.



Iconic Displays. Figure 9. Moxel visualizations of the AVIRIS dataset: a zoomed out image (left) and a zoomed in image (right).

Definition

Image comes from *Imago* in Latin and designates funeral masks. Philosophically, an image represents the static and eternal double of a volatile or ephemeral reality. More commonly, it is a two-dimensional artifact that either records the visual appearance of physical objects, like photographs, or provides a visual representation of concepts or artificial data, like graphics or synthetic images. *Digital* images were born in the early 1920s, as a representation of a two-dimensional image using ones and zeros (binary) obtained by digital cameras, scanners or dedicated materials and softwares. They exist in different forms, as illustrated in Fig. 1. Nowadays, digital images are everywhere. They are involved in a large number of leading applications and cover various domains from medicine to video games, including architecture or robotics.

Historical Background

The first use of digital images dates back to the beginning of the twentieth century with the technological

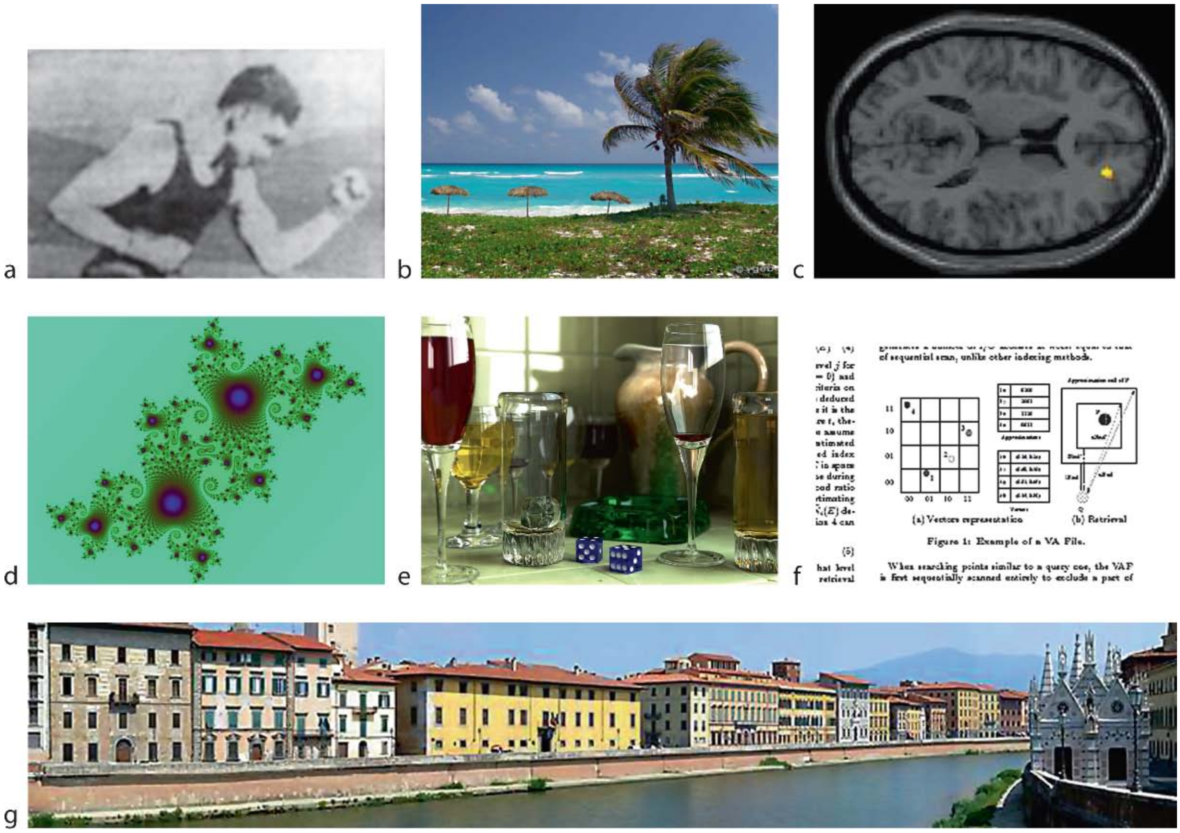

Image. Figure 1. Different representations of digital images: (a) Early digital image reproduced in 1921 by a telegraph printer with special type faces from a coded record (from McFarlane's article, 1972) (b) Photograph taken with a digital camera (c) Axial fMRI slice of a human brain (d) Synthetic image "Julia set," a fractal related to the Mandelbrot set (e) Synthetic image created by G. development of facsimile transmission for the newspaper industry. Among several systems developed for reducing picture transportation time, the Bartlane cable transmission system, invented in 1920 in Great Britain, was the first system that translated pictures into a digital code (Baudot code) for efficient picture transmission [7]; in Fig. 1, image (a) represents an image transmitted with the Bartlane system and reproduced by a telegraph printer. Scanners can be considered as the successors of telephotography input devices. The first digital image made on a computer came from a drum scanner associated with photomultiplier tubes built in 1957 by Russell Kirsch at NIST (US National Institute of Standards and Technology). But drum scanning declined and now relates to specialized applications, due to the development of low-cost flatbed and film scanners.

The advent of digital image technology is also closely tied to the development of computers as well as remote sensing applications. The first computers powerful enough to carry out meaningful image processing tasks appeared in the early 1960s, at the same time as development of space programs. With the aim of improving back transmission of images from space exploration on moon surface mapping, work using computer techniques for converting analog to digital signals began at the NASA Jet Propulsion Laboratory in Pasadena in 1964. Computer technology was advanced and pictures transmitted were processed to correct various types of image distortion inherent in the on-board television camera.

In the early 1970s, the invention of computerized axial tomography (CAT) was another important event in the development of digital imaging, in this case for medical diagnosis. From rings of sensors around the object and X-ray source, tomography consists of algorithms that construct an image that represents a slice of the object. Sir Godfrey N. Hounsfield and Prof. Allan M. Cormack shared the 1979 Nobel Prize in Medicine for this invention.

Medical research, government programs for space exploration and espionage with spy satellites clearly helped advance the science of digital imaging. However, the private sector in parallel also made significant contributions in the development of digital cameras. It first became possible to build these cameras with the availability of the CCD image sensor, invented by Willard S. Boyle and George E. Smith at Bell Labs in the early 1970s. In 1981, Sony released the Mavica, first commercial electronic still camera, followed by Canon with the RC-701 camera. Since the mid-1970s, Kodak has invented several solid-state image sensors for professional and home consumer use. In 1986, Kodak scientists invented the world's first CCD mega-pixel sensor, capable of recording 1.4 million pixels. In 1987, they released seven products for recording, storing, manipulating, transmitting, and printing still and video digital images. Since then, a large palette of digital cameras for the consumer-level market has been developed. Current research on digital cameras focuses mainly on sensors and aims at developing sensors with higher resolution, while increasing their sensitivity.

Foundations

Today, the continuing drop in prices of computers and storage, the democratization of digital images (multimedia PCs, digital cameras, cell phones, digital camcorders, etc) and the expansion of networking and communication bandwidth via the Internet or the HDTV (High-definition television) greatly contribute to the production and dissemination of larger and larger volumes of digital images. Digital images are now involved in a large number of leading applications that require the use and development of techniques belonging to several disciplines of computer science. These disciplines are presented below, after a brief introduction to the bases of digital image acquisition and representation.

Image Acquisition

Digital imaging refers to the technical process of digital image acquisition. A 2D digital image may be created directly from a physical scene by a digital camera or similar devices, as illustrated in Fig. 1 with image (b). Alternatively, it may be obtained by a scanner from a document in an analog medium, such as photographs, photographic films or printed papers. Most of these equipments have in common the digital sensors that capture light rays and convert them into electrical signals. At present, the most popular image sensors fall either in the category of charge-coupled devices (CCD) or active-pixel sensors (CMOS for Complementary Metal-Oxide-Semiconductor) for the most recent technology [6].

Unlike human vision, sensors that capture images are not limited to the visual band of the electromagnetic spectrum. Digital images can cover almost the entire spectrum, ranging from gamma to radio waves. Many other specific equipments exist to capture 2D or 3D digital images, mainly for medical, military, astronomy or satellite domains: X-radiographs, MRI scanners (Magnetic Resonance Imaging, see image (c) in Fig. 1), PET scanners (Positron Emission Tomography), SLAR radars (Side-Looking Airborne Radars), radio telescopes, etc.

Finally, a digital image can also be computed from a geometric model or mathematical formula. In this case, it refers to 2D or 3D computer graphics discipline, as illustrated with images (d), (e), and (f) in Fig. 1.

Image Representation

Digital images can be represented either as vector graphics or bitmapped representation (also called raster representation). Vector images are geometrical 2D objects created with drawing software or CAD (computer-aided design) systems. They are represented with geometrical primitives such as points, lines, curves, and shapes or polygons, which are all based upon mathematical equations.

A bitmapped digital image is composed of a set of dots or squares, called pixels (for picture elements), arranged in a matrix of columns and rows. Each pixel has a specific color or shade of gray, and in combination with neighboring pixels it creates the illusion of a continuous tone image. Managing bitmapped images requires the manipulation of several parameters such as color model, dynamic range, and resolution.

Image Processing and Analysis

Because an image can be seen as a two-dimensional signal, image processing is a sub-field of signal processing. A lot of image processing techniques involve treating the image as a two-dimensional signal and applying standard signal processing techniques to it, while other techniques are specific to images. In the digital image community, there is not an unified definition of the tasks associated with image processing. Traditionally for some people, image processing techniques refer to image manipulation or filtering and then take an image as input and provides another image as output. For others, the output can also be a set of characteristics related to the input image, for instance either low-level features obtained by detection or extraction processes (contours, regions, etc), or high-level features obtained by analysis (face recognition, behavior interpretation, etc). According to [4], image processing gathers the three following computerized processing levels:

- Low-level process: This level involves preprocessing operations such as image geometrical transformations (sub-sampling, rotation), image compression, image enhancement (noise reduction, contrast enhancement, image sharpening, etc). Both the inputs and outputs are images.
- Mid-level process: The input is an image processed at previous level and generally the outputs are visual attributes extracted from this image. Mid-level processing on images involves tasks such as automatic extraction of meaningful features (contours, key points, regions, objects). This step is then followed by the visual description of these features to be able to make the distinction between them, and more generally to reduce them to a form suitable for higher-level computer processing.
- High-level process: This ultimate level tries to artificially perform the cognitive function usually associated with human vision. Associated with previous level, it refers to image *analysis* and *interpretation* in literature. From the features extracted at previous level, plus potential external information such as prior knowledge furnished by the application/ domain or training data, the algorithms try to form a decision.

Computer Vision

As the name implies, computer vision is the science and technology that allow computers to see. Computer vision is concerned with the theory for building artificial systems that interpret images, with ultimate goal of reaching performances similar to human vision. This discipline shares many formalisms and techniques with the image processing and analysis one previously described. But in literature, image processing and analysis tends to be interested in the interpretation of 2D images, while computer vision rather focuses on the interpretation of 3D scene from its projection onto one or several images to analyze, e.g., how to reconstruct structure about the 3D scene or other geometrical information (like location of cameras or 3D trajectories of objects) from images. To achieve these tasks, one fundamental aspect of computer vision techniques is geometry and more precisely the manipulation of geometrical models [5], such as the camera model (classically *pinhole model*) and the stereovision model (*epipolar geometry*).

The problems addressed by 3D computer vision are various [3], for example: camera calibration, i.e., the automatic determination of the characteristics of the camera from one image and a 3D pattern; auto-calibration from several images; 3D reconstruction of the scene structure from several images; determination of 3D motion/trajectory of objects in video sequences.

Image Synthesis

While scanners or digital cameras allow building digital images from physical objects, image synthesis focuses on the capability to create novel images representing realistic or artificial scenes. The traditional approaches of *computer graphics* have been to create synthesis images from a given geometric model in 3D by projecting it onto a two-dimensional image. Conversely, *image-based rendering* starts from one or several two-dimensional images in order to directly generate novel two-dimensional images, skipping the manual 3D modeling stage. Applications such as video games, motion picture, audiovisual, architecture, computer simulation, tourism (virtual travels) and e-commerce stand to benefit from these technologies. The most known associated exhibition is the SIGGRAPH annual conference (Special Interest Group on GRAPHics and Interactive Techniques) convened by the ACM SIGGRAPH organization since 1974 [12].

Computer Graphics Computer graphics is concerned with the creation and the manipulation of digital images [10]. The term can refer to 2D computer graphics, where artificial images are diagrams, logos or textures that may be generated by using vector graphics modelers (see example (f) in Fig. 1), mathematical models such as fractals (see example (d) in Fig. 1), or by processing existing images. Most of the time, computer graphics implicitly means 3D computer graphics, that renders images from the three-dimensional representation of geometric data. 3D computer graphics moves on several techniques stemmed from Computer-Aided Design (CAD):

- *3D modeling* is the process of developing a mathematical representation of any three-dimensional object that describes its appearance in terms of shape, colors, and potential textures. 3D models are often created with special softwares called 3D modelers, by an artist, a specialist or engineer or scanned into a computer from real-world objects.
- The object layout and its interactions with other objects must also be described. If the object moves or deforms, *animation* refers to its temporal description. Popular methods include inverse kinematics and motion capture; this last involves the recording of human actors actions, to animate digital character models.
- *Rendering* converts the 3D object into a image by projecting it onto a 2D image with a perspective projection model, while simulating light transport according to illumination models. The basic operations are *transport* (models for light movement) and *scattering* (models for light reflection on the object's surface). Different methods are better suited for either photo-realistic rendering, or real-time rendering. When the goal is photo-realism, the most famous global methods for rendering are *ray tracing* and *radiosity.* These techniques successfully address the problems of occlusion, transparency, shadows and take the interactions between objects into account, as illustrated with the image of Fig. 1e.

Image-Based Rendering Unlike traditional computer graphics approaches previously described in which 3D geometry of the scene is known, the aim of image-based rendering techniques is to render novel views directly from input 2D images, in a realistic way without full 3D model reconstruction [11]. Previous work on image-based rendering reveals a continuum of image-based representations based on the tradeoff between how many input images are needed and how much is known about the scene geometry; such techniques directly refer to geometric and algorithmic models of computer vision. The most popular applications of image-based rendering are *view morphing* and *image mosaicing.* The first one aims at generating intermediate views between two reference images, by interpolating parts of images in correspondence. In the 1990s, they were very popular in the audiovisual industry and motion pictures, while producing aesthetic and spectacular special effects at low cost, such as one face turning into another. The novel views rendered with such techniques do not respect the geometry scene, in the sense that the objects may be distorted in the produced images. Image mosaicing produces panoramic images by registering or stitching multiple regular images that partially share a view of the scene; see example (g) of Fig. 1. The produced image can be projected to a cylindrical or a spherical map for visualization and virtual navigation with the feeling of immersion into the 3D world. The first and most popular application of mosaicing is QuickTimeVR [1].

Image Indexing and Retrieval

The huge volume of digital images now available on the Internet or simply on personal computers makes for images that cannot be easily located. Image indexing techniques aim at developing search engines that manage collections of images and in particular that facilitate their fast and accurate retrieval. But retrieval of images, more generally of multimedia data, is different from retrieval of structured data such as classical databases. It is necessary to exhibit a description of the images, often called *descriptor*, that represents the essence of the image for a given topic and that will be indexed to allow efficient retrieval among the many descriptors associated to the available images.

The most usual descriptors associated to images are textual, making tools of linguistics required to define them. Most of the time, this information is structured in *keywords* that can either be related to a controlled vocabulary (potentially connected to dedicated ontologies or semantic lexicons) or be freely assigned [13]. Keywords can be determined by analyzing the metadata associated with the image, the filename of the image, by parsing text adjacent to the image as Google Image Search does on the Internet, or by using more sophisticated methods such as text extraction from images content. Otherwise, keywords are designed manually by experts of the application domain. A popular new form of free-text keywords on the Internet is *folksonomy* where tags are assigned to images by non-experts or consumers collaboratively. Once the images are described with keywords, evaluating a search query to quickly locate images characterized with given words among a collection of images is done by exploiting an index data structure; inverted files are a popular technique for indexing text data [9].

Text-based indexing has several shortcomings such as ambiguities, subjectivity, language or context-dependence. Indexing the visual content of images is a recent alternative that may help to reduce these drawbacks by giving additional insight into the collections of images. When the number of images makes manual annotation unachievable, it is the only solution. Born in early 1990s, Content-Based Image Indexing (CBIR) is a discipline that exploits techniques of image processing/analysis in addition to databases tools [2]. Indexing an image by its content begins by extracting visual structures that describe the visual content relevantly for the considered application. Such structures are considered as the index of the image, which is digitally represented with one or several multidimensional vectors called *signature* of the image. Here, multidimensional index structures are required to perform retrieval efficiently in terms of processing time and disk access [9].

Key Applications

A classical problem in image processing, image analysis, computer vision and CBIR is the ability to determine whether or not an image contains some specific objects. This task, referred to *object recognition*, can normally be solved robustly and without effort by a human, but is still not satisfactorily solved by computers for the general case of arbitrary objects in arbitrary situations. The existing methods can at best solve it only for specific objects such as print or handwritten characters, human faces or vehicles and in specific situations, typically described in terms of well-defined illumination, background, and pose of the objects relative to the camera. Thus, while object recognition has been an active research area for 40 years [8], it is still challenging for several applications. Nevertheless, some patented approaches for specific object recognition have already proved their efficiency, they are offered as a service by consumer-oriented companies or are well established in several organizations and apply to a large palette of domains. For instance:

- *Surveillance of road traffic:* Automatic recognition of license plates is a mass surveillance method that uses character recognition on images to read plate numbers on vehicles. Many governments, police, and town councils have adopted this technology to automatically detect vehicles in driving offence, to supervise areas such as parking areas, or to control traffic in order to help monitor the movements and flows of vehicles around a road network.

- *Authentication:* Biometrics technologies provide methods for uniquely identifying humans based upon one or more intrinsic physical or behavioral traits. Systems based on visual appearance analysis are based on particular methods of image analysis dedicated to specific images representing faces, retinas, hands, veins or fingerprints. For example, several banks in Japan have adopted palm vein authentication technology on their ATMs (technology developed by Fujitsu in 2003 and called PalmSecure). Among several governments, Israel has also adopted this technology to control the border crossing points between Israel and the Gaza Strip: an ID card, with stored biometrics of fingerprints, facial geometry and hand geometry, is required to go across.
- *E-commerce:* Since few years, several companies provide to their clients the ability to link their products and services directly to specific web pages on the mobile internet by the way of bi-dimensional barcodes called "smart codes." With their mobile phone's camera, consumers can scan the code placed near or on the product, then the code is recognized by image analysis, making it possible the connection to the associated service (product purchasing, timetables consultation, prices comparison, etc).

Definition

Image Content Modeling deals with the issue of representing the content of image data; that is, designing the high- and low-level abstraction model of the raw image objects and their correlations to facilitate various operations. These operations may include media object selection, insertion, editing, indexing, browsing, querying, retrieval, and exchange. The image content model relies, therefore, on the extraction of feature vectors and their respective representations obtained during the annotation process. Several standards for representing the content of an image are known. The most prominent ones are MPEG-7 including low- and high-level abstractions or the EXIF data description vocabulary for the description of very specific technical attributes of an image.

Historical Background

Many models for describing the content of an image have been created in the past. Most of them rely on standards. Many standards are actually in use, mainly due to *different national and organizational interests* of service providers, standardization bodies, and usage groups. Whereas each standard works well in its dedicated application domain, problems arise in frequently occurring cross-domain working environments. The following is a non-exhaustive list of important standards:

- The *Exchangeable Image File (EXIF)* (http://www.exif.org/) format is an international specification that allows imaging companies to encode meta data information into the headers or application segments of a JPEG file. This meta data information includes shutter speed, aperture, date and time of the captured image. Current digital cameras store images using EXIF compressed files. It is a widespread standard, with a simple attribute/value specification. EXIF was last revised in April 2002.
- The *DIG35* Initiative Group of the I3A (International Imaging Industry Association) has also defined a meta data standard for digital images (http://www.i3a.org/i_dig35.html). The *DIG35 Specification* includes technical meta data on media, simple semantic meta data on persons, locations, events and intellectual property and rights management related meta data. The focus of DIG35 is on retrieval, categorizing and browsing of large image archives. The latest version stems from March 2000.
- The *SMPTE* (http://www.smpte-ra.org/mdd/) is a standardization organization that has created the Metadata Dictionary (MDD). Most meta data consists of media-specific attributes, such as timing information as well as some basic semantic descriptions (interpretation, administration and relationships among descriptions). The MDD definition was reviewed in 2004. The SMPTE Material eXchange Format (MXF) allows users to take advantage of non-real-time transfers, and to package together essence and metadata for effective interchange between servers and between businesses.
- The *P/Meta EBU P/Meta Project* (http://www.ebu.ch/metadata/pmeta/v0100/html/start_frame.html) has created the P_META Scheme, a set of definitions that provides a semantic framework for information which is typically exchanged along with audio-visual material. It includes the identification of concepts referenced by other elements. The P_META Scheme has been created for the use in a business-to-business scenario where the participating organizations may retain their internal data structures, workflows, and concepts. Version 1.0 appeared in 2002.
- The MPEG-7 (http://www.chiariglione.org/mpeg/standards/mpeg-7/mpeg-7.htm) is the MPEG standard for description and search of audio and visual content and is the first standard from MPEG which considers multimedia content models. From the point-of-view of the expressiveness of the proposed metadata descriptions it is the richest set, as it enables the user to describe structural, as well as semantic content of an image [3]. It supplies likewise means for the description of creation, usage and management of images. MPEG-7 version 1 was released as international standard in 2002. An improved version was published in 2006.

MPEG-7 visual description tools cover color, texture, shape and face recognition descriptors for images. They mainly use a histogram-based approach of representation; that is, they compute a vector of elements each representing the number of pixels (regions) in a given image, which have similar characteristics. For instance, the color structure descriptor computes a histogram obtained by accounting all colors in a structuring element which slides over the images and takes therefore the spatial layout better into consideration, or the color layout descriptor which uses a discrete cosine transformation to represent more compactly the histogram. MPEG-7 high-level descriptions mainly represent the structure and semantics of an image. The media decomposition tools allow the recursive sub-division of an image into regions of interest. A decomposition tree describes the image source and the spatial structure of the image regions and can be used to create a table of content. Each region can be associated with its shape information and low-level visual descriptions, then information on creation, rights and usage, simple text annotation (what, where, when, why, how), and semantic descriptions. Semantic descriptions represent a narrative world as a set of semantic entities and semantic relations among semantic entities, and segments. Possible semantic entities are objects, agent objects, events, places, and time. MPEG-7 has been employed in many retrieval and database systems. Westermann et al. gives an overview of MPEG-7 based database solutions [11] and provides a persistent DOM (Document Object Model) model that can be used for MPEG-7 systems solutions. A full-fledged database system, MPEG-7 MMDB is described in [1].

The general goal of achieving *image content data interoperability* is affirmed by many researchers. It is expressed by panels and tutorials held at various international conferences, such as ACM Multimedia 2002 and 2004 (See, http://mm02.eurecom.fr/panel.html and http://www.mm2004.org/acm_mm04_call4tutorials.htm) or by input contributions to standardization (e.g., recently proposed to W3C as Semantic Web Image Annotation Interoperability (http://www.w3.org/2001/sw/BestPractices/MM/interop.html)). It has been clearly recognized that missing interoperability is still a major burden for an effective use of image content data in industrial media engineering.

Foundations

Keywords are by far the predominant features used to describe the content of image data. An indexer using keywords or a textual abstract describes the content of the image [6]. Another method, *content-based indexing*, refers to the actual content of the image data. Intensive research has focused on content-based indexing in recent years, with the goal of indexing the image data using certain features derived directly from the data [10]. These features are also referred to as *low-level features*. Examples of low-level visual features for images are color, shape, texture, spatial information, and symbolic strings. The extraction of such features may be done by an automatic analysis of the image data. Indexing *high-level features* (e.g., objects, events, etc.) of image data is an active research area [5]. Different detection mechanisms have been proposed for segmenting the image materials into regions of interest and for attributing semantic meaningful annotation to each region and (their semantic) relationships. In addition to this, and related to the previous issues, ongoing research concentrates on image classification. For example, is this image showing a sport event? And more specifically, is this sport image about basketball? The recognition of an image as basketball facilitates the semantic annotation process, as one knows what kind of objects and persons might appear.

Image Content Modeling refers now to the design of a high- and low-level abstraction model of the raw image objects and their correlations to facilitate various operations, such as media object selection, insertion, editing, indexing, browsing, querying, retrieval, and exchange. Several abstract models have been proposed in the literature [3]. Most of them deal with special low- and high-level features. At least two models introduce a general framework to cover the whole spectrum of available features, the DISIMA model [7] and the indexing pyramid [2]. The later one served as conceptual model for the semantic part of the MPEG-7 standard.

The DISIMA model relies on two main concepts, namely the image and salient objects (logical and physical) and operators to manipulate them [7]. Principally, the image type defines the content of an image as a set of physical salient objects that are regions of the image. The semantic meaning of a physical salient object is represented by a logical salient object. Oria et al. define several properties of physical salient objects, such as color, texture, and shape. The logical salient object gives semantics to a physical salient object; proposed examples are objects, persons and so on. Predicates for comparing objects (e.g., different similarity operators, spatial operator) and a special contain operator which computes if an object is contained in an image, are proposed. As an image can be composed of more than one physical object, logical objects can be found several times. The model can be queried by Visual MOQL, an image query language based on OQL, proposed in a previous paper of [7].

Jörgensen et al. [2] introduced a representation model based on the indexing pyramid for classifying levels of indexing. The pyramid, as shown in Fig. 1, distinguishes between *syntactic* (first four levels) and *semantic* levels (next six levels). The syntactic levels hold attributes that describe the way in which the content is organized, but not their meanings. This corresponds to the definition of low-level features. In images, level 1 (type technique) could be "color image." Global distribution holds attributes that are global to the image (e.g., color histogram), whereas local structure deals with local components (e.g., lines and circles), and global composition relates to the way in which those local components are arranged in the image (e.g., symmetry). The semantic levels deal with the meaning of the elements. This corresponds to the definition of high-level features. With each level, more knowledge is required to represent the objects. They can be described at three levels:

1. Generic: every day objects (e.g., person)
2. Specific: individually named objects (e.g., Roger Moore)
3. Abstract: representing the highest semantic abstraction (e.g., power)

In a similar way, a scene (composition of elements) can be described at these three levels.

Note that the authors of the indexing pyramid also propose a retrieval system that allows a search specific to the levels of the pyramid. For instance, if a user enters "soccer" for image search at the syntactical level, one retrieves images with a description containing the keyword soccer (which does not yet mean that a soccer game is shown in the image). This is the same mechanism as the retrieval engine that Google uses (http://images.google.com). If a user enters soccer at the semantic level, only those images are retained in which the event, "soccer," took place. An online demo is available at http://www.ee.columbia.edu/~ana/mpeg-7/.

Image Content Modeling is dominated by the *use of standards*, as already mentioned in the historical considerations before. Two types of standards have to be considered. First those which intend to specify a standard way of describing the content of image data mainly for information search and exchange. Second those which aim to be used for image storage, manipulation and query. In the first category, MPEG-7 is an important representative [3]. MPEG-7 is introduced in the historical background, and is detailed in the multimedia/image metadata entries. An example MPEG-7 document is given in Fig. 2. In the second category, SQL/MM, recently been integrated into Oracle Multimedia for instance, is representative [8]. SQL/MM will be detailed in the next paragraphs.

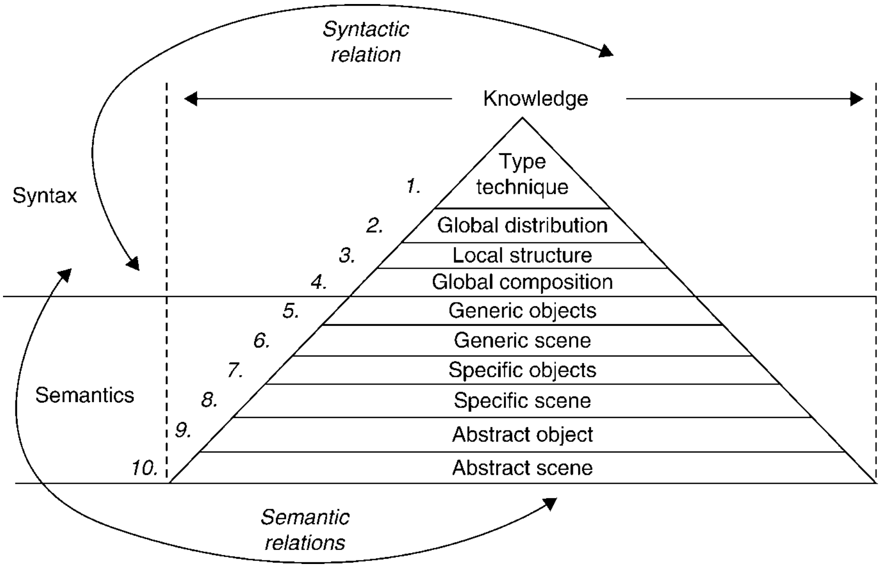

Image Content Modeling. Figure 1. Indexing Pyramid as base for MPEG-7.

SQL/MM as Conceptual Image Data Model for Databases ISO/IEC developed the SQL/MM Multimedia extensions to SQL to deal with image data in a database management system [8]. SQL/MM has been recently introduced to several commercial systems. It introduces new object data types, in the center are the *SI_StillImageType* and related feature vector representations. Principally, one color histogram (*SI_ColorHistogram*), and two non histogram color features are proposed, an average color (*SI_AverageColor*) and an array of dominant colors (*SI_PositionalColor*). The texture feature (*SI_Texture*) contains values that represent the image texture characteristics. The standard defines in addition a composite feature (*SI_FeatureList*) containing up to four different basic features and associated feature weights. A weight value specifies the importance attributed to a particular feature during image matching. The weight value varies from 0.0 to 1.0. A feature weight value of 0.0 indicates that the feature is not considered for image matching.

          </Semantic>
       </Image>
     </MultimediaContent>
  </Description>
</Mpeg7>
```

Image Content Modeling. Figure 2. MPEG-7 Example Document.

It can be clearly seen that the SQL/MM data model covers only parts of the syntactical levels of the indexing pyramid proposed in [2]. For instance no means for describing the decomposition of an image into region of interests is given.

For instance, a photo book can be described by the following table definition:

```
CREATE TABLE PHOTOBOOK (
PHOTO_ID NUMBER(6), // id for identification
PHOTO SI_StillImage, // the image itself
AVERAGE_COLOR SI_AverageColor, // here
comes the list of
COLOR_HISTOGRAM SI_ColorHistogram, // fea-
tures for querying
FEATURE_LIST SI_FeatureList,
POSITIONAL_COLOR SI_PositionalColor,
TEXTURE SI_Texture,
COMMIT;
```

Key Applications

Key applications for image content modeling are image databases and retrieval systems. SQL/MM is the standard for the use in commercial database management systems. Its simple conceptual model does not allow the use of complex low-level representations, nor high-level descriptions. Instead, a recent research issue is on image meta data databases, which for instances expresses in the search for a good mapping of an image content model into database schemes (see e.g., MPEG-7 databases in [1,11]).

Definition

Given a collection of images, a full-fledged image database provides means and technologies that support an efficient and rich modeling, storing, indexing, retrieval, and manipulation of images and its meta-data. The modeling of images can range depending on the used meta-data format (e.g., MPEG-7) from simple technical annotations such as file size, creator, etc. to more sophisticated annotations such as low level features (e.g., color) or even high level features (e.g., objects, events, etc.). The storing component is responsible for mapping the used meta-data format to an adequate database schema. Indexing facilities should support efficient retrieval and need to provide means (depending on the used meta-data) for indexing text, multidimensional feature vectors and high level representations. The retrieval and query specification should support some or all of the following concepts: query by example, query by sketch, query by textual information (e.g., creator), query by category browsing, query by concept. Finally, manipulation of images should allow operations such as rotating, shrinking, format conversion, thumbnail creation, feature extraction, etc.

Historical Background

Activities in storing and retrieving images within databases can be traced back to the late 1970s, where first conference (e.g., Data Base Techniques for Pictorial Applications, 1979) contributions introduced the use of relational databases for images [2]. In general, these early works focused on the annotation and retrieval of images by textual information. For this purpose, the images were described by keywords or textual descriptions and common relational database technologies and their text-based retrieval approaches were used for searching within the pool of annotated images. A substantial survey for text-based image retrieval can be found in [11]. The main drawbacks of these early-approaches concern the annotation of images by text. In general, manual annotation of images and its content is very time consuming and for large image sets infeasible. Furthermore, the assignment of descriptions or keywords to images is not based on the use of a controlled and universally valid vocabulary or classification scheme, and is highly affected by cultural, subjective and domain specific influences. First discussions on this topic were raised by Shatford [9] which indirectly resulted in various thesaurus catalogues (e.g., thesaurus for graphical material, Art and Architecture Thesaurus (AAT), etc.).

Based on the identified drawbacks of text-based image retrieval, researches tended to move in the late 1990s to investigate the retrieval of images by content. It is often referred in the literature as content-based image retrieval (CBIR) and concentrated on technologies for the extraction, indexing, comparison and query of images by their low level features. These low level features include representations for color, texture and shape which can be extracted automatically.

In general, a typical CBIR system covers the following main steps. First, the low level features of all searchable images are extracted and stored as high-dimensional feature vectors in a database. Then, in order to improve retrieval efficiency, the feature vectors are indexed by specific access methods which are tuned for that kind of data (see [3] for a survey of existing access methods). Finally, during the query process, an example image (represented by its features) is provided by the client. Based on this, the similarity/distance in relation to the stored features is calculated. The size of the result set depends on the chosen query type (range query or nearest neighbor) and contains the most similar (in terms of the low level features) images according to the given one.

Examples of early successful systems and applications focusing on CBIR were, for instance, the IBM QBIC system (which stands for Query by Image Context), Blobworld or CalPhotos. The CalPhotos image retrieval system had its roots in a 1993–1994 research project called Chabot, at the University of Berkeley. R. C. Veltkamp and M.Tanase compared (updated in 2004) 43 available products [12]. Smeulders et al. surveyed the early years of CBIR systems in [10] with 200 references.

Foundations

As already outlined in the historical background section, the search within image collections has a long tradition in the field of database management systems. In the following, the main components of an image database are introduced in order to support the storage, indexing, and retrieval of images.

Image Database Schema

First approaches transferred meta-data of raw media data into database relations in an ad-hoc way. These simple models only support certain types of queries and operations and were mostly limited to keyword retrieval. The nature of multimedia data, consisting of alphanumeric, graphical, image, video, and audio objects, differs in many ways to simple alphanumeric data that relational database management system are able to handle. One of the first models proposed for visual information that considers semantic queries, was called the Visual Information Management System (VIMSYS) [4] from Virage. The creators recognized within their model that image and video information is preferred to be retrieved by content rather than by keywords or additional textual descriptions. During the past years, research concentrated on the development of data models for images (e.g., [1]) and content-based retrieval. In most cases, these systems concentrate on the retrieval based on low-level features. Recently, data models for image information that support high-level features have been introduced. The data models of these systems are often specialized to one type of genre, e.g., retrieval on the basis of soccer games (e.g., [5]).

Index Structures

Besides the necessity of developing semantically rich image data models and database schemas, an efficient indexing and search of images is essential. During the last decade, image based retrieval concentrated on the use of low-level features and their feature vector representations.

In order to improve search efficiency, different access methods have been established for indexing multidimensional feature vectors, for instance (to mention just a few) LPC-File, X-tree, Pyramid Technique, R-tree and its variants, SR-tree, M-tree, etc. An excellent survey and overview paper of index structures is given by e.g., Gaede et al. [3]. An evaluation of different quantization techniques, such as A-tree versus IQ-tree is given by Garcia-Arellano (University of Toronto) in his master thesis. A complete generalized framework, called GiST, has been established by J. Hellerstein and his group at the University of California, Berkeley. It consists of a set of pre-implemented index structures and generalized access interfaces. Support is given by sophisticated graphical tools providing access statistics. The framework has been used for various image retrieval applications (e.g., Blobworld) and the development of new index structures. In addition, the framework has been integrated within research projects in the Informix database and Oracle database.

One problem in processing feature vectors is their high dimensionality. The quality of results of a similarity search depends on a high degree on the underlying data set (feature vectors). For instance, the more colors a color histogram represents the merrier the similarity search will work. This correlates with a higher dimensionality of the resulting feature vector. This is also the case, when multiple features are combined, such as for images the color, the shape and the texture. Unfortunately, query performance of access methods decreases, if dimensionality of the underlying data set becomes high. This phenomenon is known as *curse of dimensionality* [3]. One possibility of avoiding this problem is the development of specific index structures that are specialized for high-dimensional data (e.g., see [3] for a survey). Another possibility is the reduction of the vector dimension. The main goal of reducing the dimension is to find a low-dimensional representation of the vector that preserves (most of) the information of the original data. The reduction can be realized by two different approaches: *Feature selection* and *Feature extraction*. *Feature selection* stands for choosing a subset of all the features that represent most of the desired information. *Feature extraction* describes the creation of new features by combining the existing ones. Wu et al. [13] introduced a dimensionality reduction for image retrieval called *weighted multi-dimensional scaling*. Another commonly used technology is the *singular value decomposition* (SVD).

Query Optimization

A general architecture of a query optimizer has commonly the following form [1]: A query is forwarded to a *query parser* which checks the syntactical correctness and transforms the query into an internal representation (mostly an algebraic expression). In the following step, the *query optimizer* evaluates the most effective algebraic expressions which represents the given query and chooses the cheapest one. The *code generator* transforms the resulting query plan into calls to the *query processor*, which does the actual query execution. The main task of a query optimizer is to examine all possible alternatives to a given query so that the best alternative can be chosen and the query cost is minimized.

In image databases, queries often contain similarity operations, such as Range or Nearest Neighbor (NN)-operation for low-level features (e.g., color histogram), especially if the system supports content-based retrieval. This can be associated with a similarity-based selection operation in an image database management system. In general, a query optimizer should use three approaches: *selectivity*, *cost model*, or *operator ordering*. Most approaches concentrate on the cost-model and the selectivity, based on the fact that modern database systems, such as Oracle, only provide means for their enhancement.

The cost of a selection operation is in general composed of two different cost factors. The *selectivity* of an operation defines the amount of tuples returned by the selection operation. Whereas, the *cost* of an operation is counted as the amount of data pages which has to be accessed for fulfilling the given task and as the number of necessary CPU cycles. In the image environment, the cost (selectivity, and amount of data pages) of Range- and k-NN-queries in high-dimensional spaces is important. An efficient processing of such kind of queries is guaranteed by a multidimensional index. Therefore, the calculation of the amount of accessed pages (further simply called cost) needs an evaluation of the used index structure. This evaluation can be simple in one case, for instance the selectivity of a k-NN query is determined through k, or difficult, if the selectivity for a Range query is considered which needs an approximation. The cost of a Range query can be easily calculated, based on the known radius which results in an intersection operation of the hypersphere and the minimum bounding rectangles (MBRs) of the index structure. The cost for a k-NN query depends largely on the density around the query location.

In the literature, several cost models exist that concentrate on calculating the amount of page access for Range- and k-NN-queries (e.g., [6]). Selectivity estimation for Range queries is often limited to either the assumption of uniformity and independence of data sets or to the 2- or 3- dimensional data spaces in geographic information systems. The uniformity assumption does not hold for real data sets. In [6], the authors present an efficient cost model for predicting the performance of the k-NN-query independently of the used index tree. The model is accurate for low- and mid-dimensional data with non-uniform distributions. For this purpose, the authors introduce two new concepts: the regional average volume and the density function. The regional average volume is used for calculating the average radius of the hyper-sphere which contains the k-NNs. As indicated before, the average radius is not adequate for highly skewed non-uniform distributions. To overcome this limitation, the authors introduced a density function that estimates the regional radius depending on the location in the data space.

Database Extensions to Support Images

In the last decades, traditional (Object-) Relational Database Management Systems ((O)RDBMS) have been very effective and efficient in managing alphanumerical data. They basically offer services such as indexing, query optimization, buffer management, recovery or concurrency control, which are well investigated and optimized. Unfortunately, common ORDBMS and their techniques have several drawbacks in handling image data. The most important drawback concerns the concept of matching. In traditional databases, the concept of matching relies on a filtering operation which decides for every tuple whether it fits the requirements or not. Basically, the main retrieval paradigm in image data repositories is similarity search. Therefore, extensions to ORDBMS mainly concern the implementation of this search type and for ranking the results, as well as for supporting index structures and query optimization. In the following subparts, various topics for image extensions are addressed.

Query Extension for Multimedia: SQL/MM Traditional query languages, such as SQL, do not provide means for handling multimedia types and their appropriate operations to satisfy the requirements in retrieving multimedia data. Therefore, several query languages (e.g., MOQL, MMDOC-QL, etc.) have been introduced by researchers in order to overcome these limitations. One standard which has been developed explicitly for image data is SQL/MM.

The SQL/MM [8] standard (MM for MultiMedia) is an extension of SQL for supporting any kind of multimedia data. SQL/MM is a multi-part standard and was developed by an ISO subcommittee, namely JTC1/SC32. The various parts of SQL/MM are independent from one another; e.g., Part I (framework) contains definitions of common concepts that are used through out the other parts or *Still Image* (Part V) is all about image data. The SQL/MM Still Image part provides structured user defined types that allow the storage of images within databases and specifies methods for modifying them in various ways and retrieving them efficiently. Images in SQL/MM are represented by the *SI_StillImage* structured data type. The *SI_StillImage* type can store images of several formats depending on what the underlying system supports. Furthermore, it extracts information about each image, such as format, height and width in pixels, color space, etc. In addition, the type provides several methods e.g., for scaling, for rotating or for creating thumbnails of the original image. Moreover, there exist various additional data types for describing several features of images. For instance, the *SI_AverageColor* type represents the average color of a given image. The *SI_ColorHistogram* type provides information about the distribution of colors within the image. The *SI_PositionalColor* type represents the location of specific colors in an image. The SQL/MM Still Image part provides CBIR functionality by combining these types and methods with accurate index structures. For instance, the *SI_PositionalColor* type supports queries like “Give me all images with a color representation of red or orange above dark blue.”

This query would lead to images that in most cases show sunsets at sea.

Multimedia Extensions in Products

Oracle Multimedia The extensibility service provided by Oracle is called *Data Cartridge*. Oracle databases are built as a modular architecture which provides several extensible services. The common way for using Oracle's Extensibility Services is to implement a Data Cartridge that extends the extensibility interface.

Currently, several Data Cartridges have been developed to support multimedia data. Oracle itself provides among others, Cartridges for spatial data and for multimedia data such as image, audio and video. Cartridges of other vendors are for instance, the *Viisage Cartridge* from Virage which provides face recognition on behalf of images. This company provides several face recognition tools for controlling access to restricted areas e.g., Berlin Airport or identifying criminals in a crowd of people.

IBM DB2 The IBM DB2 database provides *Extenders* for enhancing their database management system to meet new requirements, e.g., the storage and retrieval of multimedia data. DB2 Extenders generally specify UDT's (user-defined types) for extending the core database types. At present, there exist a large number of available extenders from different vendors. For instance, IBM itself provides the *AIV* extender for audio, image and video data. Extenders of other vendors in this area are for instance, the *Spatial Data Extender* from Environmental Systems Research Institute (ESRI) for GIS and geo-spatial data or the *SpatialWare Extender* from MapInfo for spatial data. SQLSummit provides an accurate list of Extenders.

IBM Informix The IBM Informix database management system deploys the feature of *DataBlade Modules* to extend their functionality for new requirements. This DBMS provides three different tools for developing DataBlade modules, namely *BladeSmith* for creating DataBlade modules, *BladePack* for packaging them, and *BladeManager* for making them available in the database. Up to now, several DataBlade modules exist such as *Spatial DataBlade module* for managing spatial data inside the database, *Excalibur Image Data-Blade module* for storing and querying images and special vendor products, like DataBlades for MPEG-1.

Image Retrieval Systems from Scratch In contrast to database extensions such as Oracle's Multimedia for managing multimedia data, several image retrieval systems have been developed from scratch (e.g., DISIMA which is an image database management system developed at the University of Alberta). R. C. Veltkamp and M. Tanase compared (updated in 2004) 43 available products [5]. A survey of CBIR systems supporting high level semantics can be found in [7]. In the following, two currently active systems are introduced:

- DISIMA is a pure image database that considers images as a set of salient objects (regions of interest). Salient objects are classified according to a user defined type hierarchy. Other currently active systems are for instance:
- Behold is a large scale image retrieval system and has been developed at the Imperial College in London. It provides means for text-based search and NN-search based on a parameterized similarity metric.

Key Applications

Surveillance Systems

The detection of criminals, wanted persons and known terrorists on airports or border stations bases on face detection algorithms and large scale image (showing persons and/or faces) databases that support the retrieval among millions of data entries.

Medical Diagnosis Supporting Systems

Recent research concentrates on applying image database in the medical domain. Every hospital has a large set of x-rays showing a diversity of diseases. These image collections are used for supporting doctors in completing their diagnosis. For instance, in case of a cancer patient, the doctor can query the image database for similar x-rays based on the patient's.

Web Search

Finding meaningful and high quality images on the web is a goal which appeals to many different people, private and professional alike. The amount of images available on the web is vast, so efficient retrieval mechanisms like CBIR are essential. Research efforts in this direction are for example the before mentioned system Behold (see section, Image Retrieval Systems from scratch).

Image management for life sciences; Databases for biomedical images

Definition

Image management for biological data refers to the organization of biological images and their associated metadata and annotations in a computer in such a way that they can be searched and shared.

Historical Background

The need to manage digital micrographs stored in a computer arose in the early 1990s, when digital cameras started to replace film cameras. Rapid improvement in microscopy technology coupled with steady decline in prices led to an unprecedented increase in the collection of digital biomedical images, and the need for systems to organize, search and share the images became clear. At the same time, the successes of large scale acquisition and analysis of genomic and gene expression data have prompted an increased interest in large-scale image analysis and the use of statistical methods to find patterns in large image sets. The ability of images to capture spatial and temporal relationships not immediately available from other data sources make them vital in understanding the underlying processes in biology that produce them. Database systems for these images promise important benefits, ranging from ease of organization and maintenance to the ability to share, search, explore, summarize, and analyze the data.

Foundations

Content-Based Similarity Search

Similarity search by semantic content may be performed at the level of whole images (content-based image retrieval, CBIR) or regions (region-based image retrieval, RBIR). Datta et al. provide an excellent survey [3]. Some important image retrieval systems are SIMPLIcity, WALRUS, Virage, QBIC, NeTra, Photobook, VisualSEEk, and Keyblock. The two important components of such image comparison systems are the image features and the distance metrics. Examples of general image features are the MPEG-7 standard features, color histograms, texture, wavelets, and shape descriptors. In addition, there are domain-specific feature sets, e.g., for cultured cells or for whole organisms of the *Caenorhabditis elegans* nematode. The most commonly used distance functions are the L_2 (Euclidean) and L_1 (Manhattan) distances. The earth mover's distance (EMD) [6] has also been shown to be useful due to its ability to capture the spatial relationships among the objects and features inside the images. Relevance feedback methods [15] can improve the feature selection and the distance function by capturing the human notion of image similarity.

In biomedical images, particularly in fluorescence micrographs, large portions of the images consist of background that contains little or no information. Therefore, for RBIR purposes, it is imperative to distinguish the foreground image patterns from the irrelevant background. Segmentation and tiling are common techniques for this. Scoring-based mechanisms that model the background content have also been proposed.

Summarization

To explore an image dataset, it is useful to discover latent concepts, found in the literature under different names such as "visual vocabulary," "eigenfaces," "blobs," "visterms," and "visual keywords." Such key patterns can be thought of as analogous to keywords extracted from text, and have been useful for object detection and retrieval, as well as image classification and captioning.

Key Applications

Electronic Notebook

Computer-controlled microscopes and digital cameras have made it possible to acquire images faster than before, but the image collections are in many ways less organized than in the days of photographic films. It is common for images to be spread across personal computers, portable hard drives, and recordable compact disks. Metadata – the data about data, essentially, the description of what was imaged, how, when, and by whom – are kept in handwritten notebooks or in spreadsheets. Besides being cumbersome, this method of organization is also error prone. Images must be converted from a format specific to the vendor of the microscope to a format that is palatable to other programs. Further, contrast enhancement and other image processing is often necessary to visually inspect the images. Through these transformations, the connection between image and metadata is easily lost, and images can be lost accidentally in the process of file format conversion and image processing.

Electronic-notebook–style image databases store the original image files on a server. Derived files for visualization and image processing can be extracted, but the originals are kept pristine. Metadata are also stored on the server, persistently linked to the respective images. Queries to the electronic notebook are simple, and mostly on metadata only. Mainly, users want to find an experiment or an image based on keywords, dates, and other metadata. In particular, they already know what they are looking for, and do not expect to search by image content. They also want to browse experiments and projects by investigator or by lab, explore the images within an experiment, and download a set of images from an experiment.

It is important that the electronic notebook be flexible in regard to the metadata that can be stored. Some fields (such as the configuration of the microscope) are always useful, but others (such as the details of sample preparation and labeling) vary greatly between labs, and even between experiments. The metadata schema must be easily adaptable to the changing needs of the researchers, or the system is unlikely to be adopted.

MetaXpress (http://www.moleculardevices.com/pages/software/metaxpress.html), BioImage [2], Global Image Database (GID) [5], and Cell-Centered Database (CCDB) [9] are examples of electronic-notebook-style image databases. GID provides minimal set of annotations in a fixed format that caters to many image types and are useful for sharing. In CCDB, a backbone schema is provided which can be enhanced by specialized tables. There is additional provision for storing the results of image analyses as pre-defined object types. The open microscopy environment (OME) [13] and Bisque systems (http://www.bioimage.ucsb.edu/) also serve as electronic notebooks, although they provide more advanced functionality, described in later sections. Further, Bisque allows the user to modify the metadata schema.

Sharing and Exploration

Sharing images beyond the investigator's immediate colleagues leads to two new requirements for the image database: integration of metadata and image-content–based search. The flexibility of modifying the schema that is so valuable in an electronic notebook impedes sharing because the system will need to know which fields in one schema corresponds (perfectly or partially) to which fields in another. Schema matching techniques have been developed that unify the schemas based on both structure and contents [1]. A related problem pertains to the contents of the fields. For instance, the same antibody can be known under different names. As a second example, one researcher may describe a cell as a "photoreceptor" whereas another scientist may be more specific and call it a "cone." Whereas the Gene Ontology (GO, http://www.geneontology.org/) is a start, it will need to be combined with other ontologies or controlled vocabularies.

For *in vivo* images, the location in the tissue or organism that was imaged is another important piece of metadata. To understand and explore such information, registration and mosaicking techniques have been developed to align the image to an *atlas* [4].

So far, in addition to the images themselves, only metadata, i.e., information about the images, have been considered. A second kind of image-associated data are *annotations*. Annotations are data *derived from* the images. They can, for instance, indicate specific objects of interest (e.g., crescent-shaped nuclei, neurite branching points) or summarize measurements (e.g., cell counts, neurite length distributions). Image features can also be considered annotations. Annotations can be stored in an electronic notebook, just like metadata. Annotations are, however, more important for sharing and exploration, for they allow the user to find interesting images even if they were acquired for a completely different purpose. For instance, a researcher may want to find all perturbations (drug treatments, gene knockdowns, etc.) that led to a high rate of crescent-shaped nuclei.

Although metadata and annotations have many similarities, the latter are much more challenging for the database designer. Each metadata field has one true value which is provided by the original investigator, typically at the time the image is uploaded to the database (and perhaps updated or corrected later). In contrast, because annotations are interpreted from the image, more than one user or tool may add different values for the same annotation. Two researchers may disagree on what kind of cell a certain object is, and two cell counting tools will produce different results. The database must therefore be able to store uncertain information and track the provenance of the annotations. Handling uncertain information in databases is an active research area [7,11].

Another open question is how to control access to annotations. When sharing sets of images between labs, issues such as who owns the data, who are allowed to access them, who can run analysis tools on them, who can update the database with new results, etc., are critical. Another important factor is ensuring the quality of data, including the validation, accuracy, completeness, and integrity of the images being processed or uploaded, as well as the annotations produced by analysis tools. Similar issues are discussed by Toga et al. [14].

Although search by metadata and annotations is important and useful, it has an obvious limitation: one can only find what others have annotated. For effective exploration, one must be able to search the images by content (see Content-Based Similarity Search and Summarization in the Scientific Fundamentals section).

Analysis

The third principal application of image databases to biomedical images is as a platform for numerical and statistical analysis of the annotations derived from the images.

Combinations of analysis steps can be viewed as networks, where the results of one analysis feeds into another. For example, ridges can be extracted directly from the image, and can, therefore, be considered as low-level annotations. Next, the ridges are filtered and linked into neurites, which are then combined with cell bodies (detected by some other method) into whole neurons. Note that neurites and neurons are objects that have biological meaning. Finally, one may measure the amount of a certain protein within the cell. The Open Microscopy Environment (OME) [13] provides a module system for tracking the provenance of the resulting data. Each module execution is recorded, relating the module and its parameters to the input and output data.

Analysis of annotations frequently involves classification. The reason is that clustering and other unsupervised methods often pick up cell-cycle–dependent variations and other differences that are real and profound, but irrelevant to the question of interests. This can be avoided by classifying perturbed samples from controls [8].

Future Directions

Whereas the size of the images is a problem for image databases, managing the analyzed data is an even bigger problem because the analyses can be numerous and the annotations produced by such analyses can be queried in complex ways. As an example, a single experiment can comprise of 350 GB of images, and over 600 features are extracted from each cell for a total of over 20 GB of annotations [10]. Future experiments are expected to reach 20 times this size. Therefore, efficient index structures and database access methods will be needed.

Queries posed to databases as part of an analysis process generally involve a large number of records. For instance, a classification task may need to look at the records of all the cells perturbed in a certain way. However, due to feature selection, only part of the record may need to be examined – say, 50 of the 600 features. Column-oriented DBMSs [12] have the potential to improve the performance dramatically for such queries. Another very general approach to speeding up queries is to approximate the result based on only part of the data. Techniques that give statistical guarantees about the quality of approximation have been proposed for many query types, but are so far only available in specialized applications and in research prototypes of database systems.

Image Metadata

Frank Nack
University of Amsterdam, Amsterdam,
The Netherlands

Synonyms

Pictorial metadata; Picture metadata; Image representation

Definition

A digital image is a representation of a two- or three-dimensional image, where the representation can be of vector or raster type.

Metadata is data about data of any sort in any media, describing an individual datum, content item, or a collection of data including multiple content items. In that way, metadata facilitates the understanding, characteristics, use and management of data.

Image metadata is structured, encoded data that describes content and representation characteristics of information-baring image entities to facilitate the automatic or semiautomatic identification, discovery, assessment, and management of the described entities, as well as their generation, manipulation, and distribution.

Historical Background

Many of the techniques of digital image processing were developed in the 1960s at, among others, the MIT, Bell Labs, and the University of Maryland. These works tried to automatically generate content representations that could support research on satellite imagery, wire-photo standards conversion, medical imaging, character recognition, and photo enhancement. In the 1970s, digital image processing improved mainly because cheaper computers and dedicated hardware that allowed real-time image processing [2] became available. The next 20 years not only saw a further improvement on automatic feature extraction for domains, such as scientific, industrial, medical, and environmental research, but also a steady infiltration of those technologies in everyday media environments, such as image editing tools (Photoshop (http://en.wikipedia.org/wiki/Adobe_Photoshop), Illustrator (http://en.wikipedia.org/wiki/Adobe_Illustrator_CS2), GIMP (http://en.wikipedia.org/wiki/GTK%2B), or Maya (http://en.wikipedia.org/wiki/Maya_%28software%29)), new media authoring tools (Director/Shockwave (http://www.adobe.com/products/director), or Flash (http://www.adobe.com/products/flash)), and, more importantly, in the development of digital cameras. Images turned into a common information item that people could handle as easily as text.

The real push for the digital image came with the emergence of the world wide web (web) and the improvements of sensor technology, especially in digital photography. These swift developments in image distribution and generation in combination with easy to use web presentation technology (e.g., Dreamweaver (http://en.wikipedia.org/wiki/Dreamweaver), Frontpage (http://en.wikipedia.org/wiki/Microsoft_FrontPage), HTML (http://www.w3.org/MarkUp), and SMIL (http://www.w3.org/AudioVideo)) deeply changed the social way of exchanging information, increasing the available amount of images dramatically.

The answer to the resulting media-based information flood was research that focused again on automatic ways to index the available images in a timely and meaningful way. The goal was now to make use of image processing based on features required for interactive image understanding. Machine-generated metadata, however, turned out to be problematic as it is exclusively organized around the sensory surface structures of media, i.e., the physical features of an image, resulting in the sensory and semantic gap [14].

By the beginning of the twenty-first century this need for semantic-aware metadata schemata forced research to explore new ways of content representation. A large number of initiatives developed metadata standards to allow machines as well as humans to access the semantics of media items, such as Dublin Core (http://www.dublincore.org/), the Art and Architecture Thesaurus (AAT) by the J. Paul Getty Trust (http://www.getty.edu/research/conducting_research/vocabularies/aat/), the semantic web activity of the W3C (http://www.w3c.org/2001/sw/), and ISO's MPEG-4, MPEG-7 and MPEG-21 (http://www.chiariglione.org/mpeg/).

The interesting aspect of particularly the ISO and related standards had been that they tried to merge the high-level conceptual aspects of their content description with low-level structures of feature representation as used in signal processing, to allow the processing of audio-visual information over several semantic levels.

The common foundation for this fusion applies XML-based description languages.

A drawback of these approaches, namely regarding the process of attributing metadata to a media item as a terminated process, resulted in research that introduced new mechanisms to overcome the static structure of annotations, where flexibility is achieved by agreeing upon the collection of semantic-based and machine-processable metadata during established media workflow practices [5,6,9].

Around 2003, the web saw the growth of massive image databases, such as Flickr (http://www.flickr.com), that are mainly build on user generated content. In such environments people do not agree beforehand on an annotation taxonomy or ontology. As a result, research developed folksonomy tagging (also known as collaborative tagging, social classification, social indexing, and social tagging), a method of collaboratively creating and managing tags to annotate and categorize content. In folksonomy tagging metadata is not only generated by experts but mainly by creators and consumers of the content, where a tag is a keyword or term associated with or assigned to a piece of information (a picture, a map, etc.), which enables keyword-based classification and search. The advantage of tagging is its ease of use - creating a vocabulary based on freely chosen keywords instead of a controlled set of terms and structures. This approach, though highly popular, carries serious problems. Typically there is no information about the semantics of a tag, no matter if it is a single tag or a bag of tags. Additionally, different people may use drastically different terms to describe the same concept. This lack of semantic distinction can lead to inappropriate connections.

Foundations

When a person looks at an image, they first perceive the image on an optical level where they try to identify as many objects as possible in the available time of perception. Each object is mentally transformed into an iconic sign, which processes some properties of the object represented. The signification of iconic signs is based on socially determined small semantic systems (codes) and rules for their combination. Some of the code systems are: recognition, tonal, iconic, iconographic, rhetoric, and stylistic [7].

The iconic code is by far the most valuable code, because it defines the articulation potential of visual material. The creation of meaning in visual material is based on a *triple articulation* of figure, sign and *semes* and receives its expression by convention. The three elements are described as such:

1. A *figure* forms conditions for perception, such as relationships between object and background, or contrast in light.
2. A *sign* denotes, using conventionalized graphical methods, units of understanding (nose, sky), abstract models, or idealized diagrams of the object (the sun as a circle with thread-shaped beams).
3. *Semes* are complex iconic phrases, such as "this is a man standing in profile." They are the most simply catalogued, since the iconic code works most often on their level only.

The fact of a conventionalized triple articulation is important since it describes the essential difference from natural language, which has two articulations (phonemes and morphemes). Thus, comparing an object in an image with the corresponding word, the visual object always exceeds the concept of the word, as the image will portray specific qualities about the object for which the word is simply inadequate (see the tag problem mentioned above).

The organization of signs in an image is provided by two types of structures:

1. Syntagmatic, which represents a sequence of signs in which the relation of parts determines their meaning.
2. Paradigmatic, which represents potential substitutions in which a range of potential candidates can take the place of a sign in a syntagmatic structure.

The main application of image metadata is the retrieval of an image, where content features play an essential role. Search based low-level features functions on an iconic level, as most of the low-level feature based description methods. The key methods of how users search for an image are:

- Search by specification: aims for searching the identical replicate of the image the user has in mind or the identical object the user needs. Essential is the provision of optional variants (prosodic features) that form the conditions for perception and thus support identification [4].
- Search by categorization: aims for retrieving an arbitrary image representative of a specific class.

Categories may be derived from labels or emerge from the database [19]. This type of search usually requires a domain specific definition of similarity. Here, ontologies might become applicable.

- Search by association: aimed at browsing through a large set of images from unspecified sources. Association-based search usually implies iterative refinement of the query, which mainly asks for establishing similarities between images. Important in such search applications is the provision of relevance feedback [8] or the provision of additional sources [16].

Supporting these types of search methods are needed and allow the description of content so that a machine or a human user can access the images. Some of them can be applied in an automatic fashion, those are image feature based, and some provide high-semantic descriptions, which are often based on manual annotation. The latter are required, because, as described above, there is additional context that specifies the need of a query, e.g., the esthetics' the picture has to provide.

Content Description Based on Invariant Features

The purpose of image processing is to enhance aspects in the image data relevant to the user query. This can be achieved through the description of invariant features, such as, color, shape and texture. Invariant features tend to be object-specific information as they are insensitive to the accidental conditions of the sensing. It is important to note that it is the user who has to specify the minimal set of invariant features as it is part of his or hers intention [3].

- *Color:* The two general problems addressed in work on color are variances in color and differences in human perception. Color representation techniques, among others, are:
  - RGB color representation describes the image in its literal color properties, namely the Red, Green and Blue properties of each pixel in an image, where two-dimensional images are recorded in frontal view under standard conditions.
  - Opponent color representations, which uses the opponent color axes that isolate the brightness information on the third axis.
  - Lab-space approach, which exploits the Euclidean distance between two color representations to model human perception of color differences.
  - The HSV-representation exploits the hue, which is invariant under the orientation of the object with respect to the illumination and camera direction.
  - Hidden Markov models [11]
  - Clusters in a color histogram, where the RGB space is searched to identify which pixels in the image originate from one uniformly colored object.
- *Shape:* Shape is considered as the collected properties that capture differential geometrical details in the image [15]. Methods to represent shape are scale-based theory, conspicuous shape geometric invariants, or differential geometric invariants.
- *Texture:* Texture covers every aspect of an image that is not described through color and shape. The essential texture analysis techniques are: the Markovian analysis, multiscale autoregressive MRSAR-models, or wavelets.

Content Description Based on Semantic Features

The invariant features serve as a preprocessing step within the usual approach in content-based image retrieval, which divides the image first into parts and then computes the features for those parts. The essential segmentation methods are strong and weak segmentation.

- Strong segmentation divides the data into regions in such a way that a region contains the pixels of the silhouette of an object in the real world and nothing else. The problem is that this approach usually only succeeds sophisticated techniques in very narrow domains, such as trademark validation.
- Weak segmentation aims to support broad domains of general images by grouping image data into inconspicuous regions that are internally homogeneous according to some criterion. Weak segmentation is used in many retrieval systems, either as a purpose of its own or as a preprocessing stage for data-driven model-based object segmentation.

Both approaches end up in a preferred set of features [14], which can be classified as follows:

- Accumulating features aggregate the spatial information of a partitioning irrespective of the image data. The histogram [17] is the common method applied, such as the color histogram. Alternatives are the correlogram, or the autocorrelogram. An example of accumulative features might be those calculated from the top part of a picture, which effectively identify an image as indoor or outdoor space. The danger of accumulative features is the inability to discriminate among different entities and semantic meanings in the image.

- Salient features are a typical example of weak segmentation. The idea here is that grouping of the data is performed resulting in homogeneous regions. From the merged regions, a selection is made on their salience, where saliency is understood as those special points that survive longest while gradually blurring the image in scale space.
- Shape and object features, which focus on segmenting the object in the image. The problem is the automatic segmentation in broad domains. Yet, often it is not necessary to know exactly where an object is located but rather that its presence can be identified. Techniques for that are elastic matching and multi-resolution representation of shapes, multi-scale models of contours, the description of the object boundaries, or the description of global shape invariants.
- Combined entities of features, where calculations for different entities in the image and relationships between them are available. Such a structural feature set may contain feature values and spatial relationships, a hierarchically ordered set of feature values, relationships between point sets or object sets, or a graph of relations between blobs.

Interpretation of Features

In general there are two ways to make use of computed feature sets for the interpretation of an image.

- Deriving an unilateral interpretation from the feature set. This approach encodes an approximate subset of possible interpretations of an image relevant for a particular application. In that way the subset describes the semantics associated to features for the application [13].
- Comparing the feature set with the elements in a given data set based on similarity.

Similarity is an interpretation of the image based on the difference with another image. For each of the earlier described feature types, a different similarity measure is needed:

- *Similarity of objects* can be established through shape comparison based on transforms, moments, deformation matching, scale space matching, and dissimilarity measurement.
- *Similarity of structure* can be established based on a Bayesian framework, topological arrangements of relevant domain parts, spatial relationships between objects, or tree or graph representations.
- Similarity of *salient features* can be achieved by means of the distance between the feature vector composed of, e.g., the color, texture, position, and direction of the two ellipses, derived from the feature values measured of the blobs resulting from weak segmentation of the two images.

Under normal circumstances similarity comparison is not performed on a 1:1 image basis but rather on a 1:n image basis. For the latter cases, as in large image databases, gained experiences during the comparison of images can be exploited for better results. In that way similarity detection is understood as a classification problem to be solved based on statistical pattern recognition. Additional learning methods are the use of transduction (e.g., for partially labeled data), probabilistic constellations of features (e.g., for unlabeled data sets), or latent semantic indexing.

Image Interpretation Based on High-Level Semantic Metadata

As pointed out earlier, the representation of an image based on low-level features might be useful for narrow domains, such as the validation of trademarks. Every information that is based on higher-level codes than the iconic, e.g., the name of the image creator or the image's contribution to the technique of painting or photography, can not be extracted in that manner.

For those codes the annotation is based on concepts. The most basic form of such an annotation is a tag. The most fundamental set of tags for the annotation of images is certainly the Dublin Core set. The most complex description framework so far are those developed by MPEG-7 and the W3C's Multimedia Incubator Group (see also the Media Annotation Working Group: http://www.w3.org/2008/01/media-annotations-wg.html). The metadata falling in this category often require manual annotation [1], where the available structures are organized either in hierarchical or graph structures (the syntagmas) and use thesaurus or ontolological formats (class, subclass and their properties as well as relations between them) to allow for paradigmatic methods of choice to support advanced search (query extension) [10], or interpretation and generation.

Dublin Core [18]

The Dublin Core Metadata Element Set is a vocabulary of fifteen properties for use in resource description. The fifteen properties are: contributor, creator, date, description, format, language, publisher, relation, rights, source, subject, title, type.

Since January 2008, Dublin Core includes formal domains and ranges in the definitions of its properties. For supporting conformance of existing implementations of "simple Dublin Core" in RDF, domains and ranges have not been specified for the fifteen properties of the dc: namespace (http://purl.org/dc/elements/1.1/). Instead, the Dublin Core Metadata Initiative has opted for creating fifteen new properties with "names" identical to those of the Dublin Core Metadata Element Set Version 1.1 in the dcterms: namespace (http://purl.org/dc/terms/). These fifteen new properties have been defined as subproperties of the corresponding properties of DCMES Version 1.1 and assigned domains and ranges as specified in the more comprehensive document "DCMI Metadata Terms."

MPEG-7 [12]

MPEG-7 standardizes descriptions of AV data content in multimedia environments. It provides descriptions of multimedia content on varying complexity levels to let users search, browse, filter, or interpret content using search engines, filter agents, or any other program. MPEG-7 offers a set of AV description tools in the form of descriptors (Ds) and description schemata (DS) a valid MPEG-7 description should adhere to. Descriptors usually bind a feature to a set of values. Description schemata specify the structure and semantics of the relationships between the components of descriptors and between other description schemata. These structures let users create application-specific content descriptions (see Fig. 1 as an example).

The standard has eight parts, each responsible for one aspect of the functionality, of which 3 are relevant for visual data:

- Part 2 - the DDL specifies the language for defining the standard set of description tools (description schemata, descriptors, and data types), new tools, and the main parser requirements. The DDL is based on XML-Schema, developed by the W3C.

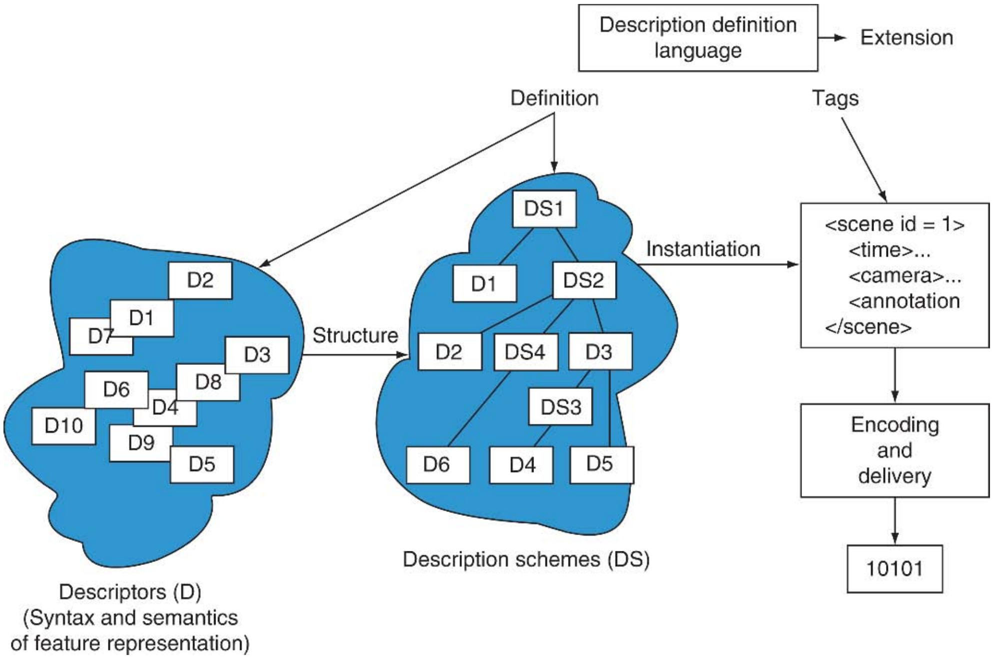

Image Metadata. Figure 1. The main MPEG-7 elements. Content authors can use these structures to create application-specific content descriptions.

- Part 3 - Visual consists of schemata and descriptors covering basic visual features such as color, texture, shape, and face recognition. It provides the descriptor syntax and description schemata in normative DDL specifications and the corresponding binary representations.
- Part 5 - Multimedia Description Schemes (MDS) specifies generic description tools pertaining to multimedia, including audio and visual content. MDS covers the basic elements for building a description, the tools for describing content and relating the description to the data, and the tools for describing content on organization, navigation, and interaction levels. The MDS alone forms more than half of the complete standard and has its own internal structure, shown in Fig. 2.

As the standard is rather large, MPEG has begun to establish media profiles (MPEG-A to MPEG-E) that integrate multiple MPEG technologies. The relevant visual profile is MPEG-C.

The W3c's Incubator Group [20]

The work of this group has explored the advantages of using Semantic Web languages and technologies for the creation, storage, manipulation, interchange and processing of image metadata. In addition, it provided guidelines for Semantic Web-based image annotation, illustrated by use cases. In its publications the relevant RDF and OWL vocabularies are discussed, along with a short overview of publicly available tools.

Key Applications

Image metadata is useful for the creation, manipulation, retrieval and distribution of 2D or 3D digital image sources within domains, such as

- The creative industries (e.g., fine arts, entertainment, journalism, etc.),
- Education (e.g., in computer based training courses, military or industrial training),
- Environmental research (e.g., Interpretation of satellite images),
- Medicine (e.g., Identification of cancer cells in a lung scan etc.).

Future Directions

Research has still to address how the merge between high-level semantic descriptions and low-level feature-based descriptions can be achieved. In this context, solutions need to be found that merge the results of folksonomy tagging and defined description vocabularies into a suitable description

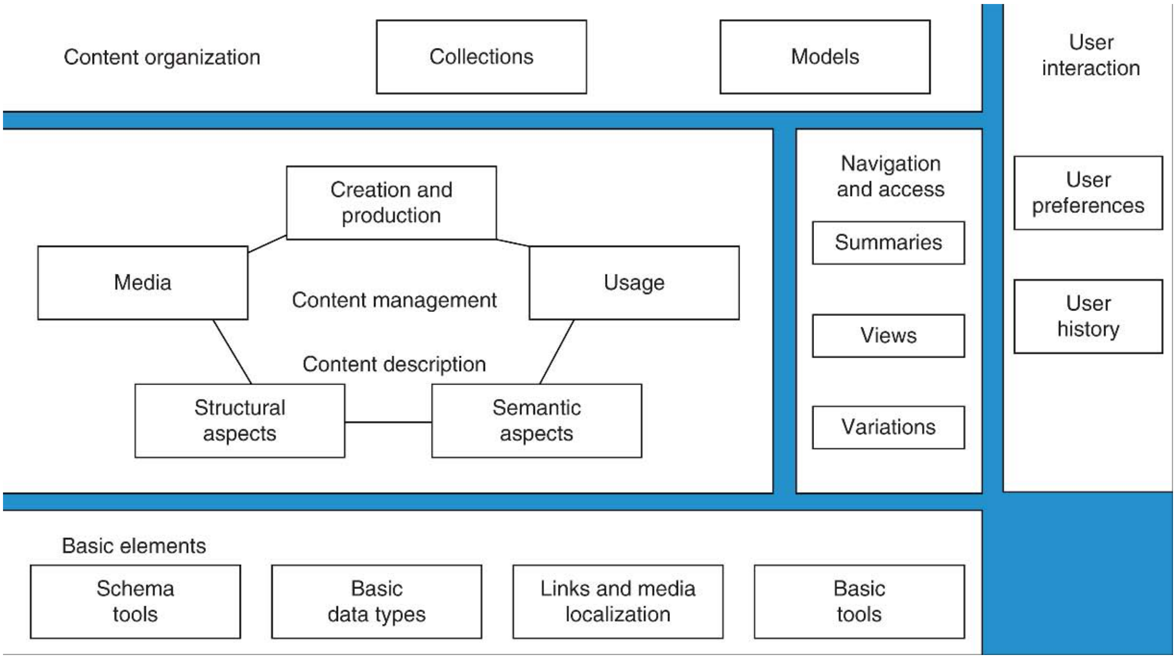

Image Metadata. Figure 2. Overall organization of MPEG-7 multimedia description schemes.

framework. Finally, it is important that easy to use annotation tools will be developed.

Image query processing

Definition

Image querying refers to the problem of finding objects that are *relevant* to a user query within image databases (Image DBs). The classical solutions to deal with such problem include the *semantic*-based approach, where an image is represented through metadata (e.g., keywords), and the *content*-based solution, commonly called *content-based image retrieval* (CBIR), where the image content is represented by means of low-level features (e.g., color and texture). While with the semantic-based approach the image querying problem is transformed into an information retrieval problem, for CBIR more sophisticated query evaluation techniques are required. The usual approach to deal with this is illustrated in Fig. 1: By means of a graphical user interface (GUI), the user provides a query image, by sketching it using graphical tools, by uploading an image she/he has, or by selecting an image supplied by the system. Low-level features are extracted for such image (possibly dividing it into regions, see below); such features are then used by the query processor to retrieve the DB images having similar characteristics.

How the set of relevant DB images is determined depends on which low-level features are used to characterize image content, on the criterion used to *compare* image features, on how DB objects are *ranked* with respect to the query (based on either a quantitative measure of similarity or qualitative preferences), and, finally, on whether the user is interested in the whole query image or only in a part of it. All these aspects strongly influence the *query evaluation* process.

Historical Background

In spite of the many efforts spent so far, the problem of retrieving relevant objects within *image databases* (Image DBs) is still a complex task. Following the semantic-based approach, images are described by means of metadata such as keywords, captions, or descriptions and the retrieval is performed over such words using *annotation-based image retrieval* techniques. In this direction, several solutions have been recently proposed, such as image extensions to public search engines like Google (http://images.google.com/) and Yahoo (http://images.search.yahoo.com/). Such systems consider the contextual information of a crawled image (like the image filename, its title, the surrounding text, etc.) to infer the relevance of the image to the query. In a similar way, some systems, like flickr (http://flickr.com/), assess the relevance of an image to the query by taking into account the characterization of the image provided by the user. However, such a manual image annotation process is expensive and time-consuming. In order to overcome such limitations, there has been a large amount of research done on (semi-)automatic image annotation with the aim to assign meaningful keywords to images by exploiting the information of a pre-annotated set of objects.

With respect to the *content-based image retrieval* (CBIR) solution, the aim is to avoid the use of textual descriptions. This is usually done by using visual similarity to retrieve images, for example, asking for images that are similar to a user-supplied query image, i.e., following the *query by example* (QBE) paradigm fist adopted in the IBM's query by image content (QBIC) system [5]. In particular, each image is characterized using global *low-level features*, such as color and texture, and the result of a query consists in the set of DB

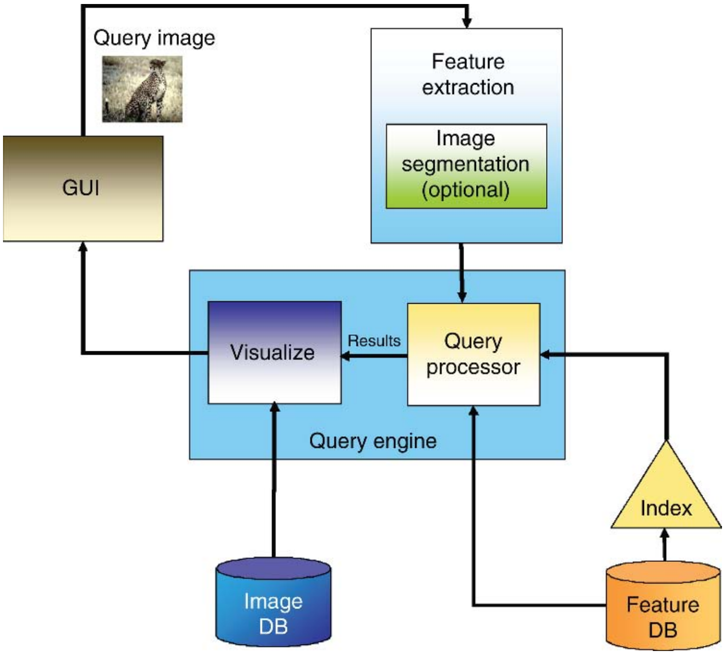

Image Querying. Figure 1. The image querying scenario for CBIR.

objects that better match the visual characteristics of the target image, according to a predefined *similarity criterion*, which is in turn based on low-level features [8]. Although CBIR represents a completely automatic solution for the image querying problem, the accuracy of its results is not always completely satisfactory for the user, especially for high-level concept queries, for which low-level features are hardly exploitable due to their low discriminative power. This is largely due to the so-called semantic gap existing between the concept of similarity as percept by the human brain and the one implemented by the system. The effectiveness of this approach still calls for improvement: The use of *relevance feedback techniques* could be of help, but it is still not enough to reach acceptable levels of accuracy.

More recently, the *region-based image retrieval* (RBIR) approach has been proposed, which has lead to promising results. With respect to the case in which images are represented by means of global descriptors, RBIR is able to characterize the image content in a more precise way by *segmenting* each image into a set of homogeneous regions from which a set of low-level features are extracted. As a consequence, most of the modern image database systems adopts the RBIR paradigm in order to improve the retrieval accuracy [9,1,3,4,6,10]. Almost all such systems treats each region as a separate query and somehow aggregate the so-obtained partial results in order to derive the final answer. This property introduces a number of new interesting query processing problems with respect to the case in which the segmentation is not considered. Among these, which constraints must be satisfied by the aggregation rule in order to provide the query result and which criterion has to be followed to order the DB images with respect to the query. Finally, with RBIR, new query types, such as partial queries, are supported.

Foundations

The general approach followed by RBIR systems is to divide an image I into a set of homogeneous regions, i.e., set of pixels that share similar visual characteristics, and to represent each of them by means of a set of low-level features, such as color and texture. Thus, any image I is seen as a complex object. Regions comparison is obtained by defining a *region similarity function*, s_R, able to produce a scoring value which quantifies their visual similarity. Given a query image I^q, the set of relevant DB images to I^q is computed starting from the similarities between the query regions and the regions of DB images. This requires first to somehow *match* regions of the query to regions of DB images, by using the proper aggregation of region similarities, and then to *rank* DB images so as to produce the query result (see Fig. 2).

Formally, the image querying problem can be concisely formulated as follows:

Problem

Given a query image I^q composed of regions, an image database $\mathcal{IDB}$, where each image $I \in \mathcal{IDB}$ is composed of regions, and a region similarity function, $s_R(R_i, R_j)$, that for each pair of regions, (R_i, R_j), returns their

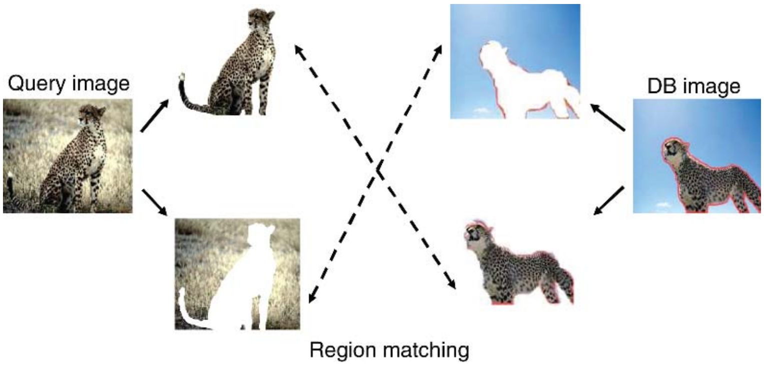

Image Querying. Figure 2. The similarity between the query image and a DB image is assessed by taking into account the similarity between matched regions.

similarity score, determine the set of relevant *images in* $\mathcal{IDB}$ *wrt* I^q.

Instantiating the general problem can be done in different ways, since different coordinates are involved in the definition of what "relevant" actually means. Among these coordinates, the rules according to which a region of the query can be coupled to regions of a DB image (conventionally called *matching type*) and the aggregation modality applied to the region similarity scores in order to assess the query result (i.e., the *ranking model*).

Matching Type

The matching type defines which set of constraints applies when the component regions of the query image $I^q = \{R_1^q,\ldots,R_n^q\}$ have to be matched to the component regions of a DB image $I = \{R_1,\ldots,R_m\}$.

Two relevant cases for matching types are the *one–to–one* ($1 - 1$) and the *many–to–many* ($n - m$) matching types. In the $1 - 1$ case, each region of image I^q is associated to at most one region of I, and vice versa. In particular, each matching has to be *complete*, i.e., if $n > m$ (respectively, $n < m$) then only $n - m$ (resp., $m - n$) regions of I^q (resp., I) have to remain unmatched (refer to Fig. 3 for an example).

With the $n - m$ matching type, each region of I^q can be associated to many regions of I, and vice versa. This, however, could lead to undesired (pathological) results. For example, a single region of the query could be matched to *all* regions of a DB image. This has been termed "the two tigers problem" in [11] since it arises when a single region (a tiger) of the query image is very similar to multiple regions of a DB image (e.g., containing two tigers).

A special case of $n - m$ matching that avoids this problem is the Earth Mover Distance (EMD) matching [7], where variable-sized pieces of regions are allowed to be matched (the size of each region defines the maximum amount for its matching). This contrasts with the $1 - 1$ matching, where elements of fixed size (i.e., regions) are matched individually.

Ranking Model

Two generic models of ranking are possible: *k-Nearest Neighbors* (*k*-NN) and *Best Matches Only* (BMO) [2]. The *k*-NN ranking model (also known as *Top-k selection*) requires to define the image similarity of a DB image I with respect to a query image I^q, $s_I(I^q,I)$, by means of a *numerical scoring function* (*sf*), such as the average, which aggregates the region similarity scores into a global similarity value. In particular, among all valid matchings that satisfy the constraints of the specific matching type, the rationale is to select the one that maximizes the aggregated score. This can be modeled as an optimization problem whose solution depends on the particular choice of the scoring function. For the most commonly used functions efficient algorithms exist: For example, when using the average function with the $1 - 1$ matching type, the problem takes the form of the well-known *assignment problem*, while with the $n - m$ (EMD) matching type (see above), this corresponds to the *transportation problem*. For both such problems the optimal solution can be efficiently found without performing an exhaustive search; however, in the general case, the optimal matching can not be easily found. Figure 3 shows an example of matching for a query image I^q with three regions and a DB image I with four regions under the assumption of $1 - 1$ matching type and the average scoring function. Similarities between regions of I^q and regions of I are arranged in a matrix. Circled cells are those involved in the matching. Note that, since $n < m$, in valid matchings $4 - 3 = 1$ region of I remains unmatched.

Finally, given the query image I^q and two DB images I_1 and I_2, image I_1 will be considered more similar than I_2 to I^q iff $s_I(I^q,I_1) > s_I(I^q,I_2)$ holds. In such a way it is possible to linearly order DB images and return to the user only the k highest scored ones.

The main limitation of the *k*-NN ranking model is that the choice of a particular scoring function clearly influences the final result, i.e., different scoring functions will likely yield different results. This can lead to missing relevant images, because the choice of the scoring function is a difficult task for the user. Moreover, the use of scoring functions limits the expressive power of queries that can be submitted to the system, since all of them will always define a simple linear order on objects. This might prevent their applicability to modern multimedia systems asking for more flexibility in querying [2]. In the BMO model, the result of the query depends on a specific *preference relation* $\succ_p$, where $\succ_p$ is only required to define a strict partial order over images. Image $I_1 \in \mathcal{IDB}$ is in the query result if and only if no other image $I_2 \in \mathcal{IDB}$ is *better* than (or *dominates*) I_1 according to $\succ_p$. Clearly, preference relation $\succ_p$ is based on regions similarity scores (see Fig. 3).

Thus, even if region scores are numerical (by definition), the BMO ranking model does not need to aggregate them using a scoring function. Actually, the result of a BMO query with image I^q is the set of undominated images in $\mathcal{IDB}$, i.e., all and only those images for which no better image (with respect to I^q and to $\succ_p$) can be found in the database.

When considering together the matching type and ranking model coordinates, different scenarios are derived. In the following, algorithms for *k*-NN and BMO queries are provided by considering the simplest way to solve the image querying problem, i.e., when using a sequential scan of the DB. Note that the efficiency of such solutions is clearly quite limited. It is possible to derive efficient algorithms [3,11,2] by exploiting index structures, such as *multi-dimensional or metric indices* (built either on regions of the DB images or on the DB images themselves).

The steps described in Algorithm 1 show the logic of the sequential algorithm for *k*-NN queries, named *k*-NNSeq, to determine the *k* nearest neighbors of the image query I^q: Given the image query I^q, the scoring function *sf*, and the cardinality of the result *k*, the algorithm correctly returns the *k* images that are most similar to I^q according to *sf*. This algorithm covers both cases of $1-1$ and $n-m$ matchings.

Algorithm 2, named BMOSeq, describes the main steps for the sequential evaluation of BMO queries, with the assumption of $1-1$ matching: Given the image query I^q and the preference relation $\succ_p$, the algorithm correctly returns set of undominated images with respect to the query I^q.

It is also important to consider the type of images the user is interested in. The above description deals with *full image* search, i.e., when the user is interested in all regions of the query, but other possibilities exist that introduce minor modifications in the query evaluation process.

For example, *part-of* queries request DB images whose regions are all matched to some query region (the presence of unmatched query regions is not penalized). Two other query types are introduced when the user is given the possibility to select, possibly exploiting a

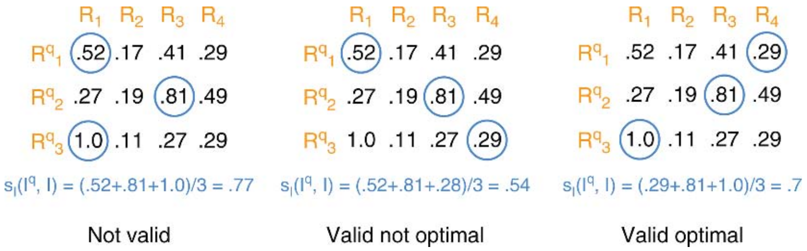

Image Querying. Figure 3. Example of similarity assessment between images I^q and I when adopting the 1–1 matching type and the average scoring function: not valid matching (*left*), valid not optimal matching (*center*), and valid and optimal matching (*right*). If an alternative matching type (e.g., the general $n-m$ matching) is considered, the left matching could become valid (and optimal).

```
Algorithm 1: $k$-NNSeq
Require: $I^q$: query image, $k$: cardinality of result, $\mathcal{IDB}$: image DB, $sf$: scoring function
Ensure: set of relevant $k$ images
  for all images $I \in \mathcal{IDB}$ do
    for all regions $R_j \in I$ do
      for all regions $R_i^q \in I^q$ do
        compute $s_R(R_i^q, R_j)$
    compute matchings between regions $R_i^q \in I^q$ and regions $R_j \in I$
    select the matching that maximizes $s_I(I^q, I)$ by means of $sf$
  return the $k$ images having the highest overall similarity scores $s_I$
```

```
Algorithm 2: BMOSeq
Require: $I_q$: query image, $\mathcal{IDB}$: image DB, $\succ_p$: preference relation
Ensure: set of undominated images
  $\mathcal{U} \leftarrow \emptyset$
  for all images $I_1 \in \mathcal{IDB}$ do
    for all regions $R_j \in I_1$ do
      for all regions $R_i^q \in I^q$ do
        compute $s_R(R_i^q, R_j)$
    $\mathcal{U} \leftarrow \mathcal{U} \cup \{I_1\}$
    for all images $I_2 \in \mathcal{U}$ do
      if $I_1 \succ_p I_2$ then
        $\mathcal{U} \leftarrow \mathcal{U} \setminus I_2$
      else if $I_2 \succ_p I_1$ then
        $\mathcal{U} \leftarrow \mathcal{U} \setminus I_1$
        break (for at line 7)
  return images in $\mathcal{U}$
```

suitable graphical interface, only a subset of query regions: In *partial match* queries the user is looking for DB images containing selected regions of the query (the presence of other regions in the DB image should not be penalized); on the other hand, with a *contains* query DB images are requested to contain selected query regions only (other existing regions reduce the image similarity, differently from the case of part-of queries).

Key Applications

Image querying is an important tool for many modern multimedia applications, such as *digital libraries*, *e-commerce* (where electronic catalogues have to be browsed and/or searched), *edu-tainment* (for example, to search in clipart repositories, or to search and organize personal photo albums in mobile phones or PDAs).

Another interesting application area is the one related to (semi-)automatic *image annotation techniques*, which can be based on assigning to an unlabeled image *I* the keywords associated to the DB images most similar to *I*. Finally, image querying techniques have been also profitably used in *image classification*, for example, to search for similar logo images, for copyright infringement issues, and for the detection of pornography images.

Image Representation

Valerie Gouet-Brunet
CNAM Paris, Paris, France

Synonyms

multimedia; File format; Image compression; Image metadata; Image content; Image standards

Definition

In computer science, the representation of an image can take many forms. Most of the time, it refers to the way that the conveyed information, such as color, is coded digitally and how the image is stored, i.e., how is structured an image file. Several open or patented standards were proposed to create, manipulate store and exchange digital images. They describe the format of image files, the algorithms of image encoding such as compression as well as the format of additional information often called metadata. Differently, the visual content of the image can also take part in its representation. This more recent concept has provided new approaches of representation and new standards, gathered together into the discipline named *content-based image indexing*.

Historical Background

The first use of digital images began in the early 1920s with the technological development of facsimile transmission, and in particular with the Bartlane cable transmission system that was the first system that translated pictures into a digital code for efficient picture transmission. Later, in the 1960s and 1970s, the advent of digital image technology is closely tied to the development of government programs for space exploration and espionage and also to medical research with the invention of computerized axial tomography. With the availability of the CCD image sensors (charge-coupled device), the private sector also began to make significant contributions in the development of digital cameras. Dissemination of digital images quickly required the proposal of common frameworks for representing images as an improvement of proprietary formats most of the time under license and not easily exchangeable. In the mid-1980s, image format TIFF was created by the company Aldus with the aim of agreeing on a common file format for bitmapped images issued from scanners. In parallel, researchers at Xerox PARC had developed the first laser printer and had recognized the need for a standard means of defining page images. After several fruitless attempts, Adobe Systems proposed the PostScript language in 1982, quickly adapted for driving laser printers. Since then, other file formats dedicated to digital images were also proposed, such as GIF (1987), JPEG (1992), PDF (1993), PNG (1995) and SVG (1998). Today, a great effort is done to propose standard formats able to preserve data integrity for archiving purposes, to migrate easily to future technologies as well as to provide efficient compression for access and dissemination. In 2000, the standard JPEG 2000 was proposed to deal with these objectives for a large range of application domains. Moreover Ambitious programs, MPEG-7 and MPEG-21, started in the late 1990s, are focusing on the harmonization of methods for representing, storing, sharing and accessing multimedia contents (text, audio, image and video) in an unified framework.

Foundations

Basics of Image Representation

Digital images can be classified into two main categories: vector graphics and bitmapped images (also called raster images). Vector images are geometrical 2D objects created with drawing software or CAD (computer-aided design) systems. They are represented with geometrical primitives such as points, lines, curves, and shapes or polygons, which are all based upon mathematical equations. Unlike bitmaps that are resolution-dependent, vector images are scalable, which means that the scale at which they are shown will not affect their appearance. Such images are dedicated to the representation of images with simple content, such as diagrams, icons or logos.

A bitmapped image is composed of a set of dots or squares, called pixels (for picture elements), arranged in a matrix of columns and rows. Each pixel has a specific color or shade of gray, and in combination with neighboring pixels it creates the illusion of a continuous tone image. Unlike human vision, sensors that capture images are not limited to the visual band of the electromagnetic spectrum. Digital images can cover almost the entire spectrum, ranging from gamma to radio waves.

Managing bitmapped images requires the choice and manipulation of several parameters such as:

- *Color model.* A color model is an abstract mathematical model describing the way human color vision can be represented as tuples of numbers. From this model, the combination of dedicated primary colors provide all the colors possible, that are embedded in the corresponding color space. RGB, CMYK, CIELAB and CIELUV are the most known color models and spaces.
- *Dynamic range.* The dynamic range of a digital image, also called color depth, determines the maximum range of gray level or color values carried by each pixel. The number of bits used to represent each pixel determines how many colors can appear in the image. Photographic-quality images are usually associated with 24-bit dynamic range, such as in the JPEG format.
- *Resolution.* Resolution expresses the density of elements, pixels for instance, within a specific area. This term does not have any sense when dealing with digital images as files, but it applies when associating a digital image with a physical support, such as display on a screen, printing on a printer or capture with a scanner. Resolution is classically represented in terms of dpi (dots per inch) unit, which was originally the unit adopted for printing. Appearance of bitmapped images, which are made up of a fixed grid of pixels, clearly depends on the resolution chosen, unlike vector images that are scalable and then have the same appearance whatever the dimensions chosen for visualization.

Image Compression

Image compression is the process of shrinking the size of digital image files. Methods have in common the processes of finding and storing redundant data (e.g., pixels with similar color information) more efficiently or of eliminating information that is difficult for the human eye to see [8]. Compression algorithms are especially characterized by two factors: compression ratio and generational integrity. Compression ratio is the ratio of compressed image size to uncompressed size and generational integrity refers to the ability for a compression scheme to prevent or mitigate loss of data, and therefore image quality, through multiple cycles of compression and decompression. Lossless compression ensures that the image data is retained, as with Run-length encoding, Huffman coding and LZW coding. On the other hand, lossy compression schemes involve intentionally sacrificing the quality of stored images by selectively discarding pieces of data. Most of them have a compression ratio that can be parameterized by the user, to optimize the results for each situation, such as the standards JPEG and JPEG 2000.

Run-Length Encoding Run-length encoding (RLE) is probably the most simple form of lossless data compression: sequences in which the same data value occurs in many consecutive data elements are stored as a single data value and count. Image data is normally run-length encoded in a sequential process that treats the image data as a 1D stream, line by line, column by column or diagonally in a zigzag fashion. Also used in fax machines, common digital image formats for run-length encoded data include TGA, PCX and is possible with BMP, TIFF and JPEG.

Huffman Coding Created in 1951 by David A. Huffman, the Huffman coding is an entropy encoding algorithm used for lossless data compression. The basic idea of this algorithm is to code with few digits the most common input symbols of a document. Each symbol is encoded by using a variable-length code table, where the codes are defined according to the estimated probability of occurrence for each possible symbol. The technique works by creating a binary tree of nodes that contain symbols with their probability for leaf nodes and cumulated probabilities for internal nodes. Traversing this binary tree from the root to the leaves, with the convention '0' when following the left child and '1' when following the right one, allows associating a bit string with each symbol. The result is a prefix-free code: the bit string representing some particular symbol is never a prefix of the bit string representing any other symbol. Today, Huffman coding is often used during the final process of some other compression methods such as JPEG and MP3.

LZW Coding Lempel-Ziv-Welch (LZW) is a lossless data compression algorithm created by Abraham Lempel, Jacob Ziv, and Terry Welch. It was published in 1984 as an improved version of the LZ77 and LZ78 algorithms published by Lempel and Ziv in 1977 and 1978. The technique was patented by IBM and Unisys Corporation in 1983 and the patents expired in 2003. The compression algorithm build a string translation table that is based on fixed-length codes (usually

12-bit). As the system character-serially examines the document, if the string read is not stored in the table, a new code is created in the table and associated with this string, otherwise the current string is encoded with an existing code. This algorithm became very widely used after it became part of the GIF image format in 1987. In contrast to other compression techniques such as JPEG, it allows preserving very sharp edges, suitable with line art images often stored in GIF format.

JPEG Compression JPEG is the most common image format used for compressing and storing digital cameras and other photographic image capture devices. "JPEG" stands for Joint Photographic Experts Group, the name of the committee that created the standard. The group was organized in 1986, issuing a standard in 1992, which was approved in 1994 as ISO 10918-1 standard. The associated algorithm, described in Fig. 1, is a lossy compression technique suited for photographs and paintings of realistic scenes, but not for line drawings and other textual or graphics, where the compression cause noticeable artifacts on sharp contrasts between adjacent pixels. This algorithm stands on the representation of the image in the frequency domain by using a two-dimensional DCT (Discrete Cosine Transform), that describes the variability of the signal in terms of low-level and high-level frequencies. The human eye notices small differences in brightness over a relatively large area, but does not distinguish the exact strength of a high frequency brightness variation very well. Consequently, the amount of information in the high frequency components of the DCT can be neglected without drastically affecting perceptual image quality: the DCT components are divided by factors of a quantization matrix that increase with the spatial frequency, and then rounded to the nearest integer. This is the main lossy operation in the whole process. Typically, many of the higher frequency components are rounded to zero and the other components become small numbers, which take many fewer bits to store [10].

File Formats

There are a lot of image formats for vector graphics as well as for bitmapped images [3,6]). Most of them are open standards and patent expired for the others. Vector image formats contain a geometric description of the objects which can be rendered smoothly at any desired size. Among the most common formats, there are:

- **SVG** (Scalable Vector Graphics) is an open XML-based standard created in 1998 and developed by the World Wide Web Consortium to address the need for a versatile, scriptable and all-purpose vector format for the web and otherwise.
- **EPS** (Encapsulated PostScript) is a standard file format created by Adobe Systems in the mid-1980s. It follows DSC (Document Structuring Conventions) rules that are a set of standards for PostScript.

File formats abound for bitmapped images, but many digital imaging projects have settled on the formula of TIFF, JPEG, GIF and also PNG files:

- **TIFF**, for Tagged Image File Format, is a file format for storing images such as photographs as well as graphics. It was originally created by the company Aldus, was then under the control of Adobe Systems and is now in the public domain. TIFF supports several lossless and lossy techniques of image

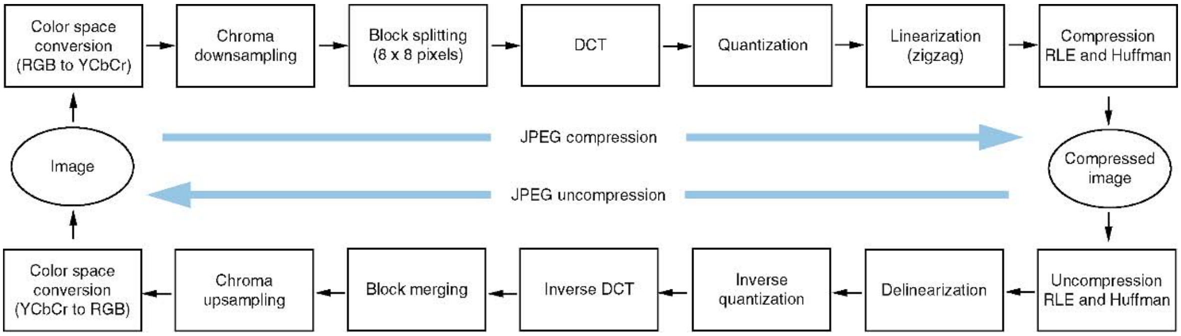

Image Representation. Figure 1. Main steps of the JPEG algorithm for compression and uncompression.

compression, such as LZW, Huffman coding and JPEG. The ability to store image data in a lossless format makes TIFF files a useful method for archiving images and preservation purposes. However, there are so many different implementations of TIFF that many applications can read certain types of TIFF images but not others.

- **JPEG**, for Joint Photographers Experts Group, is a file format that was developed specifically for high-quality compression of photographic images in a 24-bit RGB color model. It is generally employed for online presentation and dissemination; the associated lossy algorithm for compression makes it unappropriated for archiving purposes. The file format associated is JFIF (JPEG File Interchange Format, 1992), a public domain storage format for JPEG compressed images. Unlike TIFF, JFIF does not allow for the storage of associated metadata, a failing that has led to the development of SPIFF (Still Picture Interchange File Format), which is now the international standard.
- **GIF**, for Graphics Interchange Format, is an 8-bit image format for indexed colors, that was introduced by CompuServe in 1987 and has since come into widespread usage for art images such as diagrams or logos with a limited numbers of colors. The original version was called 87a; in 1989, CompuServe developed an enhanced version, called 89a, that supports animations. Due to infringement of Unisys' patent on the LZW compression technique used with GIF, in 1995 CompuServe proposed the **PNG** format (Portable Network Graphics) as a replacement for the GIF format without patent license. PNG offers a better and lossless compression technique called DEFLATE (that combines LZ77 with Huffman coding). Since 2003, it is an international standard.

Today, the status of TIFF as the de facto standard format for archival digital image files is challenged by other formats such as PNG and JPEG 2000, that are able to preserve data integrity as well as to provide efficient compression ratios for access and dissemination.

Metadata Representation

Metadata are commonly defined as "data about data." They constitute the documentation or a structured description associated with a document. Image files automatically include a certain amount of metadata that are stored in an area of the file defined by the file format and called *the header*, but information may also be stored externally.

In the widely used TIFF format, the term "Tagged" indicates that developers can define and apply dedicated tags to enable them to include their own proprietary information (called " private tags") inside a TIFF file without causing problems of compatibility. More recently, Exif format (Exchangeable image file format) was created by the Japan Electronic Industries Development Association. The latest version was published in 2002 and while the specification is not currently maintained by any industry or standards organization, its use by camera manufacturers is nearly universal. Exif fields are generated at the creation of the image and should not be modified after with the aim of including additional information like title or keywords. To do this, other formats are recommended, such as XMP (eXtensible Metadata Platform). This last is an XML-based standard for creating, processing and storing standardized, extensible and proprietary metadata, created by Adobe Systems in 2001 [1]. XMP metadata can be embedded into a significant number of popular file formats: it is used in PDF and other image formats such as JPEG, JPEG 2000, GIF, PNG, TIFF and EPS.

In parallel to generic standards, standards dedicated to specific image applications also exist, such as DICOM (Digital Imaging and Communications in Medicine). This is a standard created in 1992 and widely adopted by hospitals, for handling, storing, printing and transmitting information in medical imaging [7]. It includes a file format definition and a network communications protocol.

Metadata constitute the documentation of all aspects of digital files essential to their persistence, usefulness and access. Images without appropriate metadata may become hard to view, migrate to new technology, or to access among large volumes of images. When annotation is unappropriate or is missing, the representation of the visual content of images by image analysis may be an interesting alternative, as described in the following.

Image Content Representation

Born in early 1990s, Content-Based Image Indexing (CBIR) is a discipline that exploits techniques of image analysis and databases [2]. Indexing an image by its content consists of automatically extracting structures that describe the visual content relevantly for the considered application. These structures can describe the visual content of an image globally or locally by characterizing its distribution of color, shape and texture, or parts or objects of the image. The visual structures exhibited are considered as the index of the image, they are digitally represented with one or several multidimensional vectors called *signature* of the image. According to this description, searching for a particular image in a database of images consists of searching in multidimensional spaces.

Key Applications

JPEG 2000 is a standard that gathers an image file format and an algorithm of image compression, created by the Joint Photographic Experts Group committee in 2000 [9]. The name refers to all of the eleven parts of the standard, some of them are now published as an International Standard, while others are under development.

The coding algorithm of JPEG 2000 is similar to the JPEG one, it mainly differs in the use of wavelets instead of a DCT. Wavelets provide a decomposition of the image into a pyramid of sub-images which store different levels of resolution of the image. They can be of two types, according to the objective: (1) a Daubechies wavelet transform, that requires quantization to reduce the amount of bits representing data, as JPEG does, and then imposes lossy compression; (2) a rounded version of Le Gall wavelet transform, that uses only integer coefficients and then does not require quantization, providing lossless coding.

On average, JPEG 2000 gains up to about 20% lossy compression performance for medium compression rates in comparison to the first JPEG standard. Moreover, the edges remain sharper and more contrasting than with JPEG where blocky artifacts can also appear. The aim of this standard is not only improving compression performance but also adding features, among which transmission error resilience and region of interest (ROI). This last offers the opportunity of storing parts of the same picture using different quality. Some parts of particular interest such as faces, can be stored with higher quality, to the detriment of other ones where low quality/high compression can be tolerated. JPEG 2000 also allows delivering these parts *before* other parts of the image.

The JPEG 2000 standard defines two file formats that support embedded XML metadata: JP2, which supports simple XML, and JPX, which has a more robust XML system based on an embedded metadata initiative of the International Imaging Industry Association (the DIG35 specification). However, as of this writing, commercial implementations for JPEG 2000 are just beginning to appear. The democratization of JPEG 2000 is presently less important than the JPEG standard: It is supported in several web browsers, but is not generally used on the World Wide Web. Nevertheless, this standard will take more place in a near future, because it has been developed to efficiently deal with many applications and markets such multimedia consumers applications, military/surveillance, medical imagery, editing and storage, etc.

Future Directions

The continuing drop in prices of computers and storage, the ocean of image/video/audio data produced and the expansion of networking and communication bandwidth via the Internet or the HDTV (High-definition television) greatly contribute to the production and dissemination of larger volumes of multimedia content. Many techniques of different disciplines of computer science have been studied and developed for managing text, image, video and audio. But today, there is a need in the development of an unified framework for the creation, representation, storage, access, delivery, management and protection of multimedia contents. Standardization goes in this direction by proposing new standards for managing these contents jointly, such as the international standards MPEG-21 and MPEG-7. MPEG-21 is a standard started in 1999 by MPEG (Moving Picture Experts Group) and now normalized as ISO/IEC 21000. Its main objectives are to define an open framework for multimedia applications and more precisely to provide a standardized structure for various media contents and to facilitate their access, delivery, management and protection [4]. MPEG-7 is another ISO/IEC standard started by MPEG in 1998 and formally called *Multimedia Content Description Interface*. It aims at specifying a standard set of descriptors and description schemes dedicated to various types of multimedia information. One of its main objectives is to provide unified and efficient searching, filtering and content identification methods for these media [5].

Synonyms

Image Distance; Visual Similarity; Similarity Measure

Definition

Given a pair of images each described by a feature set, image similarity is defined by comparing the feature set on the basis of a similarity function. In a typical Visual Information Retrieval system, while searching for a query image among the elements of the data set of images, knowledge of the domain will be expressed by formulating a similarity measure between the query and data set based on some visual features. Therefore, measuring meaningful image similarity consists of two intrinsic elements: finding a set of features for adequately describing the image content and finding a suitable metric for assessing the similarity on the basis of feature space. The feature set can be computed globally for the entire image or locally for a small group of pixels such as regions or objects. The similarity measure can be different depending on the types of features. Typically, the feature space is assumed to be Euclidean. The algorithm for image similarity aims to essentially reduce the semantic gap between low-level features and high level semantics as much as possible.

Historical Background

Comparing two images is the fundamental operation for many Visual Information Retrieval systems, in which the user selects a query image and image similarity to the query according to the given criteria are retrieved and presented [11]. Figure 1 shows the role of image similarity in the context of multimedia information retrieval. A set of visual features is first computed for each image or video frame in the database and for the query. Then, given a query image, image similarity is computed for each pair of query and image based on the feature space and some distance metric, and may be further tuned in an interactive way according to user feedback. The images which are visually, semantically, or perceptually similar to the query are finally presented to the user.

A wide variety of methods for image similarity have been devised with research expanding in content-based multimedia retrieval in the last decade. In earlier work, image content is usually described by a set of global features such as color, texture, shape, and so on [8]. The advantage of global features is the high speed for both feature extraction and similarity computation. The features are then transformed and represented by a set of vectors. Image similarity is computed based on different distance metrics on these feature vectors. For example, color histogram serves as an effective representation of the distribution of colors in an image. A color histogram is created by plotting the number of pixels in the image

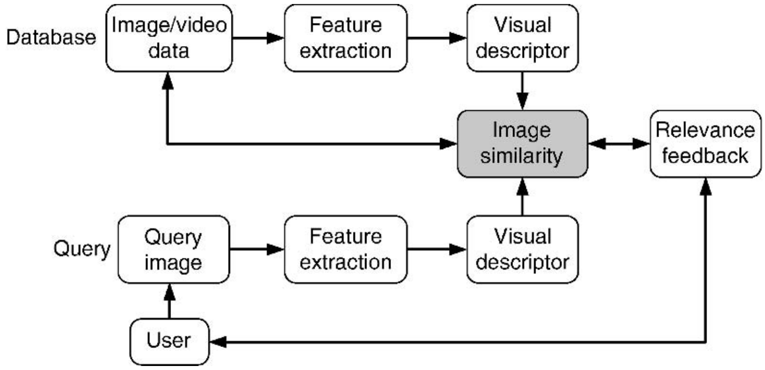

Image Similarity. Figure 1. Image similarity in the context of multimedia information retrieval.

with a particular range of quantized color value in some color space. The Minkowski-form distance or Histogram intersection can be used to compute the similarity between two histograms [5]. However, using an individual type of feature cannot well characterize image content. The multimodal methods combine the similarities from different types of features. The simplest way for combination yielding a scalar is to compute the weighted sum of these similarities based on the assumption that the features are not of the same importance. The weights can be decided manually or by relevance feedback mechanism [9].

As global features are often too rigid to represent an image, there has been a paradigm shift from global feature representation to local descriptors. Local features are computed based on a subset of the image usually in neighborhood of a salient point or a region. It is deemed that local features are closer to the perception of human visual system, as they often correspond to meaningful image components such as salient points, rigid objects, and homogenous regions [2]. The similarity is then computed based on user selected points/objects/regions or weighted sum of all of them. For example, an image is represented by a set of regions where each region is assigned a feature set and a weight indicating the importance of the corresponding region [4]. The image-to-image similarity is measured by the Earth Mover's Distance (EMD) [7] or an Integrated Region Matching method (IRM) [2]. The recent work in computer vision treated image as a set of salient points and extracted Scale Invariant Feature Transform (SIFT) features for each point [6]. Image matching is performed based on the Euclidean distances between pairs of salient points or the histogram comparison built upon a codebook.

Foundations

By the nature of the task of image retrieval, image similarity boils down to two intrinsic problems: (i) how to describe an image using a set of visual features, and (ii) how to assess the similarity between two images based on these features. Figure 2 shows the paradigms of image similarities, including three types of features for describing image content, formulation of the features, distance metrics for computing the similarities, and techniques used for computing the distance. The distance metrics used for image similarity depend on the selection of features and their corresponding formulations.

Image Descriptors

The preliminary step for image similarity is the description of image content. Research has proceeded toward effectively characterizing image content by a variety of visual features (or referred to as *signatures*). These features can be categorized into three types according to the pixels used, i.e., global, regional, and local features. The global features are extracted over the entire image or sub-image based on grid partition, the regional features are computed based on the results of image segmentation which attempts to segment the image into different homogenous regions or objects, while the local features aim at robust descriptors invariant to scale and orientation based on local maxima.

In global features, the most typical ones are color, texture, and shape which are widely used in many retrieval systems [5]. Color histogram is an effective and easy-to-compute representation of the color distribution in an image. It is also robust to the translation and rotation about the view axis, as well as slight occlusion. A color histogram is created by counting the

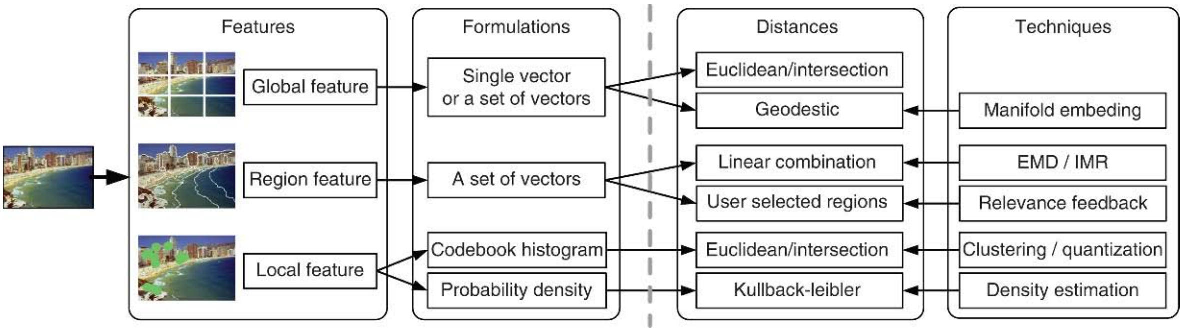

Image Similarity. Figure 2. Paradigms of image similarities, including the corresponding features, formulations, and distance metrics, and techniques. This figure is designed similar to the figure used in [5].

pixels falling into a quantized bin in a specific color space, such as RGB, HSV, and LUV spaces. In addition, color moments are also popular color features. Usually the first three order (i.e., *mean*, *variance*, and *skewness*) color moments are suitable enough to represent the color distribution of image. An alternative way to compute color histogram and moments is to divide an image into non-overlapping blocks, compute histogram or moments for each block, and concatenate all the features into one vector. To deal with large-scale image database, a compact descriptor is proposed in [12] where each image is converted to a K-bit (K is no more than 32) hash code according to its content. Other color features include color coherence, color correlogram, and so on. Texture features are intended to capture the granularity and repetitive visual patterns in an image. The basic texture features include Tamura, multi-resolution simultaneous auto-regressive model (MRSAR), Gabor filter, wavelet transform, and Wold features [11,5]. In contrast to color and texture features, shape features are usually computed after images being segmented into regions. The shape features capture the local geometrical properties. Typical shape features include normalized inertia [1], moment invariants, Fourier descriptors [5], and so on. Using global features, an image can be represented by a single vector corresponding to a uni-modaltiy or a set of vectors and weights corresponding to multi-modal features and their importances.

The regional features are similar with global features, except that they are computed over a local region with homogeneous texture rather than the whole image. The most widely used features for describing a region include color moment [1], color correlogram [8], wavelet transform texture, and normalized inertia [1]. As a result, an image is represented by a set of vectors and weights each corresponding to a region.

Local invariants such as salient points from which descriptors are derived, traditionally used for stereo matching and object recognition, are being used in image similarity. For example, the algorithm proposed by Lowe [6] constructs a scale space pyramid using Difference-of-Gaussian (DoG) filters and finds the local 3D maxima (i.e., salient point) on the pyramid. A robust Scale Invariant Feature Transform (SIFT) descriptor is computed for each point. An image is thus represented by a set of salient points and 128 dimensional SIFT features, or a histogram of codewords built upon a large visual vocabulary.

Similarity Measures

The similarity measures are based on comparisons between the features associated with images. As shown in Fig. 2, since each type of feature can have its own mathematical formulation, the distance metrics and the corresponding techniques for computing the distances are different.

Considering that an image $\mathbf{I}$ is represented by a single vector $\mathbf{f} = (f(1),\ldots,f(M))$ (e.g., histogram or some distribution) in which each dimension is independent of each other and has equal importance, the most widely adopted similarity is computed based on Minkowski-form distance, defined as

$$\mathbf{D}_{L_p}(\mathbf{I}^0,\mathbf{I}^1) = \left\{ \sum_{i=1}^{M} |f^0(i) - f^1(i)|^p \right\}^{1/p} \qquad (1)$$

where $f^0(i)$ and $f^1(i)$ denote i-th feature of image $\mathbf{I}^0$ and $\mathbf{I}^1$, respectively. For $p = 2$, this yields the Euclidean distance. The histogram intersection is a special case of L_1 distance, defined as

$$\mathbf{D}_{HI}(\mathbf{I}^0,\mathbf{I}^1) = \frac{\sum_{i=1}^{M} \min(f^0(i), f^1(i))}{\sum_{i=1}^{M} f^1(i)} \qquad (2)$$

It has been shown that histogram intersection is fairly sensitive to the changes of image resolution, occlusion, and viewing point [5]. A distance robust to noise is Jeffery distance (JD) which is based on the Kullback-Leibler divergence (KL) given by

$$\mathbf{D}_{KL}(\mathbf{I}^0,\mathbf{I}^1)=\sum_{i=1}^{M}f^0(i)\log\frac{f^0(i)}{f^1(i)} \tag{3}$$

Although it is often intuited as a distance metric, the KL divergence is not a true metric since it is not symmetric. The JD distance is defined as

$$\begin{aligned}\mathbf{D}_{JD}(\mathbf{I}^0,\mathbf{I}^1)=\sum_{i=1}^{M}\{&f^0(i)\log\frac{f^0(i)}{m_i}\\&+f^1(i)\log\frac{f^1(i)}{m_i}\}\end{aligned} \tag{4}$$

where $m_i=\frac{f^0(i)+f^1(i)}{2}$. In contrast to KL divergence, JD distance is symmetric and numerically stable when comparing two empirical distributions. Hausdorff distance [2] is another matching method which is symmetrized by computing additionally the distance with image $\mathbf{I}^0$ and $\mathbf{I}^1$ reversed and choosing the larger one of the two distances

$$\begin{aligned}&\mathbf{D}_H(\mathbf{I}^0,\mathbf{I}^1)=\max\left(\max_i\min_j\ \mathbf{d}(f^0(i),f^1(i)),\right.\\&\left.\max_J\min_i\ \mathbf{d}(f^0(i),f^1(i))\right)\end{aligned} \tag{5}$$

where $\mathbf{d}(,)$ can be any form of distance such as L_1 and L_2 distances. The Mahalanobis distance metric deals with the case that each dimension of vector is dependent and has different importance, given by

$$\mathbf{D}_M(\mathbf{I}^0,\mathbf{I}^1)=\sqrt{(\mathbf{f}^0-\mathbf{f}^1)^{\mathrm{T}}\mathbf{C}^{-1}(\mathbf{f}^0-\mathbf{f}^1)} \tag{6}$$

where $\mathbf{C}$ is the covariance matrix of the feature vectors. The above distance measures are all derived from a linear feature space which has been noted as the difficulty in measuring perceptual or semantic image distance. Manifold ranking replaces traditional Euclidean distance by the geodesic distance in a non-linear manifold [13]. The similarity is often estimated based on a distance measure $\mathbf{d}(,)$ and a positive radius parameter σ along a manifold

$$\mathbf{D}_{MR}(\mathbf{I}^0,\mathbf{I}^1)=\exp\left\{-\frac{\mathbf{d}(\mathbf{I}^0,\mathbf{I}^1)}{\sigma}\right\} \tag{7}$$

where L_1 distance is usually selected for $\mathbf{d}(,)$.

In a more general situation, an image $\mathbf{I}$ is represented by a set of vectors and weights $\{(\mathbf{f}_i,\omega_i)\}(i=1, 2,\ldots,M)$, where M is the number of modalities (e.g., color, texture, or shape). Each vector (also referred to as distribution) corresponds to a specific region or modality and the weight indicates the significance of associating this vector to the others. Note that the weight ω_i can have the same dimension to $\mathbf{f}_i$ indicating that each dimension of the features in a single vector has the same importance to each other, or just a real value indicating the importance of the entire vector. The simplest way to compute the similarity from different modalities is the weighted sum of the similarity from each single vector. The Earth Mover's Distance (EMD) represents a soft matching scheme for features in the form of set of vectors [7]. The EMD "lifts" the distance from individual features to full distributions. The EMD distance is given by

$$\mathbf{D}_{EMD}(\mathbf{I}^0,\mathbf{I}^1)=\frac{\sum_{i=1}^{M^0}\sum_{j=1}^{M^1}s_{ij}\mathbf{d}(\mathbf{f}_i^0,\mathbf{f}_j^1)}{\sum_{i=1}^{M^0}\sum_{j=1}^{M^1}s_{ij}} \tag{8}$$

where $\mathbf{d}(,)$ is the ground distance between two vectors which can be defined in diverse ways depending on the system, s_{ij} minimizes the value of (8) subject to the following constraints:

$$\begin{aligned}&s_{ij}\geq 0,\quad 1\leq i\leq M^0,\quad 1\leq j\leq M^1\\&\sum_{j=1}^{M^0}s_{ij}\leq\omega_i^0,\quad 1\leq i\leq M^0\\&\sum_{i=1}^{M^1}s_{ij}\leq\omega_j^0,\quad 1\leq j\leq M^1\\&\sum_{i=1}^{M^0}\sum_{j=1}^{M^1}s_{ij}=\min\left(\sum_{i=1}^{M^0}\omega_i^0,\sum_{j=1}^{M^1}\omega_j^1\right)\end{aligned}$$

when ω_i^0 and ω_j^1 are probabilities, EMD is equivalent to the Mallows distance [2]. Another matching-based distance is the Integrated Region Matching (IRM) distance [2]. The IRM distance uses the most similar highest priority (MSHP) principle to match different modalities or regions. The weights s_{ij} are subject to the same constraints as in the Mallows distance, except that $\mathbf{d}(,)$ is not computed by minimization. Another way to the adjustment of weights ω_i in image similarity is relevance feedback which captures the user's precise needs through iterative feedback and query refinement. The goal of relevance feedback is to find the appropriate weights to model the user's information need [9]. The weights are classified into *intra*- and *inter*- weights. The intra-weights represent the different contributions of the components within a single vector (i.e., region or modality), while the inter-weights represent the contributions of different vectors. Intuitively, the intra-weights are decided based on the variance of the same vector components in the relevant feedback examples, while the inter-weights are directly updated according to user's feedback in terms of the similarity based on each vector. For the comparison among these distance metrics, please refer to [2] for more details.

In the context of image being represented by a set of salient points and their corresponding local descriptors, image similarity is computed based on the Euclidean distance between each pair of salient points [6]. An alternative way is to represent each image by a bag of codewords which are obtained by unsupervised learning of local appearance [3]. A large vocabulary of codewords is built by clustering a large amount of local features, and then the distribution of these codewords is obtained by counting all the points or patches within an image. Since the image is described by a set of distributions, histogram intersection and EMD defined in (2) and (8) can be employed to compute the similarity.

Key Applications

Content-based Multimedia Information Retrieval/Multimedia Database

The computation of image similarity is the fundamental operation in content-based multimedia information retrieval systems and multimedia database. Given a query image or video, the images or videos reasonably similar to the query are returned based on the given features and distance metric.

Object Recognition

Object Recognition aims to identify an object in a database of images. Typically an object is represented by a set of overlapping regions each represented by a vector computed from the region's appearance. Recognition of a particular object proceeds by matching the descriptor vectors based on image similarity.

Medical/Satellite/Surveillance Applications

In the applications such as medical, satellite image, and surveillance, image similarity is usually used for managing the database and querying or recognizing a particular object. For example, image similarity can be employed to detect the regions with abnormal characteristics in medical diagnose. Moreover, image similarity can support content-based queries on large database of remote sensing images.

Future Directions

As pointed out in [2], the problem of image similarity is the reliance on visual similarity for judging semantic similarity. As directly applying distance metrics to image similarity cannot well model human similarity perception, automatic learning of image similarity with the help of contextual and human information has been explored. For example, when an image is conceived as a bag of instances which correspond to regions, multiple-instance learning (MIL) can be used for learning semantic similarity [1]. Another interesting problem concerns image similarity in human perception system [10]. The mathematical or computational models are needed to accurately assess perceptual similarity by resembling human's perception.

Image Retrieval and Relevance Feedback

Michel Crucianu
National Conservatory of Arts and Crafts, Paris, France

Definition

Relevance feedback is a means of refining a query in an information retrieval system by asking the user to specify how relevant each result of the query is. An image retrieval session relying on relevance feedback is interactive and iterative. The session is divided into several consecutive rounds. At every round, the user provides feedback regarding the current retrieval results, usually by qualifying the returned images as either "relevant" or "irrelevant"; from this feedback, the system attempts to better identify the target of the user and to return improved results. A relevance feedback mechanism must maximize the relevance of the results while minimizing the amount of interaction between the user and the system.

Historical Background

In the early years of content-based image retrieval (CBIR), query by visual example (QBVE) was a prevailing paradigm. To support QBVE, an image retrieval system must first extract, during an off-line phase, a description in terms of low-level features (e.g., distribution of colors, textures, etc.) from every image in the supplied database. Then, when a query image is provided, the system returns the images whose descriptions are the most similar to the description of this query. However, QBVE encountered important difficulties: (i) there is a *semantic gap* between the high-level concept defining what a user is searching for and the existing low-level descriptions, and (ii) a relevant image is seldom available to serve as initial query ("page zero" problem). The introduction of relevance feedback in CBIR was motivated by both difficulties. User feedback provided during consecutive rounds can allow the system to progressively learn a correspondence between the target concept and low-level descriptions, thus bridging the semantic gap. Also, since the user can amend the results at every round, the initial query is less important; many different starting images may allow to identify the target concept.

Relevance feedback is not specific to image retrieval. For other types of content, such as text, music or video, a gap can also be found between automatically extracted descriptions of the content and search criteria that users consider meaningful. Actually, relevance feedback was first introduced for the retrieval of text documents in the seminal work of Salton and van Rijsbergen. These initial proposals inspired the early feedback methods put forward for image retrieval. However, since a user can evaluate the relevance of an image faster than the relevance of a text or of a streaming media item, the appeal of relevance feedback was stronger for image retrieval.

Foundations

Understanding the specific goal of an image retrieval session is important both for defining an appropriate feedback mechanism and for identifying adequate evaluation methods. The earliest and most frequent goal involving relevance feedback consists of finding images that illustrate a target concept the user has in mind [6,10]. The concept can correspond to a perceptive characteristic, but in general has higher-level semantics. The system must solve a ranking problem: the images must be ordered and returned to the user by decreasing relevance. Nevertheless it is accepted that a precise ranking of the relevant images is not required, mainly because the user herself may be unable to define an optimal ranking; the system should simply rank most of the relevant images before the irrelevant ones.

Recently, relevance feedback was also suggested as a way to delineate the class of images illustrating a concept the user has in mind. The aim is to extend textual annotations of some images in the class to the others [7] or to help librarians perform "mass annotation" of the images [3]. To make this procedure efficient, much less effort should be required for defining the target class than for individually annotating all the images in the class. In this case, the system has to solve a classification problem: the boundary between the images belonging to the target class (the relevant images) and the others (irrelevant images) must be reliably identified. The rate of false positives (i.e., images that do not belong to the class but are assigned to it and, consequently, receive a wrong annotation) is considered to be more important than the overall error rate. However, the boundary does not have to be crisp and a degree of confidence can be associated to the resulting annotation.

Image retrieval with relevance feedback can only be effective if some important assumptions are verified. First, discrimination between relevant and irrelevant images must be possible with the available image descriptors; the "numerical gap," due to the use of inappropriate descriptors, should be avoided. Second, the target concept of the user must be consistent during the consecutive feedback rounds of a retrieval session. Third, since the amount of feedback a user can provide is very limited, the target concept that needs to be identified must have a relatively simple representation in the description space of the images.

Relevance Feedback Methods

To support relevance feedback, an image retrieval system should include two components: a *learner* and a *selector*. At every feedback round, the user marks (or labels) images returned by the system as either relevant or irrelevant. The learner makes use of this information to reestimate the target of the user (see Fig. 1). Given the current estimation of the target, the selector chooses other images for which the user is asked to provide feedback during the next round. The recent evolution of the learners and of the selection criteria is briefly presented in the following.

Learners

To estimate the target of the user, the learner can rely on the training data, consisting of the images marked by the user during consecutive feedback rounds, and on prior knowledge when it is available. The task of the learner is particularly difficult in the context of relevance feedback for several reasons (see also [16]). First, since the interaction with the user during a feedback session is limited, the amount of training data is small, sometimes much smaller than the dimension of the image description space. This highlights the importance of prior knowledge. Then, the target class may have a rather complex shape in the description space and even several disconnected modes; since training data is scarce, this can severely limit the generalization expected from the learner. Another difficulty comes from the strong imbalance in the training data: there are usually fewer positive examples (images considered relevant by the user) than negative examples (irrelevant images). The learner should have a low sensitivity to this imbalance or some remedy must be

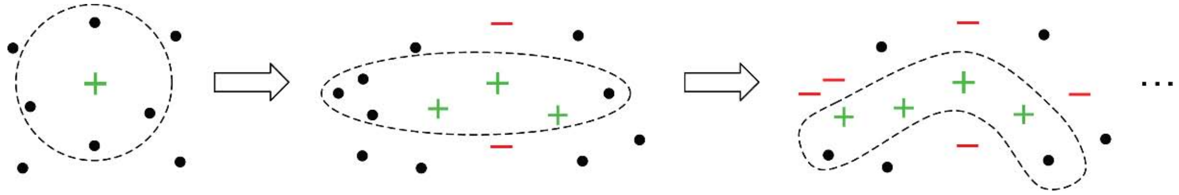

Image Retrieval and Relevance Feedback. Figure 1. Simplified view of some relevance feedback rounds. An initial similarity-based retrieval (leftmost image) returns the four nearest neighbors (points inside the dotted circle) of the query (+), relying on the default metric defined in the image description space. By marking the images returned as either relevant (+) or irrelevant (–), during consecutive rounds, the user allows the system to progressively identify the target class. At every round, the dotted boundary shows the current estimation of the target.

found. Last but not least, to preserve interactivity, both learning from the training data and the evaluation of the remaining images according to the selection criterion should be fast.

Early work on relevance feedback for CBIR directly followed from QBVE, by assuming the existence of an ideal query point and feature weighting that, if found, would allow QBVE to provide the appropriate answer to the user. This motivated the "query point movement" (QPM) approach, for which the task of the learner consists in identifying, at every round, a better query point together with a re-weighting of the individual dimensions of the image description space. Learning sometimes used only the positive examples [14], but usually employed both the positive and the negative examples [12]. These early proposals make the strong assumption that the target class corresponds to a multidimensional Gaussian distribution and some further consider that the covariance matrix of the target class is diagonal. Learning consists then in estimating the parameters of this distribution. This restrictive assumption was removed in [8,11], as a first departure from QPM. In the query expansion scheme put forward in [11], an online clustering of the examples is performed first, then all the other images are evaluated using a nearest-neighbor decision with respect to these clusters. The densities of the positive and of the negative examples are estimated with a Parzen window method in [8]; the images returned to the user are ranked according to the difference between the two densities.

For a large part of the recent work on relevance feedback, the learners employed are kernel methods and especially support vector machines (SVM [13]). With these kernel methods, the data in input space is first mapped to a higher-dimensional feature space using a non-linear transform associated to a reproducing kernel; linear methods in this feature space provide nonlinear solutions in the input space. Learning is usually based on constrained quadratic optimization and the sparsity of the solution is encouraged by various means. Two-class SVM maximize the *margin* between the discrimination boundary and the training data belonging to each class, so the resulting boundary is only defined by those examples that are closest to the boundary (the *support vectors*). One-class SVM model the support of the distribution of data in input space by finding the smallest sphere surrounding the data in feature space (according to one formulation); this sphere is only determined by the outermost examples. Since it is defined in the feature space, a kernel method can be easily applied to different types of data (e.g., vectors, sets, graphs) if an appropriate kernel is found. An SVM has some other properties that make it an interesting choice as a learner for relevance feedback. First, the decision function of an SVM allows both the definition of a boundary and of a ranking. Second, learning with few examples is very fast and, given the sparsity of the solution, computing the value of the decision function for the unmarked images can also be relatively fast. Finally, by relying only on support vectors, two-class SVM are usually less sensitive than density-based learners to the imbalance between positive and negative examples in the training data.

Among kernel methods, recent relevance feedback proposals often make use of two-class SVM to discriminate relevant and irrelevant images (see e.g., [15]). But one-class SVM were also used to model the distribution of the relevant images alone (see [1]). Other kernel methods, such as kernel biased discriminant analysis, Bayes point machines and relevance vector machines, were successfully employed in CBIR with relevance feedback.

Given the small amount of labeled data provided to the learner by user feedback, *semi-supervised* learning received significant attention in this context. Semi-supervised learning attempts to make use of both labeled and unlabeled data in order to find a better model (such as a discrimination boundary or a ranking function). It relies on the assumption that the distribution of unlabeled data does provide valuable information regarding the sought model (e.g., the density of data is lower near the boundary between classes than inside each class). When applied to relevance feedback, this approach has to face two important difficulties. First, the underlying assumption is not necessarily true for a particular image database and target class, and cannot be verified *a priori*. Second, taking unlabeled data into account frequently produces an increase in the computational complexity, which may not be compatible with interactive search.

Selection Criteria

After the learner reestimates the target of the user from the feedback received the selector must provide the user with a new set of images. The ultimate goal of a retrieval session is to present the user with as many relevant images as possible. Accordingly, the earliest and most frequently employed selection criterion returns those unmarked images that are considered to be the most relevant given the current estimation of user's target. The short description for this criterion is that it returns the "most positive" (MP) images. It has the advantage that the user can receive quite early during the retrieval session several relevant images.

However, to reach optimal results with a minimal amount of interaction, the system should elicit from the user at every round as much information as possible regarding the distinction between relevant and irrelevant images. Existing results concerning *active* learning point out that this is achieved when the examples shown to the user are those expected to remove a maximal amount of uncertainty regarding the target. This selection criterion can be briefly described as returning the "most informative" images (MI). It translates into two complementary conditions for the images being selected: each of them should be ambiguous (given the current estimation of the target class) and any two images should be as dissimilar as possible. A selection criterion based on active learning was first proposed for image retrieval with relevance feedback in [2], for a learner using density estimation. The ambiguousness condition was considered in [15] for SVM learners: the most ambiguous images (MA) are those that are nearest to the current boundary between relevant and irrelevant images. The dissimilarity (or low redundancy) condition was added later (see e.g., [3]).

Temporal Structure of the Session

The MI selection criterion was shown to minimize the number of feedback rounds required for defining the target class of the user. But since MI returns ambiguous images, it is inappropriate for presenting the user a maximum of relevant images. A first solution to this problem was to use MI during several rounds in order to define the class and then switch to MP in order to show the most relevant images; it is nevertheless difficult to know when exactly to replace MI by MP. Another solution is to combine the results of both MI and MP in the images shown to the user at every feedback round; this alternative is better adapted to nonprofessional users, who expect more immediate reward.

The initialization of search can also have an impact on the temporal structure of a retrieval session. In some cases, a relevant starting image can be provided by the user (external query) or found with the help of a visual summary of the image database. If an appropriate starting image is not available, then feedback should be used both for finding a truly relevant image (exploration stage) and then for retrieving further relevant images (exploitation stage). The session begins with some random selection of images. During the exploration stage, the system must be able so show the user images that are increasingly relevant. The user may not see any truly relevant image during several rounds, so she is expected to indicate which among the images returned by the system are more relevant than the others. Support for such an exploration stage also helps when the target class has several distinct modes. While the exploratory behavior was addressed by [2] and, to some extent, by a few QPM proposals, later work mainly focused on the exploitation stage. A competitive method for the exploration stage was recently proposed in [4].

Evaluation of Relevance Feedback in Image Retrieval

User satisfaction is the ultimate measure of the success of image retrieval with relevance feedback. Reliable evaluations or comparisons between alternative relevance feedback methods require large groups of users and real world image retrieval problems. Given the difficulty of setting up large scale experiments with real users, most evaluations are actually performed on specific ground truth databases, by emulating the user. A ground truth usually corresponds to the definition of a set of mutually exclusive image classes, covering an entire database. The emulated user knows the ground truth and is assumed to have a stoic and error free behavior: at every feedback round the emulated user correctly marks as either relevant or irrelevant each of the images returned by the selector. To obtain a reliable evaluation, it is very important to employ several ground truth databases having dissimilar characteristics. It was also argued that more diverse and realistic behaviors should be assigned to the emulated user.

When the aim is to rank the relevant images before the irrelevant ones, the quality of retrieval is usually given by the proportion of relevant images in the top N returned by an MP selector; N is the number of images in the target class of the ground truth database. When the aim is to delineate the target class, the quality of discrimination is $1 - \varepsilon$, where ε is either the overall classification error or the rate of false positives. Usually, a "right" number of feedback rounds can not be fixed *a priori.* To evaluate the performance of a relevance feedback method, the appropriate quality measure should be recorded during several consecutive feedback rounds.

Key Applications

Interactive multimedia search engines are the original motivation for content-based image retrieval in general and for the introduction of relevance feedback in particular. Such search engines are of high interest both for the general public and for professional users. Scalability and user-friendliness are fundamental requirements in this context.

Assistance in the annotation of content can be an important application mainly directed to professional users. Relevance feedback can support such users in delineating large classes of images in order to annotate at once all the images belonging to a class (mass annotation). In this case, the ability to reach a low classification error or a low rate of false positives is the major concern.

Future Directions

Since the amount of feedback provided during a retrieval session is very small, the system should make the most of all the information sources potentially available. These sources concern the users (e.g., past sessions of other users, user profiles), the images (e.g., structured or unstructured metadata) and the context of retrieval. The system should be able to evaluate and integrate all these sources with the feedback directly provided by the current user.

An important issue that was not extensively studied is the scalability of relevance feedback to very large databases. Scalability is a challenge both for the learner (especially when semi-supervised methods are employed) and for the selector. To avoid evaluating the decision function for all the unmarked images in the database, an index structure is needed. But existing multidimensional or metric index structures and associated *k*NN retrieval methods can not be directly applied, mainly because the queries that have to be processed are not classical point queries. A good example is the use of the MA (or MI) selection criterion with an SVM learner: in this case the images that are nearest to the discrimination boundary (defined by a hyperplane in feature space) should be returned. This scalability issue is addressed by some recent proposals (see [5,9]).

The interaction between users and current systems is rather limited; typically, a user can only mark as relevant or irrelevant each of the shown images. A more advanced interface should bring in more flexibility, by allowing every user to group together or to separate images, to place them in a visual summary, to mix several image retrieval paradigms, to interact online with other users, etc.

Region segmentation; Pixel classification; Edge detection; Thresholding

Definition

The rapid rate of image analysis field has grown enormously in the past few decades. Image analysis intends to construct explicit, meaningful descriptions of physical objects in images. It can be divided into two parts: low-level image analysis and high-level image analysis. Low-level tasks focus on region-based segmentation, whereas high-level tasks are related to object-oriented representation. Image segmentation, a process of pixel classification, aims to extract or segment objects or regions from the background. Intrinsic images can be generated at the low-level processing, revealing physical properties of the imaged scene. This can often be implemented with parallel computation.

Historical Background

Image segmentation is a critical step to the success of object recognition [12], image compression [2], image visualization [7], and image retrieval [3]. Pal and Pal [13] provided a review on various segmentation techniques. It should be noted that there is no single standard approach to segmentation. Many different types of scene parts can serve as the segments on which descriptions are based, and there are many different ways in which one can attempt to extract these parts from the image. Selection of an appropriate segmentation technique depends on the type of images and applications.

The level of segmentation or subdivision relies on the problem domain being dealt with. For example, in the optical character recognition (OCR), the text is separated from the document image, and further partitioned into columns, lines, words, and connected components. In building character subimages, one is often confronted with touching or broken characters that occur in degraded documents (such as fax, scan, photocopy, etc.). It is still challenging to develop techniques for properly segmenting words into their characters.

There are primarily four types of segmentation techniques: thresholding, boundary-based, region-based, and hybrid techniques. Thresholding is based on the assumption that clusters in the histogram correspond to either background or objects of interest that can be extracted by separating these histogram clusters. In addition to thresholding, many image segmentation algorithms are based on two basic properties of the pixel intensities in relation to their local neighborhood: discontinuity and similarity. Methods based on pixel discontinuity are called boundary-based or edge extraction methods, whereas methods based on pixel similarity are called region-based methods. Boundary-based methods assume that the pixel properties, such as intensity, color, and texture, should change abruptly between different regions. Region-based methods assume that neighboring pixels within the same region should have similar values (e.g., intensity, color, texture).

It is well known that such segmentation techniques – based on boundary or region information alone – often fail to produce accurate segmentation results. Hence, there has been a tendency towards hybrid segmentation algorithms which take advantage of the complementary nature of such information. Hybrid methods combine boundary detection and region growing together to achieve better segmentation [5,6,14]. Note that both results should achieve the foreground and background segmentation coherently.

Foundations

A number of image segmentation techniques, including thresholding, component labeling, locating object contours by the snake model, and automatic seeded region growing, are described below.

Thresholding

Thresholding provides an easy and convenient way to perform image segmentation based on the different intensities or colors in the foreground and background regions of an image. Not all images can be segmented successfully into foreground and background using simple thresholding. Its validity relies on the distribution of the intensity histogram. If the intensity distribution of foreground objects is quite distinct from the intensity distribution of background, it will be clear to apply thresholding for image segmentation. In this case, one expects to see distinct peaks in the histogram corresponding to foreground objects, such that threshold values can be picked to isolate those peaks accordingly. If such a peak does not exist, it is unlikely that simple thresholding can achieve a good segmentation.

There are several methods of choosing the threshold value λ. For example, the universal thresholding by Donoho et al. [4] sets

$$\lambda = \frac{\sigma\sqrt{2\log n}}{\sqrt{n}} \tag{1}$$

where σ is the standard deviation of the wavelet coefficients and n is the total size of samples. Other possibility is quantile thresholding where λ is statistically set to replace a percentage of the coefficients with the smallest magnitude to zero. Another adaptive method of automatically choosing the best threshold λ consists of four steps: (i) Choose an initial estimate λ; (ii) Calculate the two mean values μ_1 and μ_2 within the two groups of pixels after thresholding at λ; (iii) Calculate the new threshold value $\lambda = (1/2)(\mu_1 + \mu_2)$; (iv) If the new threshold value has a little change (i.e., smaller than a predefined constant), then the threshold selection is done; otherwise, go back to step 2.

Object (Component) Labeling

It is very possible to have more than one object in a scene. All the objects must be individually extracted for the purpose of establishing the object model base. The object-labeling technique is used, so that the array representation of these objects is a multivalued picture, in which the points of each component all have a unique nonzero label and the points of background are all zeros. This technique only requires two raster scans. To label 4-connected components, only the upper and left neighbors are checked. If the 8-connectedness is used, the upper two diagonal neighbors are also included.

Let the value of object points be "1" and of background points be "0." Assume that the 8-connectedness is adopted. Therefore, if all the above four neighbors (i.e., previously scanned neighbors) of the point P are zeros, then P is assigned a new label. If one of four neighbors is 1, then P gets the same label as that neighbor. If two or more of them are 1's, then P gets any one of their labels, and the equivalence table is established by marking the different labels together for later adjustment. Equivalence processing consists in merging the equivalent pair into the same class; i.e., a unique label is assigned to each class. Finally, a second scan is performed to replace each label by the representative of its class. Each component has now been uniquely labeled. After these processes, each individual model object can be fetched by its label.

Locating Object Contours by the Snake Model

In the original snake formulation of Kass et al. [9], the best snake position was defined as the solution of a variational problem requiring the minimization of the sum of internal and external energies integrated along the length of the snake. The corresponding Euler equations, which give the necessary conditions for this minimizer, comprise a force balance equation. The snake model has provided a number of applications in object segmentation, stereo matching, motion tracking, etc. In image processing, the snake model defines a snake as an energy-minimizing spline guided by external constraint forces and influenced by such forces that pull it toward image features such as lines and edges. It is a kind of the active contour model in the way that it locks on nearby edges, localizing them accurately.

There are two parts in the energy function of the snake model. The first part reflects geometric properties of the contour, and the second part utilizes the external force field to drive the snake. The first part serves to impose a piecewise smoothness constraint, and the second part is responsible for putting the snake near the local minimum of energy. The traditional snakes suffer from a great disadvantage that when an object resides in a complex background, the strong edges may not be the object edges of interest.

Therefore, researchers have proposed statistical and variational methods to enrich the energy function and extend its flexibility. They calculated the difference between the target object and the background using statistical analysis, but these limitations come from the priori knowledge requirements, such as independent probability models and template models. Unfortunately, such priori knowledge is usually unavailable unless the captured images are under very constrained settings. A problem with the snake model is that a user needs to place the initial snake points sufficiently close to the feature of interest.

The Traditional Snake Model A snake is a controlled continuity spline that moves and localizes onto a specified contour under the influence of the objective function. Let a snake be a parametric curve: $v(s) = [x(s), y(s)]$, where parameter $s \in [0, 1]$. It moves around the image spatial domain to minimize the objective energy function as defined by

$$E_{snake}(v) = \sum_{\mathrm{i=1}}^{\mathrm{n}} [\alpha \times E_{cont}(v_i) + \beta \times E_{curv}(v_i) \\ +\gamma \times E_{image}(v_i)], \tag{2}$$

where α, β and γ are weighting coefficients that control the snake's tension, rigidity, and attraction, respectively. The first and second terms are correspondingly the first- and second-order continuity constraints. The third term measures the edge strength (i.e., the image force).

The continuity force E_{cont} encouraging even spacing of points can be calculated as

$$E_{cont}[v_i] = \frac{\left|\overline{d} - |v_i - v_{i-1}|\right|}{\max_j\left\{\left|\overline{d} - |v_i(j) - v_{i-1}|\right|\right\}}, \tag{3}$$

where $\{v_i(j)|j = 1, 2, ..., m\}$ denotes the snake point v_i's m neighbors, and $\overline{d}$ denotes the average length of all the pairs of adjacent points on the snake contour as given by

$$\overline{d} = \frac{\sum_{i=1}^{n} |v_i - v_{i-1}|}{n}, \tag{4}$$

where $v_0 = v_n$. This term tends to keep the distances between each pair of adjacent vertices equal.

The energy of the second-order continuity E_{curv} is represented by

$$E_{curv}[v_i] = \frac{|v_{i-1} - 2v_i + v_{i+1}|}{\max\{|v_{i-1} - 2v_i + v_{i+1}|\}}. \tag{5}$$

The numerator can be rearranged as

$$v_{i-1} - 2v_i + v_{i+1} = (v_{i+1} - v_i) - (v_i - v_{i-1}). \tag{6}$$

If the ith vertex is pushed toward the midpoint of two adjacent vertices, E_{image} is minimized; i.e., the shape of the contour will remain $\subset^2$ continuity.

The third term, image energy E_{image}, is derived from the image so that it takes on its smaller values at the features of interest, such as boundaries. It considers the gradient (denoted as *grad*) magnitude, leading the active contour toward step edges. It is normalized to measure the relative magnitude as

$$E_{image}[v_i] = \frac{\min\{|grad|\} - |grad_{v_i}|}{\max\{|grad|\} - \min\{|grad|\}}, \tag{7}$$

where min and max denote the minimum and maximum gradients in the v_i's local m-neighborhood, respectively. Note that because the numerator in eq. (7) is always negative, E_{image} can be minimized for locating the largest gradient, which is the edge. In general, the traditional snake model can locate object contours in a simple background. If the background becomes complex, it will fail since the complex background will generate noisy edges to compete with the object edges for attracting the snake.

The Improved Snake Model The following two issues are observed when the snake model fails to locate object contours in complex backgrounds. One is the gray-level sensitivity; i.e., the more abrupt change the gray levels have (e.g., noises), the larger impact on the energy function the snake makes. The other is that the snake mistakenly locates the edges belonging to the background details due to their closeness to the snake point. Figure 1 shows a disk object in a complex background. If the snake points are initialized outside the disk, the snake cannot locate the disk contour accurately due to the disturbances from the background grids. The idea is to push the mean intensity of the polygon enclosed by the snake contour to be as close as to the mean intensity of the target object. The smaller intensity difference between the polygon and the object, the closer the snake approaches the object contour. Therefore, a new energy term, called the *Regional Similarity Energy* (RSE), is established for calculating the gray-level differences to be added into the overall energy [16].

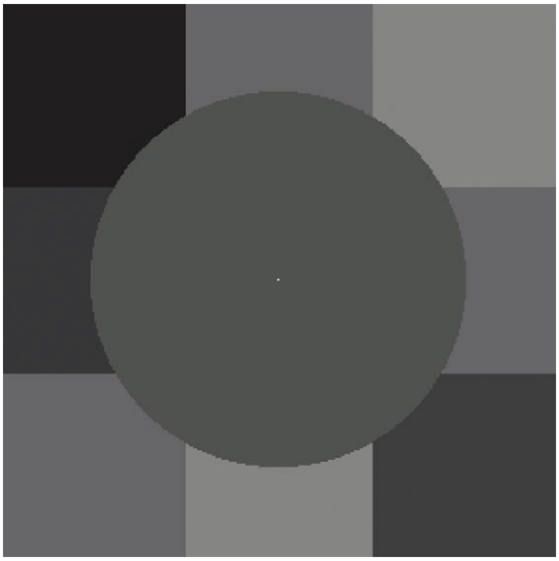

Image Segmentation. Figure 1. A disk object resides in a complex background.

The Gravitation External Force Field and the Greedy Algorithm In this section, the gravitation external force field is introduced and the greedy algorithm [8] is used for the active contour. The concept of gravitation external force field is taken from physics. Two objects attract each other by a force, which is proportional to their mass product and inversely proportional to the distance between their mass centers. Based on this concept, an external energy field, called the *Gravitation Energy Field* (GEF), is developed as given by

$$E_{gravitation} = \int \frac{g(\vec{r})}{\|\vec{r}\|}\vec{r}d\vec{r}, \tag{8}$$

where $\vec{r}$ is a position vector and $g(\vec{r})$ is a first-order derivative. Note that the edge pixels have the local maxima in the first-order derivative. The attractive force enables the snake points to move toward the object. With the gravitation energy field, the active contour can be dragged toward the object even if the snake points are far away. Therefore, the total energy function becomes

$$\begin{aligned} E_{snake} = {} & \alpha E_{cont}[v(s)] + \beta E_{curv}[v(s)] + \gamma E_{image}[v(s)] \\ & + \mu E_{gravitation}[v(s)] + \delta E_{RSE}[v(s)]. \end{aligned} \tag{9}$$

These weighting coefficients can be adjusted according to the user's application. For simplicity, $\alpha = \beta = \gamma = \mu = \delta = 1$.

Experimental Results Both the improved and the traditional snake models are applied on the added salt-and-pepper noise of Fig. 1. The results are shown in Fig. 2. It is observed that the improved model can locate the disk contour, but the traditional model fails. The improved model is suitable for random noise or fixed pattern noise. The banding noise is highly camera-dependent, and is the one which is introduced by the camera when it reads data from the digital sensor. The improved model may not perform well in an image with such noise.

Automatic Seeded Region Growing

Seeded Region Growing (SRG) is one of hybrid methods proposed by Adams and Bischof [1]. It starts with assigned seeds, and grow regions by merging a pixel into its nearest neighboring seed region. Mehnert and Jackway [10] pointed out that SRG has two inherent pixel order dependencies that cause different resulting segments. The first order dependency occurs whenever several pixels have the same difference measure to their neighboring regions. The second order dependency occurs when one pixel has the same difference measure to several regions. They used parallel processing and re-examination to eliminate the order dependencies. Fan et al. [5] presented an automatic color image segmentation algorithm by integrating color-edge extraction and seeded region growing on the *YUV* color space. Edges in *Y*, *U*, and *V* are detected by an isotropic edge detector, and the three components are combined to obtain edges. The centroids between adjacent edge regions are taken as the initial seeds. The disadvantage is that their seeds are over-generated.

Overview of the Improved Seeded Region Growing Algorithm

Figure 3 presents the overview of the improved seeded region growing algorithm [15]. Firstly, the color image is converted from *RGB* to YC_bC_r color space. Secondly, automatic seed selection is applied to obtain initial seeds. Thirdly, the seeded region growing algorithm is used to segment the image into regions, where a region corresponds to a seed. Fourthly, the region-merging algorithm is applied to merge similar regions, and small regions are merged into their nearest neighboring regions.

Apply the region-merging algorithm to overcome over-segmentation.

Image Segmentation. Figure 3. Outline of the proposed algorithm.

The Method for Automatic Seed Selection

For automatic seed selection, the following three criteria must be satisfied. First, the seed pixel must have high similarity to its neighbors. Second, for an expected region, at least one seed must be generated in order to produce this region. Third, seeds for different regions must be disconnected.

The similarity of a pixel to its neighbors can be computed as follows. Considering a 3 × 3 neighborhood, the standard deviations of Y, C_b and C_r components are calculated using

$$\sigma_x = \sqrt{\frac{1}{9}\sum_{i=1}^{9}(x_i - \bar{x})^2}, \tag{10}$$

where x can be Y, C_b, or C_r, and the mean value $\bar{x} = \frac{1}{9}\sum_{i=1}^{9} x_i$. The total standard deviation is

$$\sigma = \sigma_Y + \sigma_{C_b} + \sigma_{C_r}. \tag{11}$$

The standard deviation is normalized to [0,1] by

$$\sigma_N = \sigma/\sigma_{\max}, \tag{12}$$

where $\sigma_{\max}$ is the maximum of the standard deviation in the image. The similarity of a pixel to its neighbors is defined as

$$H = 1 - \sigma_N. \tag{13}$$

From the similarity, the first condition for the seed pixel candidate is defined as follows:

Condition 1: A seed pixel must have the similarity higher than a threshold value.

Secondly, the relative Euclidean distances (in terms of YC_bC_r) of a pixel to its 8 neighbors is calculated as

$$d_i = \frac{\sqrt{(Y - Y_i)^2 + (C_b - C_{b_i})^2 + (C_r - C_{r_i})^2}}{\sqrt{Y^2 + C_b^2 + C_r^2}} \quad i = 1, 2, \cdots, 8. \tag{14}$$

From experiments, the performance of using relative Euclidean distance is better than using normal Euclidean distance. For each pixel, the maximum distance to its neighbors is calculated as

$$d_{\max} = \max_{i=1}^{8}(d_i). \tag{15}$$

From the maximum distance, the second condition for the seed pixel candidate is defined below.

Condition 2: A seed pixel must have the maximum relative Euclidean distance to its eight neighbors which is less than a threshold value.

A pixel is classified as a seed pixel if it satisfies the above two conditions. In order to choose the threshold automatically in condition 1, Otsu's method [11] is used. The threshold is determined by choosing the value that maximizes the discrimination criterion σ_B^2/σ_w^2, where σ_B^2 is the between-class variance and σ_W^2 is the within-class variance. In condition 2, the value 0.05 is selected as the threshold based on these experiments.

Each connected component of seed pixels is taken as one seed. Therefore, the seeds generated can be one pixel or one region with several pixels. Condition 1 checks whether the seed pixel has high similarity to its neighbors. Condition 2 makes sure that the seed pixel is not on the boundary of two regions. It is possible that for one desired region, several seeds are detected to split it into several regions. The over-segmented regions can be merged later in the region-merging step. Figure 4(a) shows a color image, and (B) shows the detected seeds marked in red color. Note that the connected seed pixels are considered as one seed.

The Segmentation Algorithm

Let $A_1, A_2, \ldots, A_i$ denote initial seeds and S_i denote the region corresponding to A_i. The mean of all seed pixels in S_i in terms of Y, C_b and C_r components is denoted as $(\bar{Y}, \bar{C}_b, \bar{C}_r)$. The segmentation algorithm is described as follows:

1. Perform automatic seed selection.
2. Assign a label to each seed region.
3. Record neighbors of all regions in a sorted list T in a decreasing order of distances.
4. While T is not empty, remove the first point p and check its 4-neighbors. If all labeled neighbors of p have a same label, set p to this label. If the labeled neighbors of p have different labels, calculate the distances between p and all neighboring regions and classify p to the nearest region. Then, update the mean of this region and add 4-neighbors of p, which are neither classified yet nor in T, to T in a decreasing order of distances.
5. Perform region merging.

Note that in step 3, T denotes the set of pixels that are unclassified and are neighbors of at least one of the

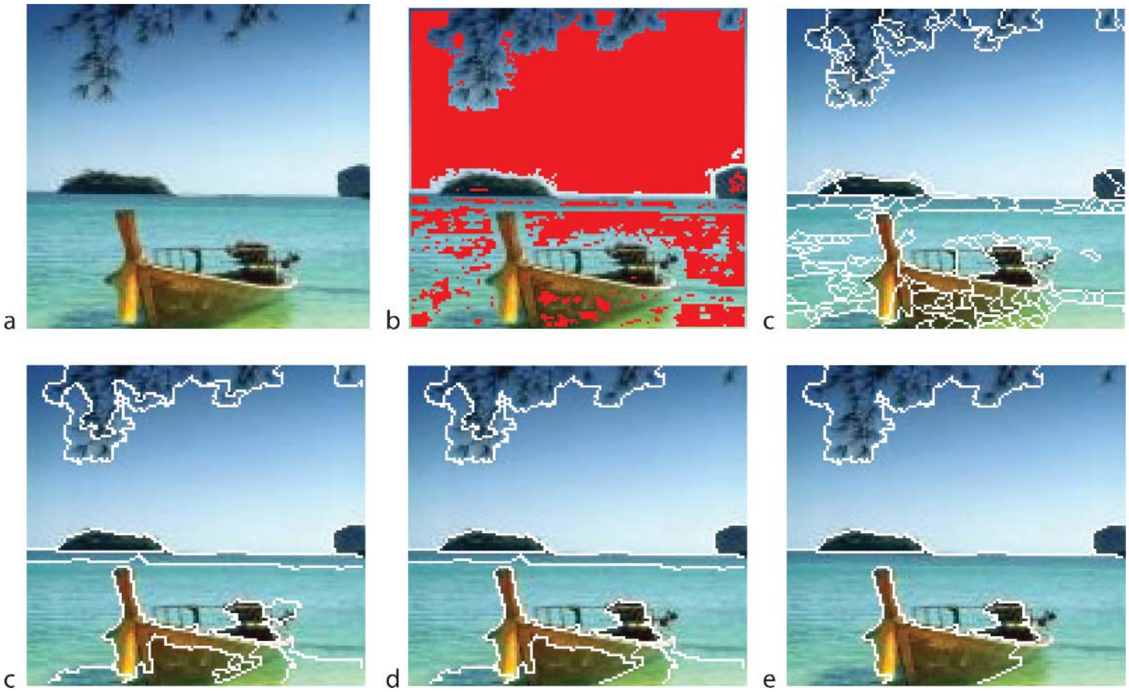

Image Segmentation. Figure 4. (a) Original color image, (b) the detected seeds are shown in red color, (c) seeded region growing result, (d) the result of merging adjacent regions with relative Euclidean distance less than 0.1, (e) the result of merging small regions with size less than 1/150 of the image, and (f) final segmented result.

region. The relative Euclidean distance d_i between the pixel i and its adjacent region is calculate by

$$d_i = \frac{\sqrt{(Y_i - \overline{Y})^2 + (C_{b_i} - \overline{C}_b)^2 + (C_{r_i} - \overline{C}_r)^2}}{\sqrt{Y_i^2 + C_{b_i}^2 + C_{r_i}^2}}, \quad (16)$$

where $(\overline{Y}, \overline{C}_b, \overline{C}_r)$ are the mean values of Y, C_b, and C_r components in that region. In step 4, the pixel p with the minimum distance value is extracted. If several pixels have the same minimum value, the pixel corresponding to the neighboring region having the largest size is chosen. If p has the same distance to several neighboring regions, it is classified to the largest region. Figure 4(c) shows the result of the proposed algorithm, where boundaries of regions are marked in white color.

Implication of Constraints

Wenfei Fan
University of Edinburgh, Edinburgh, UK

Definition

The implication problem is to decide whether or not a given set of constraints logically implies another constraint. With any constraint (dependency) language $\mathcal{L}$ there are two implication problems associated, which do not coincide in general.

In the traditional logic framework, an instance of a schema **R** is a logical structure that is either finite or infinite, referred to as an *unrestricted instance* of **R**. A set Σ of constraints over **R** *implies without restriction* a constraint φ, denoted by $\Sigma \vDash_{\text{unr}}\varphi$, if for each unrestricted instance **I** of **R** that satisfies Σ, **I** also satisfies φ. The *unrestricted implication problem* for $\mathcal{L}$ is to determine, given a set Σ of constraints in $\mathcal{L}$ and another constraint φ in $\mathcal{L}$, whether or not $\Sigma \vDash_{\text{unr}}\varphi$.

In the context of databases, only finite instances are considered and implication analysis lies within finite model theory. A set Σ of constraints over **R** *finitely implies* a constraint φ, denoted by $\Sigma \vDash_{\text{fin}}\varphi$, if for each finite instance **I** of **R** that satisfies Σ, **I** also satisfies φ. The *finite implication problem* for $\mathcal{L}$ is to determine, given any set Σ of constraints in $\mathcal{L}$ and another constraint φ in $\mathcal{L}$, whether or not $\Sigma \vDash_{\text{fin}}\varphi$.

In the context of semi-structured data or XML, implication analysis is also conducted in the absence of schema. For XML, a set Σ of constraints *implies* another constraint φ *in the absence of schema* if all XML documents that satisfy Σ also satisfy φ; similarly for semi-structured data.

Historical Background

Logical implication is one of the key issues in dependency theory. It has been studied for, and has proved valuable in, schema normalization, data integrity maintenance and query optimization, among other things. Recently there has also been renewed interest in this line of work, for XML data management, data exchange and data cleaning.

After functional dependencies were introduced by Codd in 1972, the relevance of implication to database theory was first observed by [8]. Since then the problem of logical implication has been extensively studied for a large variety of dependencies, mostly focusing on the following aspects. (i) The complexity of implication analyses (*e.g.*, [3,6,7,9,10,11,15]). In particular, the separation of finite and unrestricted implication was originally investigated in [7,10], and the chase, a powerful decision procedure for implication, was based on the idea of [3] and articulated in [7,15]. (ii) Axiomatization for characterizing logical implication, first studied by Armstrong [5] for functional dependencies, followed by a flurry of research (see, *e.g.*, [12] for a survey). (iii) View dependencies for propagating dependencies from databases to their views, originally studied in [14]. (iv) The impact of interaction between schema (types) and constraints on implication analysis, first studied by [2] for semi-structured data, and then for XML in the presence and in the absence of schema [13]. See [1,12] for comprehensive surveys.

Foundations

The remainder of this entry discusses various aspects of implication: dependencies, unrestricted and finite implication, implication and satisfiability analyses, finite axiomatization, complexity bounds, and view dependencies.

Constraints (Data Dependencies)

Implication analysis has been studied for a variety of integrity constraints (in this entry, integrity constraints and data dependencies are used interchangeably). Most constraints studied for relational databases can be expressed as first-order logic sentences of the following form, referred to as *embedded dependencies*:

$$\forall x_1 \ldots x_m \ (\phi(x_1, \ldots, x_m) \rightarrow \exists y_1 \ldots y_n \ \psi(z_1, \ldots, z_k)),$$

where (i) $\{y_1, \ldots, y_n\} = \{ z_1, \ldots, z_k\} - \{ x_1, \ldots, x_m\}$; (ii) ϕ is a conjunction of (at least one) relation atoms of the form $R(w_1, \ldots, w_l)$, using all of the variables in $\{x_1, \ldots, x_m\}$, where w_i is a variable for each $i \in [1,l]$; (iii) ψ is a conjunction of either relation atoms or equality atoms $w = w'$, using all of the variables in $\{z_1, \ldots, z_k\}$, where w, w' are variables; and (iv) there exist no equality atoms in ψ using existentially quantified variables.

Embedded dependencies are often classified as follows.

1. Full dependencies are embedded dependencies that have no existential quantifiers, *i.e.*, dependencies of the form $\forall x_1 \ldots x_m \ (\varphi(x_1, \ldots, x_m) \ \rightarrow \ \psi(z_1, \ldots, z_k))$, where $\{z_1, \ldots, z_k\}$ is a subset of $\{x_1, \ldots, x_m\}$. Full

dependencies include functional dependencies (FDs), multivalued dependencies (MVDs) and join dependencies (JDs) (see [1,12] for the definitions of FDs, MVDs, JDs and inclusion dependencies).

2. Tuple generating dependencies (TGDs) are embedded dependencies in which the right-hand side ψ is a relation atom. A TGD says that if a certain pattern of entries appears then another pattern must appear. Inclusion dependencies (INDs), MVDs and JDs are examples of TGDs.
3. Equality generating dependencies (EGDs) are embedded dependencies in which the right-hand side ψ is an equality atom. An EGD says that if a certain pattern of entries appears then a certain equality must hold. The best known equality generating dependencies are FDs.
4. Typed dependencies are embedded dependencies for which there exists an assignment of variables to column positions such that (i) variables in relation atoms occur only in their assigned position, and (ii) each equality atom involves a pair of variables assigned to the same position. Typed dependencies include FDs, MVDs and JDs.

Implication analysis has also been studied for integrity constraints on semi-structured data and XML. This entry focuses on relational dependencies only, and refer the interested reader to [4] for a survey on XML constraints.

Unrestricted Implication Versus Finite Implication

Given a set Σ of constraints and another constraint φ, if $\Sigma \models_{\text{unr}} \varphi$, *i.e.,* Σ implies φ without restriction, then obviously $\Sigma \models_{\text{fin}} \varphi$, *i.e.,* Σ finitely implies φ. However, the converse does not necessarily hold. It is possible that $\Sigma \models_{\text{fin}} \varphi$ whereas $\Sigma \not\models_{\text{unr}} \varphi$. That is, the implication problem and finite implication problem may have to be treated separately as different decision problems. Below are two examples.

1. When Σ is a set of FDs and INDs, and φ is either an FD or an IND [9].

   Consider a binary relation *R(A,B)* with attributes *A,B*. Let $\Sigma = \{A \rightarrow B, R[A] \subseteq R[B]\}$, and φ be $R[B] \subseteq R[A]$. Then from Σ it follows that for any finite instance I of R that satisfies Σ, $|\pi_A(I)| \geq |\pi_B(I)|$ (by the FD in Σ) and $|\pi_A(I)| \leq |\pi_B(I)|$ (by the IND in Σ), where π is the projection operator in the relational algebra, and $|S|$ denotes the number of distinct tuples in a relation S. Therefore, $|\pi_A(I)| = |\pi_B(I)|$. Since I is finite and $\pi_A(I) \subseteq \pi_B(I)$, it follows that $\pi_B(I) \subseteq \pi_A(I)$ and I satisfies φ. Conversely, an infinite instance $\{(i+1,i) | i \geq 0\}$ of R satisfies Σ but does not satisfy φ; thus $\Sigma \not\models_{\text{unr}} \varphi$.

   Similarly, let φ be $R[B] \rightarrow R[A]$ then one can verify that $\Sigma \models_{\text{fin}} \varphi$ but $\Sigma \not\models_{\text{unr}} \varphi$.
2. When Σ is a set of TGDs and φ is a TGD (see [7] for a proof).

   A useful technique for proving the decidability of the implication problem for a constraint language $\mathcal{L}$ is to show that the implication and finite implication problems coincide for $\mathcal{L}$, *i.e.,* for any set Σ in $\mathcal{L}$ and another constraint φ in $\mathcal{L}$, $\Sigma \models_{\text{unr}} \varphi$ if and only if $\Sigma \models_{\text{fin}} \varphi$. Indeed, all relational constraints considered so far are definable in first-order logic. For these constraints implication is *r.e.* (recursively enumerable) and finite implication is co-*r.e.*. As a result, if implication and finite implication coincide, then both are recursive, *i.e.,* decidable. For full dependencies, for example, the implication and finite implication problems coincide, and are both decidable.

Implication Versus Satisfiability

Consider Σ and φ defined over a relational schema **R**. Obviously, $\Sigma \models_{\text{unr}} \varphi$ (resp. $\Sigma \models_{\text{fin}} \varphi$) if and only if the sentence $\wedge\ \Sigma\ \wedge \neg\varphi$ is (resp. finitely) satisfiable, *i.e.,* there exists a (resp. finite) instance of **R** that satisfies the sentence. This tells us that there is close connection between (resp. finite) implication and (resp. finite) satisfiability, problems studied in (resp. finite) model theory. For a constraint language $\mathcal{L}$ that is closed under negation (*i.e.,* if $\varphi \in \mathcal{L}$ then so is $\neg\varphi$), the (resp. finite) implication problem is just a special case of the (resp. finite) satisfiability problem.

Embedded dependencies are not closed under negation, and their (finite) implication analyses are quite different from their (finite) satisfiability counterparts. For any set Σ of embedded dependencies defined over a relational schema **R**, the empty instance $\mathbf{I}\phi$ of **R**, *i.e.,* an empty database with no tuples, satisfies Σ. For the analysis of (finite) satisfiability, embedded dependencies have the *domain independence* property: when considering whether a database **I** satisfies Σ, it suffices to consider the tuples in **I** without worrying about the underlying domains of the attributes in **R**. In contrast, to verify $\Sigma \models_{\text{unr}} \varphi$ (resp. $\Sigma \models_{\text{fin}} \varphi$) one may have to consider all (resp. finite) instances of **R**, possibly ranging over all the values in the underlying domains of the attributes in **R**.

Despite this, when studying (finite) implication analyses for certain subclasses of embedded dependencies, it is still possible to capitalize on results on their (finite) satisfiability problems. For example, when Σ and φ are full dependencies, $\wedge\ \Sigma\ \wedge\neg\varphi$ is an $\exists^*\forall^*$ sentence (with equality or not), in a fragment of first-order logic known as the Bernays-Schőnfinkel-Ramsey class. It is known that for the Bernays-Schőnfinkel-Ramsey class, the satisfiability and finite satisfiability problems coincide and are decidable in NEXPTIME (non-deterministic exponential time; it is in fact NEXPTIME-complete in the absence of functions). This yields an upper bound on the implication and finite implication problems for full dependencies.

It is worth mentioning that when it comes to XML, the interaction between schemas (types) and integrity constraints becomes more intriguing than their relational counterparts, and as a result, the finite satisfiability problem becomes much harder. Indeed, for a class $\mathcal{L}_0$ of unary keys and foreign keys for XML, it is undecidable to decide, given a set Σ of constraints in $\mathcal{L}_0$ and a DTD D_0 (document type definition), whether or not there exists a finite XML document that satisfies both Σ and D_0. There are, however, interesting connections between finite satisfiability and finite implication analyses for XML constraints (see [4,13] for detailed discussions).

Finite Axiomatizability

Another important approach to studying (finite) implication of constraints is based on finite axiomatization. A finite axiom system $\mathcal{A}$ for a class $\mathcal{L}$ of constraints consists of finitely many axiom schemes and inference rules. A *proof* of a constraint φ in $\mathcal{L}$ from a set Σ of constraints in $\mathcal{L}$ *using* $\mathcal{A}$ is a finite sequence $\varphi_1,\ldots,\varphi_n$ such that φ_n is φ, and for each i ∈ [1, n], (i) $\varphi_i \in \Sigma$, or (ii) φ_i is an instance of an axiom scheme in $\mathcal{A}$, or (iii) φ_i follows from preceding constraints in the sequence by one of the inference rules in $\mathcal{A}$. If there exists such a proof, then φ is said to be *provable* from Σ using $\mathcal{A}$, denoted by $\Sigma \vdash_{\mathcal{A}} \varphi$.

For (resp. finite) implication of $\mathcal{L}$, the axiom system $\mathcal{A}$ is *sound* if $\Sigma \vdash_{\mathcal{A}} \varphi$ entails $\Sigma \models_{\text{unr}} \varphi$ (resp. $\Sigma \models_{\text{fin}} \varphi$); it is *complete* if $\Sigma \models_{\text{unr}} \varphi$ (resp. $\Sigma \models_{\text{fin}} \varphi$) entails $\Sigma \vdash_{\mathcal{A}} \varphi$. If $\mathcal{A}$ is both sound and complete then it is called a *finite axiomatization* of (finite) implication of $\mathcal{L}$, which characterizes (finite) implication of $\mathcal{L}$.

The best known example of finite axiomatizations is Armstrong's axioms for functional dependencies (FDs). Recall that an FD is of the form X → Y, where X and Y are sets of attributes. Armstrong's axiom system consists of:

Reflexivity axiom: $X \rightarrow X$.

Augmentation: If $X \rightarrow Y$ then $XZ \rightarrow YZ$, where XZ denotes $X \cup Z$.

Transitivity: If $X \rightarrow Y$ and $Y \rightarrow Z$ then $X \rightarrow Z$.

Relative to a set U of attributes, an instance of the reflexivity axiom $X \rightarrow X$ is $V \rightarrow V$ when V is a subset of U. An FD φ_i follows from preceding constraints in a proof $\varphi_1,\ldots,\varphi_n$ if there exist a reference rule (either augmentation or transitivity) ρ and a substitution σ from the variables in ρ to subsets of U, such that for each FD in the antecedent of ρ, the corresponding FD obtained via σ is φ_j for some $j < i$. For example, one can easily verify that $\varphi = A \rightarrow C$ is provable from $\Sigma = \{A \rightarrow B, B \rightarrow C\}$ using Armstrong's axioms, *i.e.,* $\Sigma \vdash \varphi$.

For finite implication of $\mathcal{L}$, the existence of a finite axiomatization is a stronger property than the existence of a testing algorithm. Indeed, from the existence of a finite axiomatization for finite implication of $\mathcal{L}$ follows the decidability of the finite implication problem for $\mathcal{L}$ (because the finite implication becomes r.e., and it is co-r.e. for first-order logic). On the other hand, there are dependencies (*e.g.,* join dependencies JDs), such that for their finite implication there is no finite axiomatization, but there is a testing algorithm (via the chase [3,15]).

Finite axiomatizations have been developed for implication and finite implication of a variety of dependencies, including FDs, INDs, MVDs, FDs and MVDs taken together, and for full typed dependencies. There is also a sound and complete axiom system for implication (*not* finite implication) of typed TGDs and EGDs. On the other hand, it is known that there exist no finite sound and complete axiom systems for FDs and INDs taken together.

Complexity of Implication Analyses

A number of complexity results have been established on the implication and finite implication problems for a variety of constraint languages. As remarked earlier, for full dependencies, the implication and finite implication problems coincide and are both decidable. For the following classes of full dependencies, the implication and finite implication have the complexity bounds given below, in which n is the length of the input constraints Σ and φ:

(i) in $O(n)$-time for FDs [6];
(ii) in $O(n \log n)$-time for MVDs;
(iii) in $O(n^2)$-time for deciding whether an MVD or an FD is implied by a set of typed full dependencies;
(iv) in $O(n^2 \log^2 n)$-time for deciding whether a JD is implied by a set of FDs.

In contrast to the NEXPTIME upper bound on the Bernays-Schőnfinkel-Ramsey class given earlier, there exists an efficient decision procedure for these fragments of full dependencies. On the other hand, several intractability results have also been established:

(v) It is NP-hard to decide whether a set of MVDs implies a JD, and it is NP-complete to decide whether a JD and an FD imply a JD.
(vi) The implication problem for full dependencies is EXPTIME-complete, typed or untyped.

Beyond full dependencies, fewer positive results are known.

(vii) The implication and finite implication problems for INDs coincide and are PSPACE-complete [9].

A well-known undecidability result is the following, proved independently by Chandra, Vardi [11] and by Mitchell:

(viii) For FDs and INDs put together, the implication and finite implication problems differ, and are undecidable.

When it comes to TGDs, the analysis of implication is also beyond reach in practice:

(ix) For TGDs, the implication and finite implication problems are undecidable, even when only typed TGDs are considered.

One of the most powerful tools for testing implication is the chase [3,15]. To determine whether or not Σ implies φ, the basic idea of the chase is to represent φ as a tableau T, and repeatedly apply constraints in Σ to T. This yields a sequence of tableaux, referred to as a chasing sequence of T by Σ, and as a terminal sequence if it is finite and no constraint in Σ can be further applied to it. If a chasing sequence reaches a tableau satisfying a certain condition (depending on what type of φ is), then one can conclude that φ is implied by Σ.

When Σ is a set of full dependencies and φ is a typed dependency, it is known that chasing terminates and has the Church-Rosser property, *i.e.*, different terminal chasing sequences yield the same unique result. Based on this an EXPTIME algorithm can be developed for testing whether $\Sigma \vDash_{\text{unr}} \varphi$ and $\Sigma \vDash_{\text{fin}} \varphi$, for full dependencies.

When Σ is a set of embedded dependencies, however, the chase may not terminate. Nevertheless, a decision procedure based on the chase can be developed such that it will give a positive answer if $\Sigma \vDash_{\text{unr}} \varphi$, and will not terminate if $\Sigma \nvDash_{\text{unr}} \varphi$. See [1] for detailed discussions.

View Dependencies

An important application of logical implication and the chase is the analysis of constraint propagation from databases to their views. Let $\mathbf{R}$ be a database schema, Σ a set of constraints over $\mathbf{R}$, V a view definition on $\mathbf{R}$, and φ a constraint defined over the view. Then $\mathbf{R}$: Σ *implies* $V: \varphi$, denoted by $\mathbf{R}: \Sigma \vDash V: \varphi$, if $V(\mathbf{I})$ satisfies φ for each instance $\mathbf{I}$ of $\mathbf{R}$ that satisfies Σ. The *constraint propagation* problem (*a.k.a.* the view dependency inference problem) is to determine, given $\mathbf{R}$, Σ, V and φ, whether or not $\mathbf{R}: \Sigma \vDash V: \varphi$. The analysis of constraint propagation is useful in, among other things, data exchange, data integration and data cleaning.

For example, when $\mathbf{R}$ consists of a relation schema R with attributes (A, B, C, D), Σ consists of an FD $A, B \rightarrow C$, V is the query $\pi_{A,\ B,\ C}(\sigma_{A=1}R)$ in the relational algebra, and φ is $B \rightarrow C$, one can see that $\mathbf{R}$: $\Sigma \vDash V: \varphi$.

The constraint propagation problem has been studied for full dependencies and for views defined in the relational algebra, based on an extension of the chase technique. The following complexity bounds are known.

(i) It is undecidable when views V are defined in the relational algebra and the constraints Σ and φ are FDs.
(ii) When $\Sigma \cup \{\varphi\}$ is a set of FDs and MVDs, and views are SPCU queries (selection, projection, Cartesian product and union), the constraint propagation problem is decidable in polynomial time.
(iii) When Σ is a set of FDs and JDs, φ is a JD, and views are SPCU queries, the problem is NP-complete.
(iv) When $\Sigma \cup \{\varphi\}$ is a set of full dependencies and views are SPCU queries, the problem is EXPTIME-complete.

Constraint propagation has also been studied in the context of XML shredding, *i.e.*, for mapping XML data to relations, from XML keys to relational FDs.

Key Applications

Traditional applications of the analysis of constraint implication include schema normalization, data integrity maintenance, storage implementation, and query optimization (see [1]). The prevalent use of the Web has motivated the development of new constraint languages for specifying the semantics of semi-structured data and XML, as well as for capturing the consistency of data. Logical implication has found new applications in XML query optimization, data integration, data exchange and data cleaning.

Future Directions

Several problems remain open for implication analysis of constraints developed for specifying XML semantics and for data cleaning. For example, the exact complexity bounds on the implication problems for certain XML functional dependencies in the presence and in the absence of DTDs are not yet settled. Another topic is the development of efficient algorithms for testing implication of constraints. For a variety of constraint languages the (finite) implication problem is intractable or even undecidable, *e.g.*, for functional and inclusion dependencies taken together. It is important and practical to find effective heuristic algorithms for their implication analyses, ideally with certain performance guarantees. This issue deserves a full treatment.

Definition

Integration of genetic test results, generated in the clinical laboratory, into the electronic medical record, in a fully structured format enabling enhanced security, contextual views, clinical decision support, pharmacovigilance, disease management, outcomes and quality assessment.

Historical Background

Clinical genetics got its start in 1948 with the founding of the American Society of Human Genetics, which formalized a scientific approach to the study of human genetics [11]. Traditionally clinical genetics requires practitioners to function as data integrators. Like traditional healthcare, tests are ordered and results returned as interpretive reports delivered in paper form. Understanding the composite picture of the *phenotype* and *genotype* of the patient requires transcribing key signs, symptoms, test values and their clinical interpretation into yet another document, contributing more paper to the aggregate patient record. This process will be repeated numerous times over the course of the patient's lifetime, as new health problems are assessed.

Correcting this problem is similar to overcoming the historical barriers to the electronic health record (EHR) [8]. Data standards need to be created and adopted, testing laboratory infrastructure built to structure genetic test results, interfaces developed to send and receive these data, and EHR's and associated clinical decision support tools and knowledgebases also must be enhanced to accept genetic data and inform clinicians of implications in the context of patient care. This introduces new challenges for the underlying database technologies used in the clinical IT infrastructure.

Foundations

Every person inherits 3 billion base pairs of DNA from each of their parents. Contained in this DNA are regions representing an estimated 22,000 genes. Each of these genes can create RNA that then goes on to create one or more proteins. These proteins participate in complex pathways that perform most of the functions within the body – everything from cell division and food metabolism, to muscle contraction and light perception, just to name a few. When an individual's genomic DNA sequence was compared to the National Center for Biotechnology Information reference nucleotide sequence assembly more than 4.1 million differences were found [6]. Some of these differences, called "DNA variants" are benign in nature, resulting in no measurable phenotypic change. Others result in non-deleterious change, for example, difference in blood type, eye and hair color. While others negatively alter the way protein pathways function within an individual and thereby impact their health. DNA variants, either individually or in combination, are a significant factor, and often an outright cause, of most human disease.

The scope and complexity of this biological genomic infrastructure creates significant knowledge and data management challenges, perhaps the most significant ever encountered. A wide variety of data types such as those associated with DNA, RNA and protein sequences and identified variations have been created. Biological entities such as genes, variants/mutations and proteins will need to be annotated in a manner that provides linkage to public databases for clinical genetic and bioinformatic information, as well as clinical phenotype in the EHR.

Integrating Genetic Data into the Clinical Record

Clinicians and molecular geneticists access genetic information in different ways and for different purposes. This creates new challenges on underlying technologies for supporting new functional requirements. Some key use case scenarios include: establishing the patient context; ensuring data integrity, with patient linkage, throughout the testing process; managing laboratory workflows (often iterative in nature); integrating with instruments; supporting both manual and automated data review; managing quality control and quality assessment; supporting a reporting mechanism; providing decision support for the clinician. In order to meet this challenge a genetic testing laboratory requires: (i) a Laboratory Information Management System (LIMS), to support collection and analysis of raw data, (ii) an interpretation and reporting tool, to assist the geneticist in translating results into clinical implications and report these results in structured form, (iii) a genetic knowledgebase, utilized by the interpretation and reporting tools, to appropriately interpret and structure the results, and (iv) a electronic medical record enhanced to accept and leverage genetic data (see Fig. 1).

Data models, ontologies, and message structure also present a challenge. Properly structuring and annotating genetic data in the EHR is key to effectively displaying, integrating into clinical workflows, and using this data in context of clinical decision support. With this goal in mind, Healthcare Information Technology (HIT) standards are used to create the message between LIMS and EHR's and provide ontological linkage to phenotypic data, while clinical genetic and

bioinformatic standards are leveraged for structuring of genetic specific data.

Key Applications

Laboratory Information Management Systems for Genetic Laboratories

Raw data files from instruments used in genetic testing contain highly structured data. It is in the process of summarizing, interpreting and translating these results that the geneticist creates a narrative report, communicating these results to the clinician. Structuring genetic data in the EHR first requires LIMS to manage genetic data during the testing process, even as the data is iteratively collected.

Laboratory Information Management Systems support process flows for individual laboratories. At times it is important to support process flows that span laboratories in which case an umbrella LIMS application, an enterprise LIMS superstructure, is required. An enterprise LIMS superstructure, called the Gateway for Integrated Genomics-Proteomics Applications and Data (GIGPAD) [14], was constructed in a collaboration between Harvard Medical School – Partners HealthCare Center for Genetics and Genomics (HPCGG), Partners HealthCare Information Systems department and Hewlett Packard [5]. GIGPAD is responsible for overall process coordination. It also manages all electronic contact between laboratories and external systems and users. GIGPAD supports multiple laboratories. In some cases, the decision was made to support laboratories by purchasing vendor LIMS and integrating them under the GIGPAD umbrella. In other cases, the decision was made to add support for laboratories by constructing custom LIMS within GIGPAD.

GIGPAD leverages a J2EE architecture backed by an Oracle database. The J2EE platform in general, and EJB in particular, is a good match for this use. GIGPAD needs to support a large number of different types of processes. However, these processes often have common elements. The J2EE platform has enabled the construction of object models that facilitate reuse.

Security is a very important consideration for a LIMS or enterprise LIMS superstructure that handles confidential data. J2EE is a good platform for constructing and enforcing object based security although the platform's generic capabilities need considerable enhancement.

Knowledgebases and Reporting Systems for Genetic Laboratories

The field of clinical genetics maintains knowledgebases called Locus Specific Databases (LSDB), in which DNA variants and associated phenotypes are cataloged [1]. However, LSDB's require manual look-up and synthesis to understand the clinical meaning of a variant and do not utilize HIT standards to code phenotype. The field of bioinformatics utilizes NCBI's dbGaP database to catalog DNA variants and associated phenotype [15]; however, this database contains research data and is not appropriate for clinical care.

In an effort to fill a necessary gap, HPCGG and Partners Healthcare created GeneInsight, a knowledge database that associates genetic variations with clinical annotations using newly extended HIT standards (LOINC, SNOMED, and RxNORM). The variants entered into GeneInsight are validated to ensure that they adhere to the clinical genetics standards for naming variants, using HGVS nomenclature and are valid when compared with locally defined reference sequences. The data stored for each variant includes the DNA change, amino acid change (if applicable), classification (e.g., Pathogenic), source classification (e.g., somatic or germline), and references to other databases including PubMed and dbSNP. In addition, GeneInsight is capable of programmatically deriving the DNA and amino acid change types and flanking sequences.

In addition to variants, GeneInsight also contains records for genes and diseases or conditions. The gene records include references to other databases including NCBI's Gene and PubMed. Reference sequences for the genes are also recorded in GeneInsight and linked to the NCBI's Nucleotide database. Diseases or conditions can represent either a typical disease, such as cystic fibrosis, or a pharmacogenetic condition, such as warfarin metabolism. Medically significant variants are then linked to one or more diseases and/or conditions to establish their clinical context or phenotype.

In order to create the narrative, human readable report (for the clinician) and the machine readable, structured genetic results (for the EHR), a geneticists uses a genetics interpretation and reporting tool which leverages data in a genetic knowledgebase, to create draft reports. Within HPCGG's Laboratory for Molecular Medicine, the Genomic Variant Interpretation Engine (GVIE) is used during the process of reporting genetic test results and co-creates both the narrative report and the structured genetic data for the EHR. GVIE contains definitions of the tests that are run by the HPCGG including the coverage of the test and also defines a series of templates for each disease or condition. The templates are dynamic to allow the automatic insertion of case specific information and can be associated with rules that govern to which cases they are applied. The rules can take into account the specific test that was run, the overall result, the number of variations detected, the classification of those variations, and other information. In addition, the overall result (e.g., Positive) is generated by a separate set of rules that change very infrequently and are driven by the disease's inheritance and the identified variation classification and allele state.

Cerner Corporation has also developed a LIMS and reporting tools for sending structured genetic data into an electronic medical record. Here Cerner uses the Clinical Bioinformatics Ontology (CBO), in lieu of the larger genetic knowledgebase, to report structured genetic variants aligned with NCBI reference sequences [4]. This is a streamlined solution focusing on reporting variants identified during testing.

Integrated Clinical and Genetic Medical Record

A genetically aware clinical medical record effectively integrates highly structured genetic testing results with other laboratory and clinical data, utilizing accepted healthcare informatics standards. These standards include Health Level Seven (HL7) [3] for messaging, Logical Observations Identifiers, Names, Codes (LOINC) [7] as a coding system, and Systematized Nomenclature of Medicine-Clinical Terms (SNOMED CT) [12] and RxNORM [10] as disease and medication terminologies. By using these standards, genetics can be integrated into existing electronic health record databases, leveraging models for storage, retrieval and indexing. Most importantly, these standards aid in the mapping of a patient's genetic information with other clinical data on the patient. As clinical genomics is an emerging field, healthcare informatics standards organizations (including HL7, LOINC, and SNOMED) are in the process of extending their models to meet these needs; therefore, the most up-to-date information can be found on standards organization websites (see Recommended Reading).

Clinical Decision Support

Genomic clinical decision support (CDS) will model existing CDS based on laboratory data. Genetic tests which provide *pharmacogenomic* information will determine how an individual will respond to medication. CDS rules, leveraging this data, would take the form of drug dosage assistance, contraindications, and recommended alternative therapy. Genetic tests which provide *diagnostic* information will feed into problem lists (that can then leverage pre-existing CDS). Genetic tests which identify a patient as being at *increased risk* for disease will feed into other clinical data used to identify high-risk populations and CDS focused on disease management. The precise instantiation models for genomic CDS are based on preexisting models and remain to be thoroughly tested for identification of gaps.

Implicit Event

Jonas Mellin, Mikael Berndtsson
University of Skövde, Skövde, Sweden

Definition

In active databases, an implicit event is an event that is implied by an ECA rule definition.

Key Points

ECA rules were developed as an optimization of condition action rules. The performance of rule evaluation was improved by allowing, or even requiring, explicit definition of when rules should be triggered in the form of events. However, it turns out that it is possible to derive events from the condition in a meaningful way in some cases and, thus, there are events that can be implied by the ECA rule definition. For example, if the condition is a logical expression $A = 5 \wedge B = 3$, then a disjunction of the events representing update to the variables can trigger the rule. That is, with implicit events (**IF** $A = 5 \wedge B = 3$ **DO** action) is equivalent to (**ON**$update_A$ **or** $update_B$ **IF** $A = 5 \wedge B = 3$ **DO** action) with explicit events.

Incomplete Information

Gösta Grahne
Concordia University, Montreal, QC, Canada

Synonyms

Uncertain information; Null values; Indefinite information

Definition

Incomplete information arises in relational databases, when a fact (tuple) has to be inserted in a relation, and values for some required columns are missing. For instance, in an employee database, the phone number of one employee might be missing, as might the address of another employee. There are numerous reasons for such missing information, e.g., the insertion was done through a view, or the incomplete tuple originated from another database that does not record these fields. In information integration and data exchange systems incomplete information is rampant. Note that here the null values only represent unknown, existing values. The other main case, namely the one that the column heading is not applicable to the tuple in question, is not covered here, for a treatment, see e.g., [17].

It is easy to *store* missing or incomplete information, by simply using a symbol, say ⊥, different from the symbols of the domain of the database. As an illustration, consider the following employee database:

Employee	Department	Home Town	Phone no.
Jerry	*Sales*	*New York*	⊥
Elaine	*Accounting*	⊥	*123*
George	*Services*	*New York*	*456*

In the table above, Jerry's phone number is unknown as is Elaine's home address. The third tuple has complete information. So far the picture is quite uncomplicated. The difficulties arise when *queries* are applied to an incomplete database. For instance, suppose the query asks for all employees living in New York. Should Elaine be included in the answer, as it is not ruled out that she lives in New York? Her unknown hometown could very well be New York. It seems that Elaine *might* be in the answer.

For another example, suppose the relation is decomposed into *R*(Employee, Department, Home Town) and *S*(Home Town, Phone no.) Now, joining back *R* and *S*, at least the original relation should be recovered. However, it is not clear how to join the *R*-tuple (*Elaine, Accounting*, ⊥) with the *S*-tuple (⊥, *123*). Nevertheless, whatever Elaine's home address is, the null-value in the *R*-tuple must clearly be the same as the null-value in the *S*-tuple, as they both represent Elaine's unknown home town. Therefore, the tuple (*Elaine, Accounting*, ⊥, *123*) should *surely* be in the result of the join.

Historical Background

The enormously successful relational model emerged out of algebra and logic, starting with Codd's fundamental 1970's papers. By the end of the decade, the problem of null values was noted and resulted in some early efforts not covered here, see e.g., [17,16]. Around this time Ray Reiter also promulgated the idea of "Proof theoretical" vs. "Model Theoretical" interpretation of the relational model (see references in [12]). Roughly, one could say that in proof theory the database is a set of ground facts in First Order Logic, and the query (also a logical formula) answers are something to deduce from the theory by proof-theoretic means. In "Model Theory" on the other hand, the database is a finite structure, and the queries are algebraic operators applied to the database. Indeed, Reiter proposed a first order interpretation of the null value: Since a regular tuple $(a, b) \in r$ is interpreted as a ground fact $R(a, b)$, it is plausible to interpret $(a, x) \in r$, where x is a null value, as the logical sentence $\exists x : R(a, x)$. Reiter then developed query answering algorithms for his (existentially) extended relational theories [12].

At the same time, relational theory started developing, creating its own apparatus, containing lossless joins, tableaux and the chase, in addition to many other useful tools and concepts, such as the "crown jewel" relational algebra. Working along these lines, T. Imielinski and W. Lipski came out in 1981 with a *VLDB* conference abstract of their landmark paper *Incomplete Information in Relational Databases*, published in *J. ACM* in 1984 [8].

First, Imielinski and Lipski call a relation containing null values a *table* (as opposed to a relation). One assumes two disjoint countably infinite sets of *constants*, denoted *a, b, c, Jerry, Elaine*,...,and of *variables*, denoted *x, y, z*,.... The table in the introduction, could be written (concisely) as {(*Jerry, Sales, New York, x*),(*Elaine, Accounting, y, 123*), (*George, Services, New York, 456*)}

Second, [8] adopts the *possible worlds* interpretation of incomplete databases: an *incomplete database is a set of complete databases*, one of which is or corresponds to the real world. In other words, the knowledge about the real world, that the incomplete database has is exactly this set. In the sequel (usually infinite) incomplete databases (sets of complete databases) are denoted by $\mathcal{X}, \mathcal{Y}, \ldots$.

Tables represent incomplete databases through valuations, that instantiate the null values to ordinary, known values. Formally, a *valuation* is a mapping from the variables to the constants, that is identity on the constants. Valuations are extended to tuples and tables in the obvious homeomorphic way. Now a database r represents one of the possible worlds of table T, if there is a valuation v, such that $r = v(T)$. For instance, let $T = \{(a,x), (b, y)\}$. Pretend for a moment that domain of constants is finite and only includes a and b. Then T represents $\mathcal{X}$, where $\mathcal{X} = \{\{(a, b), (b, b)\}, \{(a, a), (b, b)\}, \{(a, b), (b, a)\}, \{(a, a), (b, a)\}\}$. Thus $Rep(T)$, the incomplete database $\mathcal{X}$, represented by a table T, is defined as

$$Rep(T) = \{r : r \supseteq v(T), \text{for some valuation } v\}. \quad (1)$$

Note that the *open world* assumption is made, when requiring only $r \supseteq v(T)$. It means that any fact not recorded in all possible databases is considered unknown. Note further that under an open world assumption, a *complete* database r actually represents all supersets of r. Since nothing is surely false, it is clear that querying under the open world assumption cannot include negation. In a *closed world* interpretation, on the other hand, any fact *not* recorded in the database, or not instantiable from a tuple in a table is considered false. For tables T, the closed world interpretation of the possible databases it represents is defined as $Rep_{\text{cwa}}(T) = \{r : r = v(T)$, for some valuation $v\}$. This means that a tuple that does not belong to any $r \in Rep_{\text{cwa}}(T)$ is considered false.

The main insight when processing a query q on an incomplete database is as follows: since the "real" database r is one within a set $\mathcal{X}$, the "real" answer should ideally be $q(r)$. However, given only $\mathcal{X}$, what can be captured with query q is the set $q(\mathcal{X}) = \{q(r) : r \in \mathcal{X}\}$. In particular, if $\mathcal{X}$ is represented by a table T, it would be desirable to find a table, denote it $\hat{q}(T)$, such that

$$Rep(\hat{q}(T)) = q(Rep(T)). \tag{2}$$

This is where the technical development can begin.

Foundations

First, note that the open world assumption itself is causing a subtle difficulty when trying to satisfy the commutativity requirement (2). Consider the table T containing a single tuple (a, b). After applying a selection $\sigma_{A=a}$ on T one would (correctly) expect that the tuple (a, b), and nothing else, is in the resulting table $\widehat{\sigma_{A=a}}(T)$. However, (2) is not satisfied, since for instance (c, d) occurs in some $r \in Rep(\widehat{\sigma_{A=a}}(T))$, whereas $(c, d) \notin r$, for all $r \in \sigma_{A=a}(Rep(T))$, as such tuples have been dropped by the selection. Unless the closed world assumption is adopted – in which case clearly $Rep_{\text{cwa}}(\widehat{\sigma_{A=a}}(T)) = \sigma_{A=a}(Rep_{\text{cwa}}(T))$ – condition (2) has to be relaxed.

The key concept for achieving this purpose is the notion of *certain answer*. Let q be a query and $\mathcal{X}$ an incomplete database. The certain answer to q on $\mathcal{X}$ consists of those tuples that are in $q(r)$, for *every* possible database $r \in \mathcal{X}$, that is, the certain answer is $\cap_{r \in \mathcal{X}} q(r) = \cap(q(\mathcal{X}))$.

Given a fixed query language, two incomplete databases are not distinguishable if they give the same certain answer to every query in the language. Formally, let $\mathcal{Q}$ be a query language (the set of all queries expressible in the language). Then incomplete databases $\mathcal{X}$ and $\mathcal{Y}$ are said to be $\mathcal{Q}$*-equivalent*, if $\cap(q(\mathcal{X})) = \cap(q(\mathcal{Y}))$, for all $q \in \mathcal{Q}$. This $\mathcal{Q}$-equivalence is denoted $\mathcal{X} \equiv_{\mathcal{Q}} \mathcal{Y}$. There is another equivalence relation on incomplete databases called *coinitiality*. Now $\mathcal{X}$ is coinitial with $\mathcal{Y}$, in symbols $\mathcal{X} \approx \mathcal{Y}$, if $\mathcal{X}$ and $\mathcal{Y}$ have the same minimal (with regard to subset) elements. Let $\mathcal{Q}_P$ be the set of all queries expressible in *positive* relational algebra (no negation, no inequalities in selection conditions), and let $\mathcal{Q}_{RA}$ be the set of *all* queries expressible in the full relational algebra. It turns out that provably $\mathcal{X} \equiv_{\mathcal{Q}_P} \mathcal{Y}$ iff $\mathcal{X} \approx \mathcal{Y}$, and $\mathcal{X} \equiv_{\mathcal{Q}_{RA}} \mathcal{Y}$ iff $\mathcal{X} = \mathcal{Y}$ [8,4].

Therefore, if the open world assumption if followed, the best approximation of (2) is to weaken it to

$$Rep(\hat{q}(T)) \equiv_{\mathcal{Q}} q(Rep(T)) \tag{3}$$

for some query language $\mathcal{Q}$. This led [8] to the notion of *representation system*. Let $\boldsymbol{T}$ be a class of tables, *Rep* the interpretation function, and $\mathcal{Q}$ a query language. Then the triple $(\boldsymbol{T}, Rep, \mathcal{Q})$ is a *representation system* if for all $T \in \boldsymbol{T}$, and all $q \in \mathcal{Q}$, there is a $\hat{q}(T) \in \boldsymbol{T}$, such that (3) is satisfied. Then the certain answer $\cap(q(Rep(T)))$ is clearly equal to $\cap(Rep(\hat{q}(T)))$. This means that the certain answer can be extracted from $\hat{q}(T)$, in some cases efficiently, as will be seen below.

The original paper [8] considers the classes consisting of Codd Tables, Naive Tables, and Conditional Tables. Other classes of tables can be found in [2,4,9,14]. Here, the attention is restricted to the original three table classes.

A *Codd table* is a table where each occurrence of a null value is represented by the same symbol (as for example in the table in the first section of this entry). Let for instance the symbol $\perp$ denote a null value. Evaluating a query q (i.e., computation of $\hat{q}(T)$ in (3)) proceeds as in regular relational algebra, with the additional evaluation rules saying that $\perp \neq \perp$, and $\perp \neq a$, for all constants a, as long as the selection conditions are atomic, i.e., of the form $\sigma_{A=a}$ or $\sigma_{A \neq a}$. This is in fact the solution proposed by Codd, and currently implemented in most commercial database management systems. However, the largest query language that Codd tables can support consists of queries expressible in relational algebra using only projection and selection, where, notably, inequalities are allowed in selections. Using any more operators from the relational algebra makes it impossible to satisfy (3), that is, for some such queries q there is no Codd table $\hat{q}(T)$ satisfying (3). The same holds under the closed world assumption. In addition to this, selections can have arbitrary Boolean combinations of atomic selection conditions, but then testing whether a tuple satisfies such a condition becomes coNP-complete. This is due to the fact that any propositional formula can be encoded as a compound selection formula. Note however, that the coNP-completeness depends on the fact that the query is part of the input (expression complexity). For data complexity, the evaluation can be carried out in time polynomial in the size of the table.

A *Naive table* is a table using *distinguishable* nulls, denoted by variables x,y,.... Query evaluation uses the rules $x \neq a$, $x \neq y$, $x = x$, for all variables x, y and constants a. Thus the tuple (*Elaine, Accounting*,$\perp$) would indeed join with the tuple ($\perp$,*123*), resulting in tuple (*Elaine, Accounting*,$\perp$,*123*). These tuples would of course be represented as (*Elaine, Accounting*,*y*), and (*y*,*123*). It turns out that if $\mathcal{Q}_P$ is chosen as query language, then $(T_N, Rep, \mathcal{Q}_P)$, where T_N is the class of all Naive tables, indeed forms a representation system. It has also been shown that Naive tables can handle recursion, i.o.w. one can add any positive datalog program as a query, and still be able to $\approx$-represent the result [4]. More generally, one can note that query evaluation, i.e., computation of $\hat{q}(T)$, proceeds by treating the null-values as constants, pairwise distinct, and distinct from all the "real" constants. Thus query evaluation in Naive tables has the same computational complexity as in the regular case. A similar result was also independently proved in [15].

Much has been written about certain answers in the database literature, but not always with complete transparency. Recall that the *certain answer* to a query q on $\mathcal{X}$, are those tuples that are in the answer to q for *every* possible database $r \in \mathcal{X}$. In other words, the certain answer to q on $\mathcal{X}$ is $\cap(q(\mathcal{X}))$. Note that $\hat{q}(T)$ is a Naive table that satisfies (3), for all positive datalog programs, or algebraic expressions in $\mathcal{Q}_P$. Conveniently, the certain answer can be obtained by retaining all variable-free tuples in $\hat{q}(T)$, as it is easily seen that $\mathcal{X} \approx \mathcal{Y}$ implies $\cap\mathcal{X} = \cap\mathcal{Y}$. The certain answer however looses some information from $\hat{q}(T)$. For a simple example, similar to the one in the introduction, let $T = \{(a, x, c)\}$ with schema (A, B, C). The certain answer to both $\pi_{A,B}(Rep(T))$ and $\pi_{B,C}(Rep(T))$ is empty. On the other hand, the certain answer to $\pi_{A,C}(\pi_{A,B}(Rep(T)) \bowtie \pi_{B,C}(Rep(T))) = \{(a, c)\}$. Here $\widehat{\pi_{A,B}}(T) = \{(a, x)\}$, $\widehat{\pi_{B,C}}(T) = \{(x, c)\}$ and $\{(a, x)\widehat{\bowtie} \{(x, c)\} = \{(a, c)\}$. Note how variables can be shared over several tables, above the x the left-hand side of the join is the same as the x on the right-hand side of the join. (On the other hand, for instance $\{(a, x)\widehat{\bowtie} \{(y, c)\} = \emptyset$.) Thus, if the query answer is to be used as a *view* for further querying, the answer should consist of all of $\hat{q}(T)$, not just the variable-free tuples. This aspect has been emphasized in [5]. Furthermore, as Lipski has shown in an all but forgotten paper [11], if query evaluation is to be *uniformly recursive* (such as the one for Naive tables), all tuples in $\hat{q}(T)$ need to be stored in the view.

Conditional tables. Naive tables form a representation system for the positive fragment of relational algebra (and for positive recursion). However, allowing set difference or inequalities in selection conditions in the queries might produce results not expressible as Naive tables. Consider for instance $\sigma_{A \neq a}(Rep(T))$, where $T = \{(a, b),(c, d),(x, e)\}$. A moments reflection will reveal the fact that $\sigma_{A \neq a}(Rep(T)) = \{\{(c, d)\},\{(c, d),(b, e)\},\{(c, d),(d, e)\},\ldots\}$. It is easy to see that there is no Naive table that can represent this set. The problem is that the minimal elements in this set either has one tuple (when $x = a$), or two tuples (when $x \neq a$). The minimal elements in $Rep(T)$, for any (non-redundant) Naive table T, each have the same number of tuples. This problem can be overcome by using a stronger class of tables, albeit on the expense of tractability of query evaluation. This stronger class is called Conditional tables, here denoted T_C. A Conditional table is like a Naive Table, with the addition that each tuple has an associated condition, formed by a Boolean combination of atoms of the form $x = y$, $x \neq y$, $x = a$,$x \neq a$, $a = b$, $a \neq b$, for constants a,b and variables x, y. Note that for two distinct constants a and b, condition $a = b$ is tautologically false, and condition $a \neq b$ is tautologically true. In our previous example, $\sigma_{A \neq a}(Rep(T))$ can be represented by the Conditional table $U = \{(c, d);c \neq a,(x, e);x \neq a)\}$. The incomplete database represented by a conditional table T is defined as

$$\begin{aligned} Rep(T) = \{r \supseteq v(T) : v \text{ is a valuation}, v(T) = \\ \{v(t) : t \in T \text{ and } v \text{ makes the condition} \\ \text{in } t \textit{ true}\}\} \end{aligned} \tag{4}$$

For example, if v is the valuation $x \mapsto a$, and v' the valuation $x \mapsto b$, then, for U as above, $v(U) = \{(c, d)\}$ as the condition of the second tuple (x, d); $x \neq a$ becomes false. On the other hand, $v'(U) = \{(c, d),(b, e)\}$, since $v'(x \neq a)$ becomes $b \neq a$, which is true. Set difference is treated in a similar manner, for instance, subtracting $\{(c, b),(e, b)\}$ from $\{(x, b)\}$ results in the conditional table $\{(x, b);x \neq c \wedge x \neq e\}$. All in all, it holds that $(T_C, Rep, \mathcal{Q}_{P\neq})$, is a representation system. Here $\mathcal{Q}_{P\neq}$ denotes the query language obtained from $\mathcal{Q}_P$, by allowing inequalities in selection conditions. If set difference is to be incorporated, the closed world assumption has to be adopted. In this case it holds that $(T_C, Rep_{cwa}, \mathcal{Q}_{RA})$, is a representation system, actually satisfying the stronger condition (2). Positive datalog recursion can also be added both under the open and the closed world assumption.

For the computational complexity of query evaluation, recall that query evaluation in the system $(T_N, Rep, \mathcal{Q}_P)$ is polynomial in the number of tuples in T. Conditional tables are more complex. For all $q \in \mathcal{Q}_{RA}$ and conditional tables T, the conditional table $\hat{q}(T)$ can be computed in polynomial time. However, the conditions in table $\hat{q}(T)$ can have a convoluted structure. Thus testing whether a tuple t is in the certain answer, i.e., if $t \in \cap(Rep(\hat{q}(T)))$ is a coNP-complete problem. This result holds even if T is a Codd table, in which case a query $q \in \mathcal{Q}_{RA}$ is needed to get the lower bound (here the fact that $\hat{q}(T)$ is not a Codd table is ignored). On the other hand, for an arbitrary table $T \in T_C$, the query can be identity. In other words, the set $\cap\ (Rep(T))$ has a coNP-complete membership test. These, and further complexity results can be found in [2].

The theory of representation systems has also been extended to incorporate dependencies, see [8,4]. Let $\mathcal{X}$ be an incomplete database, and Σ a set of equality and weakly acyclic tuple generating dependencies. Denote by $\Sigma(\mathcal{X})$ the set of all minimal relations s, such that $s \supseteq r$, for some $r \in \mathcal{X}$, and s satisfies all dependencies in Σ. It has been shown that for all Naive tables T, there is a Naive table $\Sigma(T)$, such that $Rep(\Sigma(T)) \approx \Sigma(Rep(T))$. If conditional tables are used, the coinitiality can be replaced by equality.

The relationship between tables and constraint databases is explored in [13]. The relationship between tables and probabilistic databases, and between tables and data provenance is elegantly captured in the semiring framework of [7].

Key Applications

Three important applications of incomplete information will be discussed here. The first one is the problem of *view updates*. In this scenario, a view is defined by a query q, but the view is virtual, and only the database is materialized. As queries almost never are one-to-one functions, when a tuple t is inserted through a virtual view $q(r)$, it has to be translated to an insertion of a tuple, say $\hat{t}$, into r, s.t. $q(r \cup \{\hat{t}\}) = q(r) \cup \{t\}$. There is also a further requirement, that essentially guarantees the "minimality" of the change caused be the insertion of $\hat{t}$. Since there in general are several, sometimes infinitely many, insertions $\hat{t}$ that qualify, there actually is a set of possible databases $\{r \cup \{\hat{t}\} : \hat{t}\ qualifies\}$. For example, for $q = R \bowtie S$, where $R(A, B)$ and $S(B, C)$, the deletion of a tuple (a, b, c) from a view $q(r, s)$, can be accomplished by either deleting the tuple (a, b) from r, or deleting the tuple (b, c) from s. This can easily be achieved if the database is stored as a conditional table, by simply replacing the tuples (a, b) in r, and (b, c) in s, with the conditional tuples (a, b); $x = 1$, and (b, c); $x \neq 1$, where x is an arbitrary fresh variable.

The views in the view update scenario are virtual. If views are materialized, they can be used to speed up query processing. The case where all views are materialized, and the database virtual is the classic information integration scenario. The views represent data sources, and the database schema represents the integrated schema that queries are formulated over. Intuitively, one can imagine that the integrated database exists, the view-defining queries are executed, and the views are accordingly populated. After this, the integrated database disappears. It is easy to see that a set of materialized views represent a set of possible databases, each satisfying the requirement that the current content of the views can be derived from it. Note that there is an open world assumption, as the requirement is that the view tuples are a subset (not necessarily proper) of $q(r)$, for all view definitions q and possible databases r. The closed world assumption would require equality, not just subset. For query answers, the certain answer is usually desired. The certain answer means in this context the set of tuples that are in the query result, for every possible database. To answer queries over the integrated schema, one can either rewrite the query in terms of the view-schemas, or reconstruct a representation of all the possible databases, and evaluate the original query on this representation. It perhaps speaks for the robustness of the concept of conditional tables, that they can do the job of representing the set of possible databases, whenever the views are queries in $\mathcal{Q}_{P\neq}$, or in $\mathcal{Q}_{RA}$ if the closed world assumption is adopted [1,6].

The last application is that of *data exchange*. The setting is a peer-to-peer system, where each peer has a relational database and wants to exchange tuples with other peers. The schemas of any two peers, say p_1 and p_2 are usually different from each other, so the data has to be converted when exchanged. This is achieved by defining a mapping from p_1 to p_2. This mapping could for instance be expressed as an equation $q_1(p_1) \subseteq q_2(p_2)$. When we export data from p_1 to p_2, we evaluate q_1 on p_1, and make sure that the resulting tuples are in $q_2(p_2)$. Since the tuples have to be inserted into p_2, it is easy to see that this is similar to the familiar problem of view updates, and thereby also incomplete information. For a very simple example, suppose the schema of p_1 is $R(A, B)$, and the schema of p_2 is $S(A, C)$. Consider then the equation $\pi_A(R) \subseteq \pi_A(S)$. If r contains a tuple (a, b), it is clear, that in order to satisfy the equation, a tuple (a, x) has to be in s. It has for example been shown [10], that if $q_1 \in \mathcal{Q}_P$ and q_2 only uses projection, then given null-free instances of p_1 and p_2, there is a naive table $p_2{}'$, containing p_2, representing all minimal solutions to the equation, that is $q_1(p_1) \subseteq q_2(r)$, for all $r \in Rep(p'{}_2)$, and the equation is not satisfied by any proper subsets of these r's.

Future Directions

It is clear that new applications, new data models, and new query languages will encounter the problem of incomplete information. In order to not "re-invent the wheel," any solution should build on the foundation laid in [8]. A step in this direction has for instance been taken in [3].

Inconsistent Databases

LEOPOLDO BERTOSSI
Carleton University, Ottawa, ON, Canada

Definition

An inconsistent database is a database instance that does not satisfy those integrity constraints that have been declared together with the schema of the database.

Historical Background

Already in the classical and seminal paper by E. F. Codd [5] on the relational data model it is possible to find the notions of integrity constraint and consistency of a database. The idea of *consistent query answering*, consisting in characterizing and computing semantically correct answers to queries in inconsistent databases, was explicitly introduced in [1].

Foundations

A database can be seen as a model, i.e., as a simplified, abstract description, of an external reality. In the case of relational databases, one starts by choosing certain predicates of a prescribed arity. The *schema* of the database consists of this set of predicates, possibly *attributes*, which can be seen as names for the arguments of the predicates, together with an indication of the domains where the attributes can take their values. Having chosen the schema, the representation of the external reality is given in terms of relations, which are extensions for the predicates in the schema. This set of relations is called an *instance* of the schema.

For example, relational database for representing information about students of a university might be based on the schema consisting of the predicates *Students(StNum, StName)* and *Enrollment(StName,Course)*. The attribute *StNum* is expected to take numerical values; *StName*, character string values; and *Course*, alphanumeric string values. In Fig. 1 there is a possible instance for this schema.

In order to make the database a more accurate model of the university domain (or to be in a more accurate correspondence with it), certain conditions are imposed on the possible instances of the database. Those conditions are intended to capture more meaning from the outside application domain. In consequence, these conditions are called *semantic constraints* or *integrity constraints* (ICs). For example, a condition could be that, in every instance, the student name functionally depends upon the student number, i.e., a student number is assigned to at most one student name. This condition, called a *functional dependency* (FD), is denoted with $StuNumber \rightarrow StuName$, or $Students : StuNumber \rightarrow StuName$, to indicate that this dependency should hold for attributes of relation *Students*. Actually, in this case, since all the attributes in the relation functionally depend on *StuNum*, the FD is called a *key constraint.*

Integrity constraints can be declared together with the schema, indicating that the instances for the schema should all satisfy the integrity constraints. For example, if the functional dependency $Students : StuNumber \rightarrow StuName$ is added to the schema, the instance in Fig. 1 is consistent, because it satisfies the FD. However, the instance in Fig. 2 is *inconsistent.* This is because this instance does not satisfy, or, what is the same, violates the functional dependency (the student number *101* is assigned to two different student names.

Functional dependencies are particular cases of integrity constraints. It is also possible to consider with the schema a *referential integrity constraint* that requires that every student (number) in the relation *Enrollment* appears, associated with a student name, in relation *Students*, the official "table" of students. This is denoted with $Enrollement[StNum] \subseteq Students[StNum]$. If this IC is considered in the schema, the instance in Fig. 1 is inconsistent, because student *105* does not appear in relation *Students.* However, if only the referential constraint were in the schema, the instance in Fig. 2 would be consistent.

In can be seen that the notion of consistency is relative to a set of integrity constraints. When a database is said to be inconsistent, it is meant that the particular instance of the database at hand is inconsistent.

The two particular kinds of integrity constraints presented above and also other forms of ICs can be easily expressed in the language of predicate logic. For example, the FD above can be expressed by the symbolic sentence

$$\forall x \forall y \forall z((Students(x,y) \wedge Students(x,z)) \rightarrow y = z), \qquad (1)$$

whereas the referential constraint above can be expressed by

$$\forall x \forall y (Enrollment(x,y) \rightarrow \exists z Students(x,z)). \quad (2)$$

Notice that this language of predicate logic is determined by the database schema, whose predicates are now being used to write down logical formulas. We may also use "built-in" predicates, like the equality predicate. Thus, ICs can be seen as forming a set Σ of sentences written in a language of predicate logic.

A database instance can be seen as an *interpretation structure D* for the language of predicate logic that is used to express ICs. This is because an instance has an underlying domain and (finite) extensions for the predicates in the schema. Having the database instance as an interpretation structure and the set of ICs as a set of symbolic sentences is crucial, and makes it possible to simply apply the notion of satisfaction of a formula by a structure of first-order predicate logic [6]. In this way, the notion of satisfaction of an integrity constraint by a database instance is a precisely defined notion. The database instance D is consistent if and only if it satisfies Σ, which is commonly denoted with $D \models \Sigma$.

Since it is usually assumed that the set of ICs is consistent as a set of logical sentences, in databases the notion of consistency becomes a condition on the database instance. Thus, this use of the term "consistency" differs from its use in logic, where consistency characterizes a set of formulas.

Inconsistency is an undesirable property for a database. In consequence, one attempts to keep it consistent as it is subject to updates. There are a few ways to achieve this goal. One of them consists in declaring the ICs together with the schema, and the database management system (DBMS) will take care of the database maintenance, i.e., of keeping it consistent. This is done by rejecting transactions that may lead to a violation of the ICs. For example, the DBMS should reject the insertion of the tuple (*101*, *sue jones*) into the instance in Fig. 1 if the FD (1) was declared with the schema (as a key constraint). Unfortunately, commercial DBMSs offer limited support for this kind of database maintenance.

An alternative way of keeping consistency is based on the use of triggers (or active rules) that are stored in the database. The reaction to a potential violation is programmed as the action of the trigger: if a violation is about to be produced or is produced, the trigger automatically reacts, and its action may reject the violating transaction or compensate it with additional updates, to make sure that at the end, consistency is reestablished. Consistency can also be enforced through the application programs that interact with the DBMS. However, the correctness of triggers or application programs with respect to (with regard to) ensuring database consistency is not guaranteed by the DBMS.

It is the case that, for whatever reasons, databases may become inconsistent, i.e., they may violate certain ICs that are considered to be relevant to maintain for a certain application domain. This can be due to several reasons, e.g., poorly designed or implemented applications that fail to maintain the consistency of the database, or ICs for which a DBMS does not offer any kind of support, or ICs that are not enforced for better performance of application programs or DBMSs, or ICs that are just assumed to be satisfied based on knowledge about the application domain and the kind of updates on the database. It is also possible to have a legacy database on which semantic constraints have to be imposed; or more generally, a database on which imposing new constrains depending on specific needs, e.g., user constraints, becomes necessary.

In the area of data integration the satisfaction of desirable ICs by a database is much more difficult to achieve. One can have different autonomous databases that are separately consistent with regard to their own, local ICs. However, when their data is integrated into a single database, either material or virtual, certain desirable global ICs may not be satisfied. For example, two university databases may use the same numbers for students. If their data is put together into an integrated database, a student number might be assigned to two different students.

When trying to use an inconsistent database, the application of some *data cleaning* techniques may be attempted, to cleanse the database from data that participates in the violation of the ICs. This is done sometimes. However, data cleaning is a complex and non-deterministic process; and it may also lead to the loss of information that might be useful. Furthermore, in certain cases like virtual data integration, where the data stays at the autonomous data sources, there is no way to change the data without ownership of the sources.

One might try to live with inconsistent databases. Actually, most likely one will be forced to keep using it, because there is still useful information in it. It is also likely that most of the information in it is

Inconsistent Databases. Figure 3. Two repairs.

somehow consistent. Thus, the challenge consists in retrieving from the database only information that is consistent. For example, one could pose queries to the database at hand, but expecting to obtain only answers that are semantically correct, i.e., that are consistent with the ICs. This is the problem of *consistent query answering* (CQA).

The notion of consistency of a database is a holistic notion, that applies to the entire database, and not to portions of it. In consequence, in order to pursue this idea of retrieving consistent query answers, it becomes necessary to characterize the consistent data in an inconsistent database first. The idea that was proposed in [1] is as follows: the consistent data in an inconsistent data is the one that is invariant under all possible way of restoring the consistency by performing minimal changes on the initial database. That is, no matter what minimal consistency restoration process is applied to the database, the consistent data stays in the database. Each of the consistent versions of the original instance obtained by minimal changes is called a *minimal repair*, or simply, a *repair*.

It becomes necessary to be more precise about the meaning of minimal change. In between, a few notions have been proposed and studied (cf. [2–4] for surveys of CQA). Which notion to use may depend on the application. The notion of minimal change can be illustrated using the definition of repair given in [1]. First of all, a database instance D can be seen as a finite set of ground atoms (or database tuples) of the form $P(\bar{c})$, where P is a predicate in the schema, and $\bar{c}$ is a finite sequence of constants in the database domain. For example, *Students(101, john bell)* is an atom in the database. Next, it is possible to compare the original database instance D with any other database instance D' (of the same schema) through their symmetric difference $D\Delta D' = \{A \mid A \in (D \setminus D') \cup (D' \setminus D)\}$.

Now, a repair of an instance D with regard to a set of ICs Σ is defined as an instance D' that is consistent, i.e., $D' \models \Sigma$, and for which there is no other consistent instance D'' that is closer to D than D', i.e., for which it holds $D\Delta D'' \underset{\neq}{\subseteq} D\Delta D'$. For example, the database in Fig. 2 has two repairs with regard to the FD (1). They are shown in Fig. 3 and are obtained each by deleting one of the two conflicting tuples in relation *Students* (relation *Enrollment* does not change).

Having defined the notion of repair, a *consistent answer* from an instance D to a query $Q(\bar{x})$ with regard to a set Σ of ICs is defined as an answer $\bar{c}$ to Q that is obtained from every possible repair of D with regard to Σ. That is, if the query Q is posed to each of the repairs, $\bar{c}$ will be returned as a usual answer to Q from each of them.

For example, if the query $Q_1(x, y) : Students(x, y)$, asking for the tuples in relation *Students*, is posed to the instance in Fig. 2, then *(104, claire stevens)* and *(107, pat norton)* should be the only consistent answers wrt the FD (1). Those are the tuples that are shared by the extensions of *Students* in the two repairs. Now, for the query $Q_2(x) : \exists y Students(x, y)$, i.e., the projection on the first attribute of relation *Students*, the consistent answers are *(101)*, *(104)* and *(107)*.

There might be a large number of repairs for an inconsistent database. In consequence, it is desirable to come up with computational methodologies to retrieve consistent answers that use only the original database, in spite of its inconsistency. Such a methodology that works for particular syntactic classes of queries and ICs, was proposed in [1]. The idea is to take the original query Q that expects consistent answers, and syntactically transform it into a new query Q', such that the *rewritten query* Q', when posed to the original database, obtains as usual answers the consistent answers to query Q. The essential question is, depending on the language in which Q is expressed, what kind of language is necessary for expressing the rewriting Q'. The answer to this question should also depend on the kind of ICs being considered.

The idea behind the rewriting approach presented in [1] can be illustrated by means of an example. The consistent answers to the query $Q_1(x, y) : Students(x, y)$ above with regard to the FD (1) can be obtained by posing the query $Q'(x, y) : Students(x, y) \wedge \neg\exists z (Students(x, z) \wedge z \neq y)$ to the database. The new query collects as normal answers those tuples where the value of the first attribute is not associated to two different values of the second attribute in the relation. It can be seen that the answer set for the new query can be computed in polynomial time in the size of the database.

In this example, a query expressed in first-order predicate logic was rewritten into a new query expressed in the same language. It has been established in the literature that, for complexity-theoretic reasons, a more expressive language to do the rewriting of a first-order query may be necessary. For example, it may be necessary to do the rewritings as queries written in expressive extensions of Datalog [2–4].

If a database is inconsistent wrt referential ICs, like the instance in Fig. 1 and the constraint in (2), it is natural to restore consistency by deleting tuples or inserting tuples containing *null values* for the existentially quantified variables in the ICs. For example, the tuple (*105*, *comp120*) could be deleted from *Enrollment* or the tuple (*105*, *null*) could be inserted in relation *Students*. This requires a modification of the notion of repair and a precise semantics for satisfaction of ICs in the presence of null values [2,4].

Key Applications

Key applications of *consistent query answering* (CQA) are still missing. Applications to virtual data integration look promising, and also applications to data cleaning.

Future Directions

There are many open problems and research directions, among them, and most prominently, the development of key applications of CQA. A more precise characterization of the languages that are needed for doing CQA using query rewriting is also missing. It also becomes necessary to shed more light on the right kind of repair semantics to use depending on the application. CQA in a dynamic setting, when the databases is subject to updates, has not been investigated much. Integrity constraints and consistency issues for the relational model of data have been investigated for many years. However, there are other data models, e.g., spatial databases, for which much research of this kind is still necessary.

Incremental view maintenance

Definition

A view on a database is defined by a query over the database. When the database is updated, the value of the view (namely the answer to the query) will likely change. The computation of the new answer to the query using the old answer is called *incremental query computation* or *incremental view maintenance*. Incremental computation is typically performed by identifying the part in the old answer that need to be removed, and the part in the new answer that need to be added. Incremental computation is desirable when it is much more efficient than a re-computation of the query. Efficiency can be measured by computation time, storage space, or query language desirability/availability, etc. Incremental computation algorithms could use auxiliary relations (in addition to the query answer), which also need to be incrementally computed.

Two query languages can be involved for the incremental query computation problem. One is used for defining the view to be maintained, and the other for describing the incremental computation algorithm. For relational databases, the two languages can be relational algebra, SQL, nested relational algebra, Datalog, SQL embedded in a host programming language, etc.

Historical Background

Reference [14] was an early paper on incremental query computation of relational algebra queries. Reference [8] improved the query rewriting algorithm of [14] to ensure minimality of the changes to a query result in response to updates to base relations. Other articles in the literature (see [9]) considered the incremental computation of queries involving SQL aggregation, duplicates, etc.

Reference [7] was an early paper on incremental query computation of recursive (Datalog, including transitive closure) queries using relational calculus (or equivalently relational algebra) queries. Reference [3] provided relational-calculus queries for maintaining the transitive closure of acyclic graph (binary relation) after an edge insertion or deletion. Reference [6] discussed how to incrementally compute Datalog queries after tuple insertion. References [4,13] provided relation-calculus queries for maintaining the transitive closure of undirected graph after edge insertion or deletion. Reference [1] rewrote the maintenance queries in SQL. Reference [12] provided relational-calculus queries for maintaining the shortest paths in undirected graphs after edge insertion/deletion. Reference [11] studied the power of incremental query computation using SQL as maintenance queries. A number of theoretical results on the power of the arity of the auxiliary relations have been reported. Reference [5] gave a survey of results on the incremental computation of recursive queries up to the year 2000.

Reference [9] contains a collection of papers on incremental query computation/view maintenance.

Foundations

For brevity and concreteness, the discussion below will be restricted to relational databases, although incremental query computation also applies to other kind of databases. Moreover, the discussion is divided into two parts, one part for the incremental computation of relational-algebra queries, and the other part for the recursive queries (including Datalog and transitive closure). Algorithms for incrementally computing other kinds of queries are not covered in this entry.

Incremental query computation is not merely a means to avoid expensive re-computation. Sometimes, incremental computation is a way to do things that could not be done otherwise. For example, the transitive closure query cannot be directly expressed in relational algebra but it can be expressed in relational algebra in the incremental setting.

Some notations are now defined. Let $R_1,...,R_m$ be the base relations of a relational database D. An update to the database consists of $2m$ sets of tuples: for each relation R_i it contains two disjoint sets, R_i^+ and R_i^-, of tuples, where R_i^+ is the set of tuples to be added to R_i and R_i^- is the set of tuples to be deleted from R_i. Let D^{old} denote the old database and R_i^{old} denote the old instance of R_i before the update, and D^{new} denote the new database and R_i^{new} denote the new instance of R_i after the update. It is assumed that the update is minimal in the sense that $R_i^+ \cap R^{\text{old}} = \emptyset$ and that $R_i^- \subseteq R^{\text{old}}$.

The same notation will be used to denote the "update to the query." Let Q be a query. Then Q^- is used to denote the set of tuples to be deleted from the old answer, and Q^+ is used to denote the set of tuples to be added to the old answer, in order to get the new answer; in formula: $Q(D^{\text{new}}) = (Q(D^{\text{old}}) - Q^-) \cup Q^+$.

Incremental Computation of Relational-Algebra Queries

The relational algebra queries are expressions built from relation names using the following operations: selection (σ_p), projection (Π_A), Cartesian product ($\times$), union ($\cup$), intersection ($\cap$), difference ($-$), and join ($\bowtie$). Here p is a predicate or condition, and A is a set of attributes. A relational-algebra query over the database is a relational algebra expression.

The 16 rules [8] in Table 1 can be used to generate the queries for computing Q^+ and Q^-. These rules also ensure that the "update to the query" is minimal in the sense that $Q^+ \cap Q^{\text{old}} = \emptyset$ and $Q^- \subseteq Q^{\text{old}}$.

Observe that one also needs to store the answer to all intermediate queries in order to use the rules; these are auxiliary relations that also need to be maintained.

Incremental Computation of Recursive Queries

The framework used in the incremental computation of recursive queries is quite similar to the one for relational algebra queries as discussed above. However, there are two notable differences. One is that the

Incremental Computation of Queries. Table 1. Rules for incremental computation of relational algebra queries

Query Q	Rewriting Rule for Getting Q^-	Query Q	Rewriting Rule for Getting Q^+
R_i	R_i^-	R_i	R_i^+
$\sigma_p(S)$	$\sigma_p(S^-)$	$\sigma_p(S)$	$\sigma_p(S^+)$
$\Pi_A(S)$	$\Pi_A(S^-) - \Pi_A(S^{new})$	$\Pi_A(S)$	$\Pi_A(S^+) - \Pi_A(S^{old})$
$S \times T$	$(S^- \times T^{old}) \cup (S^{old} \times T^-)$	$S \times T$	$(S^+ \times T^{new}) \cup (S^{new} \times T^+)$
$S \cup T$	$(S^- - T^{new}) \cup (T^- - S^{new})$	$S \cup T$	$(S^+ - T^{old}) \cup (T^+ - S^{old})$
$S \cap T$	$(S^- \cap T^{old}) \cup (S^{old} \cap T^-)$	$S \cap T$	$(S^+ \cap T^{new}) \cup (S^{new} \cap T^+)$
$S - T$	$(S^- - T^{old}) \cup (S^{old} \cap T^+)$	$S - T$	$(S^+ - T^{new}) \cup ((S^{old} - S^-) \cap T^-)$
$S \bowtie T$	$(S^- \bowtie T^{old}) \cup (S^{old} \bowtie T^-)$	$S \bowtie T$	$(S^+ \bowtie T^{new}) \cup (S^{new} \bowtie T^+)$

query definition and the incremental computation may use different query languages, and the other is that the incremental computation may use auxiliary relations that are not explicitly involved in the original query.

Maintenance algorithms can be specified in different (maintenance) languages such as relational calculus, SQL, nested relational algebra, Datalog, or even a host programming language. The choice of a maintenance language can be influenced by the practical constraints imposed by real systems, and it can also be influenced by efficiency issues, as some languages are more efficient or more optimizing than others. For example, it is desirable to maintain the transitive closure query using relational algebra (or equivalently, first-order logic) queries, since the latter are available in all relational database systems and they are more efficient to evaluate. Another desirable language for maintaining recursive queries is SQL.

With the help of auxiliary relations, one can maintain queries that cannot be maintained otherwise. Moreover, the arity of the auxiliary relations bounds the amount of information to be kept and makes a difference on what can be maintained.

Sometimes the incremental computation algorithms can deal with certain special types of updates. Example types of updates include single-tuple insertions, single-tuple deletions, insertions/deletions of sets satisfying certain conditions, or combinations of these.

The following describes the relational algebra (or first-order logic) queries for maintaining the transitive closure of acyclic graphs [2,3]. The incremental queries can handle both tuple insertions and tuple deletions, and they do not use auxiliary relations.

Let G represent the input graph (directed) and TC the transitive closure of G. So a tuple (x,y) is in the relation G if and only if there is a directed edge from the node x to the node y in the input graph, and a tuple (x,y) is in the relation TC if and only if there is a directed path from the node x to the node y in the input graph. An edge insertion is allowed only if this insertion does not lead to cycles in the new graph.

Suppose an edge (a,b) is inserted. Then TC is maintained as follows. Essentially, the new transitive closure is obtained by adding to the old transitive closure the following: (i) all new paths constructed by adding the new edge (a,b) to the back of existing paths ending at a, (ii) all new paths constructed by adding the new edge (a,b) to the front of existing paths starting at b, (iii) all new paths constructed by inserting the new edge (a,b) between an existing path ending at a and an existing path starting at b, and (iv) the new edge itself. New paths added by rules (1), (2), and (3) correspond to paths of type $x \longrightarrow a$, $b \longrightarrow y$, and $x \longrightarrow y$, respectively. These rules cover all new paths because only one occurrence of the new edge is necessary in every new path.

Suppose an existing edge (a,b) is deleted. TC can be maintained as follows. Let $S_{ab} = \{\ (x,y) | TC^{old}(x,a) \wedge TC^{old}(b,y)\}$ be the set of all paths (x,y) in the old TC which go through (a,b). The letter S is for *suspicious* – it is doubtful whether these paths should belong to the new TC. Let $G^{new} = G^{old} - \{\ (a,b)\}$ and $T_{ab} = (TC^{old} - S_{ab}) \cup G^{new}$. Each pair in T_{ab} is definitely in the new TC. (The letter T is for *trusty.*) Surprisingly, the new TC can be completely reconstructed from T_{ab} using several joins and projections given by the following formula:

$$T_{ab} \cup (T_{ab} \circ T_{ab}) \cup (T_{ab} \circ T_{ab} \circ T_{ab})$$

where $R_1 \circ R_2$ is defined as $\{(x,y) | \exists u (R_1(x,u) \wedge R_2(u,y)\}$ and R_1 and R_2 are binary relations.

So the new transitive closure contains (i) all *trusty* paths, (ii) all paths constructed by concatenating two consecutive *trusty* paths, and (iii) all paths constructed by concatenating three consecutive *trusty* paths.

To maintain the transitive closure of undirected graphs in relational calculus after edge deletion, one also needs to maintain some auxiliary queries. The auxiliary relations include a total order on the nodes of the graph, a spanning forest of the graph, and a ternary relation indicating whether a node is on a path between two other nodes in the spanning forest. The details can be found in [4,5], which also discuss other queries.

While the maintenance queries for the transitive closure of undirected graphs and acyclic graphs do not need to use arithmetic operations, the maintenance queries for shortest paths [12] need to use both + and < on numbers.

Key Applications

Incremental query computation is useful for (i) maintaining materialized views, (ii) efficient checking and monitoring of integrity constraints, and (iii) the efficient management of triggers in active databases. Incremental query computation is also related to dynamic descriptive complexity theory [10]. Incremental computation of transitive closure has also been used in formal verification.

Future Directions

It is still open whether the transitive closure of arbitrary directed graphs can be maintained using relational calculus queries after edge deletions.

Incremental Crawling

Kevin S. McCurley
Google Research, Mountain View, CA, USA

Synonyms

Spidering; Crawler

Definition

Part of the success of the World Wide Web arises from its lack of central control, because it allows every owner of a computer to contribute to a universally shared information space. The size and lack of central control presents a challenge for any global calculations that operate on the web as a distributed database. The scalability issue is typically handled by creating a central repository of web pages that is optimized for large-scale calculations. The process of creating this repository consists of maintaining a data structure of URLs to fetch, from which URLs are selected, the content is fetched, and the repository is updated. This process is called *crawling* or *spidering*.

Unfortunately, maintaining a consistent shadow repository is complicated by the dynamic and uncoordinated nature of the web. URLs are constantly being created or destroyed, and contents of URLs may change without notice. As a result, there will always be URLs for which the content is not present in the repository, as well as URLs whose content is different from the copy in the repository. Many new URLs can only be discovered by recrawling old URLs whose content has now changed to include links to new URLs. In order to minimize the impact of these inconsistencies, URLs should periodically be prioritized and revisited. The process of prioritizing and revisiting URLs is usually referred to as *incremental crawling*. The primary issues in incremental crawling center around defining metrics for performance, both for the quality of the repository and the resources required to build and maintain the repository.

Historical Background

In the early days of the world wide web, it quickly became apparent that documents could be treated as living objects that could be changed at will. Thus the notion of a URL was born as a "resource locator" rather than a document ID. Early attempts to build search engines largely ignored this problem, assuming that if a document was worth retrieving later, then it would remain relatively stable at its URL. Thus early attempts to crawl and index the web simply started with a set of seed URLs, and iteratively crawled pages and extracted new URLs to be crawled. After a period of time, this repository would be used as a "snapshot" of the web to build a keyword index. If a reasonable seed set is used and URLs are appropriately prioritized, the resulting snapshot was useful for constructing a search engine or performing aggregate analysis.

The snapshot approach works well for web pages that are created and remain unchanged, but web usage has evolved quite a bit since the early days. Web authors learned that fresh content would bring repeat readers, and readers have increasingly migrated toward entertainment and news, for which freshness is increasingly important. Thus in some sense the more dynamic parts of the web are those that have the highest readership and therefore the greatest social impact. As a result, incremental crawling strategy has become increasingly important.

Foundations

In order to address the issues surrounding incremental crawling, it is important to first define the goals of the shadow repository. The primary application that has been implemented thus far have been search engines that allows users to find pages that match simply expressed information needs. A prerequisite for success of a search engine is that it reference the best content that is of interest to a majority of users at any given time. For this, the repository should be as complete as possible and as fresh as possible, since pointing users at pages that don't fulfill their information need will result in a bad user experience.

Another application that can use a shadow repository is the discovery of plagarism or copyright-protected content on the web. A third application might seek to track historical evolution of the web, for historical studies. In this case the repository should not only contain the most recent content for a URL, but all versions as they evolve over time. It is easy to see that performance metrics for these applications will vary somewhat. Moreover, these applications will differ in the the degree of cooperation that can be expected from contributors to the web.

Metrics for Incremental Crawling

There is no uniformly accepted notion of how to measure the inconsistency between the repository and the actual web. Moreover, even if there was universal agreement on the proper metric for consistency, it may be difficult to measure, and any such measure would be time-dependent since the web is constantly changing. Three possible metrics that are most obvious are:

Coverage: count the number of pages that exist on the web but are not present in the respository at any given time.
Freshness: count the number of documents that are present in the repository, but whose content was changed after insertion into the repository. Alternatively, the metric may incorporate a measure of the size of the change for individual pages.
Age: the average age of documents in the repository (e.g., time since they were last updated).

For any particular application, these metrics may all be adjusted to incorporate weights of individual pages to reflect their relative importance for the application. Thus for a search engine, documents that are dominated by thousands of other documents for every possible query should probably should be weighted lower than documents that are often found by users of the search engine. The quality of an incremental crawling strategy must also be evaluated on the basis of resources that it consumes in order to maintain a given level of metric.

Incentives and Cooperation

It should be noted that a crawler consumes resources both of the party maintaining the repository as well as the creators of content on the web. If a crawler becomes too aggressive in tracking the changes to URLs, it could quickly overwhelm small sites and degrade the value of the web site to the users of the web. At the same time, it is relatively simple to create a web site that issues dynamic content in response to any request by a crawler, essentially creating an excess of URLs that could theoretically be fetched, archived, and indexed by the crawler. Web sites may also engage in other forms of mischief, such as accepting connections and either responding slowly or with noncomformant content.

Thus both content providers and repository maintainers are threatened by potentially unconstrained resource requirements. As the web has evolved, a number of standards and standard practices have emerged that mitigate these threats, and a form of economic equilibrium has emerged to allow repositories to be maintained.

The situation is complicated by the fact that the goals of content producers and crawlers are sometimes not aligned to each other. Content providers are generally motivated by the desire to shape public opinion through their information, or their desire to drive traffic for commerce. In a competitive market, multiple content providers may find themselves in competition with each other, competing for the attention of humans. As such, they can be expected to engage in a variety of practices that will improve their share of readership.

By contrast, consider the goals of a commercial search engine. Search engines make money from advertising, and in order to maintain the traffic, they need to serve the aggregated needs of users. Even if the search engine had a completely accurate copy of the web, there is still the task of deciding which results to show, and this is where the goals of individual content providers may conflict with those of the search engine (and users). Content providers generally want their content to be indexed, but they also want their content to be shown to users ahead of their competitors. They can be expected to act in their own self interest.

One of the activities that some sites engage in is to create link farms, which are designed to enhance the ranking of pages in search engines. In order for this to be effective, the pages of link farms must be crawled and incorporated into the ranking of the search engine. This is an extreme example of the more general phenomenon that content providers and search engines may disagree on what should be crawled and indexed.

Cache Consistency

Inconsistency of a web shadow repository is similar to any other cache consistency problem, and has been studied extensively in the literature. Traditional approaches to cache consistency include time-to-live (TTL), client polling, and invalidation protocols. Most of the literature on caching has neglected the issue of discovery, which is a critical feature of crawling and one reason why pages need to be revisited (to find new links). Due to the uncoordinated nature of the web, most of the effort has gone into client polling approaches, although elements of the other approaches have also been experimented with. The HTTP protocol [5, section 13] contains a variety of optional features that can help with TTL approaches if they are properly implemented. Examples include the `Cache-Control`, `Expires`, `Last-Modified`, `If-Modified-Since`, `If-Unmodified-Since`, and `Vary` header fields. The cache-consistency protocol of the HTTP protocol is designed to facilitate human interactive browsing, and is not designed for batch processing. Moreover, relatively few web sites have taken the care to implement the existing protocols correctly.

In 2005 Google published an improved mechanism for conveying TTL cache consistency messages, known as sitemaps [7]. This followed an earlier effort called Open Archives Initiative Protocol for Metadata Harvesting (OAI-PMH), and was released under a creative commons license. The purpose of the sitemaps initiative was to provide a more efficient polling mechanism, where web sites could provide information in an XML format to specify a list of valid URLs for crawling, along with optional last-modified dates, change frequencies, and priorities. Theoretically this scales up to sites with fifty million URLs, but has only weak consistency guarantees incorporated into it. In addition to conveying information about expiration and priority, the protocol also specifies a way for sites to notify individual search engines of the existence of their sitemap, either through placement in a robots.txt file or through a ping notification message [7]. Sitemaps can also be useful in eliminating intra-site duplicates, which consume resources of search engines and degrade the quality of indexing of sites.

In theory, sitemaps can greatly improve the efficiency of maintaining a shadow repository, but they have their own problems due to previously mentinoed misalignment of incentives between content providers and search engines. Sitemaps are subject to various kinds of abuse, and cannot be completely trusted by the crawler to give an accurate view of a web site.

Resource Management

The resources consumed by incremental crawling can be significant. In one study in 2002 [9], it was estimated that 40% of Internet traffic is due to web crawlers retrieving pages. Similar figures have been observed by others, though the impact is probably higher for low-traffic sites than it is for high-traffic sites. From the point of view of the crawler, it is not obvious how to optimally design a crawl strategy in order to achieve a given level of one of a metrics such as freshness.

One tempting strategy is to adjust the crawl frequency for a page in proportion to the rate of change for the page. Thus if a page changes freqently and substantially, it would receive a higher level of crawling. It is perhaps counterintuitive that this may not be optimal. In the extreme case, a page may in fact change every time it is accessed, which means that no matter how often you access it, you will never have the "up to date copy." Accessing a page too frequently would also violate the standard "politeness" policy of web crawlers.

Another potential policy would be to revisit pages with the same frequency, ignoring the change rate of individual pages. This is evidently wasteful of resources, but Cho and Garcia-Molina [1] showed both experimentally and theoretically that this outperforms the proportional approach. The optimal strategy interpolates between the two, with a visitation schedule that increases monotonically with the change rate, but penalizes pages that change too often.

Theoretical results of this type depend upon an underlying mathematical model of how the web changes, and should be carefully examined when applying it to a restricted subset of the web, and should be re-evaluated in the future should the social forces that shape the web somehow change. Such models should reflect the rate at which new information is produced, the distribution of such production among individual websites, and the rate at which information decays or is revised. Such models are essential for deciding how to balance the resources dedicated to discovery of new content vs. the confirmation that existing content has not changed.

Key Applications

To date, the primary application that has made use of crawling is search engines. The details of their incremental crawling strategies remain unpublished, as they are based on the perceived economic value of the repository. As the web has grown, search engines have become increasingly important for users, allowing them to express an information need in fairly precise terms, and quickly navigate directly to documents on the topic of interest. From the point of view of a search engine, the dynamic nature of the web presents special problems, since a search engine will typically depend upon deep analysis of documents and links between documents. Documents whose content changes on a regular basis present a challenge for indexing, since the freshness of a search engine is a critical measure of utility for users.

Search engines are not the only applications that can make use of incremental crawling. Others include systems for prefetching proxies, notifications and alerts, mirroring and archiving, and business and political intelligence.

Future Directions

Most of the current strategies for incremental crawling are heavily dependent upon polling, and are therefore fairly inefficient. An approach built around notification and invalidation would clearly be more efficient, but there appears to be little economic incentive to implement them. Existing mathematical models for the growth and change rates of the web are fairly simplistic, treating all web pages as equal and failing to recognize the inherent organizational structure of web sites and the different purposes for which pages are created. Finally, as new applications emerge for web shadow repositories, it is natural to expect new requirements to emerge.

Incremental Maintenance of Views with Aggregates

HIMANSHU GUPTA
Stony Brook University, Stony Brook, NY, USA

Definition

Views are SQL or relational expressions over the given data sources. In a data warehouse, view expression generally involve the aggregate operator. In order to keep *materialized* (precomputed and stored) views up to date, it is necessary to maintain the views in response to the changes at the sources. *Incremental maintenance* of a view involves propagating the changes at the source onto the view so that the view reflects the changes. Incrementally maintaining a view can be significantly cheaper than recomputing the view from scratch.

Historical Background

Incrementally maintaining a view can be significantly cheaper than recomputing the view from scratch, especially if the size of the view is large compared to the size of the changes [1,2,9]. The problem of incremental maintenance of views has been studied extensively, and several algorithms have been proposed over the years [3,4,6–12]. Most works (except for [7,12]) either handled view expressions without aggregate operators [3,4,11], or *aggregate views* (view expressions with the aggregate operator as the last operator) [8,9,10]. Quass in [12] attempts to maintain general view expressions involving aggregate operators, but the expressions obtained are inefficient and very complicated. Recently, Gupta and Mumick [7] developed the change-table technique for incremental maintenance of general view expressions involving aggregate and outerjoin operators. Change table of a particular view is applied to the view using a special refresh operator. The change-table technique can be looked upon as a generalization of the technique of summary tables developed by [9] for maintenance of aggregate views. In contrast to the most other techniques which propagate data in terms of insertions and deletions through a view expression, the change-table technique propagates data (in terms of change-tables) as well as action (in terms of parameters of the refresh operation) through the given view expression.

Foundations

The first step is to explain the framework developed in [3,11] for deriving incremental view maintenance expressions and relate it to the change-table technique. Let a database contain a set of relations $\mathcal{R} = \{R_1, R_2,...,R_n\}$. A *change transaction* t is defined to contain the expression $R_i \leftarrow (R_i \dot{-} \nabla R_i) \uplus \Delta R_i$, for each relation R_i, where ∇R_i are the deletions from R_i, and ΔR_i are the insertions into R_i. Let V be a bag-algebra expression defined on a subset of the relations in $\mathcal{R}$. The *refresh-expression New*(V, t) ([3] uses the notation pre(t, V) instead) is used to compute the new value of V. Griffin and Libkin in [3] define the expression New(V, t) to be:

$$\text{New}(V,t) = (V \dot{-} \nabla(V,t)) \biguplus \Delta(V,t).$$

So, the goal in deriving view maintenance expressions for a view V is to derive two functions $\nabla(V, t)$ and $\Delta(V, t)$ such that for any transaction t, the view V can be maintained by evaluating $(V \dot{-} \nabla(V, t)) \uplus \Delta(V, t)$. In order to derive $\nabla(V, t)$ and $\Delta(V, t)$, [3] gives *change propagation equations* that show how deletions and insertions are propagated up through each of the relational operators. The work of [3] was extended to include aggregate operators by Quass in [12].

The change-table technique can be thought of as introducing a new definition for New(V, t). The expression New(V, t) is defined for general view expressions as

New(V, t) = (V *REFRESH* □(V, t)),

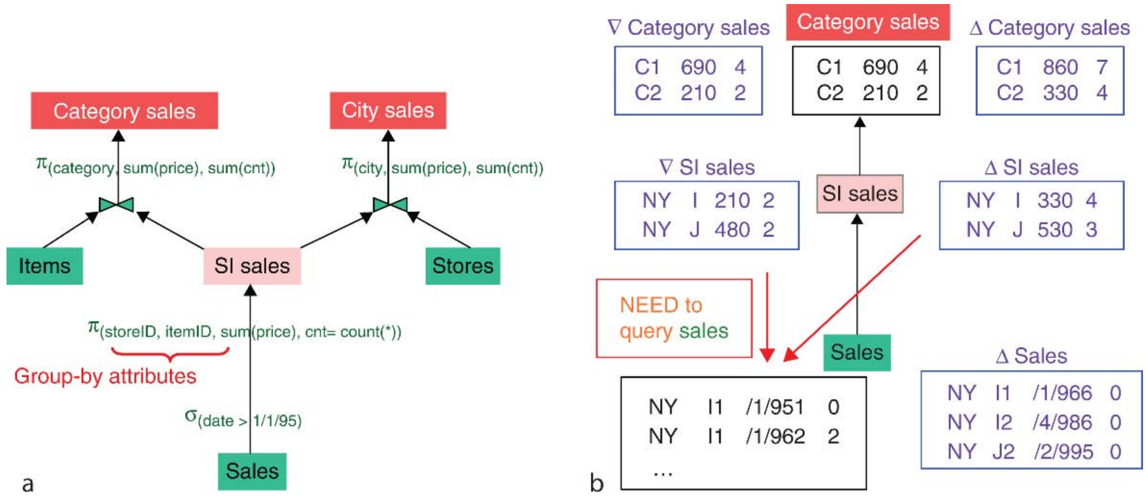
where □(V, t) is the “change-table” for the transaction $\dot{t}$ and *REFRESH* is the “refresh” operator used to apply the changes in the change table to its view. The above new definition of New(V, t) is motivated from the following observation. In the case of general view expressions involving aggregate operators, it is usually more efficient to propagate the change tables beyond an aggregate operator, instead of propagating insertions and deletions. Propagation of a change table is particularly efficient when the change table depends only on the changes to the base relation (self-maintainability [5]), while the insertions and deletions depend on the old value of the view. As shown in the example below, if the aggregate node is not materialized, the computation of insertions and deletions could be very expensive. The above new definition of New(V, t) also means that in order to obtain a complete technique it is necessary to define a general refresh operator, show how to generate a change table, and how to propagate a change table through various operators. The reader is referred to [7] for the above details.

Illustrative Example. Consider the classic example of a warehouse containing information about stores, items, and day-to-day sales. The warehouse stores the information in three base relations viz. `stores`, `items`, and `sales` having the following schemas.

`stores` (storeID, city, state)
`items` (itemID, category)
`sales` (storeID, itemID, date, price)

For each store location, the relation `stores` contains the storeID, the city, and the state in which the store is located. For each item, the relation `items` contains its itemID and its category. An item can belong to multiple categories. The relation `sales` contains detailed information about sales transactions. For each item sold, the relation `sales` contains a tuple storing the storeID of the selling store, itemID of the item sold, date of sale, and the sale price.

Views. Consider the views `SISales`, `CitySales`, and `CategorySales` defined over the base relations as shown in Fig. 1a. The view `SISales` computes for each storeID and itemID the total price of items sold after 1/1/95. The view `SISales` is an intermediate view used to define the views `CitySales` and `CategorySales`. The view `CitySales` stores, for each city, the total number and dollar value of sales of all the stores in the city. The view `CategorySales` stores the total sale for each category of items. All the above described views consider only those sales that occur after 1/1/95. The views `CitySales` and `CategorySales` are stored (materialized) at the data warehouse and this is represented below by the keyword “MATERIALIZED” (The keyword “MATERIALIZED”

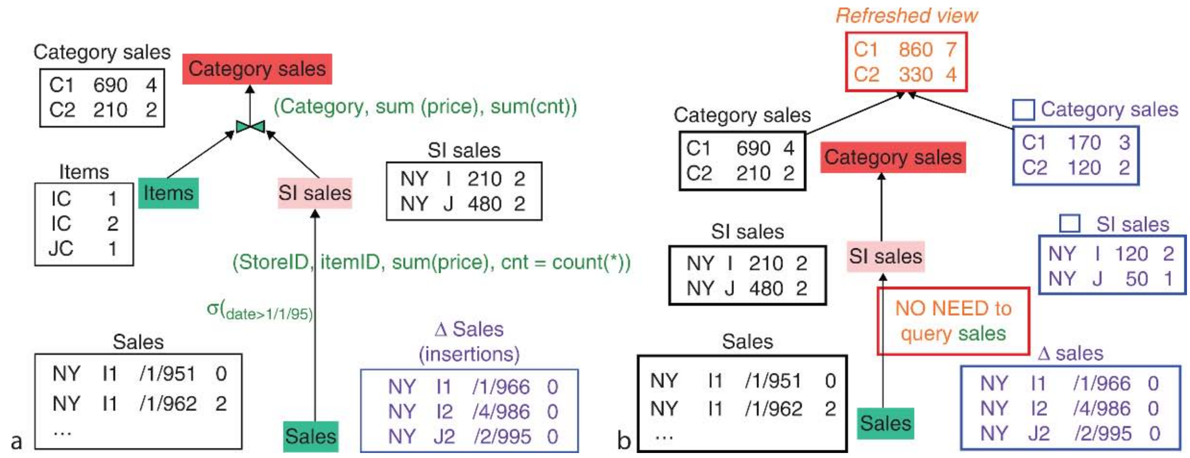


is not supported by SQL, but has been introduced in this article) in the SQL definitions of the views. It is desirable to maintain these materialized views in response to insertions to the base relation `sales` for the instance shown in Fig. 1b.

```
CREATE VIEW SISales AS
SELECT storeID, itemID, sum(price) AS
SumSISales, count(*) AS NumSISales
FROM sales
WHERE date>1/1/95
GROUP BY storeID, itemID;
CREATE MATERIALIZED VIEW CitySales AS
SELECT city, sum(SumSISales) AS SumCi-
Sales, sum(NumSISales) AS NumCiSales
FROM SISales, stores
WHERE SISales.storeID = stores.storeID
GROUP BY city;
CREATE MATERIALIZED VIEW CategorySales
AS
SELECT category, sum(SumSISales) AS
SumCaSales, sum(NumSISales) AS
NumCaSales
FROM SISales, items
WHERE SISales.itemID = items.itemID
GROUP BY category;
```

Insertion-Deletion Technique. Griffin and Libkin in [3] update view expressions by recursively computing insertions and deletions for each of the subexpressions in the view expression in response to changes at the base relations. Quass in [12] extends the techniques in [3] by including aggregate operators. Of the maintenance approaches that propagate insertions and deletions, only [12] provides techniques to maintain general view expressions involving aggregate operators. In the example, the insertions to `sales`, Δ`sales`, result in insertions (Δ`SISales`) and deletions (∇`SISales`) to the view `SISales`, which is an aggregate view over the base relation `sales`. The expressions that compute Δ`SISales` and ∇`SISales`, as derived in [12], are quite complex (see [7]). As `SISales` is not materialized, the maintenance expressions for `SISales` essentially recompute the aggregate values of the affected tuples in `SISales` from the base relation `sales`. Using the propagation equations from [12], one can propagate Δ`SISales` and ∇`SISales` upwards to obtain expressions for ∇ `CitySales`, Δ`CitySales`, ∇`CategorySales`, and Δ`CategorySales`. Figure 2a illustrates the [12] technique for updating `CategorySales` in response to insertions into `sales`. As emphasized in the figure, the computation of Δ`SISales` and ∇`SISales` require querying the base relation `sales`, because the intermediate view `SISales` is *not* materialized.

Change-Table Technique. The change-table technique proposed in [7] is as follows. Instead of computing and propagating insertions and deletions beyond an aggregate node `SISales`, a change table is computed and propagated for `SISales`. (A change table is a general form of summary-delta tables introduced in



Incremental Maintenance of Views with Aggregates. Figure 2. (a) Insertion-deletion approach ([12]), and (b) The change-table approach [8].

[9]). Propagation of change tables yields very efficient and simple maintenance expressions for general view expressions. The change table cannot be simply inserted into or deleted from the materialized view. Rather, the change table must be applied to the materialized view using a special "refresh" operator. Denote the change table of a view V by $\square V$, and a refresh operator by *REFRESH*. In practice, there are certain parameters passed with the *REFRESH* operator, but for simplicity ignore the parameters here.

For our example, start with computing the change table □SISales that summarizes the net changes to SISales. For this first level of aggregates, the expression that computes □SISales is similar to that derived in [9]. The change table □SISales is computed from the insertions and deletions into sales by using the same generalized projection (aggregation) as that used for defining SISales. More precisely,

$$\square\texttt{SISales} = \pi_{\textit{storeID,itemID,SumSISales=sum(price),NumSISales=sum(\_count)}}(\Pi_{\textit{storeID,itemID,price,\_count=1}}(\sigma_p(\triangle\text{sales})) \uplus \Pi_{\textit{storeID, itemID, price= -price,\_count= -1}}(\sigma_p(\nabla\text{sales}))), \text{ where } p \texttt{ is } (\textit{date} > \texttt{1/1/95})$$

Figure 2b presents an instance of the base relation sales and the table Δsales, which is the set of insertions into sales. For the given tables, Figure 2b also shows the computed table □SISales. Next propagate the change table □SISales upwards to derive expressions for the change tables □CitySales and □CategorySales.

$$\square\texttt{CitySales} = \pi_{\textit{City, SumCiSales=sum(SumSISales),NumCiSales=sum(NumSISales)}}(\square\text{SISales} \bowtie \text{stores})$$

$$\square\texttt{CategorySales} = \pi_{\textit{category, SumcaSales=(SumSISales), NumcaSales=sum(NumSISales)}}(\square\text{SISales} \bowtie \text{items})$$

Figure 2b shows the change table □CategorySales for the instance of the base table items in Fig. 1b. The change table □CitySales can be similarly computed. The new propagated change tables are then used to refresh their respective materialized views CitySales and CategorySales using the refresh equations below. The details of the refresh equations are in [7].

$$\texttt{CitySales} = \texttt{CitySales}\ \textit{REFRESH}\ \square\texttt{CitySales}, \text{ and}$$

$$\texttt{CitySales} = \texttt{CategorySales}\ \textit{REFRESH}\ \square\texttt{CategorySales}$$

As SISales is not materialized, it does not need to be refreshed. Also, as emphasized in Fig. 2b, it is not necessary to query the base relation sales for updating CitySales or CategorySales, which results in huge savings. The refresh operation is illustrated by showing how the CategorySales view is refreshed. Figure 2b shows the materialized table CategorySales for the given instance of base tables. For each tuple □v in □CategorySales, one looks for a matching tuple in CategorySales using the join condition CategorySales.category = □CategorySales.category (specified in one of the parameters of *REFRESH*). For example, the tuple <C1,170,3>in □CategorySales matches with the tuple v = <C1,690,4>of CategorySales. The tuple <C1,170,3>in □CategorySales means that three more sales totaling $170 have occurred for C1 category. The total number of sales for C1 is now 7 for a total amount of $860. To reflect the change, the tuple v is updated to <C1,860,7> by adding together the corresponding aggregated attributes (specified in another parameter of *REFRESH*).

Cost Comparison. It is shown in [7] that for typical sizes of base tables and changes to the base tables, the number of tuple accesses (reads and writes) incurred by the change-table technique is an order or magnitude less than that by the insertion-deletion propagation technique.

Indexing; Inverted indexes

Definition

A core element of modern information retrieval systems is the document index. The index is a set of data structures that are constructed from a source document collection with the goal of allowing an information retrieval system to provide timely, efficient response to search queries. The process of index creation typically involves reading and processing the source document collection, parsing the text in each individual document and extracting the necessary features to allow for retrieving and ranking that document in response to a user query. Additionally, indexing systems often use dimension reduction, compression, and other related techniques to drastically reduce the storage footprint of the source collection in its indexed form. Document indexes are frequently stored in a set of file structures that are conducive to rapid retrieval and ranking by an information retrieval system in response to a query.

Historical Background

As document collections have grown in size, the need to search them in an efficient and effective fashion has grown accordingly. At the time of this writing, modern, moderately-sized document collections measure in the hundreds of gigabytes, with search engines indexing tens of billions of pages [2]. Given the sheer scale of the search problem, researchers have invested a considerable amount of effort in recent years on developing efficient file structures for indexing and storing large document collections on disk. With the advent of the web (and the subsequent rapid explosion of searchable digital documents) during a time in which disk space and processing power were substantially more expensive than they are now, indexing approaches typically focused on advanced techniques for data compression to reduce the storage footprint for an index (thoroughly discussed in [3]), and on aggressive dimension reduction, such as the removal of very frequent terms ("stopwords"), or very short documents, with the goal of reducing the total number of objects of interest tracked by the index created over the collection. As processing speeds have increased and persistent storage has gotten cheaper, indexing systems have focused on more complex algorithms intended to capture a richer set of information about the documents in the collection.

In addition to extracting key features (terms, frequencies) from the source documents and constructing data structures for storage and retrieval, indexing systems often tailor their file structures to accommodate the specific needs of the information retrieval system. For example, this may involve special extensions to allow for high-performance updates to the index, distributed indexing techniques for very large collections or high-performance indexing, or the collection of special metadata that are specific to the search tasks at hand (i.e., localized search, news search, expert search, etc). Many recent research efforts have focused on these extensions to core indexing strategies. An excellent survey can be found in [4].

Foundations

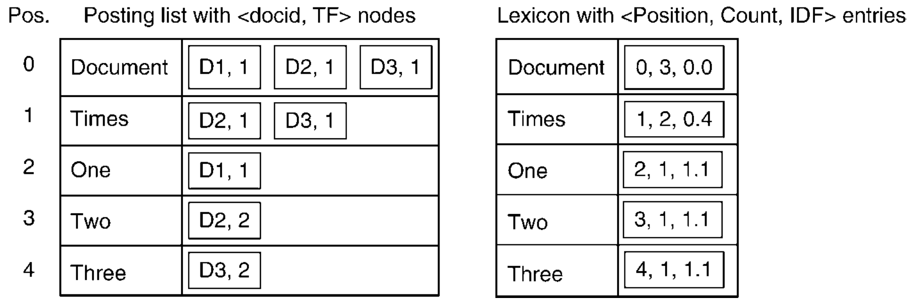
At a high level, indexing a collection of documents involves three main steps. First, the document collection must be parsed. This involves reading in each document in the collection and converting the source text of each document into a single unified form that is readable by other components in the indexing process. This step typically resolves the formatting differences between different types of source documents (i.e., HTML web pages, Microsoft Word™ documents, PDF™ files, E-Mail messages, raw text, etc). For efficiency purposes, it is often possible and desirable to perform the document parsing step in a massively parallel fashion since most documents can be parsed in a completely independent fashion.

The second major step in the indexing process involves extracting key features from the source text of each document that will be used in the retrieval process. In practice, the precise set of features is dependant on the retrieval strategy of the overall system, but distinct terms and their associated frequencies in each document are almost always included.

The final step involves sorting any intermediate representations and compiling them into a unified set of final data structures for storing on the disk. A common type of index structure that is frequently referenced in the literature is the *inverted index* [1], which represents a reasonably static document collection as a posting list, where each element in the list maps a distinct term in the collection to a set of documents containing that term. Furthermore, this list can be sorted in various ways depending on the optimization strategies imposed by the underlying search engine (sorting by descending term frequency is a common approach, but there are many others). Each node in the posting list entry (which represents a document containing the term at the head of the posting list entry) may contain extra information about that term as it pertains to the document in question. A common example of this is the term's position within the document, which is valuable for proximity search, as well as presenting results with *keyword-in-context,* meaning that result summaries will display query terms highlighted with surrounding text to give the user an idea of how their keywords are used in the result document.

In many systems, the posting list is supported by a secondary data structure known as a lexicon, which contains an entry for each distinct term in the collection along with a set of metadata that help the retrieval algorithms score target documents for relevance, including statistics like the inverse document frequency (IDF) of the term and the size of that term's posting list. Additionally, for efficiency purposes, the lexicon may include offset addresses into the inverted file, which is often stored as a random access file on the disk. Other efficiency gains may be observed if the lexicon is sufficiently small to fit in main memory, which eliminates the need for extra disk-bound I/O.

For an example of inverted index construction, consider a small collection with three documents. Document one contains the text "This is document one." Document two reads "This is document two, times two" and document three reads "This is document three, times three." The indexing system must read and parse these three documents, extract their terms, and build the posting list and lexicon. As mentioned above, a common technique used to reduce the size of the index is to remove very frequent terms that add little overall information to a document's content (typically called "stopwords"). For this example, assume that the terms "this" and "is" are considered stopwords and removed accordingly. Thus, at the end of the parsing process, five distinct terms in this example collection remain: "document", "times", "one", "two", and "three". Each distinct



Pos.	Posting list with <docid, TF> nodes			
0	Document	D1, 1	D2, 1	D3, 1
1	Times	D2, 1	D3, 1	
2	One	D1, 1		
3	Two	D2, 2		
4	Three	D3, 2		

Lexicon with <Position, Count, IDF> entries	
Document	0, 3, 0.0
Times	1, 2, 0.4
One	2, 1, 1.1
Two	3, 1, 1.1
Three	4, 1, 1.1

Index Creation and File Structures. Figure 1. Example inverted index with Lexicon.

term is represented as an entry in the posting list with the associated lexicon, as shown in Fig. 1.

As discussed above, each element in the posting list represents a distinct term in the collection, and each term references a list of documents containing that term along with the term frequency (TF) of that term in the document. The Lexicon contains a listing of all distinct terms along with their position in the posting list, the total number of posting list nodes for the term, and the inverse document frequency (IDF) of that term in the collection, which is defined as the log of the ratio of total documents to the number of documents containing the term [1]. It is easy to see how the retrieval process could operate using this data structure, simply looking up each query term in the lexicon, using the position information there to retrieve the posting list entry for that term, and using the term frequency, IDF, and any other available statistics to rank each document for inclusion in the final results presented to the user.

Key Applications

Indexing processes and index file structures are required for virtually all modern Information Retrieval systems, given the size and complexity of modern document collections. In addition to indexing large, relatively static collections of documents, there is also research that addresses the construction and maintenance of dynamic and distributed indexes, which represent a significant area of focus as the amount of searchable data continues to grow and the need to search becomes more and more pervasive and decentralized.

Index Join

Jingren Zhou
Microsoft Research, Redmond, WA, USA

Synonyms

Index join; Index loop join; Index nested loop join

Definition

The index join is a variant of the nested loop join in database systems using index. The join predicate can be either an equality predicate or a range predicate. The algorithm starts with reading the *outer* relation R. For each tuple $\mathcal{R} \in R$, instead of scanning the entire *inner* relation S, an index on S is used to find matching tuples and add them to the result.

Key Points

An index on S is applicable for an index join if one join attribute is the leading indexed key of the index. If the join predicate is an equality predicate, an index lookup is performed for each outer tuple. If the join predicate is a range predicate, for each outer tuple, an index seek is performed to locate the first matching tuple, followed by an index scan for the rest matching tuples. Compared with the nested loop join, the index join saves disk I/Os for reading the entire inner relation *S* multiple times.

Index Structures for Biological Sequences

Tamer Kahveci
University of Florida, Gainesville, FL, USA

Definition

Biological sequence databases are mainly composed of DNA, RNA, and protein sequences. DNA and RNA sequences are polymers of nucleotides, whereas proteins are polymers of amino acids. A database of biological sequences contains a set of biological sequences of the same type. The length of each sequence varies from less than a hundred to several hundred million bases. An index structure on a database of biological sequences helps in identifying sequences in that database that are similar to a given query sequence quickly. The definition of similarity depends on two orthogonal parameters; similarity function and the length of the similarity of interest.

The simplest similarity function is the edit distance, which measures the number of substitutions, insertions, and deletions needed to transform one sequence to the other. More complex functions involve variable gap penalties and substitution scores based on how frequent substitutions are observed in nature. The length of the similarity can be either the entire sequence (global alignment) or a subsequence of the database and the query sequence (local alignment). Depending on how the similarity is defined using these parameters, the similarity may or may not be metric. The index structure used for the biological sequence database needs to be suitable to accommodate the underlying similarity measure.

Historical Background

Levene identified the nucleotide bases in 1919. He found that the nucleotides can form a chain as the phosphate in a nucleotide can create bond with other nucleotide. Watson and Crick discovered the structure of the DNA in 1953 using X-ray diffraction. The efforts to create a database of DNA sequences, named GenBank, has started in 1979. By 1983, there were around 2,000 sequences in GenBank. Since then, the size of genome databases is increasing exponentially [2]. Statistics show that the size of GenBank has doubled every 15 months. In August 2005, GenBank contained over 100 billion bases. This rapid growth in the size of the biological sequence databases coupled with the costly distance measures made the use of index structures essential for this data type.

One of the earliest index structures used for biological sequences is the hash table [10]. Hash tables are often used to index *k*-grams (subsequences of length *k*) of the sequences in the database. This index structure is used to find exact matches between the *k*-grams of a given query sequence and that of the database sequences. Popular biological database search tools such as FASTA [10] and BLAST [1] employed hash tables to index *k*-grams. These tools created one hash table entry for each unique *k*-gram. Thus, the number of hash table entries is exponential in *k*. This limits the value of *k* to a small number. Another drawback of the hash table is that the value of *k* has to be predetermined at the time of index construction.

Therefore, the same sized k-grams need to be used for all the queries. Pol and Kahveci incorporated randomization to enable variable k value for hash table construction [11].

Suffix trees and suffix arrays constitute another set of commonly used index structures for biological sequences. Suffix trees were first proposed by Weiner [14] under the name *position tree*. Unlike the hash table, this structure index all the suffixes of all the sequences in the database. McCreight proposed a space efficient technique for the construction of the suffix trees [9]. Later, Ukkonen developed an on-line construction method [12]. A variety of other suffix tree implementations have also been proposed such as implicit suffix tree [12], string B-tree [4] and suffix array [8]. AVID [3] use the suffix tree structure to query biological sequences.

Hash tables and suffix trees can identify exact matches. The tools that use them perform additional processing to identify approximate matches. Reference-based index structures enable approximate searches. The VP-tree (Vantage Point tree) [15] indexes the data in general metric space with the help of references. Omni method [5] proposed to select the references near the convex hull of the database, far away from each other. Venkateswaran et al, later showed that multiple references should be used to index a database sequence, and the references should be a combination of similar and distant sequences [13].

The Sequence Search Tree (SST) [6] maps each sequence to a set of vectors in a high dimensional integer space. It then builds an index on these vectors. The Multi Resolution String (MRS) index structure [7] also maps the subsequences into a high dimensional integer space. Unlike SST, the mapping of the MRS index structure allows computation of a lower bound to the distance. This way MRS avoids false dismissals.

Foundations

Hash Tables

One of the most widely used index for sequence search is the *hash table* (also called the *lookup table*). Hash table enables quick lookup for a set of pre-specified sequences. Usually, in the bioinformatics literature, the hash table is built on the k-grams, where k is predefined.

The hash table of a sequence is built using two parameters: alphabet and k. Assume that the alphabet contains σ letters. The hash table encodes the ith letter in the alphabet as the binary representation of $i - 1$ using $\lceil log_2\sigma \rceil$ bits. For example, the letters in the DNA alphabet {A, C, G, T} are encoded as A = 00, C = 01, G = 10, and T = 11. The hash key of a k-gram is the concatenation of the binary representations of the letters that constitute that sequence. For example, the DNA sequence GGCA is represented as 10100100. Figure 1 shows the hash table built on a DNA sequence for $k = 2$. In this example, the hash table contains 4^2 entries since $\sigma = 4$. The total number of pointers to database is the $N - k + 1$, where N is the number of letters of the sequence indexed.

Suffix Trees

Suffix tree is a tree structure where each path from the root to a leaf node denotes a suffix of the sequence that it indexes. Thus, there is a bijection between the leaf nodes and the suffixes. In order to be able to create this bijection unambiguously, suffix tree increases the length of each of the database sequences by one letter by appending a unique "stop" character at the end of the sequence. This character is not contained in the alphabet that constitutes the database sequences. Figure 2 shows the suffix tree built on sequence CAGCATAG. The letter, $, marks the end of the sequence. Every path from the root node to a leaf node through the solid arrows defines a suffix of this sequence. The labels on the edges of each such path show the

5	TAG

Index Structures for Biological Sequences. Figure 3. Suffix array built on the sequence CAGCATAG and the corresponding suffixes indexed by the entries of this index.

contents on that suffix. The numbers at the leaf nodes show the starting position of the suffix denoted by that leaf. The dashed arrows in the figure are the suffix links. There is a suffix link from an internal node *u* to another internal node *v* if *u* and *v* are labeled with suffixes $c\alpha$ and α respectively for a given letter *c*. Suffix links enable faster construction of suffix trees.

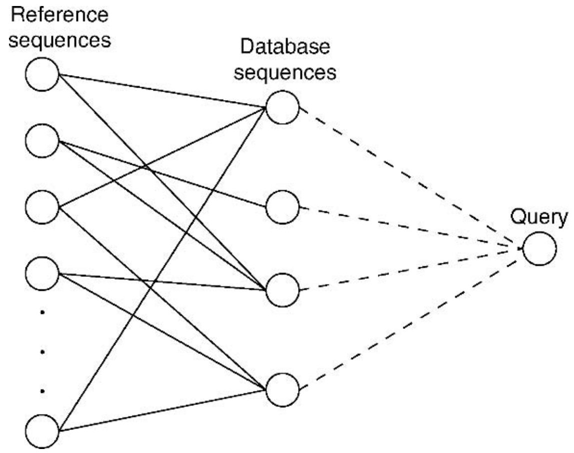
Suffix trees are notorious for their excessive memory usage. Although the space complexity is $O(n)$, the constant in the big-Oh may be large. The size of the suffix tree depends on the alphabet and the distribution of the letters in the database sequence. The literature reports the size of the suffix tree as 10–70 bytes per letter in the database.

Suffix Arrays

Suffix arrays reduces the space consumption of suffix trees to five bytes per letter at the expense of increased search time complexity. The suffix array of a sequence is an array of integers that shows the alphabetical order of all suffixes of that sequence. Figure 3 shows the suffixes of CAGCATAG and the suffix array constructed on it.

Reference-Based Indexing

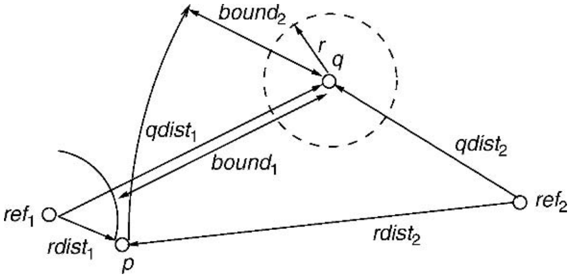
Reference-based index structures work when the distance measure is metric. The distance measure is metric when the distance function is metric and the entire sequences are aligned. An example to metric distance functions is the edit distance. Reference-based index structures select a small number of sequences, referred to as the set of *reference sequences*. Often, these references are selected from the database sequences for simplicity. However, it is possible select sequences that are not in the database as references. The structure pre-computes the distances between the references and the database sequences. For a given a query sequence, the query algorithm first computes the distance from each of the references to the query sequence. It then computes upper and lower bounds to the distance between the query sequence and the database sequences with the help of the pre-computed distances



Index Structures for Biological Sequences. Figure 4. Reference based indexing. The *small circles* represent database, reference and query sequences. Each database sequence is indexed by two references. The *solid lines* denote which references are used for each database sequence. The distances between the sequences connected by *solid line* are precomputed. The *dashed lines* denote the distance between the query and the references. These distances are computed on the fly as the query arrives.

in the index quickly. Thus, without any further comparisons, sequences that are too close to or too far away from a reference may be removed from the candidate set with the help of the triangle inequality. Figure 4 shows a reference based index where each database sequence is indexed using two references.

Figure 5 illustrates reference-based indexing in a hypothetical two-dimensional, space. Here, the database sequences are represented by points. The distance between two points in this space corresponds to the underlying distance between the two sequences (e.g., if the points denote sequences, $rdist_1$ between the points ref_1 and p corresponds to the edit distance between the sequences represented by them). In reference-based indexing, the distances between the sequence p and references ref_1 and ref_2 are pre-computed. Let $rdist_1$ and $rdist_2$ be the two pre-computed distances, respectively. Given a query q with range r, the first step is to compute reference-to-query distances $qdist_1$ and $qdist_2$. A lower bound for the distance between sequences q and p with reference ref_1 is computed as $bound_1 = |qdist_1 - rdist_1|$ using the triangle inequality. Similarly, $bound_2$ gives a lower bound for the distance between q and p with reference ref_2. Since $bound_1 > r$ with ref_1 as the reference, sequence p can be pruned from the candidate set of q.



Index Structures for Biological Sequences. Figure 5. Two dimensional illustration of reference-based indexing. Here ref_1 and ref_2 are references. The query region is given by its center q and radius r. $qdist_1$ and $qdist_2$ are query-to-reference distances. $rdist_1$ and $rdist_2$ are distances from the reference to the data p. $bound_1$ and $bound_2$ are the bounds obtained using references.

Vector Space Indexing

This set of index structures first map the sequences to a vector space (typically in a multi-dimensional integer space) and build index structure on this space. An example to this is the MRS (Multiple Resolution String) index.

Let s be a sequence from the alphabet $\Sigma = \{\alpha_1, \alpha_2,...,\alpha_\sigma\}$. Let n_i be the number of occurrences of the character α_i in s for $1 \leq i \leq \sigma$. The vector space mapping of s is computed as $f(s) = [n_1, n_2,...,n_\sigma]$. The vector, $f(s)$ is called the *frequency vector*, of s. For example, let s = AGCTTTTCATTCTGAC be a DNA sequence. The frequency vector of s is $f(s) = [3,4,2,7]$ ([#As,#Cs,#Gs,#Ts]), since the DNA alphabet contains the letters A, C, G, and T.

The MRS index structure stores a sequence of Minimum Bounding Rectangles (MBRs) at different resolution levels in the index structure. Resolutions are represented using window size, which are powers of two.

In order to obtain the MBRs of a sequence at resolution 2^i, a window of length $w = 2^i$ is placed at the leftmost point of that sequence. Later, this window is slid by one letter until it reaches to the end of that sequence. Each placement of this window produces a subsequence. The frequency vectors of all those windows are computed. First, the minimum box, called

Minimum Bounding Rectangle (MBR), that covers the frequency vector of the first subsequence is computed. This box is later extended to cover more frequency vectors until the box capacity is reached. Box capacity is an integer that denotes the maximum number of frequency vectors that an MBR can contain. Typically, this number is set to 1,000 to achieve good performance result. Once the box capacity is reached, a new MBR is created to cover the next subsequences. This process continues until all subsequences are transformed. Note that only the lower and higher end points of the MBRs along with the starting locations of the first subsequence contained in that MBR are stored for each MBR.

Key Applications

The ability to query large biological sequence databases is needed in nearly all areas of molecular biology, pharmacology, plant sciences and horticulture. Two example applications are as follows.

Repeat identification. DNA sequences contain large amounts of repeating patterns. Identifying these patterns is essential for many purposes. For example, repeat copy numbers can help in determining ancestral relationship, which is often needed to identify victims, criminals, parenthood, whether a race horse is pure breed, etc. Furthermore, identifying these repeats is needed for more accurate sequence assembly and for high quality primer production. Identifying repeats require comparing the sequences in a repeat library and the target sequence (library-based repeat identification) as well as a self comparison of the target sequence (de-novo repeat identification). The size of the target sequence and the repeat library often necessitates the use of an index structure.

Shotgun sequencing. One of the commonly used technologies to identify the letters in large chromosomes is called *shotgun sequencing*. This technology first produces multiple copies of a given long DNA sequence. It then chops these sequences into short fragments from (almost) random locations using restriction enzymes. It then identifies the sequences that have less than 1,000 letters using high throughput sequencing machines. This process produces a bag of short subsequences of the target DNA sequences. The challenge is then to reassemble the original long DNA sequence from these short fragments. This problem requires an all-to-all sequence comparison for repeat and overlap detection. The massive size of the database makes it essential to use an index structure.

Index Tuning

Philippe Bonnet[1], Dennis Shasha[2]
[1]University of Copenhagen, Copenhagen, Denmark
[2]New York University, New York, NY, USA

Definition

Index Tuning is concerned with when and how to construct an index.

Historical Background

When relational models were first introduced, customers complained that vendors had introduced them to slowed down customer applications in order to make the customers buy more hardware. Vendors and researchers responded to the performance challenge by incorporating existing data structures (notably B-trees and hash structures) and improving many new ones (notably bit vectors and multi-dimensional indexes). The decision of which data structures to create was left to the user. This entry concerns that decision.

Foundations

An *index* is a data structure plus a method of arranging the data tuples in the table (or other kind of collection object) being indexed. The syntax for constructing indexes is discussed elsewhere. This entry presents the tuning considerations.

Two data structures are most often used in practice for indexes: B+-trees and Hash structures. Of these, B+-trees are used the most often. The folk wisdom holds that if one doesn't know which kind of indexes to put on a column or set of columns and scanning is too slow, then one should use a B+-tree. When performing accesses based on equality, however, hash structures perform better.

The main tuning consideration for *B+-trees* is to avoid having too many levels. Because an access to disk secondary memory costs a few milliseconds if it requires a seek (as index accesses will) and even an access to flash memory may require switching blocks (a relatively expensive operation), the performance of a B+-tree depends critically on the number of nodes in the average path from root to leaf – the number of levels (the root will tend to be in RAM, but the other levels may or not be, and the farther down the tree the search goes, the less likely it is for the nodes to be in RAM). One technique that database management systems use to minimize the number of levels is to make each interior node have as many children as possible (1,000 or more for many B+-tree implementations). The maximum number of children a node can have is called its *fan-out*. Because a B+-tree node consists of key-pointer pairs, the larger the key is, the lower the fan-out.

For example, a B+-tree with a million records and a fan-out of 1,000 requires three levels (including the level where the records are kept). A B+-tree with a million records and a fan-out of 10 requires seven levels. If one increases the number of records to a billion, the numbers of levels increase to four and ten respectively. This is why accessing data through indexes on large keys is slower than accessing data through small keys on most systems (the exceptions are those few systems that offer good compression).

Hash structures, by contrast, store key–value pairs based on a pseudorandomizing function called a *hash function*. The hash function can be thought of as the root of the structure. Given a key of any size, the hash function returns a location that contains either a page address (usually on disk) or a directory location that holds a set of page addresses. That page either contains the key and associated record or is the first page of a linked list of pages, known as an *overflow chain* leading to the record(s) containing the key. (One can keep overflow chaining to a minimum by allocating enough hash buckets such that the space in the hash buckets is at least twice the space required to hold the data.) In the absence of overflow chains, hash structures can answer equality queries (e.g., find the employee with a certain Social Security number) in one disk access, making them the best data structures for that purpose.

The data structure portion of an index has pointers at its leaves to either data pages or data records. If there is at most one pointer from the data structure to each data page, then the index is said to be *sparse*. If there is one pointer to each record in the table, then the index is said to be *dense*.

If records are small compared to pages, then there will be many records per data page and the data structure supporting a sparse index will usually have one fewer level than the data structure supporting a dense index. This means one less disk (or flash block) access if the table is large. By contrast, if records are almost as large as pages, then a sparse index will rarely have better disk access properties than a dense index.

The main virtue of dense indexes is that they can support certain read queries within the data structure itself in which case they are said to *cover* the query. For example, if there is a dense index on the keywords of a document retrieval system, a query can determine the number of records containing some term, e.g., "derivatives scandals," without accessing the records themselves (Count information is useful for that application, because queriers frequently reformulate a query when they discover that it would retrieve too many documents). A secondary virtue is that a query that makes use of several dense indexes can identify all relevant tuples before accessing the data records. Instead, one can form intersections and unions of pointers to data records or of record identifiers.

A *clustering index* on an attribute (or set of attributes) *X* is an index that puts records close to one another if their *X*-values are *near* one another. What "near" means depends on the data structure. On B-trees, two *X*-values are near if they are close in their sort order. For example, they are close numerically or alphabetically. In hash structures, two *X*-values are near only if they are identical. Index-organized tables are clustering indexes where *X* is the primary key.

Sparse indexes must be clustering, but clustering indexes need not be sparse. In fact, clustering indexes are sparse in some systems (e.g., SQL Server, ORACLE hash structures) and dense in others (e.g., ORACLE B-trees, DB2). Because a clustering index implies a certain table organization and the table can be organized in only one way at a time, if there is a clustering index on the sequence of attributes *Y*, then any other clustering index on attributes *X* must have the property that *X* is a prefix of *Y* or *Y* is a prefix of *X*.

A *nonclustering index* (sometimes called a *secondary* index) is an index on an attribute (or sequence of attributes) *Y* that puts no constraint on the table organization. The table can be clustered according to some other attribute *X* or can be organized as a heap, as discussed below. A nonclustering index must be dense, so there is one leaf pointer per record. There can be many nonclustering indexes per table.

A *heap* is the simplest table organization of all. In the basic implementations, records are ordered according to their time of entry. That is, new insertions are added to the last page of the data structure. In this case, inserting a record requires a single page access.

Nonclustering indexes are very useful if they cover a query but can also be useful if the query retrieves significantly fewer records than there are pages in the file. The word "significant" needs explanation: a table scan can often save time by reading many pages at a time, provided the table is stored on contiguous tracks. Therefore, if a query requires most records in a table, a scan may be 2–10 times faster than an index read.

Decision support applications often entail querying on several, perhaps individually unselective, attributes. For example, "Find people in a certain income range who are male, live in California, buy boating equipment, fish, drive a sports car, and work in the computer industry." Each of these constraints is unselective in itself, but together form a relatively small result. The best all-around data structure for such a situation is the *bitmap*. A bitmap is a collection of vectors of bits. The length of each vector equals the length of the table being indexed and has a 1 in position i if the ith record of the table has some property. For example a bitmap on state in the United States would consist of 50 vectors, one for each state. The vector for California would have a 1 in its ith position if record i pertains to a person from California.

Key Applications

Indexes are necessary in any application that handles large amounts of data. Which indexes to choose can have an enormous impact on performance. An index may reduce the time to execute a query from hours to a few seconds in one application, yet increase batch load time by a factor of 80 in another application. Add them with care.

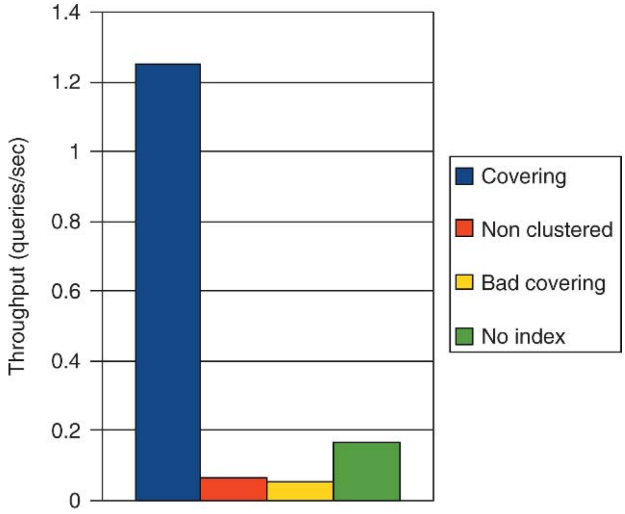
Experimental Results

Covering Experiment

This experiment illustrates two of the issues discussed above: (i) the potential benefit of covering index, and (ii) the trade-off between scans and non-clustered indexes. This experiment considers the table ACCOUNT with 25 attributes, and the following query:

select home_street, last_name from ACCOUNT where first_name='first_name12';

The ACCOUNT table has three different indexes: (i) a covering index on first_name, home_street and last_name, (ii) another covering index on home_street, first_name and last_name, and (iii) a non-clustered index on first_name. The experiment runs the same



Index Tuning. Figure 1. Covering experiment.

query using these three different indexes as well as with no index. The experiment runs those queries on MySQL 6.0 with a cold buffer (i.e., the database cache is empty and IO are required to complete the query). Figure 1 traces the results.

First, the covering index provides the best performance. The reason is that the query can be answered using the index. There is no need to dereference the index leaf pointers to access the underlying table. Second, the order of attributes in the covering index is crucial. In this query, the attribute first_name is used in the WHERE clause. A covering index has the most beneficial effect when the prefix attributes in the index key are those attributes that appear in the where clause. Third, scan sometimes wins over a non clustered index. The reason is that the few random IOs that are necessary to complete the query (the data is generated so that first_name has a 1% selectivity) take more time than the sequential IOs required to scan the whole table.

Indexed Sequential Access Method

Alex Delis[1], Vassilis J. Tsotras[2]
[1]University of Athens, Athens, Greece
[2]University of California-Riverside, Riverside, CA, USA

Synonyms

Indexed sequential file; ISAM file; ISAM

Definition

An indexed sequential access method is a *static, hierarchical*, disk-based index structure that enables both (single-dimensional) range and membership queries on an ordered data file. The records of the data file are stored in *sequential* order according to some data attribute(s). Since ISAM is static, it does not change its structure if records are added or deleted from the data file. Should new records be inserted into the data file, they are stored in an *overflow* area. Deleted records are removed from the file (leaving empty space).

Historical Background

Although transparent for the user of a DBMS, access methods play a key role in database performance. A major performance goal of a DBMS is to minimize the number of I/Os (i.e., blocks or pages transferred) between the disk and main memory. One way to achieve this goal is to minimize the number of I/Os when answering queries. Note that many queries reference only a small portion of the records in a database table. For example the query: "*find the employees who reside in Santa Monica, CA*" references only a fraction of the records in the *Employee* relation. It would be rather inefficient to have the database system sequentially read all the pages of the *Employee* file and check the residence field of each employee record for the name '*Santa Monica*'. Instead the system should be able to locate the pages with '*Santa Monica*' employee records directly. To allow such fast access, additional disk-resident structures called *indices* (or *access methods*) are designed per database relation. One of the first such methods developed was the *index sequential access method* (ISAM). ISAM was developed at IBM in late 1960s [3] and it is essentially the predecessor to the widely used B+-tree index. A major difference between ISAM and the B+-tree [1] is that instead of overflowing pages, the B+-tree introduces page splitting. The ISAM was later replaced by IBMs *virtual storage access method* (VSAM) [4] which introduced the notion of splitting (data or index pages) when there is not enough space for inserting a new record.

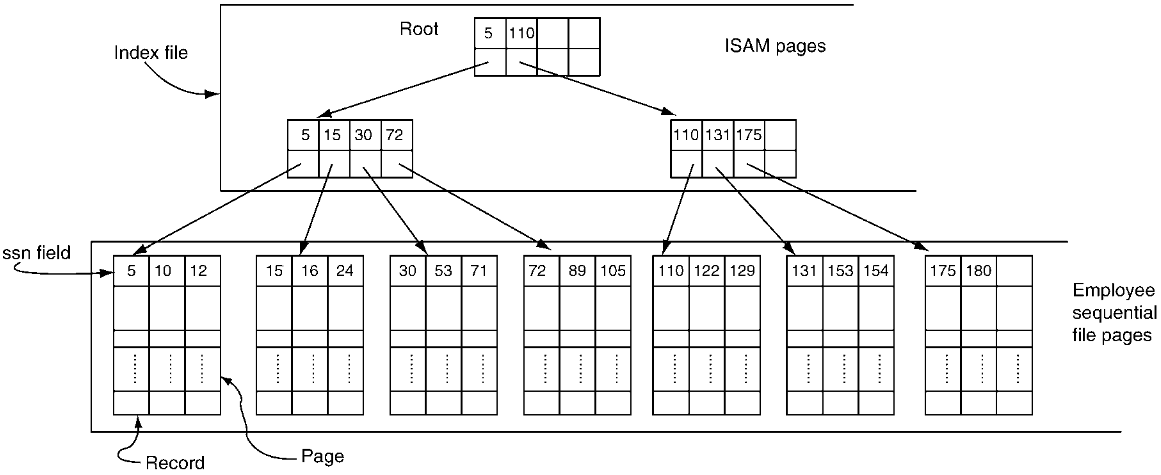
Foundations

The ISAM structure contains three separate storage areas: the data file, the index file and the overflow area. For simplicity, assume that the data file is an *Employee* relation, ordered according to the social security number or *ssn* attribute. Moreover, assume that this relation is stored sequentially on the disk, following the logical order of the *ssn* attribute. If the *Employee* file has n records and one page can hold B *Employee* records, the total number of pages in this file is $O(n/B)$. Note that each file page is full of *Employee* records except possibly the last page. Moreover, given the sequential storage of the file, each page can easily access the next page of the file in *ssn* order (it is simply the next physical page on the disk).

A straightforward way to build an index on the *Employee* file is to create a new (much smaller) file that contains one representative record from each *Employee* file page. The records in this new file are of the form: <*search_value, ptr*> where *ptr* is a pointer to an *Employee* file page (a *page-id* number uniquely identifying the page on the disk) and *search_value* is the smaller *ssn* recorded in that page. Since these records are smaller in size than the *Employee* file records, each page of the new file will contain many of them. If the *Employee* file is large, the new file will spread over a number of pages (this number is clearly bounded by $O(n/B^2)$). However, since the new file is also an ordered file (it has two attributes and is ordered according to the *search_value* attribute) it can be indexed by another (even smaller) level of index pages, and so on. This process continues until the creation of an index layer that consists of a single page. As a result a multi-way, tree-structured index is created whose nodes correspond to pages (see Fig. 1). It is worth pointing out that all index pages from possibly multiple index levels are resident in the index file area of the ISAM.

The ISAM organization is a single-dimensional (as opposed to multi-dimensional) index. It supports searches on the attribute (or collection of attributes) on which the data file is ordered. For example, searching the *indexed sequential access method* for a given *ssn* K (i.e., a membership query) is simple. The search starts from the root page where the record with the largest *search_value* that is less or equal to K is located. The search then continues to the page in the next index level, pointed by this record, until a page of the *Employee* file is reached. If K is found among the *ssn* values of that *Employee* page, the appropriate record is returned as answer to the query. If K is not found the answer is empty. It is easy to see that this search takes $O(logB(n/B))$ page accesses (I/Os) as this is the height (in pages) of the tree. The reader should note that the logarithm is base B, the size of the page, since this is a multi-way tree where each node has $O(B)$ fan-out.

Range queries (as in: *find the Employee records with ssn in the range* [25, 100]) are addressed similarly. A search is first performed for the *ssn* defining the lower part of the range (in the above query example this would be *ssn* = 25). This look-up will lead to an appropriate *Employee* record located in some file page. Records with higher *ssn* values within this page



Indexed Sequential Access Method. Figure 1. An indexed sequential access method.

are accessed until a record with *ssn* larger than the upper limit of the query range is found. If the upper limit of the query range is higher than the highest *ssn* in this page, the next page of the file is accessed and so on (recall that the file is stored sequentially). The search stops when an *Employee* page is found that contains a record with *ssn* larger than the query range.

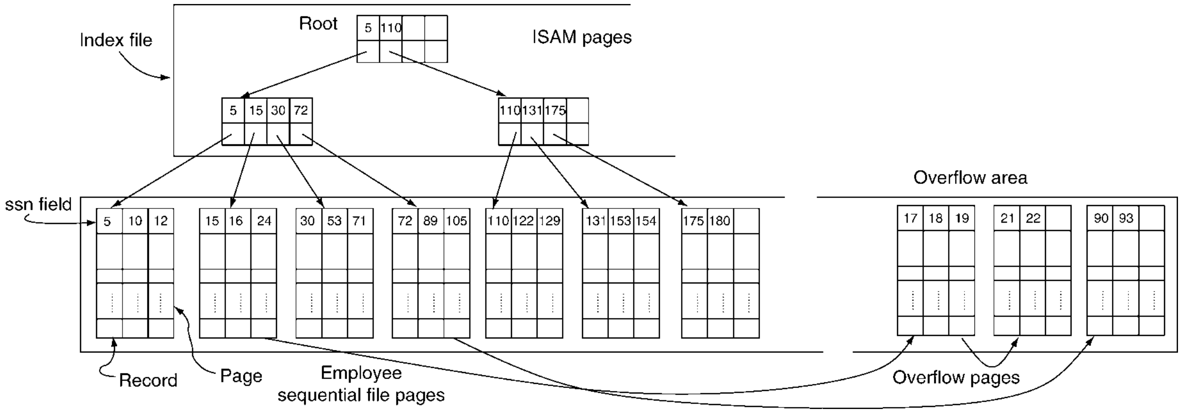
If a denotes the answer size to a range query (number of *Employee* records satisfying the query range predicate), ISAM answers a range query in $O(logB(n/B)+a/B)$ I/Os. Note that the logarithmic part is spent to find the *Employee* page with the first record that satisfies the query predicate (if any) and the $O(a/B)$ part corresponds to accessing the rest of the *Employee* pages that contain answer.

While the use of the index greatly facilitates query time, there is of course a space overhead, since the access method itself uses pages to store its records. However, this overhead is minimal. The number of pages used by the index structure is still bounded by $O(n/B)$. This is because the first level uses at most $O(n/B^2)$ pages, the second at most $O(n/B^3)$ and so on.

An interesting observation is that an indexed sequential access method imitates binary search on a disk-based environment. However, given that at each node of the index a whole page is accessed, there are $O(B)$ choices (instead of just 2 in the binary search) at each node.

The main advantages of the ISAM organization are its simplicity, small space overhead and fast query time. The structure however is *static*. If new records are added in the Employee file they are handled in an *overflow* file. Since there is no empty space in the data file, overflow pages are created to store the new records. Such pages are typically chained to the page where a record should have been stored (see Fig. 2). Various proposals exist on how to handle the overflow file [2,4,5,6]. Nevertheless, the structure of the index does not change as the size of the data file changes. This eventually affects query time. The overflow file can be merged periodically with the main *Employee* file, at which time the index needs to be recreated. Similarly, if records are deleted in the original *Employee* file, pages may be left containing very few records which affects both storage and query time. These problems are solved by the B+-tree, which is a *dynamic* indexing scheme [1].

There are two main differences between ISAM and B+-tree: firstly, when a new page is created in the B+-tree, space is left to accommodate future insertions. In practice, a newly created page starts half empty so that it can store many new records before a structural re-organization is needed. If the page becomes full of records and a new record is directed to it, the page is split into two pages (that are half full). Secondly, a page in the B+-tree is not allowed to become scarce of records (unless it is the tree's root page). As a result, when a page is accessed, it is guaranteed to contain a minimum number of records. If due to deletions a pages record occupancy falls below the threshold (half the page size) the page is merged with another page so that the combination has enough records. Note that leaving pages half empty imposes additional space overhead for the B+-tree than the ISAM; however it



Indexed Sequential Access Method. Figure 2. The indexed sequential access method with overflows.

results into a very effective dynamic height-balanced indexing scheme.

Finally, ISAM can be considered as the tree-based index alternative to the static external hashing. Both schemes are static and overflow areas are used for additional records. Their major difference is that ISAM can perform both range and membership queries, while static external hashing is designed only for membership queries.

Key Applications

ISAM has been used in early database management systems as an index method to provide fast access to range and membership queries. It was later replaced by the VSAM structure [4] which introduced the notion of page splitting. Finally, the B+-tree was proposed as a dynamic indexing structure [1] and is now the standard access method in most relational database systems.

Indexing and Similarity Search

Synonyms

Data organization; Hierarchical data organization; Space segmentation; Space partitioning

Definition

Indexing refers to the process of efficient data organization. It is closely related to similarity search because it allows such costly operations over a large dataset of objects to be efficiently sped up. Indices (or indexes) are hierarchical structures that direct the search to the most promising part of the database, hence eliminating from examination a large portion of objects. One can make the analogy with phone books, where all entries are recorded in sorted alphabetical order; therefore search involves only the lookup at the relevant portion of the book.

Historical Background

Traditional indexing structures include the B-trees. However, B-trees organize the data based on a single attribute/feature. Many of todays multimedia data contain hundreds or thousands of features. As an example, a small B&W image of 50 × 50 pixels contains 2,500 points/features. In order to accommodate objects that contain more attributes, extensions to the indexing schemes have been presented. Such indexes include kd-trees [3], grid files [9], as well as R-trees [7] and its variants [2], and the various incarnations of metric trees (VP-trees [12], M-trees [6]). The ultimate goal of a successful index is to divide object space into areas with approximately equal density using a set of heuristics.

Indexes work on simplified representations of the original data, since they do not perform well for raw data with high dimensionalities. This phenonenon is known as the "curse of dimensionality", which means that for higher dimensionalities, the pruning power of the indices diminishes exponentially, and all sequences are eventually retrieved from the disk. Therefore, when an index is utilized, it is necessary to perform some data compression, also called dimensionality reduction, because this data compaction will boost the index performance.

After the raw data are compacted from the original dimensionality n to some lower dimensionality d, the compressed d-dimensional objects/points are stored in the index structure in order to expedite the search process.

Foundations

An index can facilitate the fast similarity search over the database of objects. Therefore, a user is posing a query object q against a database and is seeking the most similar (or k most similar) objects to the query q, for a given similarity measure that assesses the affinity between a pair of objects.

Index structures attribute their search efficiency to two factors:

1. *Effective space partitioning*. Similar objects are grouped at the same portion of the index, such that for a given query large parts of the database can be eliminated from examination.
2. *Usage of simplified versions of the data objects*. This shrinks significantly the index size, compared to the storage requirements of the original database. Therefore, search operations on the index are much faster than on the original uncompressed data.

Consider a large database of objects, over which fast search needs to be enabled. If objects are high-dimensional, they will first be simplified in order to be stored in an index. Techniques like PCA, Fourier or Wavelet transform, etc., can be utilized at this step. For this example, in order to enhance visualization, the database objects correspond to images. The images can be simplified and represented using two features: the "number of red pixels" and the "number of blue pixels". Using these features, each image will be represented as a point on a two-dimensional space. Given these projected dimensions, two sets of images depicting underwater and wildlife images will be clustered as shown in Fig. 1. The way this new space is partitioned and searched, depends on the specifics of the utilized index.

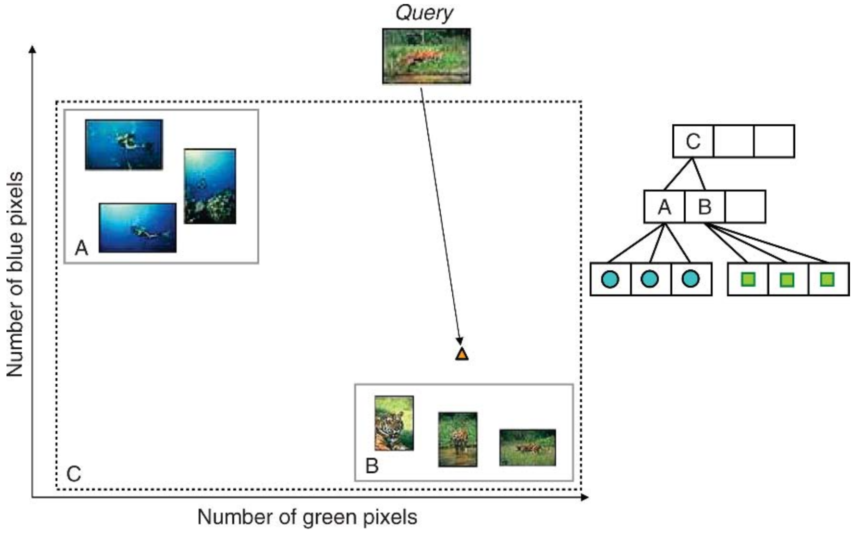
Key Applications

The following sections explain in more detail the inner-workings of widely used instances of index structures, such as the R-trees (space partitioning index) and the VP-trees (metric index).

R-Trees

The R-tree structure represents an extension of the B-tree for multiple dimensions. It has been proposed in 1984 by Antonin Guttman [7] and since then it has been utilized extensively in the database and data-mining fields.

A d-dimensional R-tree is a hierarchical structure of rectangles, with leaves and intermediate nodes. The leaves store d-dimensional hyper-rectangles



Indexing and Similarity Search. Figure 1. *Left*: Database of images and a potential two-dimensional representation. *Right*: The corresponding R-tree is a hierarchical structure of rectangles.

(or *d*-dimensional points) and a pointer to the object they describe. The intermediate nodes store a hyper-rectangle that completely contains the rectangles of their child-nodes, as well as pointers to the child-nodes.

In Fig. 1 a potential R-tree structure is depicted, based on the previously discussed example. Suppose now, that a query *q* is posed against the database of images. The query is mapped into a new point in the projected space (shown as a triangle in Fig. 1). For a *range search* one needs to find the overlapping rectangles within the requested search radius. for a *k-NN search* [10,11] one can define a `MINDIST` operator between a point and a rectangle and start traversing the tree according to the most promising path, while recording the remaining paths in a priority queue. The tree traversal can be either depth-first or breadth-first.

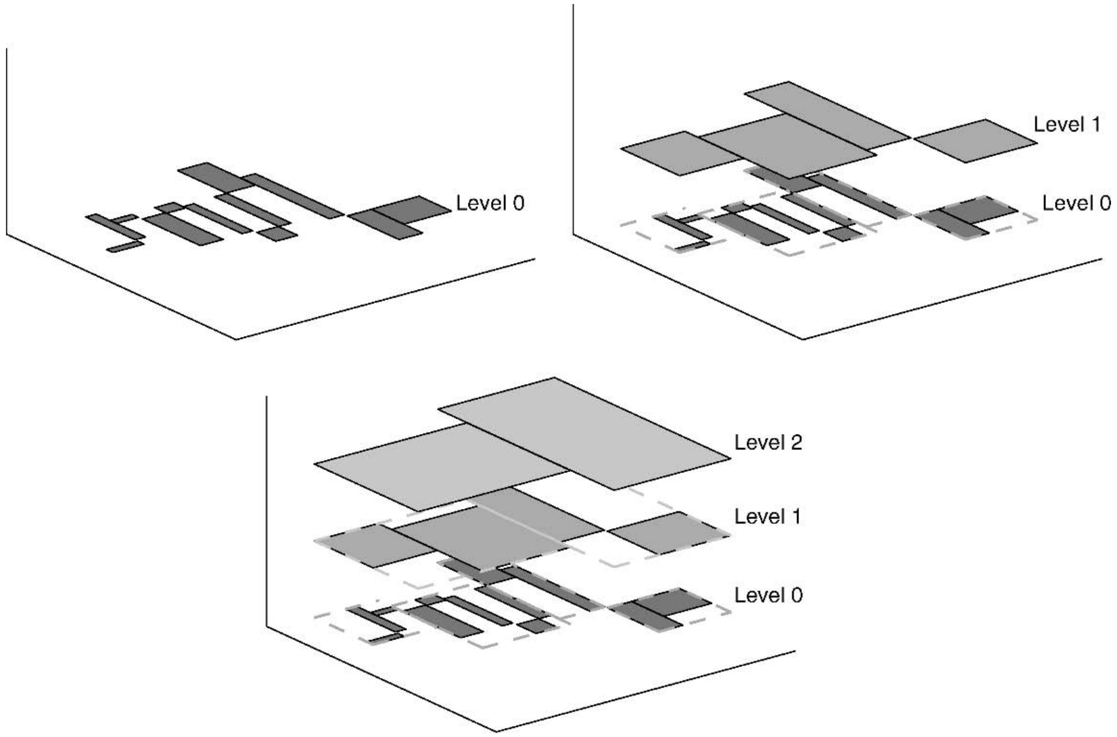
For example, if the user is seeking the 3-NN of the query *q*, then rectangle *C* will be pushed into the priority queue (see Fig. 1). It will be popped out and its children (*A* and *B*) will be pushed in and sorted according to their minimum distance to *q*. Subsequently, rectangle *B* will be examined first, because it is the closest one to the query. Its objects will be retrieved and their true distance to *q* shall be calculated. The search will end here, because the third closest neighbor found so far, has distance smaller than *MINDIST* (*q*, *Rectangle*(*A*)). Therefore, none of the objects of rectangle *A* need to be retrieved from disk.

Figure 2 demonstrates another example of the hierarchical structure of an R-tree.

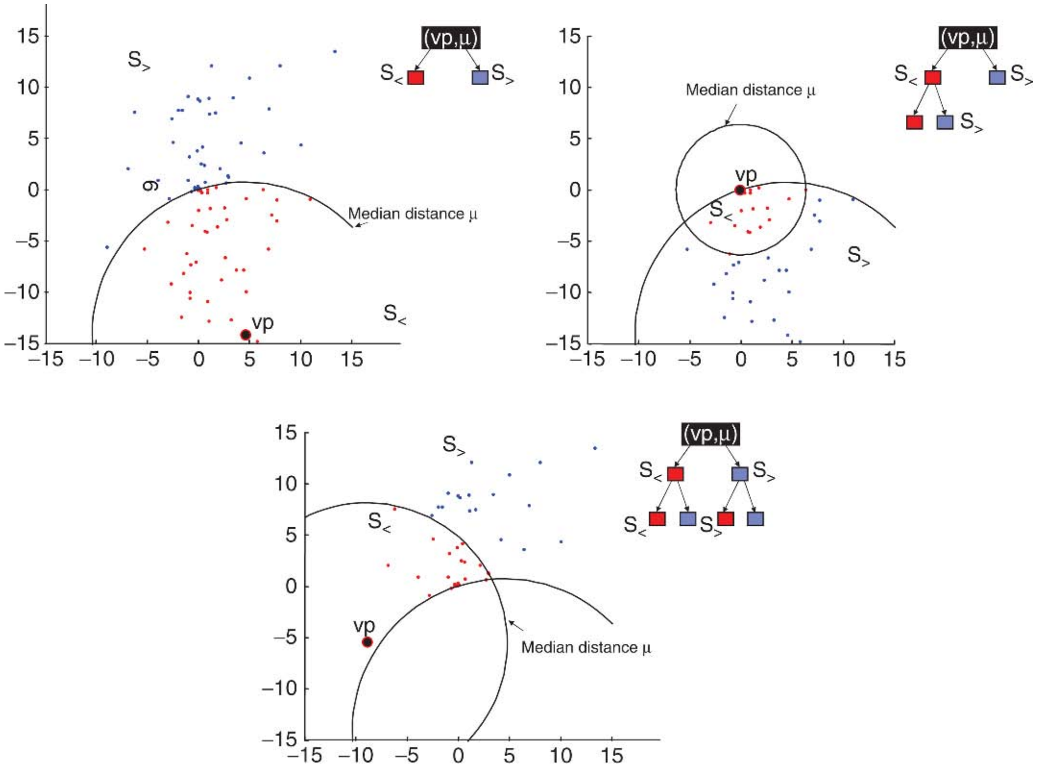
VP-Trees

According to the relevant bibliography, the pruning power of space partitioning indexing structures like R-trees, and its variants, degrades for data dimensionalities larger than 5–8. This means that at high dimensionalities the index will retrieve the majority of objects from the disk.

Metric trees exhibit better performance at larger dimensionalities (e.g., up to 20–25 dimensions). Metric trees utilize the distances between objects in order to create the tree and direct the search process. A popular instance of metric-trees are the VP-trees [4,5,12]. VP-trees partition the space based on distances to selected *vantage points* of the dataset. A tree containing the objects is constructed by recursively partitioning the dataset points into two distinct sets based on the median distance μ to the vantage point/object; the points that are closest to the vantage point ($S_<$) are stored on the left subtree, and those that are further away from the median distance ($S_>$) are directed on the right subtree. The process is repeated recursively and a different vantage point is selected for each of the remaining subsets. Figure 3



Indexing and Similarity Search. Figure 2. Bottom-up hierarchical construction of the two-dimensional R-tree.



Indexing and Similarity Search. Figure 3. Illustration of the creation of a VP-tree.

illustrates this process on two-dimensions for clarity (each point essentially represents one object).

After the tree is constructed and a query is posed, one only has to examine the proper subset based on the position of the query. Only if the query lies close to the median distance, both subsets need to be examined, otherwise one of them is discarded from examination.

Indexing Compressed Text

Paolo Ferragina, Rossano Venturini
University of Pisa, Pisa, Italy

Synonyms

Compressed full-text indexing; Compressed suffix array; Compressed suffix tree; Compressed and searchable data format

Definition

Given a text $T[1,n]$, the *Compressed Text Indexing* problem requires to building an indexing data structure over T that takes space close to the empirical entropy of the input text and answers queries on the occurrences of an arbitrary pattern $P[1,p]$ in T without any significant slowdown with respect to uncompressed indexes. There are three main queries: `count`(P), that returns the number of pattern occurrences in T, `locate`(P), that returns the starting positions of all pattern occurrences in T, and `extract`(i, j), that retrieves the substring $T[i, j]$.

Historical Background

String processing and searching tasks are at the core of modern web search, information retrieval (IR), data base and data mining applications. Most of text manipulations required by these applications involve, sooner or later, *searching* those (long) texts for (short) patterns or *accessing* portions of those texts for subsequent processing/mining tasks. Despite the increase in processing speed of current CPUs and memories/disks, sequential text searching long ago ceased to be a viable approach, and indexed text searching has become mandatory.

A *(full-)text index* is a data structure built over a text $T[1,n]$, drawn from an alphabet Σ of size σ, which significantly speeds up sequential searches for *arbitrary* pattern strings, at the cost of some additional space. *Suffix trees* and *suffix arrays* are the most well-known full-text indexes [5]. The *suffix tree* of a text T is a trie (or digital tree) built on all the n text suffixes $T[i, n]$, where unary paths are compacted to ensure $O(n)$ overall size. The suffix tree has n leaves, one per text suffix, and each internal node corresponds to a unique substring of T that occurs more than once. The suffix tree can count the *occ* occurrences of any pattern $P[1,p]$ in time $O(p)$ by descending in the suffix tree according to the symbols of P, and it can locate these occurrences in optimal $O(occ)$ time by traversing the subtree of the node reached by counting. The suffix tree, however, uses much more space than the text itself because it requires $\Theta(n \log n)$ bits, whereas the text needs $n\lceil \log \sigma \rceil$ bits (logarithms are in base 2). In practice, a suffix tree requires from 10 to 20 times the text size, if carefully engineered [5].

The *suffix array* is a compact version of the suffix tree, obtained by storing in $SA[1,n]$ the starting positions of the suffixes of T listed in lexicographical order. This data structure still requires $\Theta(n \log n)$ bits in the worst case, but the constant hidden in the big-Oh notation is small in practice, namely it is no more than 4. SA can be obtained by traversing the leaves of the suffix tree, or it can be built directly in optimal linear time via ad-hoc sorting methods [5]. Since any substring of T is the prefix of a text suffix, finding all pattern occurrences boils down to finding all text suffixes that start with P. These suffixes form a lexicographic interval in SA that can be binary searched in $O(p \log n)$ time, as each comparison in the binary search requires examining up to p symbols of the pattern and of a text suffix. The time complexity can be improved to $O(p + \log n)$ by using an auxiliary data structure that doubles the space requirement of the suffix array, or it can be further reduced to $O(p + \log \sigma)$ by a proper sampling of the indexed suffixes (cfr. Suffix Trays). Once the interval $SA[sp,ep]$ containing all text suffixes starting with P has been identified, `count`(P) is answered by returning the value $occ = ep - sp + 1$, and `locate`(P) is answered by retrieving the entries $SA[sp]$, $SA[sp + 1]$,...,$SA[ep]$.

The use of full-text indexes is not limited to (full-) text searching over one single text. It can be easily extended to multiple texts, and can also be used to support (prefix, suffix, or substring) queries over a dictionary $\mathcal{D}$ of strings having variable length. This problem is called *Dictionary Indexing* and occurs frequently in the implementation of IR and data mining applications. It can be solved via a (compressed) index built on a string S_D which is obtained by concatenating all dictionary strings, separated with a special symbol #. A prefix search for P in $\mathcal{D}$ can be implemented by counting/locating the query pattern #P in S_D; a suffix search can be implemented by searching for P# in S_D; substring searches are directly executed on S_D.

Foundations

The large space occupancy of full-text indexes has driven programmers to resort to inverted indexes to solve their searching operations on large textual datasets, and some researchers have actually concluded that the increased query power of full-text indexes has to be paid by additional storage space. Fortunately, a recent body of research showed that *compressed* full-text indexes can be designed by deploying algorithmic techniques and mathematical tools which lie at the crossing point of three distinct fields – data compression, algorithmics and databases (see e.g., [9,13,14]). Most of these indexes can be classified into two families – FM-indexes (FMI) and Compressed Suffix Arrays (CSA) – and achieve efficient query times and space close to the one achievable by the best known compressors, like gzip or bzip2. In theory, these indexes require $O(nH_k(T)) + o(n \log \sigma)$ bits of space, where $H_k(T)$ is the kth order empirical entropy of T (see Table 1). This bound is appealing because it can be sublinear in n, for highly compressible texts, and $nH_k(T)$ is the classic Information-Theoretic lower bound to the storage complexity of T by means of any kth order compressor, like gzip and bzip2 (recall that `extract`$(1,n) = T$).

The FM-Index Family

These compressed indexes were introduced by Ferragina and Manzini in [9], who devised a way to orchestrate in efficient time and space the relation that exists between the suffix array data structure and the *Burrows-Wheeler Transform* (shortly, BWT [4]). The BWT is a reversible transformation that permutes the symbols of the input string T into a new string `bwt`(T) which is easier to compress, and can be computed in three steps (see Fig. 1):

1. Append at the end of T a special symbol \$ smaller than any other symbol of Σ;
2. Form a *conceptual* matrix $\mathcal{M}(T)$ whose rows are the cyclic rotations of string $T\$$ in lexicographic order;
3. Set string `bwt`(T) to the last column L of the sorted matrix $\mathcal{M}(T)$.

Every column of $\mathcal{M}(T)$, hence also the transformed string L, is a permutation of $T\$$. In particular the first column of $\mathcal{M}(T)$, call it F, is obtained by lexicographically sorting the symbols of $T\$$ (or, equivalently, the symbols of L). Note that the sorting of the rows of

Indexing Compressed Text. Table 1. Best known complexities for the time (in big-Oh) and space (in bits) required by the main families of compressed full-text indexes

Indexing Compressed Text. Figure 1. Example of Burrows-Wheeler transform for T = mississippi. The matrix on the right has the rows sorted in lexicographic order. The output of the BWT is the column L = ipssm$pissii.

$\mathcal{M}(T)$ is essentially equal to the sorting of the suffixes of T, because of the presence of the special symbol \$. This shows that: (i) symbols preceding the same substring (*context*) in T are grouped together in L, and thus give raise to clusters of nearly identical symbols; (ii) there is an obvious relation between $\mathcal{M}(T)$ and SA. Property (1) is the key for devising modern data compressors, Property (2) is crucial for designing compressed indexes and, additionally, suggests a way to compute the BWT through the construction of the suffix array of T: $L[0] = T[n]$ and, for any $1 \le i \le n$, set $L[i] = T[SA[i] - 1]$.

Burrows and Wheeler [4] devised two properties for the invertibility of the BWT:

1. Since the rows in $\mathcal{M}(T)$ are cyclically rotated, $L[i]$ *precedes* $F[i]$ in the original string T.
2. For any $c \in \Sigma$, the ℓth occurrence of c in F and the ℓth occurrence of c in L correspond to the *same* symbol of the string T.

As a result, the original text T can be obtained backwards from L by resorting to a function LF that maps row indexes to row indexes, and is defined as follows: if the BWT maps $T[j-1]$ to $L[i']$ and $T[j]$ to $L[i]$, then $LF(i) = i'$ (so LF implements a sort of *backward* step over T) [9]. Now, since the first row of $\mathcal{M}(T)$ is \$T, it can be stated that $T[n] = L[0]$ and, in general, $T[n-i] = L[LF^i(0)]$, for $i = 1,\ldots,n-1$.

Starting from these basic properties, Ferragina and Manzini [9] proposed a way to combine the compressibility of the BWT with the indexing power of the suffix array. In particular, they have shown that searching operations on T can be reduced to counting queries of *single* symbols in L, now called rank operations. For any symbol $c \in \Sigma$ and position i in L, the query $\mathtt{rank}_c(L, i)$ returns how many times the symbol c appears in $L[1,i]$. An FM-index then consists of three key tools: a compressed representation of $\mathtt{bwt}(T)$ that supports efficient rank queries, a small array $C[c]$ which tells how many symbols smaller than c appear in T (this takes $O(\sigma \log n)$ bits), and the so called *backward search* algorithm which carefully orchestrates the former two data structures in order to implement efficiently the count query. More precisely, FMI searches the pattern $P[1,p]$ backwards in p steps, which eventually identify the interval of text suffixes that are prefixed by P or, equivalently, the interval of rows of $\mathcal{M}(T)$ that are prefixed by P. This is done by maintaining, inductively for $i = p, p-1,\ldots,1$, the interval $SA[sp_i, ep_i]$ that stores all text suffixes that are prefixed by the pattern suffix $P[i, p]$. At the beginning it is $i = p$, and so $SA[sp_p, ep_p]$ corresponds to all suffixes which are prefixed by the last symbol $P[p]$: hence, it is enough to set $sp_p = C[P[p]] + 1$ and $ep_p = C[P[p] + 1]$. At any other step, the algorithm has inductively computed $SA[sp_{i+1}, ep_{i+1}]$, and thus it can derive the next interval of suffixes prefixed by $P[i, m]$ by setting $sp_i = C[P[i]] + \mathtt{rank}_{P[i]}(L, sp_{i+1} - 1) + 1$ and $ep_i = C[P[i]] + \mathtt{rank}_{P[i]}(L, ep_{i+1})$. These two computations are actually mapping (via *LF*) the first and last occurrences (if any) of symbol $P[i]$ in the substring $L[sp_{i+1}, ep_{i+1}]$ to their corresponding occurrences in *F*. (Indeed, [9] showed that any *LF* computation boils down to a `rank` query on *L*.) As a result, the backward-search algorithm requires to solve $2p$ rank queries on $L = \mathtt{bwt}(T)$ in order to find out the (possibly empty) range $SA[sp, ep]$ of text suffixes prefixed by *P*. `count`(P) can be then solved by returning the value $occ = ep_1 - sp_1 + 1$.

Conversely, `locate` and `extract` need some extra information about the underlying suffix array, this impacts onto the space occupancy of the FMI. Recall that `locate`(P) requires to return, for any $i \in [sp, ep]$, the position $pos(i) = SA[i]$. For space reasons *SA* cannot be stored explicitly so that, for a fixed parameter $\mu = \lceil \log^{1+\in} n \rceil$, FMI samples the rows of $\mathcal{M}(T)$ which correspond to text suffixes that start at positions of the form $1 + j \cdot \mu$. Each such pair ⟨row, position⟩ is stored explicitly in a data structure $\mathcal{S}$ that supports membership queries in constant time (on the *row*-component). Now, given a row index *i*, the value $pos(i)$ can be derived immediately from $\mathcal{S}$, if *i* is a sampled row; otherwise, the algorithm computes $j = LF^t(i)$, for $t = 1,2,\ldots,$ until *j* is a sampled row. In this case, $pos(i) = pos(j) + t$. The sampling strategy ensures that a row in $\mathcal{S}$ is found in at most μ iterations, and thus the *occ* occurrences of the pattern *P* can be located via $O(\mu \cdot occ)$ `rank` queries. The algorithm for `extract`(i,i') requires a similar approach and takes no more than $(i' - i + \mu + 1)$ rank queries.

The net result is that the space and time complexities of FMI depend on the value μ and on the performance guaranteed by the data structure used to compute rank queries on the BWT-string. The extra space required by the data structures added to support `locate` and `extract` is bounded by $O((n \log n)/\mu)$ bits, which is $o(n)$ whenever $\in > 0$. The real challenge thus consists of representing $\mathtt{bwt}(T)$ in a compressed form and answering efficiently rank queries over it. Actually, all implementations of FMI differentiate themselves by the strategy used to solve this problem, as the alphabet size grows. Today, the literature offers many solutions, the most efficient ones are summarized below.

Lemma 1 *Let* $T[1,n]$ *be a string over an alphabet of size* σ, *and let* $L = \mathtt{bwt}(T)$.

1. For $\sigma = O(\mathtt{polylog}(n))$, *there exists a data structure which supports* `rank` *queries on L in* $O(1)$ *time using* $nH_k(T) + o(n)$ *bits of space, for any* $k \leq \alpha \log_\sigma n$ *and* $0 < \alpha < 1$, *and retrieves any symbol of L in the same time bound* [10, *Theorem 5*].
2. *For general* Σ, *there exists a data structure which supports* `rank` *queries on L in* $O(\log \log \sigma)$ *time, using* $nH_k(T) + n\ o(\log \sigma)$ *bits of space, for any* $k \leq \alpha \log_\sigma n$ *and* $0 < \alpha < 1$, *and retrieves any symbol of L in the same time bound* [2, *Theorem 4.2*].

By plugging this Lemma into the FMI data structure, one derives a compressed full-text index that supports efficiently the three full-text queries – namely, `count`, `locate`, `extract`– and occupies space approaching the *k*th order empirical entropy of *T* (see Table 1).

In practice, there are various implementations of FMI, whose engineering choices mainly refer to the way the `rank`-data structure built on $\mathtt{bwt}(T)$ is compressed and scales with the alphabet size of the indexed text. The site Pizza&Chili (see below) reports several implementations for FMI that mainly boil down to the following trick: $\mathtt{bwt}(T)$ is split into blocks (of equal or variable length) and values of $\mathtt{rank}_c$ are precomputed for all block beginnings and all symbols $c \in \Sigma$. A query $\mathtt{rank}_c(L, i)$ is answered by summing up the answer available for the beginning of the block that contains $L[i]$ plus the rest of the occurrences of *c* in that block – they are obtained either by sequentially decompressing the block or by using a proper compressed data structure built on it (e.g., the Wavelet Tree of [12]). The former approach favors compression, the latter favors query speed.

The CSA family. These compressed indexes were introduced by Grossi and Vitter [13], who showed how to compactly represent the suffix array *SA* in O(n log σ) bits and still be able to access any of its entries in efficient time. Their solution is based on a function Ψ, which is the inverse of the function LF introduced for BWT:

$$\Psi(i) = \begin{cases} i' \textit{such that } SA[i'] = SA[i] + 1 & (\textit{if } SA[i] > n) \\ i' \textit{such that } SA[i'] = 1 & (\textit{if } SA[i] = n) \end{cases}$$
