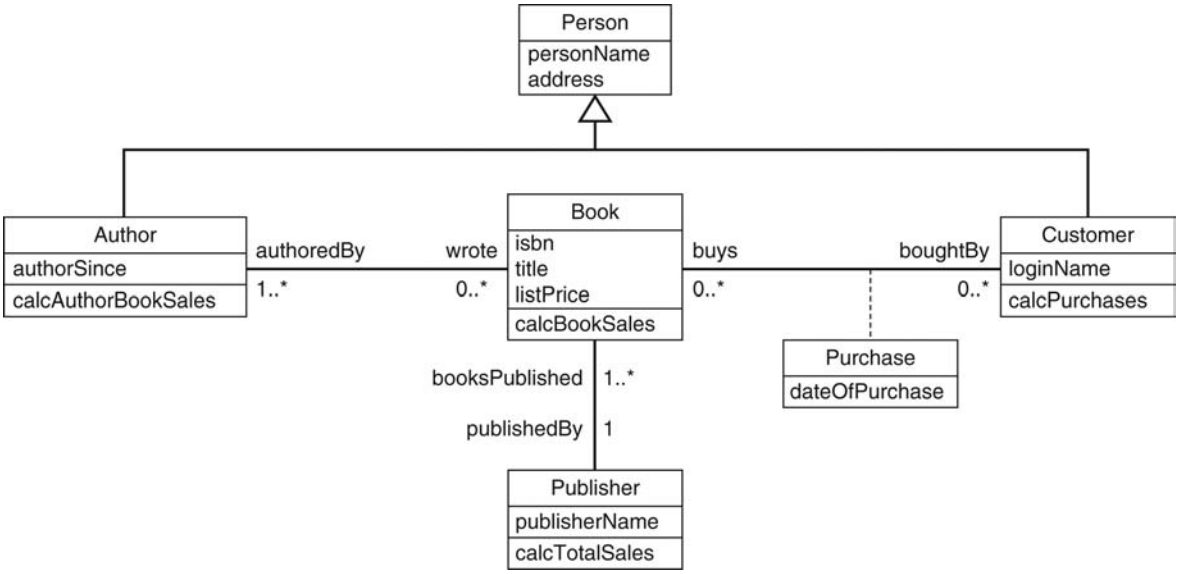
Classes in an object model can be organized into class hierarchies, defining superclass and subclass relationships between classes. A class hierarchy allows for the inheritance of the state and behavior of a class, allowing subclasses to inherit the properties and methods of its superclasses while extending the subclass with additional properties or behavior that is specific to the subclass. Inheritance hierarchies provide a powerful mechanism to represent generalization/specialization relationships between classes, which simplify the specification of an object schema, as well as queries over the schema.

As an example of the above concepts, consider the Publisher application described in Fig. 1 using a Unified Modeling Language (UML) class diagram [11]. A Book is a class that is based on an object type that defines the state of a book (isbn, title, and listPrice), as well as the behavior of a book (the method calcBookSales for calculating the total sales of a book based on customer purchases). Publisher, Person, Author, and Customer are additional classes, also having state and behavior. Since authors and customers are specific types of people, the Author and Customer classes are defined to be subclasses of Person. Since personName and address are common to authors and customers, these attributes are defined at the Person level and inherited by instances of the Author and Customer classes. Furthermore, Author introduces additional state and behavior that is specific to authors, defining the date (authorSince) when an author first wrote a book as well as a method (calcAuthorBookSales) for calculating the total sales of the author's books. The Customer class similarly introduces state and behavior that is specific to a customer.

Relationships are also defined between the classes of the application:

- A book is authored by one or more authors; an author writes many books
- A book is published by one publisher; a publisher publishes many books
- A book is bought by many customers; a customer buys many books, also recording the date of each purchase



Object Data Models. Figure 1. The publisher object data model.

For each relationship, specific instances of each class are related based on the object identity of each instance. For example, a book will establish a relationship to the publisher of the book using the oid of the publisher. In the relational model, the publisher name would be used as a foreign key to establish the relationship. If the publisher name changes, then the change in name must be propagated to the book that references the publisher. In the object data model, such changes in state do not affect relationships between objects since the relationship is based on an immutable, internal object identity.

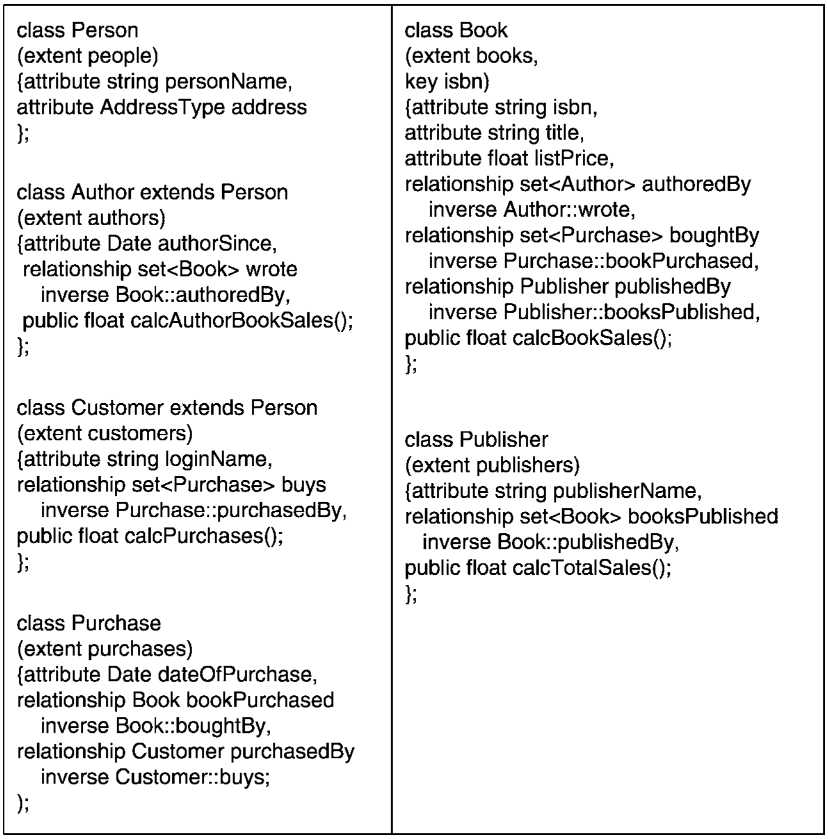
A generic object model, such as the one shown in Fig. 1, can be mapped to either an object-oriented data model or an object-relational data model. The following subsections use the Publisher application in Fig. 1 to illustrate and explain OODB and ORDB approaches to object data modeling.

Object-Oriented Data Model

An object-oriented database (OODB) is a term typically used to refer to a database that uses objects as a building block and an object-oriented programming language as the database language. The database system supports the persistence of objects along with the features of concurrency and recovery control with efficient access and an ad hoc query language.

The Object Data Standard [2] developed as a standard to describe an object model, including a definition language for an object schema, and an ad-hoc query language. The object model supports the specification of classes having attributes and relationships between objects and the behavior of the class with methods. The Object Definition Language (ODL) provides a standard language for the specification of an object schema including properties and method signatures. A property is either an attribute, representing an instance field that describes the object, or a relationship, representing associations between objects. In ODL, relationships represent bidirectional associations with the database system being responsible for maintaining the integrity of the inverse association. An attribute can be used to define a unidirectional association. If needed, the association can be derived in the other direction using a method specification. The decision is based on trade-offs of storing and maintaining the association versus deriving the inverse direction on demand.

Fig. 2 provides an ODL specification of the Publisher application. Each class has a named extent, which represents the set of objects of that type. The Author and Customer classes inherit from the Person class, extending each subclass with specialized attributes. The Book class has the isbn attribute that forms a key, being a unique value across all books. The association between Author and Book is represented as an inverse relationship, and the cardinality of the association is many-to-many since an author can write many books and a book can be written by multiple authors. The set collection type models multiple



```
class Person
(extent people)
{attribute string personName,
attribute AddressType address
};

class Author extends Person
(extent authors)
{attribute Date authorSince,
 relationship set<Book> wrote
    inverse Book::authoredBy,
 public float calcAuthorBookSales();
};

class Customer extends Person
(extent customers)
{attribute string loginName,
relationship set<Purchase> buys
    inverse Purchase::purchasedBy,
public float calcPurchases();
};

class Purchase
(extent purchases)
{attribute Date dateOfPurchase,
relationship Book bookPurchased
    inverse Book::boughtBy,
relationship Customer purchasedBy
    inverse Customer::buys;
);
```

```
class Book
(extent books,
key isbn)
{attribute string isbn,
attribute string title,
attribute float listPrice,
relationship set<Author> authoredBy
   inverse Author::wrote,
relationship set<Purchase> boughtBy
   inverse Purchase::bookPurchased,
relationship Publisher publishedBy
   inverse Publisher::booksPublished,
public float calcBookSales();
};

class Publisher
(extent publishers)
{attribute string publisherName,
relationship set<Book> booksPublished
   inverse Book::publishedBy,
public float calcTotalSales();
};
```

Object Data Models. Figure 2. ODL schema of the publisher application.

books and authors. Since the Purchase association class from Fig. 1 has an attribute describing the association, Purchase is modeled in ODL using reification, which is the process of transforming an abstract concept, such as an association, into a class. As a result, the Purchase class in Fig. 2 represents the many-to-many association between Book and Customer. Each instance of the Purchase class represents the purchase of a book by a customer. The Purchase class has the dateOfPurchase instance field, as well as two relationships indicating which Book (bookPurchased) and which Customer (purchasedBy) is involved in the purchase. The inverse relationships in Book (boughtBy) and Customer (buys) are related to instances of the Purchase class.

This ODL specification forms the basis of the definition of the object schema within the particular OOPL used with the OODB, such as C++, Java, and Smalltalk. The specification of the schema and the method implementation using a given OOPL is known as a language binding. In some OODB products, the ODL specification of the properties of the class are used to automatically generate the definition of the schema for the OOPL being used.

The standard also includes a declarative query language known as the Object Query Language (OQL). The OQL is based on the familiar select-from-where syntax of SQL. The select clause defines the structure of the result of the query. The from clause specifies variables that range over collections within the schema, such as a class extent or a multivalued property. The where clause provides restrictions on the properties of the objects that are to be included in the result. Object references are traversed through the use of dot notation for single-valued properties and through the from clause for multivalued properties.

Consider a simple query that finds the name of a publisher of a book given its isbn:

```
select b.publishedBy.publisherName
from books b
where b.isbn = "0-13-042898-1";
```

This OQL query looks quite similar to SQL. In the from clause, the alias b ranges over the books extent.

The where clause locates the book of interest. The select clause provides a path expression that navigates through the publishedBy single-valued property to return the name of the publisher.

Consider another query that finds the title and sales for books published by Springer-Verlag:

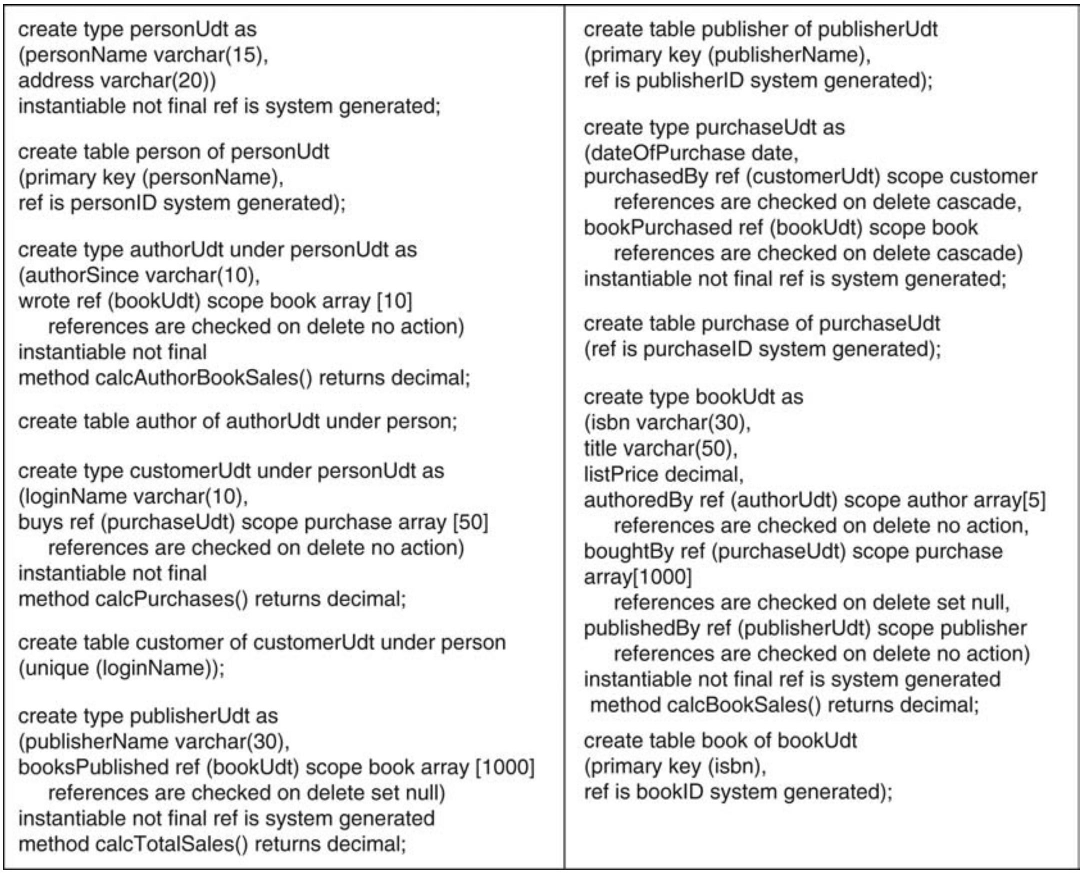
```
select title: b.title, sales: b.calcBookSales()
from p in publishers, b in p.booksPublished
where p.publisherName = ‘‘Springer-Verlag’’
```

This query illustrates the alternative syntax for the alias in the from clause, using the syntax "variable in collection". The alias p ranges over the publishers extent, whereas the alias b ranges over the multivalued relationship booksPublished of each publisher that satisfies the where condition. The select clause returns the name of each field and its value, where sales returns the results of a method call.

Object-Relational Data Model

An object-relational database (ORDB) refers to a relational database that has evolved by extending its data model to support user-defined types along with additional object features. An ORDB supports the traditional relational table in addition to introducing the concept of a typed table, which is similar to a class in an OODB. A typed table is created based on a user-defined type (UDT), which provides a way to define complex types with support for encapsulation. UDTs and their corresponding typed tables can be formed into class hierarchies with inheritance of state and behavior. The rows (or instances) of a typed table have object identifiers that are referred to as object references. Object references can be used to define relationships between tables that are based on object identity.

Figure 3 presents an ORDB schema of the Publisher application that is defined using the object-relational extensions to the SQL standard. The type personUdt is



```
create type personUdt as
(personName varchar(15),
address varchar(20))
instantiable not final ref is system generated;

create table person of personUdt
(primary key (personName),
ref is personID system generated);

create type authorUdt under personUdt as
(authorSince varchar(10),
wrote ref (bookUdt) scope book array [10]
   references are checked on delete no action)
instantiable not final
method calcAuthorBookSales() returns decimal;

create table author of authorUdt under person;

create type customerUdt under personUdt as
(loginName varchar(10),
buys ref (purchaseUdt) scope purchase array [50]
   references are checked on delete no action)
instantiable not final
method calcPurchases() returns decimal;

create table customer of customerUdt under person
(unique (loginName));

create type publisherUdt as
(publisherName varchar(30),
booksPublished ref (bookUdt) scope book array [1000]
   references are checked on delete set null)
instantiable not final ref is system generated
method calcTotalSales() returns decimal;

create table publisher of publisherUdt
(primary key (publisherName),
ref is publisherID system generated);

create type purchaseUdt as
(dateOfPurchase date,
purchasedBy ref (customerUdt) scope customer
   references are checked on delete cascade,
bookPurchased ref (bookUdt) scope book
   references are checked on delete cascade)
instantiable not final ref is system generated;

create table purchase of purchaseUdt
(ref is purchaseID system generated);

create type bookUdt as
(isbn varchar(30),
title varchar(50),
listPrice decimal,
authoredBy ref (authorUdt) scope author array[5]
   references are checked on delete no action,
boughtBy ref (purchaseUdt) scope purchase
array[1000]
   references are checked on delete set null,
publishedBy ref (publisherUdt) scope publisher
   references are checked on delete no action)
instantiable not final ref is system generated
 method calcBookSales() returns decimal;

create table book of bookUdt
(primary key (isbn),
ref is bookID system generated);
```

Object Data Models. Figure 3. ORDB schema of publisher application.

an example of specifying a UDT. The UDT defines the structure of the type by identifying attributes together with their type definitions. The phrase "instantiable not final ref is system generated" defines three properties of the type:

1. "Instantiable" indicates that the type supports a constructor function for the creation of instances of the type. The phrase "not instantiable" can be used in the case where the type has a subtype and instances can only be created at the subtype level.
2. "Not final" indicates that the type can be specialized into a subtype. The phrase "final" can be used to indicate that a type cannot be further specialized.
3. "Ref is system generated" indicates that the database system is responsible for automatically generating an internal object identifier. The SQL standard supports other options for the generation of object identifiers, which include user-specified object-identifiers as well as identifiers that are derived from other attributes.

Definition of the personUdt type is followed by the specification of the person typed table, which is based on the personUdt type. The person typed table automatically acquires columns for each of the attributes defined in personUdt. In addition, the person typed table has a column for an object identifier that is associated with every row in the table. The phrase "ref is personID" defines that the name of the object identifier column is personID. The definition of a typed table can add constraints to the columns that are defined in the type associated with the table. For example, personName is defined to be a primary key in the person typed table.

The authorUdt type is defined as a subtype of personUdt, as indicated by the "under personUdt" clause. In addition to defining the structure of the type, authorUdt also defines behavior with the definition of the calcAuthorBookSales method. Since authorUdt is a subtype of personUdt, authorUdt will inherit the object identifier (personID) defined in personUdt. For consistency, the author table is also defined to be a subtable of the person object table. The typed table hierarchy therefore parallels the UDT hierarchy. In a similar manner, customerUdt is defined to be a subtype of personUdt and the customer typed table, based on customerUdt, is defined to be a subtable of the person table. UDTs and typed tables are also defined for the Book and Publisher classes from Fig. 1, as well as the (reified implementation of the) Purchase association class.

Figure 3 also illustrates the use of object references to represent identity-based relationships between UDTs. Recall from the object data model in Fig. 1 that a book is published by one publisher; a publisher publishes many books. In an ORDB, this relationship is established through the use of reference types. In the bookUdt, the publishedBy attribute has the type ref (publisherUdt), indicating that the value of publishedBy is a reference to the object identifier (publisherID) of a publisher. In the inverse direction, the type of booksPublished in the publisherUdt is an array of ref(bookUdt), indicating that booksPublished is an array of object references to books. Each attribute definition includes a scope clause and a "references are checked" clause. Since a UDT can be used to define multiple tables, the scope clause defines the table of the object reference. The references clause specifies the same options for referential integrity of object references as originally defined for traditional relational tables.

To establish the fact that a book is published by a specific publisher, the object identifier of publisher is retrieved to create the relationship:

```
update book
set publishedBy = (select publisherID
                   from publisher
                   where publisherName =
                   ''Prentice Hall'')
where isbn = ''0-13-042898-1'';
```

A similar update statement can be used to establish the relationship in the inverse direction by adding the book oid to the array of object references of the publisher.

References can be traversed to query information about relationships. For example, to return the name of the publisher of a specific book, the following query can be used:

```
select publishedBy.publisherName
from book
where isbn = ''0-13-042898-1'';
```

The dot notation in the select clause performs an implicit join between the book table and the publisher table, returning the name of the publisher. The deref() function can also be used to retrieve the entire structured type associated with a reference value. For example, the following query will return the full instance of the publisherUdt type, rather than just the publisherName:

```
select deref(publishedBy)
from book
where isbn = ‘‘0-13-042898-1’’;
```

In this case, the result of the query is a value of type publisherUdt, containing the publisher name and the array of references to books published by the publisher.

Definition

Object identity is a property of data that is created in the context of an object data model, where an object is assigned a unique internal object identifier, or oid. The object identifier is used to define associations between objects and to support retrieval and comparison of object-oriented data based on the internal identifier rather than the attribute values of an object.

Key Points

In an object data model, an object is created as an instance of a class. An object has an object identifier as well as a state. An object identifier is immutable, meaning that the value of the object identifier cannot change over the lifetime of the object. The state, on the other hand, is mutable, representing the attributes that describe the object and the relationships that define associations among objects. Relationships in an object data model are defined using object references based on internal object identifiers rather than attribute values as in a relational data model. As a result, the attribute values of an object can freely change without affecting identity-based relationships.

Variables that contain object references can be compared using either object identity or object equality. Two object references are identical if they contain the same object identifiers. In contrast, two object references, that possibly contain different object identifiers, are equal if the values of attributes and relationships in each object state are identical. Shallow equality is the process of comparing the immediate values of attributes and relationships. Deep equality involves the traversal of object references in the comparison process. Query languages for objects must incorporate operators to distinguish between object identity and object equality in the specification of object queries.

Definition

Object recognition is concerned with determining the identity of an object being observed in the image from a set of known labels. Oftentimes, it is assumed that the object being observed has been detected or there is a single object in the image.

Historical Background

As the holy grail of computer vision research is to tell a story from a single image or a sequence of images, object recognition has been studied for more than four decades [9,22]. Significant efforts have been spent to develop representation schemes and algorithms aiming at recognizing generic objects in images taken under different imaging conditions (e.g., viewpoint, illumination, and occlusion). Within a limited scope of distinct objects, such as handwritten digits, fingerprints, faces, and road signs, substantial success has been achieved. Object recognition is also related to content-based image retrieval and multimedia indexing as a number of generic objects can be recognized. In addition, significant progress towards object categorization from images has been made in the recent years [17]. Note that object recognition has also been studied extensively in psychology, computational neuroscience and cognitive science [4,9].

Foundations

Object recognition is one of the most fascinating abilities that humans easily possess since childhood. With a simple glance of an object, humans are able to tell its identity or category despite of the appearance variation due to change in pose, illumination, texture, deformation, and under occlusion. Furthermore, humans can easily generalize from observing a set of objects to recognizing objects that have never been seen before. For example, kids are able to generalize the concept of "chair" or "cup" after seeing just a few examples. Nevertheless, it is a daunting task to develop vision systems that match the cognitive capabilities of human beings, or systems that are able to tell the specific identity of an object being observed. The main reasons can be attributed to the following factors: relative pose of an object to a camera, lighting variation, and difficulty in generalizing across objects from a set of exemplar images. Central to object recognition systems are how the regularities of images, taken under different lighting and pose conditions, are extracted and recognized. In other words, all the algorithms adopt certain representations or models to capture these characteristics, thereby facilitating procedures to tell their identities. In addition, the representations can be either 2D or 3D geometric models. The recognition process, either generative or discriminative, is then carried out by matching the test image against the stored object representations or models.

Geometry-Based Approaches

Early attempts at object recognition were focused on using geometric models of objects to account for their appearance variation due to viewpoint and illumination change. The main idea is that the geometric description of a 3D object allows the projected shape to be accurately predicated in a 2D image under projective projection, thereby facilitating recognition process using edge or boundary information (which is invariant to certain illumination change). Much attention was made to extract geometric primitives (e.g., lines, circles, etc.) that are invariant to viewpoint change [13]. Nevertheless, it has been shown that such primitives can only be reliably extracted under limited conditions (controlled variation in lighting and viewpoint with certain occlusion). Mundy provides an excellent review on geometry-based object recognition research [12].

Appearance-Based Algorithms

In contrast to early efforts on geometry-based object recognition, most recent efforts have been centered on appearance-based techniques as advanced feature descriptors and pattern recognition algorithms are developed [8]. Most notably, the eigenface method has attracted much attention as it is one of the first face recognition systems that are computationally efficient and relatively accurate [21]. The underlying idea of this approach is to compute eigenvectors from a set of vectors where each one represents one face image as a raster scan vector of gray-scale pixel values. Each eigenvector, dubbed an eigenface, captures certain variance among all the vectors, and a small set of eigenvectors captures almost all the appearance variation of face images in the training set. Given a test image represented as a vector of gray-scale pixel values, its identity is determined by finding the nearest neighbor of this vector after being projected onto a subspace spanned by a set of eigenvectors. In other words, each face image can be represented by a linear combination of eigenfaces with minimum error (often in the L2 sense), and this linear combination constitutes a compact reorientation. The eigenface approach has been adopted in recognizing generic objects across different viewpoints [14] and modeling illumination variation [2].

As the goal of object recognition is to tell one object from the others, discriminative classifiers have been used to exploit the class specific information. Classifiers such as k-nearest neighbor, neural networks with radial basis function (RBF), dynamic link architecture, Fisher linear discriminant, support vector machines (SVM), sparse network of Winnows (SNoW), and boosting algorithms have been applied to recognize 3D objects from 2D images [16,6,1,18,19]. While appearance-based methods have shown promising results in object recognition under viewpoint and illumination change, they are less effective in handling occlusion. In addition, a large set of exemplars needs to be segmented from images for generative or discriminative methods to learn the appearance characteristics. These problems are partially addressed with parts-based representation schemes.

Feature-Based Algorithms

The central idea of feature-based object recognition algorithms lies in finding interest points, often occurred at intensity discontinuity, that are invariant to change due to scale, illumination and affine transformation (a brief review on interest point operators can be found in [8]). The scale-invariant feature transform (SIFT) descriptor is arguably one of the most widely used feature representation schemes for vision applications [8]. The SIFT approach uses extrema in scale space for automatic scale selection with a pyramid of difference of Gaussian filters, and keypoints with low contrast or poorly localized on an edge are removed. Next, a consistent orientation is assigned to each keypoint and its magnitude is computed based on the local image gradient histogram, thereby achieving invariance to image rotation. At each keypoint descriptor, the contribution of local image gradients are sampled and weighted by a Gaussian, and then represented by orientation histograms. For example, the 16 × 16 sample image region and 4 × 4 array of histograms with 8 orientation bins are often used, thereby providing a 128-dimensional feature vector for each keypoint. Objects can be indexed and recognized using the histograms of keypoints in images. Numerous applications have been developed using the SIFT descriptors, including object retrieval [15,20], and object category discovery [5].

Although the SIFT approach is able to extract features that are insensitive to certain scale and illumination changes vision applications with large base line changes entail the need of affine invariant point and region operators [11]. A performance evaluation among various local descriptors can be found in [10], and a study on affine region detectors is presented in [11]. Finally, SIFT-based methods are expected to perform better for objects with rich texture information as sufficient number of keypoints can be extracted. On the other hand, they also require sophisticated indexing and matching algorithms for effective object recognition [8,17].

Key Applications

Biometric recognition, and optical character/digit/document recognition are arguably the most widely used applications. In particular, face recognition has been studied extensively for decades and with large scale ongoing efforts [23]. On the other hand, biometric recognition systems based on iris or fingerprint as well as as handwritten digit have become reliable technologies [3,7]. Other object recognition applications include surveillance, industrial inspection, content-based image retrieval (CBIR), robotics, medical imaging, human computer interaction, and intelligent vehicle systems, to name a few.

Future Directions

With more reliable representation schemes and recognition algorithms being developed, tremendous progress has been made in the last decade towards recognizing objects under variation in viewpoint, illumination and under partial occlusion. Nevertheless, most working object recognition systems are still sensitive to large variation in illumination and heavy occlusion. In addition, most existing methods are developed to deal with rigid objects with limited intraclass variation. Future research will continue searching for robust representation schemes and recognition algorithms for recognizing generic objects.

Data Sets

Numerous face image sets are available on the web

Object Relationship Attribute Data Model for Semi-structured Data

Gillian Dobbie[1], Tok Wang Ling[2]
[1]University of Auckland, Auckland, New Zealand
[2]National University of Singapore, Singapore

Synonyms

ORA-SS data model; ORA-SS schema diagram

Definition

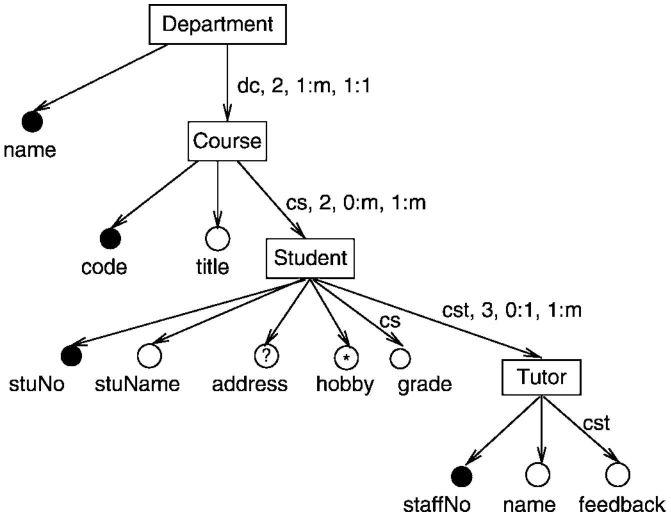
When a database schema is designed, a data model is initially used to model the real world constraints that are taken into account in the design of the schema. For semi-structured database design, it is necessary to capture the following constraints: object classes, n-ary relationship types, attributes of object classes, attributes of relationship types, cardinality, participation and uniqueness constraints, ordering, irregular and heterogeneous structures, for both data- and document-centric data.

Key Points

The ORA-SS (Object-Relationship-Attribute Data Model for Semi-structured Data) data model was designed [1] specifically to capture the constraints that are necessary for designing semi-structured databases, for normalization of schemas, and for defining views.

Figure 1 models the scenario where there is a department, with a name and many courses. A course has a unique code, a title, and many students, and a student has a unique student number, name, address, and many hobbies. For each course that a student takes, they have a grade. There is a tutor for each student in each course they take. A tutor has a unique staff number and a name, and each student can give feedback for the tutor they have in each course that they take.

A closer look is now taken at the notation used. Each of the rectangles represents an object class, the circles represent attributes and the labeled directed edges between object classes represent relationship types. A filled circle is an identifier, which is similar to a key in relational databases and an identifier of an object class. The "?" in the circle represents zero or one occurences of that attribute, while a "*" represents zero or more occurences. The default is one. An attribute in an ORA-SS diagram could be represented as an attribute or an element in an XML document. The label on the edge has *name, n, a:b, c:d*, where *name* is the name of the relationship type, *n* is the degree, *a:b* is the participation constraint on the parent and *c:d* is the participation constraint on the child. The participation constraint *a:b* indicates that the parent object participates in a minimum of *a* and a maximum of *b* relationships. Whereas, the participation constraint *c:d* indicates that the child object participates in a minimum of *c* and a maximum of *d* relationships. A label on the edge between an object class and an attribute, *name*, indicates that the attribute belongs to relationship type *name*.



Object Relationship Attribute Data Model for Semi-structured Data. Figure 1. An ORA-SS schema diagram.

Consider the example in Fig. 1. There are object classes *Department*, *Course*, *Student* and *Tutor*. Object class *Department* has an identifier *name*, and is the parent object class in the relationship type between *Department* and *Course*. The relationship type is a binary relationship with name *dc*, and the participation constraint *1:m* indicates that a department has a minimum of *one* course and a maximum of *m* courses, where *m* means many, i.e., any number of courses. The participation constraint *1:1* indicates that each course must belong to *one* department and can belong to a maximum of *one* department. Each course has an identifier *code*, a required attribute *title*, and is the parent object class in the relationship type, *cs*, between *course* and *student*. Object class *Student* has an identifier *stuNo*, a required attribute *stuName*, an optional attribute *address*, and zero or more *hobby*. There is a binary relationship type, *cs*, between *Course* and *Student*, where a *Course* can have zero or more *Students*, and a *Student* takes one or more *Courses*. The attribute *grade* belongs to the relationship type, *cs*, that is it represents the grade a student scored in a particular course. There is a ternary relationship type among object classes *Course*, *Student* and *Tutor*. Each course-student pair can have zero to one tutor, and each tutor belongs to one or more course-student pairs. Each tutor has an identifier *staffNo*, a required attribute *name*, and there is an attribute *feedback* for each tutor from a particular student in a particular course.

Object-Role Modeling

Terry Halpin
Neumont University, South Jordan, UT, USA

Synonyms

Fact-oriented modeling; NIAM

Definition

Object-Role Modeling (ORM), also known as *fact-oriented modeling*, is a conceptual approach to modeling and querying the information semantics of business domains in terms of the underlying facts of interest, where all facts and rules may be verbalized in language readily understood by non-technical users of those business domains. Unlike Entity-Relationship (ER) modeling and Unified Modeling Language (UML) class diagrams, ORM treats all facts as relationships (unary, binary, ternary etc.). How facts are grouped into structures (e.g., attribute-based entity types, classes, relation schemes, XML schemas) is considered a design level, implementation issue that is irrelevant to the capturing of essential business semantics.

Avoiding attributes in the base model enhances semantic stability, populatability, and natural verbalization, facilitating communication with all stakeholders. For information modeling, fact-oriented graphical notations are typically far more expressive than those provided by other notations. Fact-oriented textual languages are based on formal subsets of native languages, so are easier to understand by business people than technical languages like UML's Object Constraint Language (OCL). Fact-oriented modeling includes procedures for mapping to attribute-based structures, so may also be used to front-end other approaches.

The fact-oriented modeling approach comprises a family of closely related "dialects", known variously as Object-Role Modeling (ORM), Natural Language Information Analysis Method (NIAM), and Fully-Communication Oriented Information Modeling (FCO-IM). While not adopting the ORM graphical notation, the Object-oriented Systems Model (OSM) [4] and the Semantics of Business Vocabulary and business Rules (SBVR) [13] initiative within the Object Management Group (OMG) are close relatives, with their attribute-free philosophy.

Historical Background

In 1973, Falkenberg generalized work by Abrial and Senko on binary relationships to *n*-ary relationships, and excluded attributes at the conceptual level to avoid "fuzzy" distinctions and to simplify schema evolution. Later, Falkenberg proposed the fundamental ORM framework, which he called the "object-role model" [5]. This framework allowed *n*-ary and nested relationships, but depicted roles with arrowed lines. Nijssen adapted this framework by introducing a circle-box notation for objects and roles, and adding a linguistic orientation and design procedure to provide a modeling method called ENALIM (Evolving NAtural Language Information Model) [12]. Nijssen's team of researchers at Control Data in Belgium developed the method further, including van Assche who classified object types into lexical object types (LOTs) and non-lexical object types (NOLOTs). Today, LOTs are commonly called "entity types" and NOLOTs are called "value types". Meersman added subtyping to the approach, and made major contributions to the RIDL query language [11] with Falkenberg and Nijssen. The method was renamed "aN Information Analysis Method" (NIAM). Later, the acronym "NIAM" was given different expansions, and is now known as "Natural language Information Analysis Method".

In the 1980s, Nijssen and Falkenberg worked on the design procedure and moved to the University of Queensland, where the method was further enhanced by Halpin, who provided the first full formalization, including schema equivalence proofs, and made several refinements and extensions. In 1989, Halpin and Nijssen co-authored a book on the approach, followed a year later by Wintraecken's book [16]. Today several books, including major works by Halpin [10], and Bakema et al. [1] expound on the approach.

Many researchers contributed to the fact-oriented approach over the years, and there is no space here to list them all. Today various versions exist, but all adhere to the fundamental object-role framework. Habrias developed an object-oriented version called MOON (Normalized Object-Oriented Method). The Predicator Set Model (PSM), developed mainly by ter Hofstede et al. [7], includes complex object constructors. De Troyer and Meersman developed a version with constructors called Natural Object-Relationship Model (NORM). Halpin developed an extended version simply called ORM, and with Bloesch and others developed an associated query language called ConQuer [2]. Bakema et al. [1] recast all entity types as nested relationships, to produce Fully Communication Oriented NIAM, which they later modified to Fully Communication Oriented Information Modeling (FCO-IM).

More recently, Meersman and others adapted ORM for ontology modeling, using a framework called DOGMA (Developing Ontology-Grounded Methodology and Applications) (http://www.starlab.vub.ac.be/website/). Nijssen and others extended NIAM to a version called NIAM2007. Halpin and others developed a second generation ORM (ORM 2), whose graphical notation is used in this article.

Foundations

ORM includes graphical and textual *languages* for modeling and querying information at the conceptual level, as well as *procedures* for designing conceptual models, transforming between different conceptual representations, forward engineering ORM schemas to implementation schemas (e.g., relational database schemas, object-oriented schemas, XML schemas, and external schemas) and reverse engineering implementation schemas to ORM schemas.

Attributes are not used as a base construct. Instead, all fact structures are expressed as *fact types* (relationship types). These may be unary (e.g., Person smokes), binary (e.g., Person was born on Date), ternary (e.g., Person visited Country in Year), and so on. This attribute-free nature has several advantages: *semantic stability* (minimize the impact of change caused by the need to record something about an attribute); *natural verbalization* (all facts and rules may be easily verbalized in sentences understandable to the domain expert); *populatability* (sample fact populations may be conveniently provided in fact tables); *null avoidance* (no nulls occur in populations of base fact types, which must be elementary or existential). Although attribute-free diagrams typically consume more space, this apparent disadvantage is easily overcome by using an ORM tool to automatically create attribute-based structures (e.g., ER, UML class, or relational schemas) as views of an ORM schema.

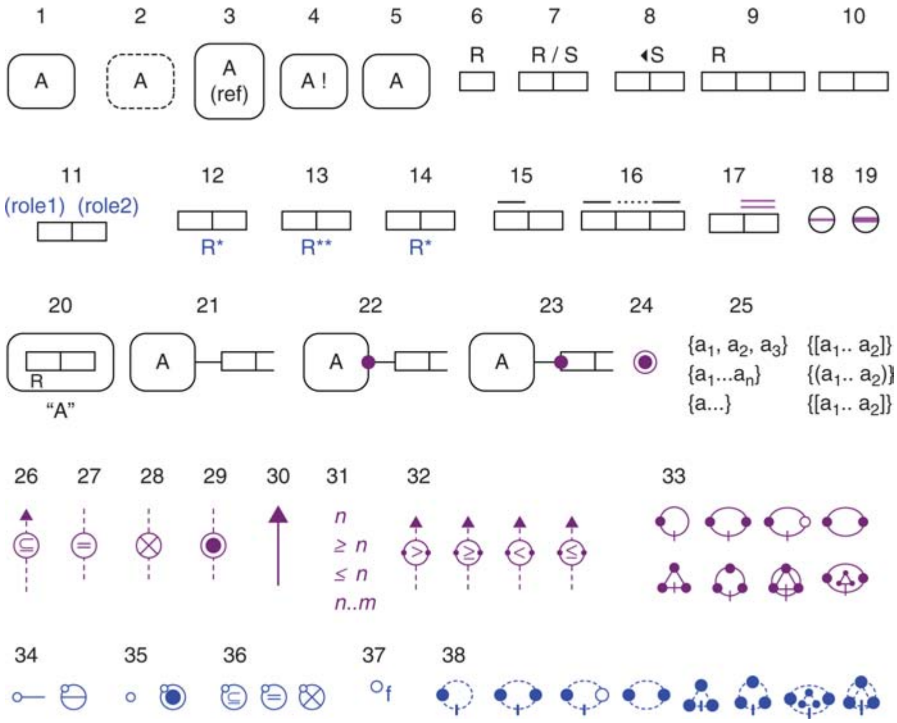
ORM's graphical language is far more expressive for data modeling purposes than that of UML or industrial versions of ER, as illustrated later. The *rich graphical notation* makes it easier to detect and express constraints, and to visually transform schemas into equivalent alternatives.

ORM includes *effective modeling procedures* for constructing and validating models. In step 1a of the Conceptual Schema Design Procedure (CSDP), the domain expert informally verbalizes facts of interest. In step 1b, the modeler formally rephrases the facts in natural yet unambiguous language, using standard reference patterns to ensure that entities are well identified. Verbalized fact instances are abstracted to fact types, which are then populated with sample instances. The constraints on the fact types are verbalized formally, a process that may be automated [8], and these verbalizations are checked with the domain expert, using positive populations to illustrate satisfaction of the constraints as well as counterexamples to illustrate what it means to violate a constraint. This approach to model *validation by verbalization and population* has proved extremely effective in industrial practice, with correct models typically obtained from the outset rather than going through unreliable iterative procedures.

Figure 1 lists the main graphical symbols in the ORM 2 notation [8], numbered for easy reference. An *entity type* (e.g., Person) is depicted as a named, soft rectangle (symbol 1), or alternatively an ellipse or hard rectangle. *Value type* (e.g., Person Name) shapes have dashed lines (symbol 2). Each entity type has a *reference scheme*, indicating how each instance may be mapped via predicates to a combination of one or more values. Injective (1:1 into) reference schemes mapping entities (e.g., countries) to single values (e.g., country codes) may be abbreviated as in symbol 3 by displaying the *reference mode* in parentheses, e.g., Country (.code). The reference mode indicates how values relate to the entities. Values are constants with a known denotation, so require no reference scheme.

Relationships used for *preferred reference* are called *existential facts* (e.g., there exists a country that has the country code ‘US’). The other relationships are *elementary facts* (e.g., The country with country code ‘US’ has a population of 301,000,000). The exclamation mark in symbol 4 declares that an object type is *independent* (instances may exist without participating in any elementary facts). Object types displayed in multiple places are shadowed (symbol 5).

A fact type results from applying a logical *predicate* to a sequence of one or more object types. Each predicate comprises a named sequence of one or more *roles* (parts played in the relationship). A predicate is



Object-Role Modeling. Figure 1. Main ORM graphic symbols.

sentence with object holes, one for each role, with each role depicted as a box and played by exactly one object type. Symbol 6 shows a unary predicate (e.g., ... smokes), symbols 7 and 8 depict binary predicates (e.g., ... loves ...), and symbol 9 shows a ternary predicate. Predicates of higher *arity* (number of roles) are allowed. Each predicate has at least one *predicate reading*. ORM uses *mixfix* predicates, so objects may be placed at any position in the predicate (e.g., the fact type Person introduced Person to Person involves the predicate "... introduced ... to ..."). Mixfix predicates allow natural verbalization of *n*-ary relationships, as well as binary relationships where the verb is not in the infix position (e.g., in Japanese, verbs come at the end). By default, forward readings traverse the predicate from left to right (if displayed horizontally) or top to bottom (if displayed vertically). Other reading directions may be indicated by an arrow-tip (symbol 8). For binary predicates, forward and inverse readings may be separated by a slash (symbol 7). Duplicate predicate shapes are shadowed (symbol 10).

Roles may be given *role names*, displayed in square brackets (symbol 11). An asterisk indicates that the fact type is *derived* from one or more other fact types (symbol 12). If the fact type is derived and stored, a double asterisk is used (symbol 13). Fact types that are semi-derived are marked "+" (symbol 14). *Internal uniqueness constraints*, depicted as bars over one or more roles in a predicate, declare that instances for that role (combination) in the fact type population must be unique (e.g., symbols 15, 16). For example, a uniqueness constraint on the first role of Person was born in Country verbalizes as: **Each** person was born in **at most one** Country. If the constrained roles are not contiguous, a dotted line separates the constrained roles (symbol 16). A predicate may have many uniqueness constraints, at most one of which may be declared *preferred* by a double-bar (symbol 17). An *external uniqueness constraint* shown as a circled uniqueness bar (symbol 18) may be applied to two or more roles from different predicates by connecting to them with dotted lines. This indicates that instances of the role combination in the join of those predicates are unique. For example, if a state is identified by combining its state code and country, an external uniqueness constraint is added to the roles played by Statecode and Country in: State has Statecode; State is in Country. Preferred external uniqueness constraints are depicted by a circled double-bar (symbol 19).

To talk about a relationship, one may *objectify* it (i.e., make an object out of it) so that it can play roles. Graphically, the objectified predicate (a.k.a. *nested* predicate) is enclosed in a soft rectangle, with its name in quotes (symbol 20). Roles are connected to their players by a line segment (symbol 21). A *mandatory role constraint* declares that every instance in the population of the role's object type must play that role. This is shown as a large dot placed at the object type end (symbol 22) or the role end (symbol 23). An *inclusive-or* (*disjunctive mandatory)* constraint applied to two or more roles indicates that all instances of the object type population must play at least one of those roles. This is shown by connecting the roles by dotted lines to a circled dot (symbol 24).

To restrict the population of an object type or role, the relevant values may be listed in braces (symbol 25). An ordered range may be declared separating end values by "..". For continuous ranges, a square/ round bracket indicates an end value is included/excluded. For example, "(0..10)" denotes the positive real numbers up to 10. These constraints are called *value constraints*.

Symbols 26–28 denote *set comparison constraints*, which apply only between compatible role sequences. A dotted arrow with a circled subset symbol depicts a *subset constraint*, restricting the population of the first sequence to be a subset of the second (symbol 26). A dotted line with a circled "=" symbol depicts an *equality constraint*, indicating the populations must be equal (symbol 27). A circled "X" (symbol 28) depicts an *exclusion constraint*, indicating the populations are mutually exclusive. Exclusion and equality constraints may be applied between two or more sequences. Combining an inclusive-or and exclusion constraint yields an *exclusive-or constraint* (symbol 29).

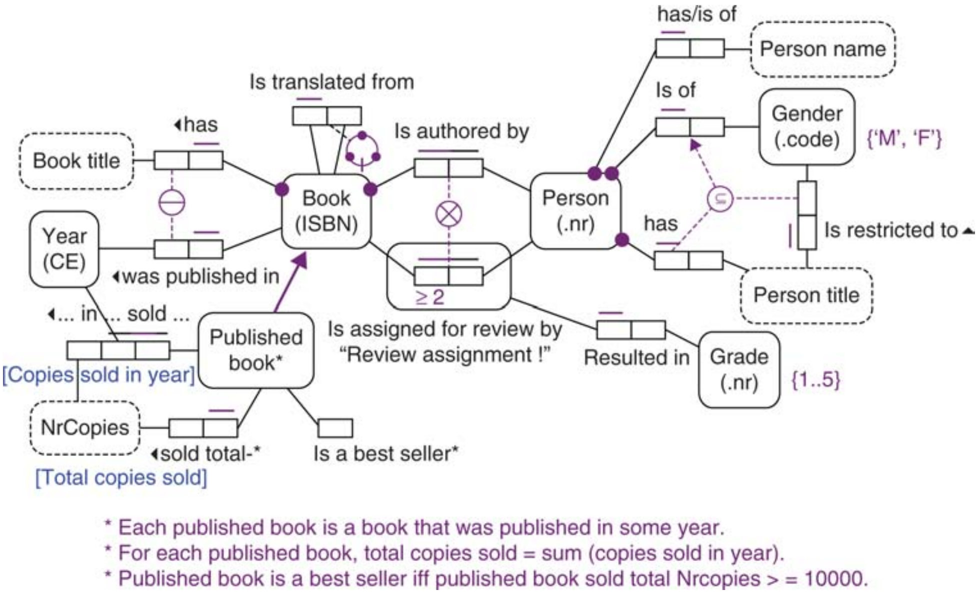
A solid arrow (symbol 30) from one object type to another indicates that the first is a (proper) *subtype* of the other (e.g., Woman is a subtype of Person). Mandatory (circled dot) and exclusion (circled "X") constraints may be displayed between subtypes, but are implied by other constraints if the subtypes have formal definitions. Symbol 31 shows four kinds of *frequency constraint*. Applied to a role sequence, these indicate that instances that play those roles must do so *exactly n* times, *at least n* times, *at most n* times, or *at least n and at most m* times. Symbol 32 shows four varieties of *value-comparison constraint*. The arrow shows the direction in which to apply the circled operator between two instances of the same type (e.g., **For each** Employee, hiredate > birthdate).

Symbol 33 shows the main kinds of *ring constraint* that may apply to a pair of compatible roles. Read left to right and top row first, these indicate that the binary relation formed by the role population must respectively be irreflexive, asymmetric, antisymmetric, reflexive, intransitive, acyclic, intransitive and acyclic, or intransitive and asymmetric.

The previous constraints are *alethic* (necessary, so can't be violated) and are colored violet. ORM 2 also supports *deontic* rules (obligatory, but can be violated). These are colored blue, and either add an "o" for obligatory, or soften lines to dashed lines. Displayed here are the deontic symbols for uniqueness (symbol 34), mandatory (symbol 35), set-comparison (symbol 36), frequency (symbol 37) and ring (symbol 38) constraints.

Figure 2 shows a sample ORM schema for a book publishing domain. A detailed discussion using the CSDP to develop this schema may be found elsewhere [9]. Each book is identified by an International Standard Book Number (ISBN), each person is identified by a person number, each grade is identified by a grade number in the range 1 through 5, each gender is identified by a code ('M' for male and 'F' for Female), and each year is identified by its common era (CE) number. Published Book is a derived subtype determined by the subtype definition shown at the bottom of the figure. Review Assignment objectifies the relationship Book is assigned for review by Person, and is independent since an instance of it may exist without playing any other role (one can known about a review assignment before knowing what grade will result from that assignment).

The internal uniqueness constraints (depicted as bars) and mandatory role constraints (solid dots) verbalize as follows: **Each** Book is translated from **at most one** Book; **Each** Book has **exactly one** Book Title; **Each** Book was published in **at most one** Year; **For each** Published Book **and** Year, **that** Published Book in **that** Year sold **at most one** NrCopies; **Each** Published Book sold **at most one** total NrCopies; **It is possible that the same** Book is authored by **more than one** Person **and that more than one** Book is authored by **the same** Person; **Each** Book is authored by **some** Person; **It is possible that the same** Book is assigned for review by **more than one** Person **and that more than one** Book is assigned for review by **the same** Person; **Each** Review Assignment resulted in **at most one** Grade; **Each** Person has **exactly one** Person Name; **Each** Person has **at most one** Gender; **Each** Person has **at most one** Person Title; **Each** Person Title is restricted to **at most one** Gender.



Object-Role Modeling. Figure 2. An ORM schema for a book publishing domain.

The external uniqueness constraint (circled bar) indicates that the combination of BookTitle and Year applies to at most one Book. The acyclic ring constraint (circle with three dots and a bar) on the book translation predicate indicates that no book can be a translation of itself or any of its ancestor translation sources. The exclusion constraint (circled cross) indicates that no book can be assigned for review by one of its authors. The frequency constraint (≥ 2) indicates that each book that is assigned for review is assigned for review by at least two persons. The subset constraint (circled subset symbol) means that if a person has a title that is restricted to some gender, then the person must be of that gender. The first argument of this subset constraint is a person-gender role pair projected from a join path that performs a conceptual join on PersonTitle. The last two lines at the bottom of the schema declare two derivation rules, one specified in attribute-style using role names and the other in relational style using predicate readings.

Key Applications

ORM has been used productively in industry for over 30 years, in all kinds of business domains. *Commercial tools* supporting the fact-oriented approach include Microsoft's Visio for Enterprise Architects, and the FCO-IM tool CaseTalk (www.casetalk.com). CogNIAM, a tool supporting NIAM2007 is under development at PNA Active Media (http://cogniam.com/). *Free ORM tools* include VisioModeler and Infagon (www.mattic.com). Dogma Modeler (www.starlab.vub.ac.be) and T-Lex [15] are academic ORM-based tools for specifying ontologies. NORMA (http://sourceforge.net/projects/orm), an open-source plug-in to Microsoft® Visual Studio, is under development to provide deep support for ORM 2 [3].

Future Directions

Research in many countries is actively extending ORM in many areas (e.g., dynamic rules, ontology extensions, language extensions, process modeling). A detailed overview of this research may be found in [9]. General information about ORM, and links to other relevant sites, may be found at www.ORMFoundation.org and www.orm.net.

One-Copy-Serializability

Bettina Kemme
McGill University, Montreal, QC, Canada

Synonyms

Transactional consistency in a replicated database

Definition

While transactions typically specify their read and write operations on logical data items, a replicated database has to execute them over the physical data copies. When transactions run concurrently in the system, their executions may interfere. The replicated database system has to isolate these transactions. The strongest, and most well-known correctness criterion for replicated databases is one-copy-serializability. A concurrent execution of transactions in a replicated database is one-copy-serializable if it is equivalent to a serial execution of these transactions over a single logical copy of the database.

Key Points

A transaction is a sequence of read and write operations on the data items of the database. A read operation of transaction T_i on data item x is denoted as $r_i(x)$, a write operation on x as $w_i(x)$. A transaction T_i either ends with a commit c_i (all operations succeed) or with an abort a_i (whereby all effects on the data are undone before the termination).

A replicated database consists of a set of database servers A, B, ... and each logical data item x of the database has a set of physical copies x^A, x^B, ... where the index refers to the database server on which the copy resides. *Replica Control* translates each operation $o_i(x), o_i \in \{r, w\}$ of a transaction T_i on data item x into operations $o_i(x^A), o_i(x^B)$ on physical data copies. Given a set of transactions $\mathcal{T}$, a replicated history RH describes the execution of these transactions in the replicated database. For simplicity the following discussion only considers histories where all transactions commit. A database server A executes the subset of operations of the transactions in $\mathcal{T}$ performed on copies residing on A. The local history RH^A describes the order in which these operations occur. For simplicity a local history is assumed to be a total order. RH is the union of all local histories with some additional ordering. In particular, if a transaction T_i executes $o_i(x)$ before $o_i(y)$, and RH^A contains $o_i(x^A)$ and RH^B contains $o_i(y^B)$, then $o_i(x^A) <_{RH} o_i(y^B)$.

As an example, given $T_1 = w_1(y)w_1(x)$ and $T_2 = r_2(y)$ $w_2(x)$, and database servers A and B, both having a copy of both x and y, the local histories could be:

$$RH^A : w_1(y^A)r_2(y^A)w_1(x^A)w_2(x^A)c_1c_2$$

$$RH^B : w_1(y^B)w_1(x^B)w_2(x^B)c_2c_1$$

The replicated history *RH* is the union of these two local histories plus the ordering of $r_2(y^A) <_{RH} w_2(x^B)$.

Using this notation, the following defines one-copy-serializability for the case that replica control uses ROWA (read-one-write-all-approach), i.e., where each read operation is performed on one copy while write operations are performed on all copies of the data item. Failures are ignored. In this restricted case *conflict-equivalence* can be exploited. Two operations o_i and o_j conflict, if they are from two different transactions, access the same data copy, and at least one is a write operation.

Definition *A replicated history RH over a set of transactions* $\mathcal{T}$ *in a replicated system with servers A, B,...is one-copy-serializable if it is conflict-equivalent to a serial history H over* $\mathcal{T}$ *in a single-copy system with one logical server L. This means that if* $o_i(x^A)$, $o_j(x^A) \in RH$ *and the operations conflict, then* $o_i(x^L) <_H o_j(x^L) \in H$ *if and only if* $o_i(x^A) <_{RH^A} o_j(x^A) \in RH$.

Using conflict-equivalence, one can easily determine whether *RH* is one-copy-serializable. For each local history RH^A the serialization graph $SG(RH^A)$ has each committed transaction as node, and contains an edge from T_i to T_j if $o_i(x^A) <_{RH^A} o_j(x^A)$ and the two operations conflict. The serialization graph *SG*(*RH*) is then the union of the local serialization graphs.

Theorem *A replicated history RH over a set of transactions* $\mathcal{T}$ *and database servers A, B,...following the ROWA strategy is one-copy-serializable if and only if its serialization graph SG(RH) is acyclic.*

The example history above is one-copy-serializable because its serialization graph contains only an edge from T_1 to T_2, i.e., in all local histories, and for any conflict between T_1 and T_2, T_1's operations are ordered before T_2's operation.

As soon as node failures are considered or both read and write operations only access a subset of copies, conflict-equivalence is not appropriate anymore because it might miss catching conflicts at the logical level. For that purpose, one can define one-copy-serializability based on view-equivalence which observes which data versions a read operation accesses and in which order write operations occur.

One-Pass Algorithm

Nicole Schweikardt
Johann Wolfgang Goethe-University, Frankfurt am Main, Frankfurt, Germany

Synonyms

One-pass algorithm; Streaming algorithm; Data stream algorithm

Definition

A one-pass algorithm receives as input a list of data items x_1, x_2, x_3,.... It can read these data items only once, from left to right, i.e., in increasing order of the indices $i = 1, 2, 3$,.... Critical parameters of a one-pass algorithm are (1) the size of the memory used by the algorithm, and (2) the processing time per data item x_i. Typically, a one-pass algorithm is designed for answering one particular query against the input data. To this end, the algorithm stores and maintains a suitable data structure which, for each i, is updated when reading data item x_i.

The two parameters *processing time per data item* and *memory size* are usually measured as functions depending on the size *N* of the input (different measures of the *input size* are considered in the literature, among them, e.g., the number of data items occurring in the input, as well as the total number of bits needed for storing the entire input). The ultimate goal when designing a one-pass algorithm is to keep the processing time per data item and the memory size *sublinear*, preferably polylogarithmic, in *N*. In particular, one typically aims at algorithms whose memory size is far smaller than the size of the input.

Key Points

The design and study of one-pass algorithms has a long tradition in many areas of computer science. For example, they are used in the area of *data stream processing*, where streams of huge amounts of data have to be monitored *on-the-fly* without first storing the entire data. A deterministic finite automaton on words can be viewed as a (very simple) example of a one-pass algorithm whose memory size and processing time per data item is constant, i.e., does not depend on the input size. For most computational problems, however, the amount of memory necessary for solving the problem grows with increasing input size. *Lower bounds* on the memory size needed for solving a problem by a one-pass algorithm are usually obtained by applying methods from *communication complexity* (see, e.g., [1,2] for typical examples).

For many concrete problems it is even known that the memory needed for solving the problem by a deterministic one-pass algorithm is at least linear in the size N of the input. For some of these problems, however, *randomized* one-pass algorithms can still compute good *approximate* answers while using memory of size sublinear in N (cf. [1,2,3]). Typically, such algorithms are based on *sampling*, i.e., only a "representative" portion of the data is taken into account, and *random projections*, i.e., only a rough "sketch" of the data is stored in memory (see [3] for a comprehensive survey of according algorithmic techniques).

In the context of database systems these techniques are relevant, for example, for maintaining information needed for cost-based query optimization, e.g., estimates for the number of distinct values of an attribute, or the self-join size of a database relation. Efficient one-pass algorithms for incrementally updating these estimates can be found in [1].

In some application areas, rather than just a single pass, a small number P of sequential passes over the data may be available; the resulting algorithms are called *multi-pass algorithms* (see e.g., [2] for an analysis of the trade-off between the memory size and the number of passes necessary for solving particular problems).

OLAP

Definition

On-line analytical processing (OLAP) describes an approach to decision support, which aims to extract knowledge from a data warehouse, or more specifically, from data marts. Its main idea is providing navigation through data to non-expert users, so that they are able to interactively generate ad hoc queries without the intervention of IT professionals. This name was introduced in contrast to on-line transactional processing (OLTP), so that it reflected the different requirements and characteristics between these classes of uses. The concept falls in the area of business intelligence.

Historical Background

From the beginning of computerized data management, the possibility of using computers in data analysis has been evident for companies. However, early analysis tools needed the involvement of the IT department to help decision makers to query data. They were not interactive at all and demanded specific knowledge in computer science. By the mid-1980s, executive information systems appeared introducing new graphical, keyboard-free interfaces (like touch screens). However, executives were still tied to IT professionals for the definition of ad hoc queries, and prices of software and hardware requirements where prohibitive for small companies. Eventually, cheaper and easy-to-use spreadsheets became very popular among decision makers, but soon it was clear that they were not appropriate for using and sharing huge amounts of data. Thus, it was in 1993 that Codd et al. [2], coined the term OLAP. In that report, the authors defined 12 rules for a tool to be considered OLAP. These rules caused heated controversy, and they did not succeed as Codd's earlier proposal for relational database management systems (RDBMS). Nevertheless, the name OLAP became very popular and is broadly used.

Although the name OLAP comes from 1993 and the idea behind them goes back to the 1980s, there is not a formal definition for this concept, yet. As proposed by Nigel Pendse [6], OLAP tools should pass the FASMI (fast analysis of shared multidimensional information) test. Thus, they should be fast enough to allow interactive queries; they should help analysis task by providing flexibility in the usage of statistical tools and what–if studies; they should provide security (both in the sense of confidentiality and integrity) mechanisms to allow sharing data; they should provide a multidimensional view so that the data cube metaphor can be used by users; and, finally, they should also be able to manage large volumes of data (gigabytes can be considered a lower bound for volumes of data in decision support) and metadata. However, there are not measures and thresholds for all these characteristics in order to be able to establish whether one of them is fulfilled or not, and therefore it is always arguable that a given tool fulfills them. Nevertheless, it is generally agreed that in order to be considered an OLAP tool, it must offer a multidimensional view of data.

Since their first days, OLAP tools have been losing weight and lowering prices, while at the same time, offering more functionality, better user interfaces and easier administration. Thus, time has come for small companies to use OLAP. They can afford it and they are willing to use it in their decision processes. Part of OLAP industry was associated into the OLAP Council (created in January 1995), whose aim was the promotion and standardization of OLAP terminology and technology. However, some major vendors never became members of this council, so eventually it disappeared (last news date from 1999). Nowadays, there is no standardization institution specifically devoted to OLAP. Therefore, it seems difficult to have a standard data model and query language in the near future, despite the fact that it is clearly desirable.

Foundations

OLAP environments have completely different requirements, compared to OLTP. Figure 1 summarizes the main differences. Firstly, their usage is different. While OLTP systems are conceived to solve a concrete problem and are used in the daily work of companies, OLAP systems are used in decision support. Thus, in the first case, since the addressed problem can be completely specified, the workload of the system is clearly predefined. Conversely, a decision support system aims to solve new problems every day. Therefore, ad hoc queries are executed. OLTP systems read as well as write data, while OLAP systems are considered read-only, because decision makers do not directly modify data. Nevertheless, the queries in a decision support system are much more complex, since they usually include big volumes of information processed by joining several tables, grouping data and calculating functions. Queries in OLTP systems do not usually involve volumes of data of the same magnitude, neither as many tables, nor groupings or calculations. The

	OLTP	OLAP
Usage	Application specific	Decision support
Workload	Predefined	Unforeseeable
Access	Read/Write	Read-only
Query structure	Simple	Complex
Records per operation	Tens/Hundreds	Thousands/Millions
Number of users	Thousands/Millions	Tens/Hundreds

On-Line Analytical Processing. Figure 1. Comparing OLTP Versus OLAP.

number of records in OLTP operations can be estimated as tens or hundreds at most, while OLAP queries usually involve thousands or even millions of records. Finally, the number of users is also different in both kinds of systems. OLTP systems can have thousands or millions of users (like in the case of cash machines), while OLAP systems have tens or maybe hundreds of users.

The main characteristic of OLAP is multidimensionality. The data cube metaphor is used to make user interaction easier and closer to decision makers' way of thinking, who would probably find SQL or any other text-based query language hard to understand and error prone. Thus, it is much easier for them to think in terms of the multidimensional model, where a Fact is a subject of analysis and its Dimensions are the different points of view that analysts could use to study the Fact. In this way, the instances of a Fact are shown in an *n*-dimensional space usually called Cube or Hypercube.

In order to show *n*-dimensional Cubes in two-dimensional interfaces, Cross-tabs or Statistical Tables such as the one in Fig. 2 (its data is entirely fictitious) are used. While in relational tables it is found that fixed columns and different instances are shown in each row, in Cross-tabs both columns and rows are fixed and interchangeable. In this example, you see three dimensions (i.e., Product, Place, and Year) that show the different points of view to analyze the OLAP tools market.

Multidimensionality is based on this fact-dimension dichotomy. A Dimension is considered to contain a hierarchy of aggregation levels representing different granularities (or levels of detail) to study data, and an aggregation level to contain descriptive attributes. On the other hand, a Fact contains quantitative attributes that are called measures. Dimensions of analysis arrange the multidimensional space where the Fact of study is depicted. Each instance of data is identified (i.e., placed in the multidimensional space) by a point in each of its analysis dimensions. Two different instances of data cannot be spotted in the same point of the multidimensional space. Therefore, given a point in each of the analysis dimensions they only determine one, and just one, instance of factual data. Moreover, data summarization that is performed must be correct, i.e., aggregated categories must be a partition (complementary and disjoint) and the kind of measure, aggregation function, and the dimension along which data is aggregated must be compatible. For example, stock, sum and time are not compatible, since stock measures cannot be added along temporal dimensions.

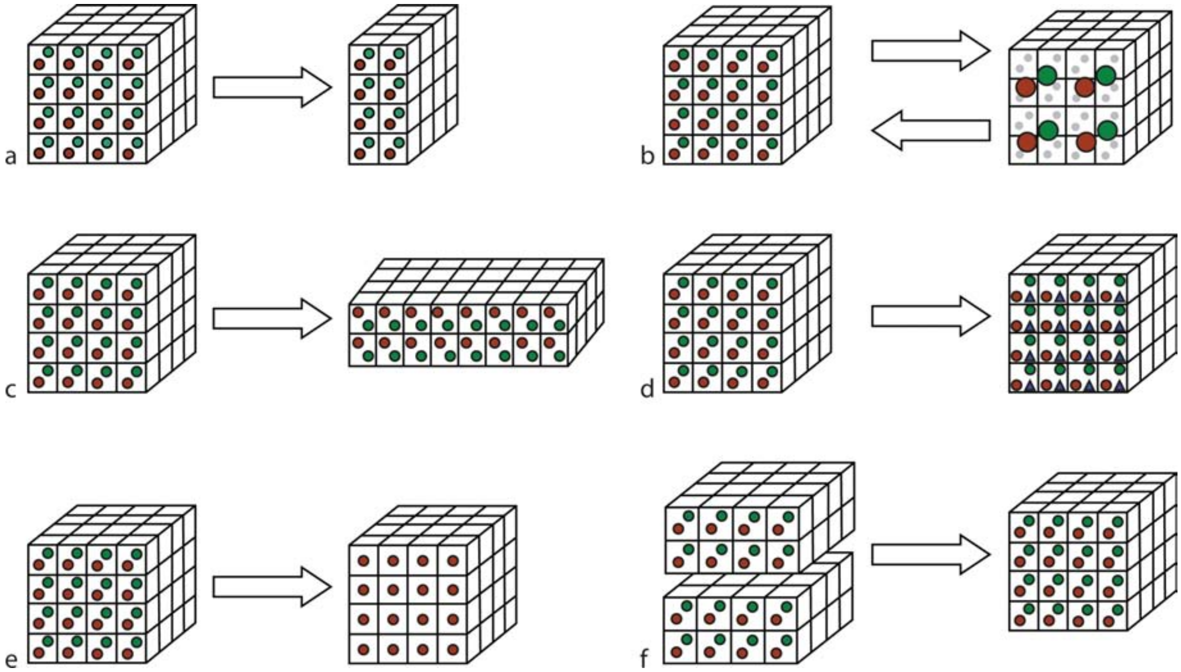
Operations

Unfortunately, there is no consensus on the set of multidimensional operations and how to name them. However, [10] provides a comparison of algebraic proposals in the academic literature, as well as a set of operations subsuming all of them. A sequence of these operations is known as an OLAP session. An OLAP session allows transformation of a starting query into a new query. Figure 3 draws the transitions generated by each one of these operations (circles and triangles represent different attributes for Fact instances):

1. *Selection or dice*. By means of a logic predicate over the dimension attributes, this operation allows users to choose the subset of points of interest out of the whole *n*-dimensional space (Fig. 3a).
2. *Roll-up*. Also called "Drill-up", it groups cells in a Cube based on an aggregation hierarchy. This operation modifies the granularity of data by means of a many-to-one relationship which relates instances of two aggregation levels in the same Dimension, corresponding to a part-whole relationship (Fig. 3b from left to right). For example, it is possible to roll-up monthly sales into yearly sales moving from "Month" to "Year" aggregation level along the temporal dimension.
3. *Drill-down*. This is the counterpart of Roll-up. Thus, it removes the effect of that operation by going down through an aggregation hierarchy, and showing more detailed data (Fig. 3b from right to left).
4. *ChangeBase*. This operation reallocates exactly the same instances of a Cube into a new *n*-dimensional space with exactly the same number of points (Fig. 3c). Actually, it allows two different kinds of changes in the space: rearranging the multidimensional space by reordering the Dimensions, interchanging rows and columns in the Cross-tab (this



On-Line Analytical Processing. Figure 3. Schema of operations on cubes.

is also known as Pivoting), or adding/removing dimensions to/from the space.

5. *Drill-across*. This operation changes the subject of analysis of the Cube, by showing measures regarding a new Fact. The *n*-dimensional space remains exactly the same, only the data placed in it change so that new measures can be analyzed (Fig. 3d). For example, if the Cube contains data about sales, this operation can be used to analyze data regarding production using the same Dimensions.
6. *Projection*. It selects a subset of measures from those available in the Cube (Fig. 3e).
7. *Set operations*. These operations allow users to operate two Cubes defined over the same *n*-dimensional space. Usually, Union (Fig. 3f), Difference and Intersection are considered.

This set of algebraic operations is minimal in the sense that none of the operations can be expressed in terms of others, nor can any operation be dropped without affecting functionality (some tools consider that the set of measures of a Fact conform to an artificial analysis dimension, as well; if so, Projection should be removed from the set of operations in order to be considered minimal, since it would be done by Selection over this artificial Dimension). Thus, other operations can be derived by sequences of these. It is the case of Slice (which reduces the dimensionality of the original Cube by fixing a point in a Dimension) by means of Selection and ChangeBase operations. It is also common that OLAP implementations use the term Slice&Dice to refer to the selection of fact instances, and some also introduce Drill-through to refer to directly accessing the data sources in order to lower the aggregation level below that in the OLAP repository or data mart.

Declarative Languages

There are some research proposals of declarative query languages for OLAP. Cabibbo and Torlone [1] propose a graphical query language, while Gyssens and - Lakshmanan [3] propose a calculus. From the industry point of view, MDX (standing for multidimensional expressions) [5] is the de facto standard. It was introduced in 1997, and in spite of the specification being owned by Microsoft, it has been widely adopted. Its syntax resembles that of SQL:

```
[WITH <MeasureDefinition>+]
SELECT <DimensionSpecification>+
FROM <CubeName>
[WHERE <SlicerClause>]
```

However, its semantics are completely different. Roughly speaking, an MDX query gets the instances of a given Cube stated in the FROM clause and places them in the space defined by the SELECT clause. Moreover, complex calculations can be defined in the WITH clause, and the dimensions not used in the SELECT clause can be sliced in the WHERE clause (if not explicitly sliced, it is assumed that dimensions that do not appear in the SELECT are sliced at the higher aggregation level: All).

```
WITH MEMBER [Measures].[pending] AS
‘[Measures].[Units Ordered]-[Mea-
sures].[Units Shipped]’ SELECT
 {[Time].[2006].children} ON COLUMNS,
 {[Warehouse].[Warehouse Name].mem-
bers} ON ROWS
FROM Inventory
WHERE ([Measures].[pending],[Trade-
mark].[Acme]);
```

In the previous MDX query, an ad hoc measure “pending” is first defined as the difference between units ordered and shipped. Then, the children of the instance representing year 2006 (i.e., the 12 months of that year) are placed on columns, and the different members of the aggregation level “Warehouse Name” on rows. Now, this matrix is filled with the data in “Inventory” cube, showing the previously defined measure “pending” and slicing “Acme” trademark.

Key Applications

Managers are usually not trained to query databases by means of SQL. Moreover, if the query is relatively complex (several joins and subqueries, grouping, and functions) and the database schema is not small (with maybe hundreds of tables), using interactive SQL could be a nightmare even for SQL experts. Thus, OLAP is used to ease the tasks of these managers in extracting knowledge from the data warehouse by means of Drag&Drop, instead of typing SQL queries by hand.

OLAP market is estimated around US$ 6 billion in 2006, which is mainly devoted to decision making. However, this paradigm can also be used in any other field with non-expert users, where schemas and queries are relatively complex. For example, its usage is under investigation in bioinformatics [8], and the semantic web [9].

Future Directions

OLAP is used to extract knowledge from the data warehouse. Data mining tools can also be used for this purpose. Until now, both research communities have been evolving separately. The former must be interactive, while the latter presents computational complexity problems. However, it seems promising to integrate both kinds of tools so that one can benefit from the other [4]. Some tools like Microsoft Analysis Services already integrate them in some way. Nevertheless, there is still much work to do in this field.

On the other hand, security is usually a flaw in data warehousing projects. Reference [7] contains a survey of OLAP security problems. In the past, OLAP tools used to have just a few users and all of them had high responsibilities in the organization, so this was not really a concern in the sense of confidentiality. Nowadays, with the increase in potential users of OLAP systems inside as well as outside the organization, security has emerged as a priority in these projects. Moreover, personal data (like those of customers) are usually analyzed in almost all companies. Thus, inference control mechanisms need to be studied in data mining as well as OLAP tools.

Other research directions in OLAP can be the improvement of user interaction and flexibility in the calculation of statistics, and the integration of what–if analysis (see What–if Analysis definitional entry).

Online Recovery in Parallel Database Systems

RICARDO JIMENEZ-PERIS
Universidad Politecnica de Madrid, Madrid, Spain

Synonyms

High availability; Continuous availability; 24x7 operation

Definition

Replication (also known as clustering) is a technique to provide high availability in parallel and distributed databases. High availability aims to provide continuous service operation. High availability has two faces. On one hand, it provides fault-tolerance by introducing redundancy in the form of replication, that is, having multiple copies or replicas of the data at different sites. On the other hand, since sites holding the replicas may crash and/or fail, in order to keep a given degree of availability, failed or new replicas should be reintroduced into the system. Introducing new replicas requires transferring to them the current state in a consistent fashion (known as *recovery*). A simple solution to this problem is *offline recovery*, that is, in order to obtain a quiescent state, request processing is suspended, then the state is transferred from a working replica (termed *recoverer replica*) to the new replica (*recovering replica*) and finally, request processing is resumed. Unfortunately, offline recovery results in a loss of availability, which defeats the original goal of replication, that is to provide high availability. The alternative is *online recovery*, in which transaction processing is not stopped while the recovery is performed. The main challenge for online recovery is to attain consistency, since the state to be transferred to the recovering replica(s) is a moving target. While the recovery takes place, new transactions are processed and the state evolves during the recovery itself. Online recovery needs to be coordinated with the replica control protocol to enforce consistency.

Historical Background

Recovery is used in centralized databases to bring the database to a consistent state after a crash [1]. The consistency is attained by ensuring that the updates of committed transactions are reflected in the database and the updates of uncommitted (aborted) transactions are not reflected in it. In clustered databases, centralized recovery is used to bring a failed replica to a local consistent state, but then, since other working replicas may have processed transactions, centralized recovery is not sufficient and it has to be followed by a replica recovery [11]. During replica recovery, the failed replica (or a fresh new one) recovers the current state from the working replicas. What is meant by *current state* the state reflecting all the updates from transactions that will not be processed by the recovering replica, and not reflecting any of the updates from transactions that will be processed by the recovering replica after recovery. A failed replica only needs to recover the missed updates, while a new replica needs to recover the full database.

The seminal paper on online recovery for clustered databases is [8]. In this paper, a suite of protocols for online recovery is proposed. One of the protocols lies in a locking-based online recovery. The full database is locked atomically using recovery locks, a special kind of read lock. This guarantees a quiescent state of the database. Then, the recovery locks are released as data is transferred to the recovering replica. The atomic setting of the recovery locks acts as a synchronization point. All update requests processed before the recovery lock setting should be reflected in the transferred state. Requests submitted after the recovery locks are set should be processed by the recovering replica after recovery finishes. This protocol lies inbetween offline and online recovery. In the beginning, all the data are locked, and therefore the database is unavailable. This situation improves as recovery progresses, since recovery locks are released and the corresponding data become available. Another online recovery protocol proposed in [8] is a multi-round recovery. In this protocol, the state to be transferred (missed updates) to the recovering replica is sent in rounds. The first round would contain all the updates missed until the start of recovery. In the second round, the updates performed during the first round are sent, and so on. When the number of updates performed during the last round is small enough, a last round is run. During the last round, the recovering replica has to store all client requests to process them after finishing recovery. This recovery protocol if fully online and also significantly reduces the number of transactions to be stored during recovery, since it is only during the last round that the recovering replica has to store incoming transactions (typically only the resulting updates from them).

Another piece of work on online recovery was presented in [5]. This paper describes a log-based online recovery protocol in which a failed replica receives the prefix of the log corresponding to the update transactions it has missed. Since the log grows as the recovery progresses, the protocol has a special handshake protocol to finish recovery. The recoverer traverses the log from the first transaction the failed replica missed until it reaches the end of the log. At this point, the end recovery handshake protocol is started to determine which will be the last transaction to be sent as part of the recovery. The recovering replica starts storing requests that follow this transaction to process them after recovery finishes.

Online recovery has also been used for replicated data warehouses across the Internet [9]. In this work, each replica is located at an autonomous organization and exhibits an interface to execute queries. The online recovery protocol exploits the underlying architecture and performs recovery by issuing queries from the recovering replica to the working replicas. It also takes advantage of a facility for historical queries that enables executing a read only query providing a timestamp T. This historical query will return the same results as it happened at time T. The recovery protocol has 3 phases. In the first phase, the recovering site determines the latest time T for which it has all the committed updates. In the second phase, the recovering site runs historical queries at working replicas (that act as recoverer replicas) with a timestamp between the recovery point and a time closer to the present to catch up missed updates. Historical queries do not set read locks, and therefore do not block updates at the recoverer sites. In the final phase, a regular query (non-historical) is run to get the latest updates. In this case, read locks are set to guarantee the consistency.

Online recovery has also been studied in other contexts, such as diverse data replication and Byzantine data replication. In diverse data replication [4], each replica runs a database from a different vendor. This approach enables tolerating software failures since it has been observed that bugs in one product typically do not appear in a database from a different vendor [4]. In diverse data replication, recovery is slightly more complex, since it requires using a common abstract representation of the data. This might need some tuple translation during recovery in order to align fields with slightly different types.

Byzantine data replication [17] tolerates intrusions and provides continuous correct service despite them. An intrusion happens at a site when it is attacked. This site may behave arbitrarily to disrupt service provision. Intrusions are modeled as Byzantine (also known as arbitrary) failures. Byzantine replication typically resorts to diverse data replication to avoid common vulnerabilities. Typically tolerating f Byzantine failures requires $3 \cdot f+1$ replicas. Byzantine data replication has a more involved recovery, since it should also mask Byzantine recoverers. This means that a sufficient number of recoverers is needed in order to mask Byzantine failures during recovery [2]. An additional issue in Byzantine fault tolerance is that once one replica has been successfully attacked, another one can be attacked, and so on. In order to reduce the window of vulnerability, proactive recovery has been proposed [2]. This approach recovers replicas proactively without waiting until they are crashed or attacked. During recovery, the recovering replica boots from read-only media and recovers the state from working replicas using a Byzantine recovery protocol. During recovery, the state is transferred from multiple working replicas to be able to tolerate Byzantine (attacked) recoverers. Replicas are recovered in a round-robin fashion forced by a reboot provoked by a hardware watchdog. In this way, even if a replica has been attacked silently (without the system and administrator noticing it), it will become operative again, thus, reducing the window of vulnerability of the system.

Foundations

High availability consists of two inseparable aspects. On one hand, it requires the ability to tolerate failures. This is typically achieved by introducing redundancy in the form of replication. However, in order to keep a given degree of availability, the ability to recover failed (or new) replicas is also necessary. Recovering failed replicas requires obtaining a quiescent state from a working replica (or *recoverer replica*) and transferring it to the new replica (or *recovering replica*). This quiescent state can be easily obtained by stopping transaction processing. This results in *offline recovery.* Although offline recovery guarantees the consistency of recovery, its major drawback is that it results in a loss of availability during the recovery process that defeats the original goal of replication, which is to provide high availability. The alternative is *online recovery*, that is, to transfer the state to a recovering replica without stopping transaction processing.

Replication can be used to provide scalability in addition to providing availability. In this case, availability results insufficient as a metrics to express the goodness of a recovery protocol [5]. Performability becomes a more appropriate metrics in this context. *Performability* is defined as the cumulative performance of a highly available system over a period of time in the presence of failures and recoveries. To understand why it is important, an extreme situation will be illustrated. A replicated system has a throughput of 1000 transactions per second (tps). During online recovery the system remains available, but its throughput decreases to 1 tps. Although this system is available, it is clearly worse than a system that would deliver 990 tps during the online recovery (assuming that online recovery takes the same amount of time in both systems). However, when comparing the performability of both systems during online recovery, the former system would offer a very poor performability, while the second would offer a very high one close to the one in which the system is not recovering any replica.

Online recovery protocols typically consist of five phases:

1. *Local Recovery* brings the local state to a consistent state by means of centralized recovery.
2. *Find Last Committed Update Transaction* determines the last update transaction reflected in the local state.
3. *Global Recovery Start* initiates online recovery taking care of obtaining a quiescent state from one or more working replicas to be transferred to the recovering replica.
4. *Global Recovery* transfers a quiescent state from a working replica to the recovering replica.
5. *Global Recovery End* is the handshake protocol to determine the end of recovery.

The first and second phases depend on whether the recovering replica is a failed replica or a fresh new replica. For a failed replica, the first phase is typically performed automatically by the underlying database system upon recovery after a crash. For a failed replica, the second phase implies traversing the log or any other recovery information repository to find out which was the last committed update transaction. In most protocols, this information does not need to be precise. It can be enough to obtain the identifier of a committed transaction (e.g., a timestamp, log sequence number or transaction identifier, TID) close to the failure instant such that all previously committed transactions are also reflected in the local state. If some updates of latter transactions are reflected in the state, they will be rewritten during recovery. For a fresh new replica, the first phase is empty and the second phase first involves obtaining a checkpoint of the database and then performing the same processing as a failed replica. The checkpoint of the database also needs to be obtained in an online fashion using techniques such as point-in-time recovery [16] in order to keep the system available.

In the third phase, there is some communication between the recovering replica and the working replicas. This interaction has several purposes. First, the working replicas become aware of the new replica wanted to join the system. Second, the recovering replica informs the working replicas about the last known update. Third, a recoverer is elected to transfer the state to the recovering replica.

The fourth phase transfers the state from the recoverer to the recovering replica. The recovery process is synchronized with replica control to guarantee that a quiescent state is transferred to the recovering replica.

The fifth phase aims at finishing the recovery, which requires splitting the sequence of transactions into two disjoint sets (the ones whose state is reflected in the state transfer to the recovering replica, and the ones that should be processed by the recovering replica after finishing the recovery).

Online recovery depends on the specific features of the replica control protocol being used, such as eager vs. lazy, primary-backup vs. update-everywhere, kernel-based vs. middleware-based replication, etc. In eager replication, the coordination between replica control and online recovery is very tight to guarantee consistency [6,7,13,14,10]. In lazy replication, the coordination can be looser. For instance, in a freshness-based approach [12,3], as far as the freshness requirement is satisfied the coordination can be more relaxed. In a primary-backup approach, the recovery of backups is simpler since they do not execute updates on their own, they just apply the updates coming from the primary [15]. In update-everywhere approaches [6,7,13,14,10] the recovery needs to be interleaved carefully with replica control to guarantee consistency [8,5]. In kernel-based approaches, it is possible to use recovery protocols that use mechanisms within the kernel (such as locking) [8]. However, in middleware-based approaches, the recovery can only use those mechanisms available at the database interface [5].

In this entry, two approaches will be examined in detail: an online recovery for kernel-based replication based on locking [8], and an online recovery for middleware-based replication based on logging [5].

First, a locking-based online recovery approach is studied. This approach is based on the most basic protocol from [8]. This basic version of the protocol transfers the full database. The recovery is coordinated with replica control to guarantee consistency. This coordination is materialized through locking. In what follows, the first generic phases of online recovery for this particular protocol are described. The first phase, local recovery, is orthogonal to online recovery it can just be ignored. The second phase consists in determining the last update known by the recovering replica. Since in this approach the full database is sent, this phase does not exist.

The third phase is recovery start. The recovering replica notifies to the working replicas that is willing to join the system and recover. In this protocol, in order to guarantee the quiescence of the transferred state, the recovery is started by initiating a transaction that sets atomically special read locks or recovery locks over all the tuples in the database. The quiescent state to be transferred corresponds to the state just after the atomic setting of the recovery locks. The recovery then takes place gradually. As soon as a recovery lock is granted, the tuple is read and sent to the recovering replica. Then, the lock is released. It should be noted that recovery locks are read locks and therefore do not delay read operations, only update ones. During the recovery, the recovering replica should store the incoming transactions (only those involving updates) to process them after recovery, since the associated updates are not incorporated in the state being transferred to it.

The end-of-recovery handshake is simple in this protocol. It is initiated after the sending of the last tuple, and the recovery message piggybacks is marked to indicate this fact. After receiving this message, the recovering replica starts to process all the stored transactions during the recovery. Depending on the replica control in place the recovering replica will execute the update transactions, or will receive the resulting updates from the other replicas (which is usually the case). In the latter case, incoming transactions do not need to be stored-just the update propagation messages from the other replicas.

There are many optimizations that can be performed over this basic protocol as described in [8]. Batching recovery messages limit the amount of data transferred during recovery by recording the updates performed during recovery, shortening the amount of updates to be stored during online recovery by using multiple phases, etc.

The second protocol that will be described is a log-based protocol [5]. This protocol is combined with a pessimistic replica control implemented as a middleware layer. A pessimistic replica control freely executes non-conflictive transactions in the replicated system, while conflictive ones are executed in the same relative order at all replicas. The replica control protocol over which online recovery is built is Nodo, described in [13]. Nodo is based on the notion of conflict classes. A transaction might access one or more conflict classes. Each conflict class has a master replica. Each combination of conflict classes also has a master replica, one of the master replicas of the individual conflict classes. Each conflict class has an associated transaction queue. Update transactions are sent to all replicas in the same order. Read-only transactions are only sent to one of the replicas. Transactions are queued in the conflict class queues relevant to them (the ones that they read or write). When a transaction is at the front of all the queues it has been enqueued, the master of the conflict class combination associated to the transaction executes it locally. If the transaction is read-only, then the results are returned directly to the client and removed from all the queues. If the transaction contains updates, the master extracts them from the database and sends them to all other replicas. Nodo keeps a log for each individual conflict class that is exploited by the online recovery protocol.

The online recovery protocol for Nodo guarantees consistent recovery by careful coordination with the replica control protocol of Nodo. Individual conflict classes can be recovered independently, that is, each individual conflict class could use a different recoverer replica. The recovery of an individual conflict class is detailed in what follows. The first phase, local recovery, occurs when the replica recovers. The second phase, determining the last update reflected in the replica state, is done by looking at the local log. The recovering replica traverses the log to determine the identifier of the last transaction processed for the conflict class being recovered. This identifier is used in the fourth phase to initiate the recovery of the conflict class. One of the working replicas is elected as recoverer replica for this conflict class. In the fourth phase, the recoverer replica traverses the log of the conflict class being recovered. The recoverer replica continues processing updates involving this conflict class. This means that the log grows as is being traversed. The recovering replica just applies all the updates corresponding to the conflict class under recovery, but will discard them, since it is receiving them via the recovery. The recoverer replica will eventually reach the end of the log. At this point the fifth phase is performed to finish recovery. In the end-of-recovery handshake three different roles are involved, namely, the recoverer and recovering replicas, and the master replica of the conflict class under recovery. There is a race condition, since the master produces updates from locally executed transactions, while the recoverer needs to know the last update to be forwarded to the recovering replica and the recovering replica needs to know from which transaction it has to start to process update transactions. When the recoverer reaches the end of the log, it sends a request-end-of-recovery message to all replicas (only the master needs this message in the failure-free case). The master will then piggyback with the next update it forwards an end-of-recovery marker. This marker will indicate to the recoverer that this is the last update to be sent to the recovering replica. The marker will tell the recovering replica which is the last update part of the recovery, and therefore it will know from which point it has to apply updates received from the master replica.

The online recovery for Nodo, as stated before, allows recovering conflict classes independently. In fact, once a conflict class is recovered, the recovering replica could become master of that class. Additionally, several conflict classes can be recovered in parallel using different recoverers for each of them. The online recovery for Nodo has been designed to be adaptive. The goal is to obtain the highest performability.

If the replicated system has a low load, the resources employed to recover the replica are increased (i.e., increasing the number of recoverers). If there is a peak load, during recovery, then the resources devoted to recovery can be decreased (i.e., decreasing the number of recoverers). In this way, performability is maximized. Nodo also enables dealing with overlapping recoveries in parallel. If a batch of sites is recovered in a time interval, they will start recovery at slightly different times. The recovery protocol takes care of recovering simultaneously conflict classes for all recovering replicas it knows. In this way, if one replica starts recovery after another one has recovered two conflict classes, they will perform simultaneously the recovery of the remaining N-2 conflict classes, being N the number of conflict classes, and alone the recovery of the first two conflict classes. This enables a more efficient dissemination of the recovery messages (e.g., exploiting multicast) and efficiently recovering batches of replicas.

Key applications

Online recovery is a crucial technique to provide true high availability, that is, 24×7 operation. Its main potential users are all those organizations that provide services that should be continuously available. Among these potential users one can find enterprise data centers, software as a service (SaaS) platforms, services governed by service level agreements (SLAs), services for critical infrastructures (health-care, energy, police, etc.).

Knowledge management

Definition

Biology is a knowledge-rich discipline. Much of bioinformatics can, therefore, be characterized as *knowledge management*: organizing, storing and representing that knowledge to enable search, reuse and computation.

Most of the knowledge of biology is categorical; statements such as "fish gotta swim, birds gotta fly" cannot be easily represented as mathematical or statistical relationships. These statements can, however, be formalized using ontologies: a form of model which represents the key concepts of a domain.

Ontologies are now widely used in bioinformatics for a variety of tasks, enabling integration and management of multiple data or knowledge sources, and providing a structure for new knowledge as it is created.

Historical Background

Biological knowledge is highly complex. It is characterized not by the large size of the data sets that it uses, but by the large number of data types; from relatively simple data such as raw nucleotide sequence, through to anatomies, systems of interacting entities, to descriptions of phenotype.

In addition to its natural complexity, biology has traditionally operated as a "small science" – with a large number of individual, autonomous laboratories working independently. This has resulted in highly heterogeneous data; in addition to the natural complexity of the data, knowledge is often represented in many different ways [5]. There are, for example, at least twenty different file formats for representing DNA sequence.

Ontologies can be used to enable the knowledge management that overcomes these two forms of complexity. First, they can be used to represent complex, categorical knowledge of the sort common in biology. Second, by describing the heterogeneity of the representation of knowledge, they can provide a common, shared understanding that can be used to overcome this heterogeneity.

In post-genomic biology, the first of these has been the most common usage. Here, ontologies are used to generate a controlled vocabulary; for this, the Gene Ontology (GO) [14] provides the paragon for biological sciences. It represents three key aspects of genetics; the *molecular function* of a gene (product), the *biological process* in which the product is involved, and the *cellular component* in which it is located. GO has been used to annotate many genomes and has been used for annotations in UniProt and InterPro. Following on from the success of GO, the Open Biomedical Ontologies (OBO) now provides controlled vocabularies for describing many aspects of biological knowledge (http://obo.sf.net).

The second major use has been to enable access to or querying over multiple independent data sources. EcoCyc [8], for example, uses an ontology to provide a schema to integrate genome, proteome data and a number of pathway resources, while RiboWeb [1] was a similar style of ontology driven application for storing, managing and analyzing data from experiments on ribosomal structure. The TAMBIS system [7] used an ontology to mediate queries to a number of different data sources.

Most of these examples are *post-hoc* additions to existing systems; GO, for example, presents knowledge which is already present in other, less formal, representations. More recently, however, there has been a shift to the use of ontologies as a primary representation. The MGED Ontology (MO) [17] provides a vocabulary for reporting microarray experiments, while the Systems Biology Ontology (SBO) (http://www.ebi.ac.uk/sbo/) supports the representation of systems biology models.

Over the past decade, the use of ontologies has now become well-entrenched as a tool for organizing and structuring biomedical knowledge and, therefore, has become a key part of life science knowledge management [3].

Foundations

It was recognized early in bioinformatics that there is a massive problem with heterogeneous representations of data [5]. Such heterogeneities, particularly at the semantic level, exist both in the meanings of the structures that hold values (the schema) and in the meanings of the values themselves. To query or analyze meaningfully across data from different sources, therefore, there is a necessary reconciliation step to enable the data to be understood. A database, for example, might have either separate tables for substrate or product, or just one for reactant; as an orthogonal issue, a chemical might be "acetic acid" in one or "ethanoic acid" in another. Both types of mis-match need to be overcome.

This heterogeneity can occur both in descriptions of biology and also bioinformatics: it is possible to disagree on which genes are involved in a process, what those genes are called and what structure is used to hold information about those genes.

Ontologies provide a computable mechanism for working around these problems; they describe the entities and what is known about these entities within the data of biology, and provide a set of labels to describe these entities and their properties. As a result, an ontology can be used to describe the entities within a biological database. Terms from the Gene Ontology, for example, are used to describe the major functional attributes of gene products in many databases; this, in turn, allows comparative studies of genes and their actions across species.

Ontologies need to be represented in a language; these are often called knowledge representation languages. They have a set of language elements for describing categories (also called classes, types, concepts or universals) of instances (also called objects, entities, individuals or particulars). The languages vary in their expressivity – that is, how much is it possible to say about what these elements mean. For example, if we state that *ArB*, where *A* and *B* are classes and *r* is a relationship, does this mean that every *A* has a *B* related to it by *r*; that for any *A* with a *r* relation, this *r* is to a *B*; to how many *B*'s can an *A* have a relationship; that *r* has an inverse relationship, and so on. Some languages allow only trees of categories to be made, others more complex graphs. Finally, languages differ in their computational amenability [11].

Ontologies have found a variety of uses within bioinformatics:

- **Reference Ontology:** An ontology can be used simply as a reference, encompassing what is understood about a domain with high-fidelity. Such an ontology is not skewed by any application bias, except that of correctness.

- **Controlled Vocabulary:** The labels on the categories in an ontology provide a vocabulary with which discussion of those categories can be accomplished. By committing to use that vocabulary – controlling the words used in communication – a controlled vocabulary is established. This is the principal means of overcoming a large portion of heterogeneity.

- **Computational Component:** An ontology can form a component in a software application. The strict semantics of its representation language can be used to make inferences from data described in terms of that ontology. This can simply be retrieving all the children of a given category (all instances of a child are also instances of the parent) to recognizing membership of a category based on facts known about an object.

  There are many technical and social difficulties associated with using an ontology for data management. The choice of representation language can be key; an ontology for use as a computational component probably needs a more computationally amenable and expressive language than an ontology intended to provide a controlled vocabulary. It is often hard to engage with domain experts to ensure that the ontology reflects the domain, while maintaining ontological precision. There are a number of methodologies for ontology building [6], but the discipline is still nascent. Finally, adapting and updating the ontology when it is already in use can require rigorous, yet flexible policies.

Key Applications

Perhaps the best known ontology in biology is the Gene Ontology (GO) [14]. It started in 1998 with an aim of enabling queries across multiple databases for the key aspects or properties of the genes or proteins; it achieves this not by schema reconciliation but enabling the augmentation of existing knowledge; in short, it is one of the best examples of a reference ontology.

Another domain well served by reference models is that of anatomy. The Foundational Model of Anatomy, for example, aims to provide a "symbolic modeling of the structure of the human body in a computable form that is also understandable by humans" [12]. The aim is that this ontology provides a common representation into which others can be mapped.

One of the early uses for ontologies was enabling schema and value reconciliation. The TAMBIS [7] system was an early example. It uses an ontological representation of entities and their properties in biology expressed in a description logic [2]. These descriptions, that could be composed to more complex concept descriptions, were then transformed to queries against bioinformatics analysis services capable of retrieving instances of the concepts within the ontology. The ontology, then, could tell that the user that a `Protein` might have one or more `Homologs`, while the system would understand that a BLAST search might reveal these `Homologs`. A concept therefore also defined a query plan. More recently, the BioPAX ontology [10] provides a schema for representing biological pathway data; the different contributing databases could then release knowledge in the format. Both of these operate on the level of schema, but reconciliation to a common model also occurs at the level of the values held within a schema. The Gene Ontology, for example, in providing a controlled vocabulary for the functional attributes of gene products has allowed many genome resources to use common values within their schema.

Both BioPAX and TAMBIS enabled querying by assigning objects to categories in the ontology. Ontologies represent the properties by which objects can be recognized to be a member of a category. If these properties are recognizable computationally, then the ontology can be used to classify these members automatically. This approach has been used to classify the phosphatase proteins from three parasite genomes [4]. A final approach to ontological querying is to use the ontology as a basis for statistical analysis of individuals annotated with these ontologies. GO has been widely used for this purpose [9,15].

Finally, ontologies have begun to be used for the representation of metadata about primary experimental data. The MGED society has led the way with the MGED Ontology (MO) which has been used for describing microarray data[17]. This ontology describes a number of aspects about an experiment including: the biological material used; experimental design and microarray equipment. Similar work is now underway for describing proteomics experiments [13]. These are coming together in the Ontology for Biomedical Investigations OBI that is providing a general framework for describing the protocols and analyses for many different kinds of experiment [16].

Future Directions

In the past decade ontologies have come to form a major aspect of information management in the life sciences. The field of ontology development in the life sciences now faces several challenges in the short and medium term.

- The wide scope of biology is a challenge; to describe many parts of it, also needs descriptions of closely related areas such as chemistry, geology and geography.
- Ontologies are starting to get very large. It is not clear whether current methodologies are scalable, both in terms of building, maintaining or using them. This has many implications for the formal expressive structures of the knowledge representation language, the ability to support modularity of these languages, and the social processes used to build ontologies.
- Dealing with change both as a result of the ontology development process and, perhaps more importantly, as a result of changes in knowledge itself. There are many different techniques for dealing with the former situation; there are many fewer for dealing with the latter. If datasets gathered over a long period of time are to be understood in the future, it may become as important to understand what was thought in the past as it is to manage the current sate of knowledge.
- Currently many ontologies deal with a single level of granularity or the view point of a single discipline building sophisticated, computationally amenable ontologies necessitates crossing boundaries of granularity and discipline. It remains, however, unclear how to integrate these sorts of ontology.
- Ontologies currently fulfill the luxury end of the metadata market; they can be very expensive to build, maintain and deploy. Lower the cost is critical. Probably the best way to achieve this is to make them easier for domain scientists to build which leads to a second challenge; maintaining usability of ontologies and representation languages, while increasing their scale and computability.

It seems clear that ontologies will be in heavy use in the future within the life sciences. How well these challenges are answered will determine the uses to which they are put.

Definition

In the context of computer and information sciences, an ontology defines a set of representational primitives with which to model a domain of knowledge or discourse. The representational primitives are typically classes (or sets), attributes (or properties), and relationships (or relations among class members). The definitions of the representational primitives include information about their meaning and constraints on their logically consistent application. In the context of database systems, ontology can be viewed as a level of abstraction of data models, analogous to hierarchical and relational models, but intended for modeling knowledge about individuals, their attributes, and their relationships to other individuals. Ontologies are typically specified in languages that allow abstraction away from data structures and implementation strategies; in practice, the languages of ontologies are closer in expressive power to first-order logic than languages used to model databases. For this reason, ontologies are said to be at the "semantic" level, whereas database schema are models of data at the "logical" or "physical" level. Due to their independence from lower level data models, ontologies are used for integrating heterogeneous databases, enabling interoperability among disparate systems, and specifying interfaces to independent, knowledge-based services. In the technology stack of the Semantic Web standards

[1], ontologies are called out as an explicit layer. There are now standard languages and a variety of commercial and open source tools for creating and working with ontologies.

Historical Background

The term "ontology" comes from the field of philosophy that is concerned with the study of being or existence. In philosophy, one can talk about an ontology as a theory of the nature of existence (e.g., Aristotle's ontology offers primitive categories, such as substance and quality, which were presumed to account for All That Is). In computer and information science, ontology is a technical term denoting an artifact that is *designed* for a purpose, which is to enable the modeling of knowledge about *some* domain, real or imagined.

The term had been adopted by early Artificial Intelligence (AI) researchers, who recognized the applicability of the work from mathematical logic [6] and argued that AI researchers could create new ontologies as computational models that enable certain kinds of automated reasoning [5]. In the 1980s the AI community came to use the term ontology to refer to both a theory of a modeled world (e.g., a Naïve Physics [5]) and a component of knowledge systems. Some researchers, drawing inspiration from philosophical ontologies, viewed computational ontology as a kind of applied philosophy [10].

In the early 1990s, an effort to create interoperability standards identified a technology stack that called out the ontology layer as a standard component of knowledge systems [8]. A widely cited web page and paper [3] associated with that effort is credited with a deliberate definition of ontology as a technical term in computer science. The paper defines ontology as an "explicit specification of a conceptualization," which is, in turn, "the objects, concepts, and other entities that are presumed to exist in some area of interest and the relationships that hold among them." While the terms specification and conceptualization have caused much debate, the essential points of this definition of ontology are:

- An ontology defines (specifies) the concepts, relationships, and other distinctions that are relevant for modeling a domain.
- The specification takes the form of the definitions of representational vocabulary (classes, relations, and so forth), which provide meanings for the vocabulary and formal constraints on its coherent use.

One objection to this definition is that it is overly broad, allowing for a range of specifications from simple glossaries to logical theories couched in predicate calculus [9]. But this holds true for data models of any complexity; for example, a relational database of a single table and column is still an instance of the relational data model. Taking a more pragmatic view, one can say that ontology is a tool and product of engineering and thereby defined by its use. From this perspective, what matters is the use of ontologies to provide the representational machinery with which to instantiate domain models in knowledge bases, make queries to knowledge-based services, and represent the results of calling such services. For example, an API to a search service might offer no more than a textual glossary of terms with which to formulate queries, and this would act as an ontology. On the other hand, today's W3C Semantic Web standard suggests a specific formalism for encoding ontologies (OWL), in several variants that vary in expressive power [7]. This reflects the intent that an ontology is a specification of an abstract data model (the domain conceptualization) that is independent of its particular form.

Foundations

Ontology is discussed here in the applied context of software and database engineering, yet it has a theoretical grounding as well. An ontology specifies a vocabulary with which to make assertions, which may be inputs or outputs of knowledge agents (such as a software program). As an *interface specification*, the ontology provides a language for communicating with the agent. An agent supporting this interface is not required to use the terms of the ontology as an *internal encoding* of its knowledge. Nonetheless, the definitions and formal constraints of the ontology do put restrictions on what can be *meaningfully* stated in this language. In essence, committing to an ontology (e.g., supporting an interface using the ontology's vocabulary) requires that statements that are asserted on inputs and outputs be *logically consistent* with the definitions and constraints of the ontology [3]. This is analogous to the requirement that rows of a database table (or insert statements in SQL) must be consistent with integrity constraints, which are stated declaratively and independently of internal data formats.

Similarly, while an ontology must be formulated in *some* representation language, it is intended to be a semantic level specification – that is, it is independent of data modeling strategy or implementation. For instance, a conventional database model may represent the identity of individuals using a primary key that assigns a unique identifier to each individual. However, the primary key identifier is an artifact of the modeling process and does not denote something in the domain. Ontologies are typically formulated in languages which are closer in expressive power to logical formalisms such as the predicate calculus. This allows the ontology designer to be able to state semantic constraints without forcing a particular encoding strategy. For example, in typical ontology formalisms one would be able to say that an individual was a member of class or has some attribute value without referring to any implementation patterns such as the use of primary key identifiers. Similarly, in an ontology one might represent constraints that hold across relations in a simple declaration (A is a subclass of B), which might be encoded as a join on foreign keys in the relational model.

Ontology engineering is concerned with making representational choices that capture the relevant distinctions of a domain at the highest level of abstraction while still being as clear as possible about the meanings of terms. As in other forms of data modeling, there is knowledge and skill required. The heritage of computational ontology in philosophical ontology is a rich body of theory about how to make ontological distinctions in a systematic and coherent manner. For example, many of the insights of "formal ontology" motivated by understanding "the real world" can be applied when building computational ontologies for worlds of data [4]. When ontologies are encoded in standard formalisms, it is also possible to reuse large, previously designed ontologies motivated by systematic accounts of human knowledge or language [11]. In this context, ontologies embody the results of academic research, and offer an operational method to put theory to practice in database systems.

Key Applications

Ontologies are part of the W3C standards stack for the Semantic Web, in which they are used to specify standard conceptual vocabularies in which to exchange data among systems, provide services for answering queries, publish reusable knowledge bases, and offer services to facilitate interoperability across multiple, heterogeneous systems and databases. The key role of ontologies with respect to database systems is to specify a data modeling representation at a level of abstraction above specific database designs (logical or physical), so that data can be exported, translated, queried, and unified across independently developed systems and services. Successful applications to date include database interoperability, cross database search, and the integration of web services.

Definition

Ontology elicitation embraces the family of methods and techniques to explicate, negotiate, and ultimately agree on a partial account of the structure and semantics of a particular domain, as well as on the symbols used to represent and apply this semantics unambiguously.

Ontology elicitation only results in a *partial* account because the formal definition of an ontology cannot completely specify the intended structure and semantics of each concept in the domain, but at best can approximate it. Therefore, the key for scalability is to reach the appropriate amount of consensus on relevant ontological definitions through an effective meaning negotiation in an efficient manner.

Historical Background

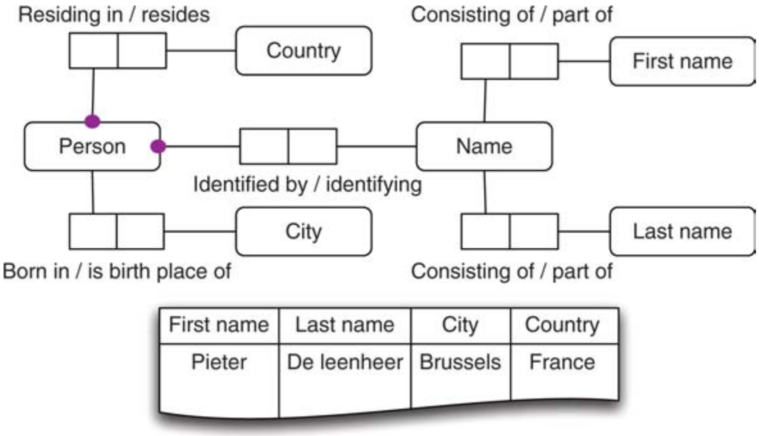
Ontology elicitation is based on techniques of *knowledge acquisition*, a subfield of AI that is concerned with eliciting and representing knowledge of human experts so that it can later be used in some application. Two typical knowledge acquisition methods can be distinguished:

1. *Top-down* (deductive) *knowledge elicitation* techniques are used to acquire knowledge directly from human domain experts. Examples include interviewing, case study, and mind mapping techniques.
2. *Bottom-up* (inductive) *machine learning* techniques use different methods to infer knowledge (e.g., concepts and rules) patterns from sets of data. A well-known example is *formal concept analysis* [10].

More formal methods for top-down knowledge acquisition use *knowledge modeling* as a way of structuring projects, acquiring and validating and storing knowledge for future use. Knowledge models include: symbolic character-based languages (e.g., logic, OWL), diagrammatic representations (networks, ladders, taxonomies, concept maps), tabular representations (e.g., matrices), structured text (e.g., hypertext) [16], and conceptual modeling.

Conceptual Modeling

Certain methods and techniques from the database field for *conceptual modeling* (e.g., ER, UML, dataflow diagrams) have been proven useful for ontology elicitation. For example, in [13], ORM/NIAM has been adopted. Figure 1 shows an example of a minimal ORM diagram (on top) explicating the semantics that is implicit in the relational table schema and population (on the bottom). For example, this ORM diagram already reveals what the table cannot, the semantics of



First name	Last name	City	Country
Pieter	De leenheer	Brussels	France

Ontology Elicitation. Figure 1. Illustration of a minimal ORM diagram explicating the implicit semantics for a relational table.

the relation of attribute "person" to attributes "city" and "country," and that "first name" and "last name" are both part of a "name." Furthermore, "city" and "country" appear not to be related at all.

A key characteristic of NIAM/ORM is that the analysis of information is based on natural language. This brings the advantage that the analysis can be done by the domain experts using their own vocabulary, and hence avoiding invalid interpretations. Furthermore, this attribute-free approach seen in the NIAM/ORM approach promotes semantic stability.

Data Schema Versus Ontology

Data models, such as data or XML schemas, typically specify the structure and integrity of data sets. Hence, building data schemas for an enterprise usually depends on the specific needs and tasks that have to be performed within this enterprise. *Data engineering* languages such as SQL aim to maintain the integrity of data sets and only use a typical set of language constructs to that aim, e.g., foreign keys. The schema vocabulary is basically to be understood intuitively (via the terms used) by the human database designer(s). The semantics of data schemas often constitute an informal agreement between the developers and an intended group of users of the data schema, and finds its way only in application programs that use the data schema instead of manifesting itself as an agreement that is shared amongst the community [20]. When new functional requirements pop up, the schema is updated on the fly. One designated individual usually controls this schema update process.

In (collaborative) ontology elicitation, however, absolute meaning is essential for all practical purposes, hence all elements in an ontology must ultimately be the result of agreements among human agents such as designers, domain experts, and users. In practice, correct and unambiguous reference to concepts or entities in the schema vocabulary is a real problem; often harder than agreeing about their properties, and obviously not solved by assigning system-owned identifiers.

Foundations

In collaborative ontology elicitation, multiple stakeholders have overlapping or contradicting perspectives about the intended structure, semantics, and vocabulary of the domain concepts [5]. This is principally caused by three facts: (i) no matter how expressive ontologies might be, they are all in fact lexical representations of concepts, relationships, and semantic constraints; (ii) linguistically, there is no bijective mapping between a concept and its lexical representation; and (iii) concepts can have different properties and values in different contexts of use. Hence, humans play an important role in the interpretation and negotiation of meaning during the elicitation and application of ontologies [7]. These principles can be illustrated by considering Stamper's *semiotic ladder* [21] that consists of six views or levels on signs from the perspective of physics, empirics, syntactics, semantics, pragmatics and the social world, that together form a complex conceptual structure. In this article, we only consider syntactical or *lexical* level, *semantic* level, and *pragmatic* level (Fig. 2). Ontology elicitation can be considered as a process that gradually takes ontological elements through these levels.

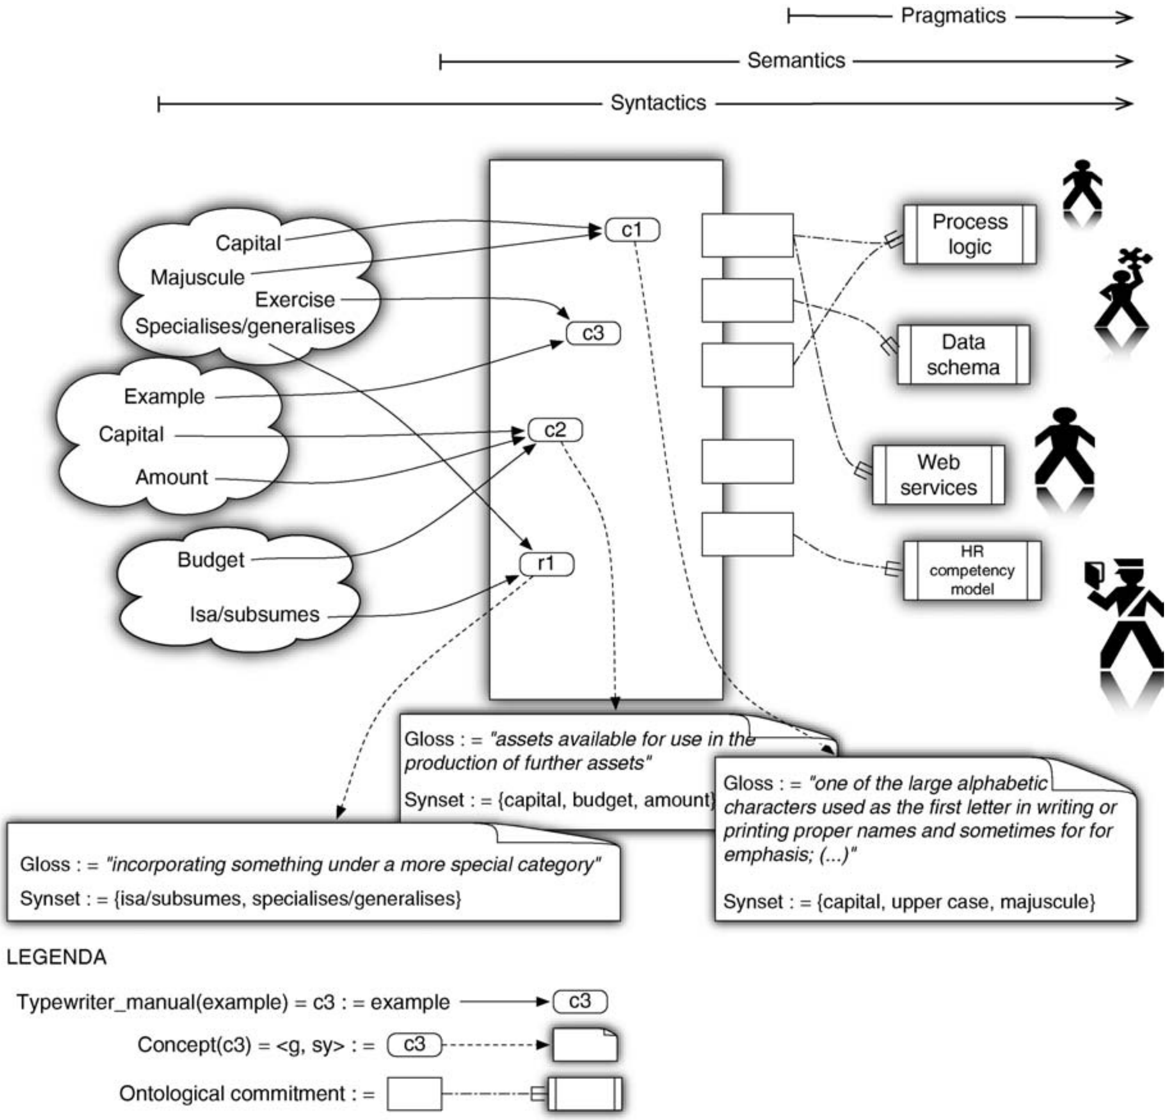
Lexical Versus Semantic Level

At the start of the elicitation of an ontology, its basic terminology for labeling concepts and relationships are extracted from various resources such as a text corpus [3], existing schemas [16], from so-called *serious games* [19] or rashly formulated by human domain experts through, e.g., tagging [22]. Many ontology engineering approaches focus merely on the conceptual modeling task, hence the distinction between lexical level (term for a concept) and semantic level (the concept itself) is often weak or ignored. In order to represent concepts and relationships lexically, they usually are given a uniquely identifying term (or label). However, the meaning of a concept behind a lexical term is influenced by the *elicitation context*, which is the context of the resource the term was extracted from. When eliciting and unifying information from multiple sources, this can easily give rise to misunderstandings and ambiguities, therefore the meaning of all terms used for ontology representation purposes should be articulated appropriately.

This is illustrated in Fig. 2: the full arrows denote the *meaning articulation* mappings between terms in organizational vocabularies (cloud on the left) and unique *concept identifiers* (e.g., c_1, r_1, etc.). The mapping of each unique concept identifiers to a particular explication of a meaning, i.e., a *concept definition* is defined by the dashed arrows.

Lexical Variability and Reusability

Even within one conversation, it turned out that in a less than a quarter of the cases, two individuals use



Gloss : = *"assets available for use in the production of further assets"*

Synset : = {capital, budget, amount}

Gloss : = *"one of the large alphabetic characters used as the first letter in writing or printing proper names and sometimes for for emphasis; (...)"*

Synset : = {capital, upper case, majuscule}

Gloss : = *"incorporating something under a more special category"*

Synset : = {isa/subsumes, specialises/generalises}

Typewriter_manual(example) = c3 : = example

Concept(c3) = <g, sy> : =

Ontological commitment : =

Ontology Elicitation. Figure 2. Three levels of ontology elicitation: lexical level, semantic level, and pragmatic level.

the same symbolic reference for a concept, and hence the freedom to use synonyms should be accommodated [8]. To engender creativity, domain experts should initially be allowed to use their own vocabularies, instead of being harshly restricted by an unfamiliar controlled taxonomy dictated by a central authorship. Gradually, this variability will converge towards one or more vocabularies that are commonly accepted.

For example, thousands of shared vocabularies or so-called folksonomies emerge, are sold and advertised, prosper or wither in a self-organizing manner on Web 2.0, through reuse and adaptation of natural language labels for tagging their resources. Natural language labels for concepts and relationships bring along their inherent ambiguity and variability in interpretation. Folksonomies provide on the one hand an unbounded reusability potential for specific reference in a given application context, which is important for scalable ontology elicitation. On the other hand, however, an analysis of multiple contexts is generally needed to disambiguate successfully [1,5].

Semantic Versus Pragmatic Level

The meaning articulation mappings and the concept definition service respectively provide unambiguous reference and semantic explication of terms, independent of the preferred vocabulary. However, the meaning of these concepts should be further formalized for appropriately serving application purposes, by combining and linking them with other concepts, and axiomatizing them with semantic constraints and rules. In the section on applications, there is an overview of typical applications, including process logic and (legacy) information system interoperability, web service orchestration, and competency model gap analysis in human resources (HR).

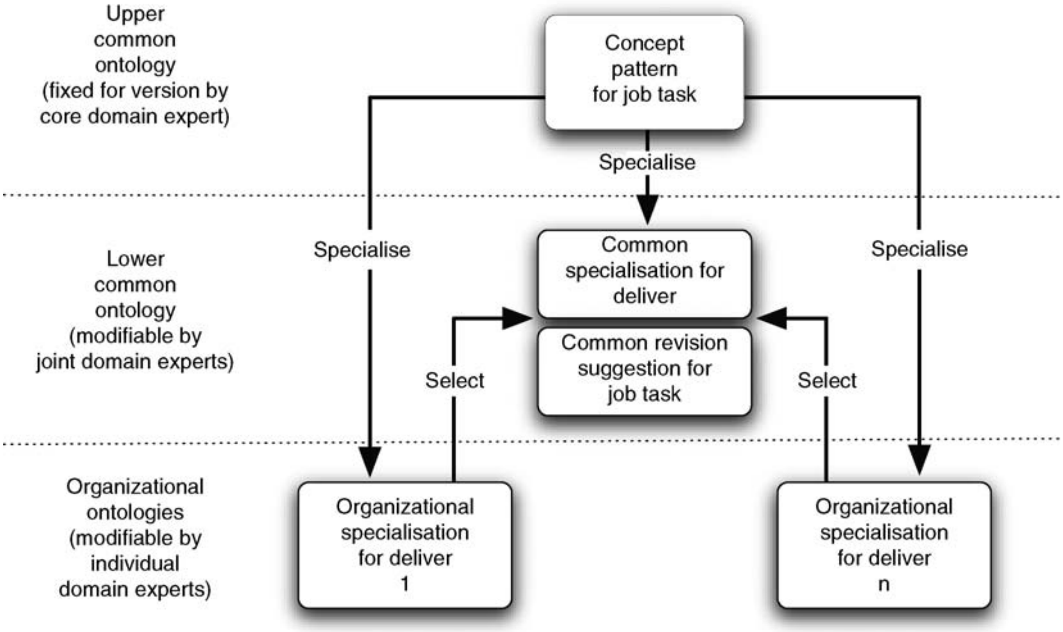
The relevant properties and values for the concepts to be agreed on, depend on the application requirements. For the sake of scalability, as in any realistic system or knowledge engineering scenario, in ontology elicitation, (parts of) existing semantic resources are reused and adopted as much as possible for new application purposes. This asks for a methodological trade-off between the reuse of relevant consensus from existing application contexts as much as possible, while allowing specific variations for new application requirements at stake to be collaboratively negotiated, based on (parts of) existing consensus.

Figure 3 illustrates this with a model for collaborative ontology elicitation, as introduced by [7], and inspired by the Delphi method (http://en.wikipedia.org/wiki/Delphi_method.). For bootstrapping the elicitation of a concept, knowledge workers are given a *pattern* that defines the current insights and interests of the community for that type of concepts. The example here concerns the elicitation of a concept "Deliver," which is a type of "Job Task." Each of the stakeholding organizations elicit the relevant properties and values of "Deliver" by specializing the pattern abstracted from "Job Task." If no pattern exists, it is bootstrapped by the core domain experts overlooking the domain.

Divergence and Conflict

Divergence is the point in collaborative ontology elicitation where domain experts disagree or have a conflict about the meaning of some concept in such a way that consequently their ontologies evolve in widely varying directions. Although they share common goals for doing business, divergent knowledge positions appear as a natural consequence when people collaborate in order to come to a unique common understanding.

Rather than considering it to be a problem, conflicts should be seen as an opportunity to *negotiate* about the subtle differences in interpretation of the domain, which will ultimately converge to a shared understanding disposed of any subjectivity. However, meaning conflicts and ambiguities should only be resolved when relevant. It is possible that people have



Upper common ontology (fixed for version by core domain expert)
Concept pattern for job task
Specialise
Lower common ontology (modifiable by joint domain experts)
Specialise
Common specialisation for deliver
Specialise
Common revision suggestion for job task
Select
Select
Organizational ontologies (modifiable by individual domain experts)

Organizational specialisation for deliver n

Ontology Elicitation. Figure 3. A model for collaborative ontology elicitation.

alternative conceptualizations in mind for business or knowledge they do not wish to share. Therefore, in building the shared ontology, the individual ontologies of the various partners only need to be aligned insofar necessary, in order to avoid wasting valuable modeling time and effort.

Basically they only need to agree on a common specialization of the current properties present in the pattern. However, it could be the case that a considerable part of the stakeholders identifies new relevant properties, or see other properties to be obsolescent. This provides a feedback suggestion to revise the patterns for a next version of the ontology.

Relevant techniques for collaborative ontology negotiation and argumentation include [14,17].

Convergence and Patterns

Once, a common specialization is agreed on, it is lifted up in the upper common levels of the ontology. Gradually, this would result in the emergence of increasingly stable generally deployable ontology patterns that are key for enabling future business interoperability needs in a scalable manner [2,6,9,7].

Key Applications

Ontologies have become an integral part of many academic and industrial applications in various domains, including Semantic Web services, regulatory compliance, and human resources.

Semantic Web Services

Service-oriented (SOA) is an architecture that relies on *service-orientation* as its fundamental design principle. In a SOA environment, independent services can be accessed without knowledge of their underlying platform implementation. Within this paradigm, the creation of automation logic is specified in the form of services. Service orientation is another design paradigm that provides a means for achieving a separation of concerns, which obviously increases the potential for software reusability.

The Semantic Web aims to make data accessible and understandable to intelligent machine processing. Semantic Web services additionally aim to do the same for services available on the Semantic Web, targeting automation of service discovery, composition and invocation. For describing Semantic Web services, it is required to elicit the so-called "domain ontologies" or that formalize the knowledge necessary for capturing the meaning of services and exchanged data. In other words, given a particular business goal, the domain ontologies enable the weaving of the relevant concerns that are separated in relevant services.

A key challenge here is to overcome the *ontology-perspicuity bottleneck* [11] that constrains the use of ontologies, by finding a compromise between top-down imposed formal semantics expressed in expert language and bottom-up emerging real-world semantics expressed in layman user language.

For more on infrastructure, theory, business aspects, and experiences on ontology elicitation and management for Semantic Web applications, see [12].

Regulatory Compliance

Businesses and government must be able to show compliance of their outputs, and often also of their systems and processes, to specific regulations. Demonstrable evidence of this compliance is increasingly an auditable consideration and required in many instances to meet acceptable criteria for good corporate governance. Moreover the number and the complexity of applicable regulations in Europe and elsewhere is increasing. This includes mandatory compliance audits and assessments against numerous regulations and best practice guidelines over many disciplines and against many specific criteria. The implementation of information communications technology also means that previous manual business processes are now being performed electronically and the degree of compliance to applicable regulations depends on how the systems have been designed, implemented and maintained. Keeping up with the rate of new regulations for a major corporation and small business alike is a never ending task. What is the answer to all of this regulatory complexity? First one should simplify regulations where possible and then apply automatic tools to assist.

The automated data demands of networked economies and an increasingly holistic view on regulatory issues are driving and yet partially frustrating attempts to simplify regulations and statutes. In an ideal world companies and other organizations would have the tools and online services to check and measure their regulatory compliance; and governmental organizations would be able to electronically monitor the results. This requires a more systemic shared approach to regulatory assurance assessment and compliance certification.

Lessig [15] has a simple yet profound thesis "Code is law." The application of this concept taken in conjunction with the emergence of regulatory ontologies opens up a new way of assessing whether burgeoning systems are compliant with regulations they seek and claim to embody. First specific regulations (e.g., data privacy, digital rights management) are converted into and expressed as "Regulatory Ontologies." These ontologies are then used as the base platform for a "Trusted Regulatory Compliance Certification Service."

Over time the resulting ontology describing and managing the areas analyzed can literally replace the regulations and compliance criteria. So much so, it is envisaged that an eventual outcome could be that the formal writing (codification) of future laws will start with the derived ontologies and use intelligent agents to help propose specific legal text which ensures that the policy objectives are correctly coded in law. In addition automatic generation of networked computer applications that are perfectly compliant with the wide variety of directives and laws in any country is one of the ultimate goals of this type of ontology based work.

For an overview of ontology-grounded trusted regulatory compliance, see [18].

Human Resources

Competencies describe the skills and knowledge individuals should have in order to be fit for particular jobs. Especially in the domain of vocational education, having a central shared and commonly used competency model is becoming crucial in order to achieve the necessary level of interoperability and exchange of information, and in order to integrate and align the existing information systems of competency stakeholders like schools or public employment agencies. Only few organizations however, have successfully implemented a company-wide "competency initiative," let alone a strategy for inter-organizational exchange of competency related information.

Several projects (See, e.g., the EU-funded CoDrive project.) aim at contributing to a competency-driven vocational education by using state-of-the-art ontology methodology and infrastructure in order to collaboratively develop a conceptual, shared and formal KR of competence domains.

For a business case study on vocational competency ontology elicitation, see [4].

Future Directions

The ever-changing interoperability requirements between the stakeholding communication partners (See, e.g., diverse (legacy) systems in the open extended enterprise.) requires ontologies to continuously evolve. Usually the domain is too large and complex to be explicated in one single effort, and the knowledge workers understanding of the domain is in continuously changing, requiring timely renegotiation of existing consensus. Therefore, one should not merely focus on the practice of eliciting ontologies in a project-like context, but consider it as a real-time collaborative and continuous process that is integrated with and in the operational processes of the community itself. The shared background of communication partners is continuously negotiated as are the characteristics or values of the concepts that are agreed upon.

There are many additional complexities that should be considered. As investigated in FP6 integrated projects (See, e.g., http://ecolead.vtt.fi/.) on collaborative networked organizations, the different professional, social, and cultural backgrounds among communities and organizations can lead to misconceptions, resulting in costly ambiguities and misunderstandings if not aligned properly. This is especially the case in inter-organizational settings, where there may be many pre-existing organizational sub-ontologies, inflexible data schemas interfacing to legacy data, and ill-defined, rapidly evolving collaborative requirements. Furthermore, participating stakeholders usually have strong individual interests, inherent business rules, and work practices. These may be tacit, or externalized in workflows that are strongly interdependent, hence further complicate the conceptual alignment. Finally this also involves ontology elicitation cost estimation. Simperl and Sure (chapter 7, [12]) propose a parametric cost estimation model for ontologies by identifying relevant cost drivers having a direct impact on the effort invested in ontology elicitation.

For an overview of future directions towards community-driven ontology elicitation and management, see [6].

Ontological engineering

Definition

Ontology Engineering is "the set of activities that concern the ontology development process, the ontology life cycle, and the methodologies, tools and languages for building ontologies" [2]. It provides "a basis of building models of all things in which computer science is interested" [4]. Ontology engineering aims at providing standard components for building knowledge models. Ontologies play a similar role to design rationale in mechanical design. It allows the reuse of knowledge in a knowledge base by providing conceptualization, reflecting assumptions and requirements made in the problem solving using the knowledge base. Ontology engineering provides the means to build and use ontologies for building models.

Key Points

Eight levels (from shallow to deep) of using ontologies can be defined [4]. At level 1, ontologies are used as a common vocabulary for communication. At level 2, it is used as a conceptual schema of a relational data base. At the third level, ontologies are used as backbone information for using a knowledge base. The remaining five levels are the levels where ontology engineering comes into play. Ontologies at the fourth level are used to answer competence questions and then they are used for standardization (of terminology or of tasks) at level 5. At level 6, ontologies are used for structural and semantic transformation of schemas. Reusing knowledge is done at the seventh level and knowledge reorganization is considered the eighth and highest level of using ontologies.

Ontology engineering makes use of ontologies (in the sense of levels 4–8) to generate standard tools for knowledge representation. This does not imply that knowledge is standardized. Using ontology engineering, one can design knowledge for specific applications, similar to production based on engineering tools in other engineering fields.

The use of ontology engineering is now illustrated in two key applications, namely functional design and schema matching. For the former, [3] describes a seventh level of using ontologies in a real world application of plant and production systems. There, an ontology that describes two types of functional models, two types of organization of generic knowledge, and two ontologies of functionality were put into use in sharing functional design knowledge on production systems. The users (engineers) of the system have indicated that this framework enabled them to make implicit knowledge possessed by each designer explicit, and to share it among team members.

Ontologies are used in schema matching in many ways. One of these, corresponding to the sixth level of use, was presented in the OntoBuilder toolcase [1]. Special ontological constructs were identified for the matching of Web form data. Ontologies were built using these constructs and dedicated matching algorithms were constructed to determine the amount of certainty to assign with the matching of attribute pairs. An example of an ontological construct, unique to OntoBuilder, is *precedence*. This construct determines the order in which attributes are presented to the user on a Web form and generate a partial order on attributes. Attribute similarity is then measured based on their relative positioning in their own ontologies.

Ontology Visual Querying

Sean Bechhofer, Norman W. Paton
University of Manchester, Manchester, UK

Definition

An *ontology definition language* provides constructs that can be used to describe concepts and the relationships in which they participate. Because such languages define the properties concepts can exhibit, they can be used to restrict the questions that can meaningfully be asked about the concepts. Given a specification of the questions that can legitimately be asked, a user interface can direct query construction tasks towards meaningful requests, which in turn are expected to yield non-empty answers. Thus *ontology visual querying* is the use of an ontology to direct interactive query construction. A related topic is *faceted browsing*, in which the incremental description of concepts of interest is closely integrated with retrieval, thereby providing information about the results of a request as it is being constructed.

Historical Background

The history of visual query languages is almost as long as that of textual query languages, with Query-by-Example [14] developed in parallel with SQL. Query-by-Example contained two features that recur in almost all visual query languages: (i) a representation of the model over which the query is to be expressed; and (ii) a notation for incrementally constructing queries from the collections, relationships and value ranges of interest, with reference to the representation in (i). The evolution of visual query languages [4] has tracked the evolution of data models and interactive paradigms, and proposals have been made that support querying over many different data models (relational, object-oriented, temporal, etc) using a variety of interaction objects (forms, graphs, icons, etc). An orthogonal aspect is the closeness of the relationship between query construction and answer presentation; for example, in *dynamic queries* the answer to a request is constructed automatically and incrementally as a query is refined [12]. This provides immediate feedback to users on the size and nature of the result, but may require specialised storage structures to support incremental result computation.

Ontology visual querying has been developed so that the knowledge expressed in an ontology can be used to direct query construction; query answers may then be constructed from an instance store that is closely integrated with the ontology definition language, or by evaluating requests over external data sources. The latter is quite common, as ontologies are widely used to provide conceptual models for web (e.g., [1]) or data (e.g., [3]) resources.

Foundations

As in other visual query languages, ontology visual querying requires a visual representation of the concepts over which a request is to be constructed. Visual query formulation allows users to explore the domain of interest by *recognition* rather than *recall*: that is, it should not be necessary to remember (or even be fully aware of) the ontology in order to express a query over it.

Ontologies are represented visually other than for querying; for example, ontology design tools typically support both form and graph-based views of concepts and their relationships (e.g., [10]). As concept definition and query formulation may have significant common ground, representations that are useful for ontology browsing and concept definition may also be relevant for querying. For example, in the TAMBIS ontology-based data integration system [2], a query is a concept definition in a Description Logic (DL) [8], so writing a query is essentially the same as defining a new concept.

Although expressive ontology languages may present challenges for navigation and thus query construction, they also present certain opportunities for query interface designers, as various forms of reasoning may be useful for guiding query construction. For example, an interface can prevent the submission of queries that are unsatisfiable (i.e., that are known from the definitions in the ontology to return no results) either by making it impossible for the user to construct such queries or by detecting when such requests have been created (e.g., [7,5]). Such feedback can be seen as *intensional*, with the constraints or knowledge in the ontology determining the behaviour of the interface. Feedback may also be *extensional*, for example, with the number of results to be returned being shown to the user. This is common in facted browsing systems, and such direct result construction is generally supported in combination with closely integrated stores.

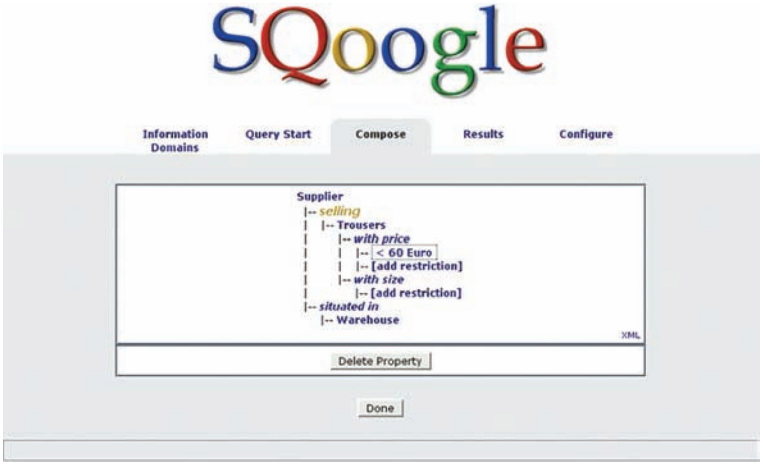
In addition to the feedback described above, systems may also provide alternative renderings of the query being constructed – for example a natural language description of the query. This can be of use in helping naïve or inexperienced users in forming appropriate queries. Note that this involves the rendering of the query in natural language, rather than translating a query posed using natural language.

A common approach is to specify queries through an iterative refinement process, in which the content of the ontology and current context of the query impact on the options presented. The principle of intensional navigation uses the vocabulary to guide the user during query formulation, employing constraints in the ontology to either flag to the user that the query is in some way violating the constraints, or preventing the user from forming queries that would be unsatisfiable, and thus return no results. Operations available for query manipulation in SEWASIE [5] include the addition of a new role/property with an associated filler, or the replacement of a filler value. In the latter case, a classification or super/sub class taxonomy is used to support the manipulation, with value fillers being specialised or generalised. Although ontology languages differ in the constructors and expressivity offered, some notion of hierarchical classification is nearly always present, and so can be exploited in visual query interfaces. An additional operation offered by the TAMBIS system is to *refocus* the query, which takes a sub node of the query and reorganises the query to promote that node to the root. This operation introduces an additional requirement on the ontology language, namely that properties or relations have *inverses*.

Various of the notions discussed above are illustrated in Figs. 1 and 2 for SQoogle, which was developed in the SEWASIE project. Figure 1 shows the composition phase, with the graphical depiction of the query. In Fig. 2, the user is being offered generalisations or specialisations of a particular node in the query.

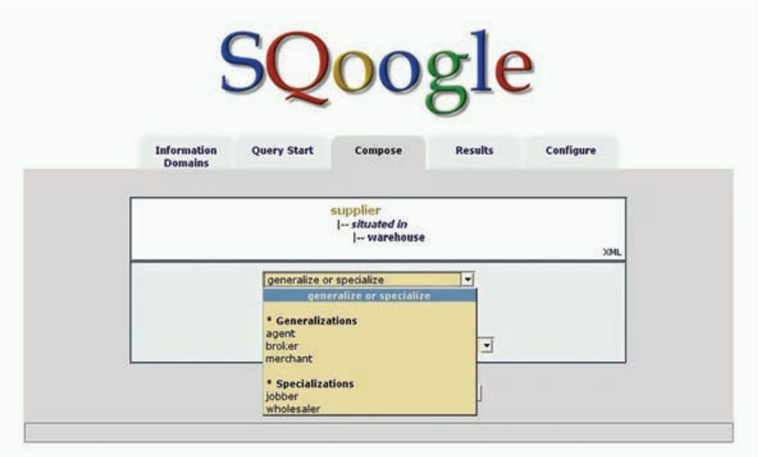
Overall, ontology visual query systems can be characterized by a number of features:

- *Identification of starting points.* The construction of a query has to start from some place in the ontology; systems may offer predetermined entry points, user defined bookmarks, or a search mechanism across the concepts in the ontology.
- *Query language.* More expressive query languages support more precise question answering, but may contain constructs that require explanation for



```
Supplier
 |-- selling
 |    |-- Trousers
 |         |-- with price
 |         |    |-- < 60 Euro
 |         |    |-- [add restriction]
 |         |-- with size
 |              |-- [add restriction]
 |-- situated in
      |-- Warehouse
```

Ontology Visual Querying. Figure 1. Visual query expression in SQoogle. The query is to select suppliers that sell trousers that cost less than 60 euros, where the supplier is situated in a warehouse.



```
supplier
 |-- situated in
      |-- warehouse
```

Ontology Visual Querying. Figure 2. Visual query refinement in SQoogle. The query can be revised by replacing the concept supplier with a more general (e.g., agent, broker) or specialized (e.g., wholesaler) concept.

users or that are challenging to represent using certain visual paradigms. Ontology visual query languages rarely support features such as aggregation or grouping.

- *Query modification operations.* Query construction involves manipulation of query expressions, for example, to include additional relationships or to specialise a concept named in the query.
- *The ontology definition language.* Richer ontology definition languages are generally more complex to display and navigate, but may provide more options for generalizing and specializing query components, and can express constraints that are useful for directing query construction.
- *Relationship between query language and ontology language.* Proposals implement different relationships between the query language and the ontology definition language. For example, in SEWASIE, the query language and ontology language are explicitly separated. The ontology language supports reasoning services that are used to guide the intensional navigation process described above. In contrast, in TAMBIS, queries *are* concept descriptions, thus the interface is tied more closely to the ontology language.
- *Feedback mechanisms.* Feedback can inform the user about the results of the query or the state of the query with respect to the underlying ontology. Feedback may be intensional (in terms of the ontology), or extensional (in terms of the result set).
- *Query presentation.* Queries may be presented solely using the visual query, or may also offer, for example, natural language renderings of the query.
- *Domain specificity.* Visual interfaces provide the opportunity to represent models or results using general-purpose or domain-specific representations. Most ontology visual query languages are general purpose, but faceted browsing interfaces are often designed to support specific applications.

Table 1 describes a collection of representative visual query systems using a selection of the above criteria: the TAMBIS and SEWASI visual query languages, and the Flamenco and /facet faceted browsing systems. In all these proposals, the ontology directs query construction, and thus the design of the ontology has a significant influence on the utility of the interface.

Key Applications

Ontology visual query systems have most commonly been deployed in areas of science and culture where there are rich data resources to be explored. For example, TAMBIS provided access to multiple biological information sources. Faceted browsing and querying has been widely used to browse image collections and in the cultural heritage domain, for example to support access to Finnish Museums [9] and galleries in the Netherlands [11]. The faceted approach is also common in on-line shopping sites such as eBay.

Ontology Visual Querying. Table 1. Representative examples of ontology visual query systems

Proposal	TAMBIS	SEWASIE	Flamenco	facet
Reference	[7]	[5]	[13]	[8]
Query language	Concept definition	Conjunctive queries	Path expressions	Path expressions
Query modification operations	Property add/remove; filler specialization or generalization; refocus	Property add/remove; filler specialization or generalization	Property add/remove; filler specialization or generalization	Property add/remove; filler specialization or generalization
Ontology definition language	Description logic	Description logic	Hierarchical categories	RDFS
Feedback mechanism	Intensional	Intensional	Extensional	Extensional
Query presentation	Visual	Visual plus NL rendering	Path expression	Path expression
Domain specificity	Generic	Generic	Specific (image repositories)	Generic

Future Directions

Large amounts of a data are beginning to emerge using representation languages like OWL. Current work in ontology languages should see standardisation of the SPARQL query language finalised in the near future. Query interfaces that sit on top these standardized languages will then be required in order to support access to this data – interfaces that support naïve or non-expert users will clearly be required.

Open Database Connectivity

Changqing Li
Duke University, Durham, NC, USA

Synonyms

ODBC

Definition

Open Database Connectivity (ODBC) [1] is an Application Programming Interface (API) specification to use database management systems (DBMS). The ODBC API is a library of functions for the ODBC-enabled applications to connect any ODBC-driver-available database, execute Structured Query Language (SQL) statements, and retrieve results. ODBC is independent of programming languages, database systems and operating systems.

Key Points

ODBC (pronounced as separate letters), is a standard database access method developed by the SQL Access Group in 1992. Its objective is to make any application to access any data regardless of the database management systems. To achieve this objective, ODBC inserts a database driver as a middle layer between an application and the DBMS, the purpose of which is to translate the application queries to commands understood by the DBMS. In practice, both the application and the DBMS must be ODBC-compliant; that is, the application must be capable of issuing ODBC commands and the DBMS must be capable of responding to them.

A procedural API is offered by the ODBC specification for using SQL queries to access data. One or more applications will be contained in an implementation of ODBC, a core ODBC library, and one or more "database drivers." Independent of the applications and DBMS, the core library acts as an "interpreter" between the applications and the database drivers, whereas the database drivers contain the DBMS-specific details. Thus applications can be written to use standard types and features without concerning the specifics of each DBMS that the applications may encounter. Similarly, database driver implementors only need to know how to attach to the core library. This makes ODBC modular.

ODBC operates with a variety of operating systems and drivers existing for relational database as well as non-relational data such as spreadsheets, text and XML files.

Open Nested Transaction Models

Alejandro Buchmann
Darmstadt University of Technology, Darmstadt, Germany

Synonyms

Extended transaction models; advanced transaction models

Definition

Open nested transactions are hierarchically structured transactions with relaxed ACID properties. Individual subtransactions may commit independently before the complete top level transaction commits. Therefore, conventional rollback is not possible and the effects of a commited subtransaction have to be compensated if the top level transaction aborts. Depending on the particular open nested transaction model, subtransactions may be vital or non-vital and may have alternative or contingency subtransactions. Open nested transaction models are characterized through relaxed visibility rules, abort and commit dependencies.

Historical Background

Open nested transaction models evolved in the 1980s in response to two major sets of requirements: the needs of federated multidatabase systems integrating autonomous legacy database systems, and the demands of long running, cooperative processes for higher levels of concurrency while maintaining some of the main benefits of transactional processes. Extended transaction models influenced the tightly coupled transaction model of distributed object systems and the activity model of the OMG, as well as the transaction and coordination models of Web Services.

Foundations

Transaction models are characterized by the structure of its transactions, the commit and abort dependencies and the visibility rules among transactions.

Nested transactions are hierarchically structured transactions consisting of a top level transaction and subtransactions that may themselves be tree-structured. Typical of the execution model of nested transactions is the fact that higher level transactions do not execute while their subtransactions are active. The order of execution of subtransactions can be either sequential or parallel. The closed nested transaction model proposed by Moss does not specify an execution order and preserves the atomicity, consistency, isolation and durability properties of traditional flat transactions. The commit dependencies of closed nested transactions specify that all subtransactions must commit to their immediate ancestor and the top level transaction can only commit after all the subtransactions terminated. The abort dependencies specify that the whole transaction tree must be aborted if the top level transaction aborts while the abort of a subtransaction can be handled by the immediate ancestor transaction. The visibility rules among transactions and subtransactions specify that subtransactions may see changes of other subtransactions only once they are commited to the common ancestor. Changes of a nested transaction become visible to the outside world only after the top level transaction commits. Since changes of committed subtransactions are made visible only after the top level transaction commits, they can be undone through conventional roll-back.

Open nested transaction models are also based on hierarchically structured transactions. However, depending on the particular transaction model, the subtransactions may be of different types. Different types of subtransactions require different commit and/or abort dependencies. The visibility rules are also relaxed with respect to those of closed nested transaction models.

Open nested transactions may consist of the following component transactions:

- One top level transaction that has mostly a coordination function
- Vital subtransactions that must all commit for the top level transaction to be allowed to commit
- Non-vital subtransactions of which one or more may abort without causing the top level transaction to fail
- Contingency transactions are alternative subtransactions that often are executed by different autonomous systems or service providers
- Compensating transactions that must be defined to undo the changes of subtransactions that may have committed but must be undone
- Triggers that are executed as subtransactions and may execute either immediately, deferred before the commit of the triggering transaction or as detached transactions.

Open nested transaction models were defined for long running transactions and for transactions executing on federated autonomous (legacy) systems. Therefore, the degree of control of the coordinating top level transaction over the execution of the subtransactions is reduced compared to closed nested transactions running on a single database management system. Distributed short lived transactions and closed nested transactions are typically implemented through a two-phase commit protocol. In a two-phase commit protocol the first phase serves to reach agreement among the participants whether to commit or to abort, and once consensus to commit has been reached, the commit is carried out in the second phase. This protocol requires holding all the resources required by all the subtransactions through the negotiation phase until the global commit. This approach is not feasible for long running transactions because of performance reasons and in federated multidatabase systems because of the autonomy of the participating database systems.

The coordinating top level transaction in an open nested transaction model cannot secure the resources of the participating systems that execute subtransactions as autonomous individual short transactions until all participating systems have executed their subtransactions and are ready to commit. Therefore, subtransactions may commit immediately upon completion and their results are thus visible to the outside world before the top level transaction commits. Compensating transactions execute the semantically inverse operation of the committed subtransaction but do not guarantee that the exact initial state can be restored since other transactions may have executed in the interim.

The commit dependencies of open nested transaction models depend on whether they distinguish between vital and non-vital subtransactions or not. A commit dependency exists between the top level transaction and all vital subtransactions, i.e., the coordinating top level transaction may only commit if all the vital subtransactions committed. This is the default case if non-vital subtransactions are not provided. The abort of a non-vital transaction does not affect the possibility to commit the top level transaction.

The abort dependencies of open nested transaction models are the same as for closed nested transactions: the abort of the parent transaction causes the abort and undo (roll-back or compensation) of the subtransaction. The abort of a non-vital subtransaction is handled by the parent transaction, the abort of a vital transaction causes the abort of the parent and all siblings.

Contingency transactions represent alternative actions. For example, if the top-level transaction represents the booking of a trip consisting of a roundtrip flight, a hotel and a rental car booking, two different flights on different airlines may be defined as a subtransaction and a contingency transaction. Contingency transactions may only commit if the primary subtransaction aborts. Open nested transaction models that do not provide contingency transactions must implement this functionality as application-specific code in the corresponding parent transaction or the top-level transaction.

Triggers have become commonplace mechanisms in commercial relational databases and execute as subtransactions according to the semantics of closed nested transactions. The order of execution may be immediate or deferred, meaning that the trigger executes either at the point of occurrence of the triggering event or at the end of the triggering transaction, respectively. Some extended transaction models allow the triggering of subtransactions as detached or autonomous transactions, i.e., following the semantics of open nested transactions. This, however, implies all the problems resulting from the violation of the isolation and atomicity properties and requires the definition of compensating transactions for those triggers.

The concepts developed as part of extended transaction models resulted in the definition of the CORBA Activity Service Framework. The Activity Service is a general purpose event signalling mechanism that can be used to program activities to coordinate themselves according to the transaction model under consideration. The Activity Service has also been incorporated in the J2EE framework but is not widely used.

Key Applications

The main application areas for open nested transaction models are multidatabase systems in which autonomous systems are loosely coupled. Web Services with their loose coupling, distribution and often long running interactions prompted renewed interest in extended transaction models and open nested transactions. Applications based on Web Services span the whole range of e-business applications. Mobile commerce is another key application domain for open nested transactions. Proposed mobile transaction models are instances of open nested transaction models, e.g., the model proposed by Chrysanthis and extended in Kangaroo Transactions.

Future Directions

Several proposals for long running activities based on Web Services have been advanced by different consortia. The OASIS Business Transaction Protocol was proposed in 2001 by a consortium consisting of HP, BEA, and Oracle. Their model provides for the execution of business logic between the two phases of a 2 phase commit protocol. Arjuna, Oracle, Sun Microsystems, IONA Technologies and Fujitsu in 2003 founded the OASIS Web Services Composite Application Framework that defines three transaction protocols, each aimed at a specific use case. The WS-TX builds on and extends the web Services Coordination specification and provides two kinds of transaction models. These are not meant to cover all possible use cases and can be extended with the semantics of other extended transaction models as required by emerging applications.

Atomic Transactions are meant for short lived transactional interactions within trusted domains and provide full isolation (no dirty reads and repeatable reads), atomicity (well-formedness and two-phase commit protocol), and durability. For loosely coupled, long running interactions Web Services Transactions can use the Business Activity protocol, a more flexible transaction and coordination protocol that relaxes the ACID properties and draws heavily on previous research on open nested transaction models.

Business Activities are designed for long-lived transactions. They are based on the original Sagas open nested transaction model. Services are treated as Sagas and if there is the appropriate compensation behaviour defined, they can execute the undo behaviour if so instructed by the Business Activity. The responsibility of writing correct compensation services to ensure consistency rests with the developer of a service.

Business Activities consist of (possibly nested) Saga-like service invocations. Such scopes can handle errors, i.e., the abort of a task, through application logic and continue processing without globally aborting. Upon completion a child subtransaction can either leave the scope of the Business Activity or it can signal the parent that its work can be compensated later. In any event, the visibility rules are such that the results of child tasks can be seen by the outside world. Business Activities must record application state and keep a record of all sent and received messages, all request messages must be acknowledged, and requests and responses are decoupled. Two different protocols exist for Business Activities: Business Agreement With Coordinator Complete and Business Agreement With Participant Complete. The main difference between these two protocols is that in the former a participating task may not leave the scope of the Business Activity unilaterally and must wait for it to terminate. In case of abort, the subtask must compensate. In the latter a task may leave the scope of the Business Activity unilaterally.

Operator-Level Parallelism

Nikos Hardavellas, Ippokratis Pandis
Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

Inter-operator parallelism

Definition

Operator-level parallelism (or inter-operator parallelism) is a form of intra-query parallelism obtained by executing concurrently several operators of the same query. By contrast, intra-operator parallelism is obtained by executing the same operator on multiple processors, with each instance working on a different subset of data.

Historical Background

Parallelism has been a key focus of database research since the 1970s. For example, as early as 1978 Teradata was building highly-parallel database systems and quietly pioneered many of the ideas on parallel query execution [5]. However, the intra-query parallelism employed by these early systems was mostly intra-operator or independent parallelism (see Classes of Parallelism below). Gamma [4] was one of the first database systems that allowed operator-level parallelism through pipelining.

Foundations

Parallel processing uses multiple processors cooperatively to improve the performance of application programs. With relations growing larger and queries becoming more complex, parallel processing is an increasingly attractive option for improving the performance of database management systems. The widespread adoption of the relational database model has enabled the parallel execution of relational queries, as these queries are composed of uniform operators applied to uniform streams of data. Each operator produces a new relation, so the operators can be composed into highly parallel dataflow graphs. At the same time, multiprocessor systems and high-speed interconnection networks have become mainstream, providing an excellent basis for parallel execution.

Classes of Parallelism

Parallelism in the evaluation of database queries is classified into two main categories: inter-query parallelism (see Inter-Query Parallelism), in which different queries execute on different processors to improve the overall throughput of the system, and intra-query parallelism, in which several processors cooperate for the faster execution of a single query. Intra-query parallelism is further classified into intra-operator and inter-operator parallelism. Intra-operator parallelism (see Intra-Operator Parallelism) is obtained by executing the same operator on multiple processors, with each instance working on a different subset of data. Operator-level parallelism (or inter-operator parallelism), is obtained by executing concurrently several operators of the same query. This latter form of parallelism is the subject of this chapter.

Operator-level parallelism is in two forms: independent parallelism and pipelined parallelism. Independent parallelism (or bushy parallelism) is achieved when there is no dependency between the operators executed in parallel. For example, consider a simple query plan with two select operators and a join, that it is not nested-loops. The select operators are independent of each other and can execute concurrently, thereby exhibiting independent parallelism. Algebraically, independent parallelism can be expressed by a relation of the form f(g(X), h(Y)), where X and Y are relations and f, g, and h are relational operators. In this example, g and h exhibit independent parallelism.

Because the operators participating in bushy parallelism are independent, they do not directly affect the execution of one another. Interference is only indirect, e.g., due to the concurrent use of shared resources like disks, caches, or main memory bandwidth. Thus, independent parallelism is simpler to employ as it is easier to schedule the execution of the participating independent operators, and it has the potential to deliver high performance improvements.

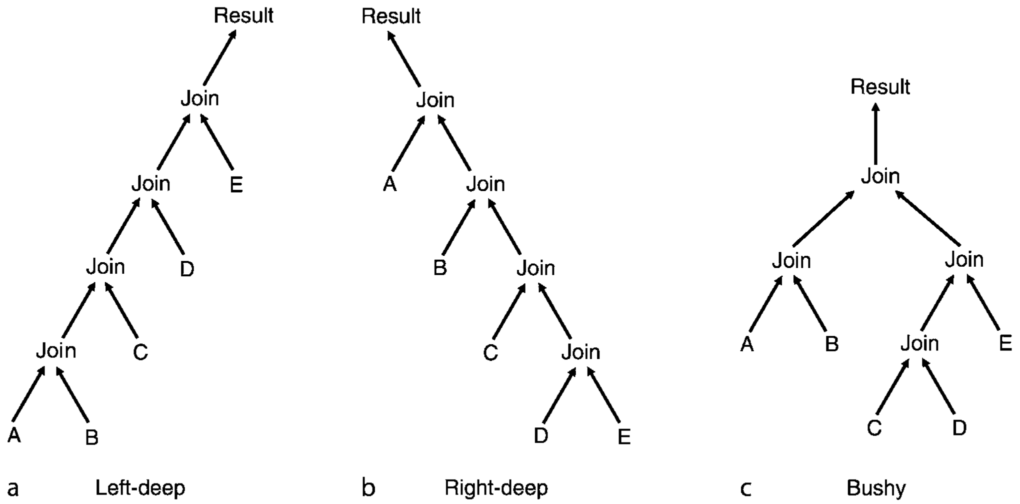
Alternatively, operator-level parallelism can take the form of pipelined parallelism, also called dataflow parallelism. Pipelined parallelism can be achieved when the concurrent operators form producer/consumer pairs in which the consumer can start executing without requiring its entire input to be available. For example, consider the aforementioned simple query that consists of two select operators and a join. The select operator can execute in parallel with the join operator. However, they are not independent, because the intermediate results produced by the select are consumed by the subsequent join. Thus, the tuples output by the select can be pipelined to the join operator to be consumed immediately. This example illustrates a significant advantage of pipelined parallelism: intermediate results are used immediately and are not materialized, saving memory and disk accesses. Algebraically, pipelined parallelism can be expressed by a relation of the form f(g(X)), where X is a relation and f and g are relational operators. The operators that cannot produce tuples unless they have processed their entire input are called Stop-&-Go operators.

Effect of Query Plan Selection on Operator-Level Parallelism

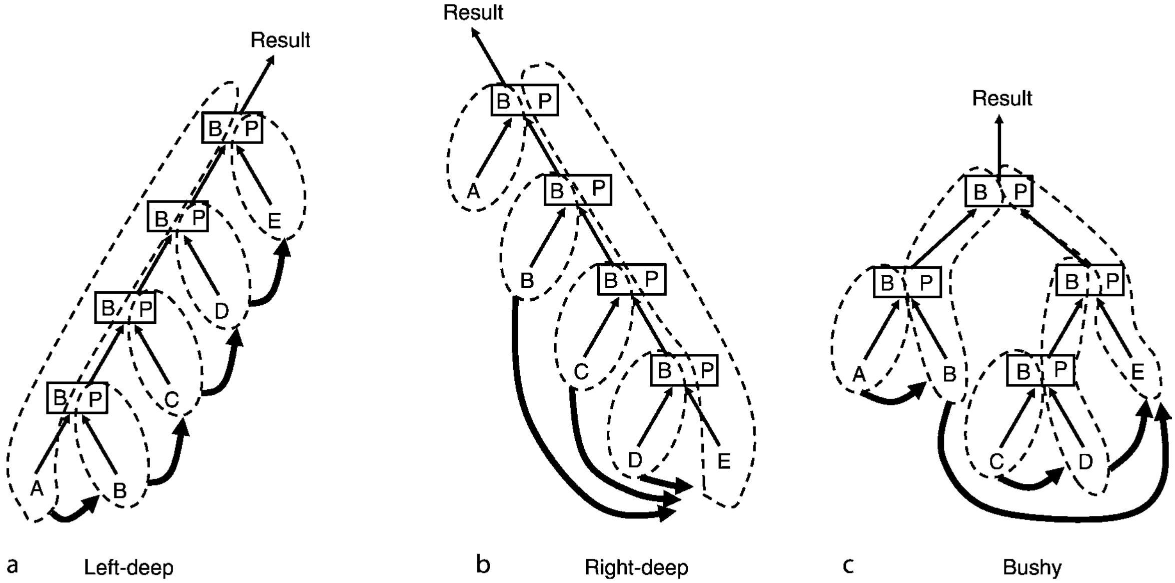
The query plan determines the execution sequence of a query's operators. The selection of a query plan greatly affects the degree of attainable operator-level parallelism. To illustrate this point, and without loss of generality, let's assume a multi-way hash-join query with four joins: A×B×C×D×E where A, B, C, D, E are relations and × is the join operator. The query plan is typically depicted graphically as a tree with vertices representing relations. Because every operator in the relational model defines a new relation, the operators in the internal vertices denote the relation they represent. If an operator Y takes relation X as one of its inputs, then a directed edge connects X to Y in the tree representation.

Three forms of query execution trees are explored in the literature: left-deep trees, right-deep trees, and bushy trees. Figure 1 shows the query execution trees for the example multi-way join query used above. Left-deep trees and right-deep trees represent the two extreme strategies of query execution, while bushy trees claim a middle ground.

To compare the trade-offs between the alternative query plans, Fig. 2 shows the execution dependencies



Operator-Level Parallelism. Figure 1. (a) Left-deep, (b) right-deep, and (c) bushy query plans.



Operator-Level Parallelism. Figure 2. Operator dependencies for (a) left-deep, (b) right-deep, and (c) bushy plans.

between the operators of each execution strategy in Fig. 1. The execution dependencies are shown using operator dependency graphs [10]. The dotted lines encircle the operators amenable to pipelined parallelism. The bold directed arcs between subgraphs show which sets of operators must be executed before other sets of operators are executed, thereby determining the maximum level of parallelism and resource requirements (e.g., memory) for the query. As discussed in [10] hash joins have two distinct phases, the build and the probe phase. Since the first phase must completely precede the second, the hash joins in Fig. 2 can be viewed as if consisting of two operators, the build and the probe operator.

The operator dependency graph of the left-deep query plan shows that only a scan, the build phase of a join, and the probe phase of a join can execute in parallel. Thus, although the left-deep query plan has low memory requirements (it needs enough memory to fit the hash tables of two joins) it offers only limited pipelined parallelism and no independent parallelism. In contrast, the operator dependency graph for the right-deep query plan shows that significant operator-level parallelism is available: all scans but one have a producer/consumer relationship with the build phase of the subsequent hash join, thereby exhibiting pipelined parallelism, while the scan/build pairs are independent of one another so they exhibit independent parallelism. However, the high degree of parallelism comes at the expense of high shared resource pressure. The hash tables for all joins should fit in main memory simultaneously, or risk spilling to disk.

Finally, the operator dependency graph for the bushy query plan has characteristics that are between the left-deep and the right-deep query plans. The bushy plan enables independent parallelism, albeit at a lower degree than the right-deep plan, as about half the scans can proceed in parallel. However, the bushy plan imposes lower pressure on shared resources than the right-deep plan, because fewer operators execute in parallel. Bushy query plans allow the formation of deeper pipelines, some of which extend all the way from a leaf to the root of the tree. Thus, bushy trees enable pipelined parallelism as well, but it may be harder to balance the load within their deeper pipelines due to execution skew.

Because bushy plans achieve a balance between pipelined parallelism, independent parallelism, and resource utilization, researchers further investigated their applicability in improving query execution. For example, segmented right-deep trees [3] (bushy trees of right-deep subtrees) have been shown to outperform their left-deep and right-deep counterparts.

Other Factors Limiting Operator-Level Parallelism

The selection of the query plan determines the degree of available operator-level parallelism. This section discusses factors that limit the effectiveness of operator-level parallelism, given a query plan. Among other things, the discussion in this section touches on issues of load balancing and processor allocation.

The operators participating in independent parallelism interfere only indirectly through the concurrent use of shared resources. The factors limiting the benefit of independent parallelism are the constraints imposed by the hardware resources. All relations that execute in parallel produce intermediate results which increase the data footprint of the application, resulting in higher cache miss rates and higher memory pressure. The larger data footprint, in turn, may oversubscribe memory bandwidth or induce more spills to disk if the relations do not fit in main memory.

Resource contention affects pipelined parallelism as well, but to a lesser degree because the intermediate data in pipelined parallelism are short lived as they are consumed immediately after their production. The benefits of pipelined parallelism are generally limited by three factors [5]: (i) relational pipelines are rarely very long – a chain of length ten is unusual. (ii) some relational operators are blocking operators, i.e., they do not emit their first output until they have consumed all their inputs. Sort and the partitioning phase of hash join are examples of blocking relational operators. Such operators cannot be pipelined, and (iii) there are dependencies between the operators participating in a pipeline. Often, the execution cost of one operator is much greater than the others, a phenomenon referred to as execution skew. In this case, the performance of the pipelined execution is dominated by the slowest operator, which significantly limits parallelism.

The execution skew also gives rise to startup/teardown execution delays: processors assigned to operators at the end of a pipeline are idle at the beginning of the computation, whereas processors assigned to operators at the beginning of a pipeline are idle towards the end of the computation. It is important to note here that data skew may induce execution skew in some cases. For example, in a sort-merge join with data skew, some sort partitions may be much larger than others, creating execution skew.

A potential solution to execution skew is to predict the execution load for each operator and schedule them accordingly across the parallel processors. However, the predictions may fail as the costs are estimated in the query optimization phase using typically inaccurate cost models and statistics.

The assignment of processors to operators and their scheduling is an important and hard problem that affects all forms of operator-level parallelism. It is an optimization problem that attempts to utilize all the available processors efficiently to minimize the execution time of a query. Sometimes operators may need to be scheduled as a team (e.g., producer/consumer pairs), while other times gang scheduling should be avoided (e.g., scheduling together the first and the last operator of a deep pipeline would leave the last operator mostly idle). Scheduling is easier when there are no dependencies between the operators executing in parallel, in which case load balancing is of primary concern.

The processor allocation is based on the selection of the query plan and estimates on the execution cost of each operator. If the execution cost of some operators is much higher than others, the system may be subject to fragmentation: after a sequence of processor allocations and releases there may be a few processors left idle and rebalancing the workload dynamically is not always possible or beneficial. These cases may benefit from the concurrent employment of multiple forms of parallelism (see next section). However, the application of multiple forms of parallelism adds an extra dimension to the processor allocation problem, making it harder to solve.

Relation to Inter-Query and Intra-Operator Parallelism

Operator-level parallelism is orthogonal to inter-query and intra-operator parallelism and can work synergistically with them to improve performance even further. For example, if there is imbalance in the execution times of a query's operators and there are free processors, intra-operator parallelism can be applied to split a long-running operator into multiple ones, each executing on a smaller subset of data. This will allow for faster execution of the expensive operators and may balance the execution times of operators participating in a pipeline, avoiding execution skew.

For a more comprehensive treatment of operator-level parallelism, the interested reader is referred to [5,10,11].

Key Applications

Several parallel database systems have been developed that utilize operator-level parallelism to improve performance. Systems built in academic institutions include GAMMA [4], BUBBA [2], Volcano [6], MonetDB/X100 [1], and StagedDB [7]. Commercial systems that support operator-level parallelism include Oracle [9] and IBM DB2 [8].

Sentiment analysis

Definition

Given a set of evaluative text documents D that contain opinions (or sentiments) about an object, opinion mining aims to extract attributes and components of the object that have been commented on in each document $d \in D$ and to determine whether the comments are positive, negative or neutral.

Historical Background

Textual information in the world can be broadly classified into two main categories, *facts* and *opinions*. Facts are objective statements about entities and events in the world. Opinions are subjective statements that reflect people's sentiments or perceptions about the entities and events. Much of the existing research on text information processing has been (almost exclusively) focused on mining and retrieval of factual information, e.g., information retrieval, Web search, and many other text mining and natural language processing tasks. Little work has been done on the processing of opinions until only recently. Yet, opinions are so important that whenever one needs to make a decision one wants to hear others' opinions. This is not only true for individuals but also true for organizations.

One of the main reasons for the lack of study on opinions is that there was little opinionated text before the World Wide Web. Before the Web, when an individual needs to make a decision, he/she typically asks for opinions from friends and families. When an organization needs to find opinions of the general public about its products and services, it conducts surveys and focused groups. With the Web, especially with the explosive growth of the user generated content on the Web, the world has changed. One can post reviews of products at merchant sites and express views on almost anything in Internet forums, discussion groups, and blogs, which are collectively called the *user generated content*. Now if one wants to buy a product, it is no longer necessary to ask one's friends and families because there are plenty of product reviews on the Web that give the opinions of the existing users of the product. For a company, it may no longer need to conduct surveys, to organize focused groups or to employ external consultants in order to find consumer opinions or sentiments about its products and those of its competitors.

Finding opinion sources and monitoring them on the Web, however, can still be a formidable task because a large number of diverse sources exist on the Web and each source also contains a huge volume of information. In many cases, opinions are hidden in long forum posts and blogs. It is very difficult for a human reader to find relevant sources, extract pertinent sentences, read them, summarize them and organize them into usable forms. An automated opinion mining and summarization system is thus needed. *Opinion mining*, also known as *sentiment analysis*, grows out of this need.

Research on opinion mining started with identifying *opinion* (or *sentiment*) *bearing words*, e.g., great, amazing, wonderful, bad, and poor. Many researchers have worked on mining such words and identifying their *semantic orientations* (i.e., positive or negative). In [5], the authors identified several linguistic rules that can be exploited to identify opinion words and their orientations from a large corpus. This method has been applied, extended and improved in [3,8,12]. In [6,9], a bootstrapping approach is proposed, which uses a small set of given seed opinion words to find their synonyms and antonyms in WordNet (http://wordnet.princeton.edu/). The next major development is sentiment classification of product reviews at the document level [2,11,13]. The objective of this task is to classify each review document as expressing a positive or a negative sentiment about an object (e.g., a movie, a camera, or a car). Several researchers also studied sentence-level sentiment classification [9,14,15], i.e., classifying each sentence as expressing a positive or a negative opinion. The model of feature-based opinion mining and summarization is proposed in [6,10]. This model gives a more complete formulation of the opinion mining problem. It identifies the key pieces of information that should be mined and describes how a structured opinion summary can be produced from unstructured texts. The problem of mining opinions from comparative sentences is introduced in [4,7].

Foundations

Model of Opinion Mining

In general, opinions can be expressed on anything, e.g., a product, a service, a topic, an individual, an organization, or an event. The general term *object* is used to denote the entity that has been commented on. An object has a set of *components* (or *parts*) and a set of *attributes*. Each component may also have its subcomponents and its set of attributes, and so on. Thus, the object can be hierarchically decomposed based on the *part-of* relationship.

Definition (object): An *object O* is an entity which can be a product, topic, person, event, or organization. It is associated with a pair, (T, A), where T is a hierarchy or taxonomy of *components* (or *parts*) and *subcomponents* of O, and A is a set of *attributes* of O. Each component has its own set of sub-components and attributes.

In this hierarchy or tree, the root is the object itself. Each non-root node is a component or sub-component of the object. Each link is a part-of relationship. Each node is associated with a set of attributes. An opinion can be expressed on any node and any attribute of the node.

However, for an ordinary user, it is probably too complex to use a hierarchical representation. To simplify it, the tree is flattened. The word "*features*" is used to represent both components and attributes. Using features for objects (especially products) is quite common in practice. Note that in this definition the object itself is also a feature, which is the root of the tree.

Let an evaluative document be d, which can be a product review, a forum post or a blog that evaluates a particular object O. In the most general case, d consists of a sequence of sentences $d = \langle s_1, s_2,\ldots,s_m\rangle$.

Definition (opinion passage on a feature): The *opinion passage* on a feature f of the object O evaluated in d is a group of consecutive sentences in d that expresses a positive or negative opinion on f.

This means that it is possible that a sequence of sentences (at least one) together expresses an opinion on an object or a feature of the object. It is also possible that a single sentence expresses opinions on more than one feature, e.g., "The picture quality of this camera is good, but the battery life is short."

Definition (opinion holder): The *holder* of a particular opinion is a person or an organization that holds the opinion.

In the case of product reviews, forum postings and blogs, opinion holders are usually the authors of the posts. Opinion holders are important in news articles because they often explicitly state the person or organization that holds a particular opinion [9]. For example, the opinion holder in the sentence "John expressed his disagreement on the treaty" is "John."

Definition (semantic orientation of an opinion): The *semantic orientation* of an opinion on a feature f states whether the opinion is positive, negative or neutral.

Putting things together, a *model* for an object and a set of opinions on the features of the object can be defined, which is called the *feature-based opinion mining model*.

Model of Feature-Based Opinion Mining: An object O is represented with a finite set of features, $F = \{f_1, f_2,\ldots,f_n\}$, which includes the object itself. Each feature $f_i \in F$ can be expressed with a finite set of words or phrases W_i, which are *synonyms*. That is, there is a set of corresponding synonym sets $W = \{W_1, W_2,\ldots, W_n\}$ for the n features. In an evaluative document d which evaluates object O, an opinion holder j comments on a subset of the features $S_j \subseteq F$. For each feature $f_k \in S_j$ that opinion holder j comments on, he/she chooses a word or phrase from W_k to describe the feature, and then expresses a positive, negative or neutral opinion on f_k. The opinion mining task is to discover all these hidden pieces of information from a given evaluative document d.

Mining output: Given an evaluative document d, the mining result is a set of quadruples. Each quadruple is denoted by (H, O, f, SO), where H is the opinion holder, O is the object, f is a feature of the object and SO is the semantic orientation of the opinion expressed on feature f in a sentence of d. Neutral opinions are ignored in the output as they are not usually useful.

Given a collection of evaluative documents D containing opinions on an object, three main technical problems can be identified (clearly there are more):

Problem 1: Extracting object features that have been commented on in each document $d \in D$.

Problem 2: Determining whether the opinions on the features are positive, negative or neutral.

Problem 3: Grouping synonyms of features (as different opinion holders may use different words or phrase to express the same feature).

Opinion Summary: There are many ways to use the mining results. One simple way is to produce a *feature-based summary* of opinions on the object [6]. An example is used to illustrate what that means.

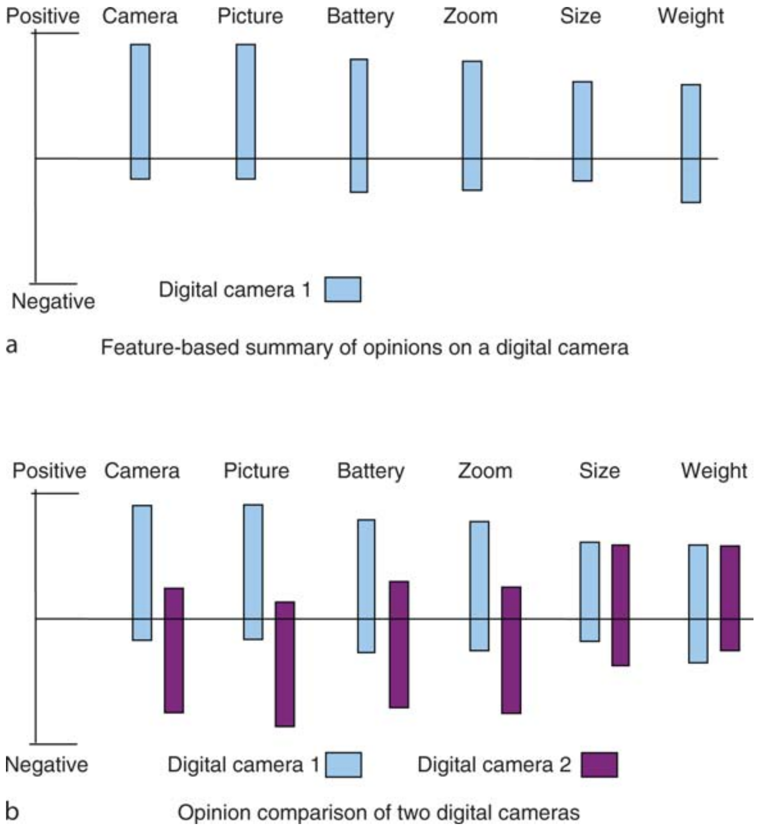
Figure 1 summarizes the opinions in a set of reviews of a particular digital camera, *digital_camera*_1. The opinion holders are omitted. In the figure, "CAMERA" represents the camera itself (the root node of the object hierarchy). One hundred and twenty-five reviews expressed positive opinions on the camera and seven reviews expressed negative opinions on the camera. "picture quality" and "size" are two product features. One hundred and twenty-three reviews expressed positive opinions on the picture quality, and only 6 reviews expressed negative opinions. The ⟨individual review sentences⟩ points to the specific sentences and/or the whole reviews that give the positive or negative comments about the feature. With such a summary, the user can easily see how existing customers feel about the digital camera. If he/she is very interested in a particular feature, he/she can drill down by following the ⟨individual review sentences⟩ link to see why existing customers like it and/or dislike it.

*Digital_camera*_1:

Camera:
    Positive: 125   <individual review sentences>
    Negative: 7   <individual review sentences>
Feature: **picture quality**
    Positive: 123   <individual review sentences>
    Negative: 6   <individual review sentences>
Feature: **size**
    Positive: 82   <individual review sentences>
    Negative: 10   <individual review sentences>
...

Opinion Mining. Figure 1. An example of a feature-based summary of opinions.

The summary in Fig. 1 can be easily visualized using a bar chart [10]. Figure 2(a) shows such a chart. In the figure, each bar above the *X*-axis gives the number of positive opinions on a feature (listed at the top), and the bar below the *X*-axis gives the number of negative opinions on the same feature. Obviously, other visualizations are also possible. For example, one may only show the percentage of positive (or negative) opinions on each feature. Comparing opinion summaries of a



Opinion Mining. Figure 2. Visualization of feature-based opinion summary and comparison.

few competing objects is even more interesting [10]. Figure 2(b) shows a visual comparison of consumer opinions on two competing digital cameras. One can clearly see how consumers view different features of each camera.

Sentiment Classification

Sentiment classification has been widely studied in the natural language processing (NLP) community [e.g., 2,11,13]. It is defined as follows: Given a set of evaluative documents D, it determines whether each document $d \in D$ expresses a positive or negative opinion (or sentiment) on an object. For example, given a set of movie reviews, the system classifies them into positive reviews and negative reviews.

This is clearly a classification learning problem. It is similar but also different from the classic topic-based text classification, which classifies documents into predefined topic classes, e.g., politics, sciences, and sports. In topic-based classification, topic related words are important. However, in sentiment classification, topic-related words are unimportant. Instead, opinion words that indicate positive or negative opinions are important, e.g., great, excellent, amazing, horrible, bad, worst, etc. There are many existing techniques. Most of them apply some forms of machine learning techniques for classification (e.g., [11]). Custom-designed algorithms specifically for sentiment classification also exist, which exploit opinion words and phrases together with some scoring functions [2,13].

This classification is said to be at the document level as it treats each document as the basic information unit. Sentiment classification thus makes the following assumption: Each evaluative document (e.g., a review) focuses on a single object O and contains opinions of a single opinion holder. Since in the above opinion mining model an object O itself is also a feature (the root node of the object hierarchy), sentiment classification basically determines the semantic orientation of the opinion expressed on O in each evaluative document that satisfies the above assumption.

Apart from the document-level sentiment classification, researchers have also studied classification at the *sentence-level*, i.e., classifying each sentence as a subjective or objective sentence and/or as expressing a positive or negative opinion [9,14,15]. Like the document-level classification, the sentence-level sentiment classification does not consider object features that have been commented on in a sentence. Compound sentences are also an issue. Such a sentence often express more than one opinion, e.g., "The picture quality of this camera is amazing and so is the battery life, but the viewfinder is too small."

Feature-Based Opinion Mining

Classifying evaluative texts at the document level or the sentence level does not tell what the opinion holder likes and dislikes. A positive document on an object does not mean that the opinion holder has positive opinions on all aspects or features of the object. Likewise, a negative document does not mean that the opinion holder dislikes everything about the object. In an evaluative document (e.g., a product review), the opinion holder typically writes both positive and negative aspects of the object, although the general sentiment on the object may be positive or negative. To obtain such detailed aspects, going to the feature level is needed. Based on the model presented earlier, three key mining tasks are:

1. Identifying *object features*: For instance, in the sentence "The picture quality of this camera is amazing," the object feature is "picture quality." In [10], a supervised pattern mining method is proposed. In [6,12], an unsupervised method is used. The technique basically finds frequent nouns and noun phrases as features, which are usually genuine features. Clearly, many information extraction techniques are also applicable, e.g., conditional random fields (CRF), hidden Markov models (HMM), and many others.
2. Determining opinion orientations: This task determines whether the opinions on the features are positive, negative or neutral. In the above sentence, the opinion on the feature "picture quality" is positive. Again, many approaches are possible. A lexicon-based approach has been shown to perform quite well in [3,6]. The lexicon-based approach basically uses opinion words and phrases in a sentence to determine the orientation of an opinion on a feature. A relaxation labeling based approach is given in [12]. Clearly, various types of supervised learning are possible approaches as well.
3. Grouping synonyms: As the same object features can be expressed with different words or phrases, this task groups those synonyms together. Not much research has been done on this topic. See [1] for an attempt on this problem.

Mining Comparative and Superlative Sentences

Directly expressing positive or negative opinions on an object or its features is only one form of evaluation. Comparing the object with some other similar objects is another. Comparisons are related to but are also different from direct opinions. For example, a typical opinion sentence is "The picture quality of camera x is great." A typical comparison sentence is "The picture quality of camera x is better than that of camera y." In general, a comparative sentence expresses a relation based on similarities or differences of more than one object. In English, comparisons are usually conveyed using the *comparative* or the *superlative* forms of adjectives or adverbs. The structure of a comparative normally consists of the stem of an adjective or adverb, plus the suffix -*er*, or the modifier "more" or "less" before the adjective or adverb. The structure of a superlative normally consists of the stem of an adjective or adverb, plus the suffix -*est*, or the modifier "most" or "least" before the adjective or adverb. Mining of comparative sentences basically consists of identifying what features and objects are compared and which objected are preferred by their authors (opinion holders). Details can be found in [4,7].

Key Applications

Opinions are so important that whenever one needs to make a decision, one wants to hear others' opinions. This is true for both individuals and organizations. The technology of opinion mining thus has a tremendous scope for practical applications.

Individual consumers: If an individual wants to purchase a product, it is useful to see a summary of opinions of existing users so that he/she can make an informed decision. This is better than reading a large number of reviews to form a mental picture of the strengths and weaknesses of the product. He/she can also compare the summaries of opinions of competing products, which is even more useful.

Organizations and businesses: Opinion mining is equally, if not even more, important to businesses and organizations. For example, it is critical for a product manufacturer to know how consumers perceive its products and those of its competitors. This information is not only useful for marketing and product benchmarking but also useful for product design and product developments.

Optimistic Replication and Resolution

Marc Shapiro
INRIA Paris-Rocquencourt and LIP6, Paris, France

Synonyms

Optimistic Replication; Reconciliation-Based Data Replication; Lazy Replication; Multi-Master System

The term "Optimistic Replication" is prevalent in the distributed systems and distributed algorithms literature. The database literature prefers "Lazy Replication"

Definition

Data replication places physical copies of a shared logical item onto different sites. *Optimistic replication* (OR) [11] allows a program at some site to read or update the local replica at any time. An update is *tentative* because it may conflict with a remote update. Such conflicts are resolved after the fact, in the background. Replicas may *diverge* occasionally but are expected to converge eventually (see entry on EVENTUAL CONSISTENCY).

OR avoids the need for distributed concurrency control prior to using an item. It allows a site to execute even when remote sites have crashed, when network connectivity is poor or expensive, or while disconnected from the network. *Disconnected operation,* the capability to compute while disconnected from a data source, e.g., in mobile computing, requires OR. In *computer-supported co-operative work*, OR enables a user to temporarily insulate himself from other users.

The defining characteristic of OR is that any synchronization between sites occurs in the background, after local termination, i.e., off the critical path of the application.

Historical Background

The first historical instance of OR is Johnson's and Thomas's replicated database (1976). (The vocabulary used in this history is defined in Section "Foundations.")

Usenet News (1979) was an important and inspirational development. News supports a large-scale ever-growing database of (read-only) items, posted by users all over the world. A Usenet site connects infrequently (e.g., daily) with its peers. New items are flooded to other sites, and are received in arbitrary order. Users occasionally observe ordering anomalies, but this is not considered a problem. However, system administrators must deal manually with conflicts over administrative operations.

In 1984, Wuu and Bernstein's replicated mutable key-value-pair database use an operation log, transmitted by an *anti-entropy* protocol: site A sends to site B only the tail of A's log that B has not yet seen [15]. Concurrent operations either commute or have a natural semantic order; non-concurrent operations execute in happens-before order.

The Lotus Notes system (1988) supports co-operative work between mobile enterprise users. It replicates a database of discrete items in a peer-to-peer manner. Notes is state-based, and uses a Last-Writer Wins policy. A deleted item is replaced by a *tombstone.*

Several file systems, designed in the early 1990s to support disconnected work, e.g., Coda [6], are state based and uses version vectors for conflict detection. Conflicts over some specific object types (e.g., directories or mailboxes) cause automatic resolver programs to run. The others must be resolved manually.

Golding (1992) [3] studies a replicated database of mutable key-value pairs. This system purges an operation from the log when it can prove that it was delivered to all sites. Consistency is ensured by defining a total order of operations.

Bayou (1994–1997) is an innovative general-purpose database for mobile users [9]. Bayou is operation-based and uses an anti-entropy protocol. Each site executes transactions in arbitrary order; transactions remain tentative. The eventual serialization order is the order of execution at a designated *primary* site. Other sites roll back their tentative state, and re-execute committed transactions in commit order.

In 1996, Gray et al. argued that OR databases for disconnected work cannot scale [4], because conflict reconciliation is expensive, conflict probability rises as the third power of the number of nodes, and the wait probability further increases quadratically with disconnection time.

Breitbart et al. [1] describe a partially-replicated database that uses a form of OR. Each item has a designated primary site and may be replicated at any number of secondary sites. A read may occur at a secondary site but a write must occur on the primary. It follows that write transactions update a single site. If transactions are serialisable at each site, and update propagation is restricted to avoid ordering anomalies, then transactions are serialisable despite lazy propagation.

The Computer-Supported Cooperative Work (CSCW) community invented (1989) a form of OR called Operational Transformation (OT). Conflicting operations are *transformed*, by modifying their arguments, in order to execute in arbitrary order [12].

Foundations

Figure 1 depicts a logical item *x*, concretely replicated at three different sites. In OR, any site may *submit* or *initiate* a transaction reading or writing the local replica. If the transaction succeeds locally, the system *propagates* it to other sites, and *replays* the transaction on the remote sites, in a *lazy* manner, in the background. Local execution is *tentative* and may be rolled back later, because of a *conflict* with a concurrent remote transaction. (The happens-before and concurrency relations are defined formally by Lamport [7]. Transaction A happens-before B, if B was initiated on some site after A executed at that site. Two transactions are concurrent if neither happens-before the other.)

OR is opposed to pessimistic (or eager) replication, where a local transaction terminates only when it commits globally. Pessimistic replication establishes a total order for committed transactions, at the latest when each transaction terminates. In contrast, OR generally relaxes the ordering requirements and/or converges to a common order *a posteriori*. The effects of a tentative transaction can be observed, thus OR protocols may violate the *isolation* property and allow cascading aborts and retries to occur.

Transmitting and Replaying Updates

In OR, updates are propagated lazily, in the background, after the transaction has terminated locally. Transmission usually uses peer-to-peer epidemic or anti-entropy techniques (see entry on Peer-to-Peer Content Distribution).

A site that receives a remote update *replays* it, i.e., incorporates it into the local replica. There are two main approaches. In the *state-based* approach, the initiator site transmits the after-values of the transaction, and other sites assign the after-value to their local replica. In the *operation-based* approach, the initiator sends the program of the transaction itself, and other sites re-execute the transaction.

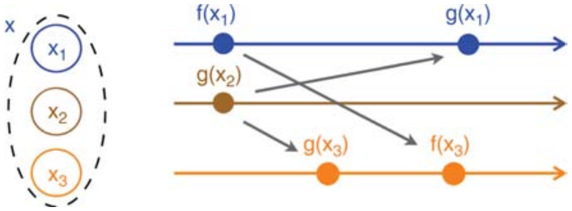
State-based replay is guaranteed to be deterministic. State-based replay can be more efficient, since the replay code is just a write. On the downside, if the granularity is large, then state-based transmission is expensive and replay is subject to false conflicts. Furthermore, logical operations are more likely to commute than writes, thus operation-based replay typically causes fewer aborts.

Conflicts

Each transaction taken individually is assumed correct (the C of the ACID properties), i.e., it maintains semantic invariants. For example, ensuring that a bank account remains positive, or that a person is not scheduled in two different meetings at the same time.

As is clear from Fig. 1, concurrent transactions may be delivered to different sites in different orders. (Dependent transactions are assumed to execute in dependency order; see Section "Scheduling Transactions Content and Ordering.") However, consistency requires that local schedules be equivalent. In this respect, one may classify pairs of concurrent transactions as commuting, non-commuting, and antagonistic. Transactions *conflict* if they are mutually non-commuting or mutually antagonistic.

The relative execution order of *commuting* transactions is immaterial; they require no remote synchronization. Formally, two transactions T_1 and T_2 commute if execution order $T_1;T_2$ returns the same results to the



Optimistic Replication and Resolution. Figure 1. Three sites with replicas of logical item *x*. Site 1 initiates transaction *f*, Site 2 initiates *g*. The system propagates and replays on remote sites. Site 3 executes in the order *g;f*, whereas Site 1 replays *f* before *g*. Eventually, Site 2 will also execute *f*.

user and leaves the database in the same state as the order $T_2;T_1$. For instance, depositing €10 in a bank account commutes with a depositing €20 into the same account, and also commutes with withdrawing €100 from an independent account.

If running concurrent transactions together would violate an invariant, they are said *antagonistic*. Safety requires aborting one or the other (or both). For instance, if T_1 schedules me in a meeting from 10:00 to 12:00, and T_2 schedules a meeting from 11:00 to 13:00, they are antagonistic since no combination of both T_1 and T_2 can be correct.

If two transactions are *non-commuting* and neither is aborted, then their relative execution order must be the same at all sites. Consider for instance T_1 = "transfer balance to savings" and T_2 = "deposit €100." Both orders $T_1;T_2$ and $T_2;T_1$ make sense, but the result is clearly different. There must be a system-wide consensus on the order chosen.

Conflict Resolution and Reconciliation

Conflict resolution rewrites or aborts transactions to remove conflicts. Conflict resolution can be either manual or automatic. Manual conflict resolution simply allows conflicting transactions to proceed, thereby creating conflicting versions; it is up to the user to create a new, merged version.

Reconciliation detects and repairs conflicts, and combines non-conflicting updates. Thus transactions are *tentative*, i.e., a tentatively-successful transaction may have to roll back for reconciliation purposes. OR resolves conflicts *a posteriori* (whereas pessimistic approaches avoid them *a priori*).

In many systems, data invariants are either unknown or not communicated to the system. In this case, the system designer conservatively assumes that, if concurrent transactions access the same item, and one (or both) writes the item, then they are antagonistic. Then, one of them must abort, or both.

A few systems, such as Bayou [14] or IceCube [10] support an application-specific check of invariants.

Last Writer Wins

When transactions consist only of writes, a common approach is to ensure a global precedence order.

For instance, many replicated file systems follow the "Last Writer Wins" (LWW) approach. Files have timestamps that increase with successive versions. When the file system encounters two concurrent versions of the same file, it overwrites the one with the smallest timestamp with the "younger" one (highest timestamp). The write with the smallest timestamp is lost; this approach violates the Durability property of ACID.

Semantic Resolvers

A resolver is an application-specific conflict resolution program that automatically merges two conflicting versions of an item into a new one. For example, the Amazon online book store resolves problems with a user's "shopping cart" by taking the union of any concurrent instances. This maximizes availability despite network outages, crashes, and the user opening multiple sessions.

A resolver should ensure that the conflicting transactions are made to commute. In a state-based approach, a resolver generally parses the item's state into small, independent sub-items. Then it applies a LWW policy to updated and tombstoned sub-items, and a union policy to newly-created sub-items.

The most elaborate example exists in Bayou. A Bayou transaction has three components: the dependency check, the write, and the merge procedure. The former is a database query that checks for conflicts when replaying. The write (a SQL update) executes only if the consistency check succeeds. If it fails, the merge procedure (an arbitrary but deterministic program) provides a chance to fix the conflict. However, it is very difficult to write merge procedures in the general case.

Operational Transformation

In Operational Transformation (OT), conflicting operations are *transformed* [12]. Consider two users editing the shared text "abc". User 1 initiates *insert ("X",2)* resulting in "aXbc" and User 2 initiates *delete (3)*, resulting in "ab." When User 2 replays the insert, the result is "aXb" as expected. However for User 1 to observe the same result, the delete must be transformed to *delete(2)*.

In essence, the operations were specified in a non-commuting way, but transformation makes them commute. OT assumes that transformation is always possible. The OT literature focuses on a simple, linear, shared edit buffer data type, for which numerous transformation algorithms have been proposed.

OT requires two correctness conditions, often called TP1 and TP2. TP1 requires that, for any two concurrent operations A and B, running "A followed by {B transformed in the context of A}" yield the same result as "B followed by {A transformed in the context of B}." TP1 is relatively easy to satisfy, and is sufficient if replay is somehow serialized.

TP2 requires that transformation functions themselves commute. TP2 is necessary if replay is in arbitrary order, e.g., in a peer-to-peer system. The vast majority of published non-serialized OT algorithms have been shown to violate TP2 [8].

Scheduling Transactions Content and Ordering

In order to capture any causal dependencies, transactions execute in happens-before order. As explained in Section "Conflicts," antagonistic transactions cause aborts, and non-commuting transactions must be mutually ordered. This so-called *serialization* requires a consensus.

Whereas pessimistic approaches serialize *a priori*, most OR systems execute transactions tentatively in arbitrary order and serialize a posteriori. Some executions are rolled back; cascading aborts may occur.

A prime example is the Bayou system [14]. Each site executes transactions in the order received. Eventually, the transactions reach a distinguished *primary* site. If a transaction fails its dependency check at the primary, then it aborts everywhere. Transactions that succeed commit, and are serialized in the execution order of the primary.

The IceCube system showed that it is possible to improve the user experience by scheduling operations intelligently [10]. IceCube is a middleware that relieves the application programmer from many of the complexities of reconciliation. Multiple applications may co-exist on top of IceCube. Applications expose semantic annotations, indicating which operation pairs commute or not, are antagonistic, dependent, or have an inherent semantic order. The user may create atomic groups of operations from different applications. The IceCube scheduler performs an optimization procedure over a batch of operations, minimizing the number of aborted operations. The user commits any of the alternative schedules proposed by the system.

Freshness of Replicas

Applications may benefit from *freshness* or quality-of-service guarantees, e.g., that no replica diverges by more than a known amount from the ideal, strongly-consistent state. Such guarantees come at the expense of decreased availability.

The Bayou system proposes qualitative "session guarantees" on the relative ordering of operations [13]. For instance, Read-Your-Writes (RYW) guarantees that a read observes the effect of a write by the same user, even if initiated at a different site. RYW ensures, that immediately after changing his password, a user can log in with the new password. Other similar guarantees are Monotonic-Reads, Writes-Follow-Reads, and Monotonic-Writes.

Systems such as TACT control replica divergence quantitatively [5]. TACT provides a time-based guarantee, allowing an item to remain stale for only a bounded amount of time. TACT implements this by pushing an update operation to remote replicas before the time limit elapses. TACT also provides "order bounding," i.e., limiting the number of uncommitted operations: when a site reaches a user-defined bound on the number of uncommitted operations, it stops accepting new ones.

Finally, TACT can bound the difference between numeric values.

For this, each replica is allocated a quota. Each site estimates the progress of other sites, using vector clock techniques. The site stops initiating operations once its cumulative modifications, or the estimated remote updates to the item, reach the quota. At that point the site pushes its updates and pulls remote operations. For example a bank account might be replicated at ten sites.

To guarantee that the balance observed is within €50 of the truth, each site's quota is €50/10 = €5. Whenever the difference estimated by a site reaches €5, it synchronises with the others.

Optimistic Replication Versus Optimistic Concurrency Control

The word "optimistic" has different, but related, meanings when used in the context of replication and of concurrency control.

Optimistic replication (OR) means that updates propagate lazily. There is no *a priori* total order of transactions. There is no point in time where different sites are guaranteed to have the same (or equivalent) state. Cascading aborts are possible.

Optimistic concurrency control (OCC) means that conflicting transactions are allowed to proceed concurrently. However, in most OCC implementations, a transaction validates before terminating. A transaction is serialized with respect to concurrent transactions, at the latest when it terminates, and cascading aborts do not occur.

Key Applications

Usenet News pioneered the OR concept, allowing to share write-only information over a slow, but cheap network using dial-up modems over telephone lines.

Mobile users want to be able to work as usual, even when disconnected from the network. Thus, mobile computing is a key driver for OR applications. Systems designed for disconnected work that use OR include the Coda file system [6], the Bayou shared database [14], or the Lotus Notes collaborative suite.

Another important application area is Computer-Supported Collaborative Work. In this domain, users must be able to update shared artefacts in complex ways without interfering with one another. OR allows a user to insulate himself temporarily from other users. A key example is the Concurrent Versioning System (CVS), which enables collaborative authoring of computer programs [2]. Bayou and Lotus Notes, just cited, are also designed for collaborative work.

OR is used for high performance and high availability in large-scale web sites. A recent example is Amazon's "shopping cart," which is designed to be highly available, even if the same user connects to several instances of the Amazon store discussed earlier.

Optimization and Tuning in Data Warehouses

Ladjel Bellatreche
LISI/ENSMA–Poitiers University, Futuroscope Cedex, France

Definition

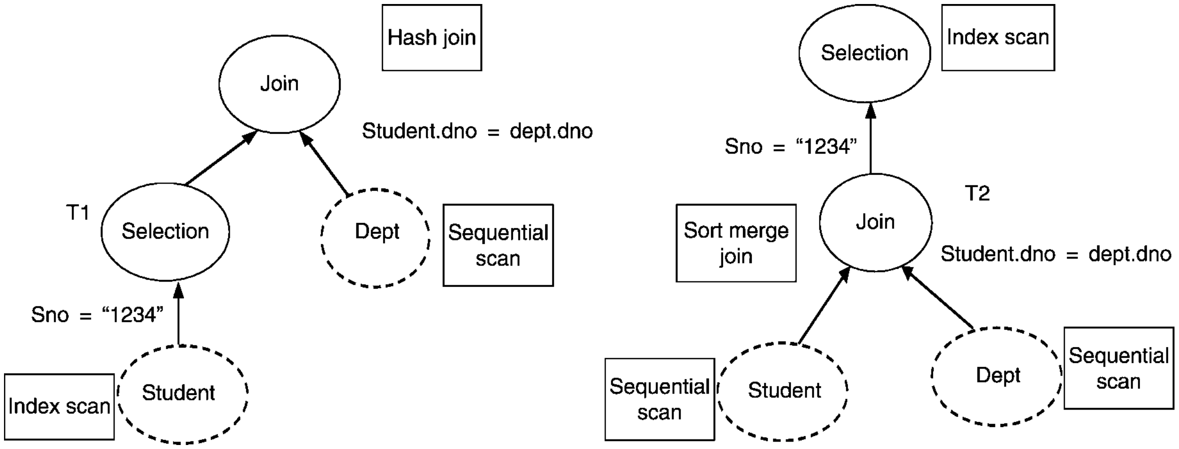
Optimization and tuning in data warehouses are the processes of selecting adequate optimization techniques in order to make queries and updates run faster and to maintain their performance by maximizing the use of data warehouse system resources. A data warehouse is usually accessed by complex queries for key business operations. They must be completed in seconds not days. To continuously improve query performance, two main phases are required: physical design and tuning. In the first phase, data warehouse administrator selects optimization techniques such as materialized views, advanced index schemes, denormalization, vertical partitioning, horizontal partitioning and parallel processing. Generally, this selection is based on most frequently asked queries and typical updates. Physical design generates a configuration Δ containing a number of optimization techniques. This configuration should evolve, since data warehouse dynamically changes during its lifetime. These changes necessitate a tuning phase so as to keep the performance of the warehouse from degrading. Changes may be related to the content of tables, sizes of optimization structures selected during physical design (materialized views, indexes and partitions), frequencies of queries/updates, addition/deletion of queries/updates, etc. The role of the tuning phase is to monitor and to diagnose the use of configuration Δ and different resources assigned to Δ (like buffer, storage space, etc.). For instance, if an optimization technique, like an index, is not used by the whole workload, it will be dropped by a tuning tool and might be replaced with another technique.

Historical Background

There has been extensive work in query optimization since the early 1970s in traditional databases. Several algorithms and systems have been proposed, such as *System-R project*, and its ideas have been largely incorporated in many commercial optimizers. Note that each SQL query corresponding to a select-project-join query in the relational algebra may be represented by many query trees. The leaves of each query tree represent base relations and non-leaf nodes are algebraic operators like selections, projections, unions, joins. An intermediate node indicates the application of the corresponding operator on the relations generated by its children, the result of which is then sent further up. Thus, the edges of a tree represent data rows from bottom to top, i.e., from the leaves which correspond to data in the database, to the root, which is the final operator producing the query answer. For a complicated query, the number of all possible query trees may be very high due to many algebraic laws that hold for relational algebra: commutative and associative laws of joins, laws involving selection and projection push down along the tree, etc.

To choose an optimal query tree, a database optimizer may employ one of two optimization techniques: *rule-based optimization approach* and *cost-based optimization approach*. The rule-based optimizer is the oldest one. It is simple since it is based on a set of rules concerning join algorithms, the use of an index or not, the choice of the external relation in a nested loop, and so on. The optimizer chooses an execution plan based on the available access paths and their ranks. For instance, Oracle's ranking of the access paths is heuristic. If there is more than one way to execute a query, then the rule-based optimizer always uses the operation with the lower rank. Usually, operations of lower rank execute faster than those associated with constructs of higher rank. In cost-based optimization, the optimizer estimates the cost of each possible execution plan (Query execution plan is a set of steps used to access data in relational databases. Figure 1 gives an example of an execution plan, where dashed circles and solid circles represent base tables and algebraic operations, respectively. Other execution plans might be generated.) by applying heuristic formulas using a set of statistics concerning database (sizes of tables, indexes, tuple length, selectivity factors of join and selection predicates, sizes of intermediate results, etc.) and hardware (size of buffer, page size, etc.). For each execution plan, the query optimizer performs the following tasks: (i) it selects an order and grouping for associative-and-commutative operations like joins, unions and intersection, (ii) it chooses implementation algorithms for different algebraic operations: for example, selections may be implemented using either a sequential scan or an index scan; join operation may be implemented in different ways: *nested loop*, *sort-merge join* and *hash join* (see Fig. 1), (iii) it manages additional operators like group-by, sorting, etc., and (iv) it manages the intermediate results ($T1$ and $T2$ are an example of intermediate results of two execution plans of the same query in Fig. 1), etc. Cost-based optimizer chooses the plan that has the lowest cost using dynamic programming approaches (e.g., in System R).

Cost-based optimization is more effective than rule-based optimization, since all decisions taken on a query execution plan are validated by a cost model. An important point to be mentioned is that the quality of cost-based optimization depends strongly on the



Optimization and Tuning in Data Warehouses. Figure 1. Two different query execution plans.

recency of the statistics. Determining which statistics to create is a difficult task [6].

Due to the difficulty query optimizers have in selecting an optimal execution plan, some commercial database systems offer the data warehouse administrator to use *hints* in order to force query optimizer to choose an execution plan.

The above cited optimization techniques are enough to optimize traditional database applications (called, OLTP: On-Line Transaction Processing). It will be interesting to see whether they are also sufficient for decision support applications built around a large data warehouse.

A data warehouse is usually modeled with a relational schema (star schema, snow flake schema). A star schema consists of a single fact table that is related to multiple dimension tables via foreign key joins. Dimension tables are relatively small compared to the fact table and rarely updated. They are typically *denormalized* so as to minimize the number of join operations required to evaluate a query. Due to the interactive nature of decision support applications, having a fast query response time is a critical performance goal. The above optimization techniques are not suitable for data warehouse applications due to their different requirements and workload. Data warehouse applications operate in mostly-read environments, which are dominated by large and complex queries. The typical queries on the star schema are called *star join queries*. They are characterized by: (i) a *multi-table* join among a *large fact table* and dimension tables and (ii) each of the dimension tables involved in the join operation has *multiple* selection predicates (a selection predicate has the following form: $D_i.A_j\ \theta\ value$, where A_j is an attribute of dimension table D_i and θ is one of six comparison operators $\{=,<,>,\leq,\geq\}$, and value is the predicate constant) on its descriptive attributes and (iii) no join operation between dimension tables. Unfortunately, conventional query optimization techniques are not efficient for star-join queries for two main reasons. First, traditional indexing techniques (B-tree) are not efficient to process such a selection predicate. This is due to the fact that dimension attributes often have low cardinality (e.g., gender) and each selection predicate typically has a low selectivity. Second, since the fact table is very large, computing the multi-table joins using traditional join algorithms (nested loop, sort-merge, hash joins) is inefficient because it requires scanning the fact table.

Without efficient optimization techniques, such queries may take hours or days, which is unacceptable in most cases. As a consequence, the physical design becomes sophisticated to cope with complex decision support queries [6]. To speed up these queries, in addition to the existing ones (developed for OLTP applications), a large spectrum of optimization techniques were proposed in the literature and mostly supported by commercial database systems. These techniques include materialized views, partitioning, advanced indexing schemes, denormalization, parallel processing. In the next section, all these techniques will be described in details. For each one, its principle, advantages, disadvantages and selection problem will be presented.

Foundations

The various optimization techniques selected during the physical design process may be classified into two main categories: redundant techniques and non-redundant techniques.

Redundant Techniques

This category includes four main techniques: materialized views, advanced indexing schemes, denormalization, and vertical partitioning.

1. *Materialized views.* A virtual view (A view is a derived relation defined in terms of base relations.) can be materialized by storing its tuples in the databases. Materialized views are used to precompute and to store aggregated data. They can also be used to precompute joins with or without aggregations. So, materialized views are suitable for queries with expensive joins or aggregations. Once materialized views are selected, all queries will be rewritten using materialized views (this process is known as *query rewriting*). A rewriting of a query Q using views is a query expression Q' referencing to these views. The query rewriting is done *transparently* by the query optimizer. To generate the best rewriting for a given query, a cost-based selection method is used. Two major problems related to materialized views are: (i) the view selection problem and (ii) the view maintenance problem.

Views selection problem. The database administrator cannot materialize all possible views, as he/she is constrained by some resources like, disk space, computation time, maintenance overhead and cost required for query rewriting process. Hence, he/she needs to select an appropriate set of views to materialize under some resource constraint. Formally, view selection problem (VSP) is defined as follows: given a set of most frequently used queries $Q = \{Q_1, Q_2, \ldots, Q_n\}$, where each query Q_i has an access frequency f_i ($1 \leq i \leq n$) and a resource constraint M, the view selection problem consists of selecting a set of materialized views that minimizes one or more objectives, possibly subject to one or more constraints. Many variants of this problem have been studied: (i) minimizing the query processing cost subject to storage size constraint [5], (ii) minimizing query cost and maintenance cost subject to storage space constraint [9], (iii) minimizing query cost under a maintenance constraint [8], etc. This problem is known to be an NP-hard problem [8]. Several algorithms were proposed to deal with this problem [8,9]. The following table summarizes all possible formalizations of view selection problem. Two symbols are used in this table (√ and ?), where each one has its own interpretation: √: formalizations and selection algorithms already exist and ?: Inapplicable.

Objectives	*Constraints*		
	Without constraints	Maintenance cost	Storage cost
Query cost	√	√	√
Maintenance cost	√	?	√
Query cost & Maintenance Cost	√	?	√

View maintenance problem. Note that materialized views store data from base tables. In order to keep the views in the data warehouse up to date, it is necessary to maintain the materialized views in response to the changes at the base tables. This process of updating views is called view maintenance which has generated a great deal of interest. Views can be either recomputed from scratch, or incrementally maintained by propagating the base data changes onto the views. As recomputing the views can be prohibitively expensive, the incremental maintenance of views is of significant value [8].

2. *Indexing* has been at the foundation of performance tuning for databases for many years. A database index is a data structure that improves the speed of operations in a table. Indexes can be created using one or more columns. An index can be either clustered or non-clustered. It can be defined on one table (or view) or many tables using a join index [10]. The traditional indexing strategies used in database systems do not work well in data warehousing environments since most OLTP queries are point queries. B-trees, which are used in most common relational database systems, are geared towards such point queries. In the data warehouse context, indexing refers to two different things: (i) indexing techniques and (ii) index selection problem.

Indexing techniques. A number of indexing strategies have been suggested for data warehouses: Value-List Index, Projection Index, Bitmap Index, Bit-Sliced Index, Data Index, Join Index, and Star Join Index. Bitmap index is probably the most important result obtained in the data warehouse physical optimization field. The bitmap index is more suitable for low cardinality attributes since its size strictly depends on the *number of distinct values of the column on which it is built*. Besides disk space saving (due to their binary representation and potential compression), such index speeds up queries having Boolean operations (such as AND, OR and NOT) and COUNT operations. Bitmap join index is proposed to speed up join operations. In its simplest form, it can be defined as a bitmap index on a table *R* based on a single column of another table *S*, where *S* commonly joins with *R* in a specific way.

Index selection problem. The task of index selection is to automatically select an appropriate set of indices for a data warehouse (having a fact table and dimension tables) and a workload under resource constraints (storage, maintenance, etc.). It is challenging for the following reasons [3]: the size of a relational data warehouse schema may be large (many tables with several columns), and indices can be defined on a set of columns. Therefore, the search space of indices that are relevant to a workload can be very large [2]. To deal with this problem, most selection approaches use two main phases: (i) *generation of candidate attributes* and (ii) *selection of a final configuration*. The first phase prunes the search space of index selection problem, by eliminating *non-relevant* attributes. In the second phase, the final indices are selected using greedy algorithms [4], linear programming algorithms [3], etc. The *quality of the final set of indices depends essentially on the pruning phase*. To prune the search space of index candidates, many approaches were proposed [1–3], that can be classified into two categories: *heuristic enumeration-driven approaches* and *data mining driven approaches*.

In heuristic enumeration-driven approaches, heuristics are used. For instance, in [4], a greedy algorithm is proposed that uses optimizer cost of SQL Server to accept or reject a given configuration of indices. The weakness of this work is that it *imposes the number of generated candidates*. IBM DB2 Advisor is another example belonging to this category [15], where the query parser is used to pick up selection attributes used in workload queries. The generated candidates are obtained by a few *simple combinations* of selection attributes [15].

In data mining-driven approaches, the pruning process is done using data mining techniques, like in [2]. In this approaches the number of index candidates is not a priori known as in the first category. The basic idea is to generate frequent closed itemsets representing groups of attributes that could participate in selecting the final configuration of bitmap join indexes. A data mining based approach has been developed for selecting bitmap join indexes [2].

3. *Vertical partitioning* can be viewed as a redundant structure even if it results in little storage overhead. The vertical partitioning of a table *T* splits it into two or more tables, called, sub-tables or vertical fragments, each of which contains a subset of the columns in *T*. Note that the key columns are duplicated in each vertical fragment, to allow "reconstruction" of an original row in *T*. Since many queries access only a small subset of the columns in a table, vertical partitioning can reduce the amount of data that needs to be scanned to answer the query. Unlike horizontal partitioning, indexes or materialized views, in most of today's commercial database systems there is no native database definition language support for defining vertical partitions of a table [14].

To vertically partition a table with m non-primary keys, the number of possible fragments is equal to $B(m)$, which is the mth Bell number [12]. For large values of m, $B(m) \cong m^m$. For example, for m = 10; $B(10) \cong 115{,}975$. These values indicate that it is futile to attempt to obtain optimal solutions to the vertical partitioning problem. Many algorithms were proposed and classified into two categories: grouping and splitting [12]. Grouping starts by assigning each attribute to one fragment, and at each step, joins some of the fragments until some criteria is satisfied. Splitting starts with a table and decides on beneficial partitionings based on the query frequencies.

In the data warehousing environment, [7] proposed an approach for materializing views in vertical fragments, each including a subset of measures possibly taken from different cubes, aggregated on the same grouping set. This approach may unify two or more views into a single fragment.

4. *Denormalization* is the process of attempting to optimize the performance of a database by adding redundant data to save join operations. Denormalization is usually promoted in a data warehouse environment.

Non Redundant Techniques

In this category, two main techniques exist: horizontal partitioning and parallel processing.

1. *Horizontal partitioning* represents an important aspect of physical database design. It allows tables, indexes and materialized views to be partitioned into *disjoint* sets of rows that are physically stored and accessed separately [14] or in parallel. Horizontal partitioning may have a significant impact on performance of queries and manageability of very large data warehouses. Not only do data partitions reduce the time it takes to perform database maintenance and management tasks, by eliminating non-relevant partition(s), they also have a positive effect on the performance of applications. Another characteristic of horizontal partitioning is its ability to be combined with other optimization structures like indexes, materialized views. Splitting a table, a materialized view or an index into smaller pieces makes all operations on individual pieces much faster. Contrary to materialized views and indexes, data partitioning does not replicate data, thereby reducing space requirements and minimizing update overhead [13].

A native database definition language support is available for horizontal partitioning, where several fragmentation modes are available [11]: range, list and hash. In the range partitioning, an access path (table, view, and index) is decomposed according to a range of values of a given set of columns. The hash mode decomposes the data according to a hash function (provided by the system) applied to the values of the partitioning columns. The list partitioning splits a table according to the listed values of a column. These methods can be combined to generate composite partitioning (List-List, Range-Range, Hash-Hash, Range-List, ...). Recently, a new mode of horizontal partitioning became available in Oracle11g [11], called *virtual column-based partitioning*. It is defined by one of the above mentioned techniques and the partitioning key is based on a virtual column. Virtual columns are not stored on disk and only exist as metadata.

Two versions of horizontal partitioning are available [12]: *primary* and *derived* horizontal partitioning. Primary horizontal partitioning of a table is performed using predicates defined on that relation. It can be performed using the different fragmentation modes above cited. Derived horizontal partitioning is the partitioning of a table that results from predicates defined in other table(s). The derived partitioning of a table R according to a fragmentation schema of table S is feasible if and only if there is a join link between R and S.

In the context of relational data warehouses, derived horizontal partitioning is well adapted. In other words, to partition a data warehouse, the best way is to *partition some/all dimension tables using their predicates, and then partition the fact table* based on the fragmentation schemas of dimension tables. This fragmentation takes into consideration requirements of star join queries (these queries impose restrictions on the dimension values that are used for selecting specific facts; these facts are further grouped and aggregated according to the user demands). To illustrate this fragmentation, suppose that a relational warehouse is modeled by a star schema with d dimension tables and a fact table F. Among these dimension tables, g tables are fragmented ($g \leq d$). Each dimension table D_i ($1 \leq i \leq g$) is partitioned into m_i fragments: $\{D_{i1}, D_{i2}, ..., D_{im_i}\}$, where each fragment D_{ij} is defined as: $D_{ij} = \sigma_{cl_j^i}(D_i)$, where cl_j^i and σ ($1 \leq i \leq g, 1 \leq j \leq m_i$) represent a conjunction of simple predicates and the selection operator, respectively. Thus, the fragmentation schema of the fact table F is defined as follows: $F_i = F \ltimes D_{1j} \ltimes D_{2k} \ltimes ... \ltimes D_{gl}$, ($1 \leq i \leq m_i$), where $\ltimes$ represents the semijoin operation.

Derived horizontal partitioning has two main advantages in relational data warehouses, in addition to classical benefits of data partitioning: (i) precomputing joins between fact table and dimension tables participating in the fragmentation process of the fact table [1] and (ii) optimizing selections defined on dimension tables. Similar advantages hold for bitmap join indexes.

2. *Parallel Processing* Data partitioning is always coupled with parallel processing. To design a parallel data warehouse, two main issues must be addressed: data partitioning and data placement (allocation). Data placement is a key factor for high performance parallel data warehouses. Determining an effective data placement is a complex administration problem depending on many parameters including system architecture, database and workload characteristics, hardware configuration, etc. The easier way to design a parallel data warehouse is to first partition dimension tables using the primary horizontal partitioning and then derived partition the fact table. This partitioning alternative generates a set of sub-star schemas. In order to ensure a high performance of complex queries, these sub-star schemas shall be allocated to various machines in efficient manner.

Tuning

Before talking about tuning phase, a summarization of physical design is required to understand the need for tuning.

The first point concerns the different formalizations of problems of selecting optimization techniques in physical design phase. They are mostly based on a set of most frequently asked queries, *a priori known.* However, in dynamic environments, like data warehousing with various ad-hoc queries, it is difficult to identify potential useful optimization structures in advance. The second point is about the similarities between optimization techniques: materialized views and indexes, bitmap join indexes and derived horizontal partitioning. These similarities are not always taken into account during physical design phase. This situation may incur the following limitations: (i) non-consideration of the mutual interdependencies between optimization structures (sometimes it is better to select more materialized views than indexes and vice-versa or replacing bitmap join indexes by a non redundant technique like derived horizontal partitioning to reduce maintenance overhead) gives sub-optimal solutions, (ii) absence of metrics for efficient distribution of storage space between redundant optimization techniques and (iii) redistribution of space among optimization structures after update operations.

Based on the above points, tuning tools are recommended since they supervise the good use of different optimization techniques selected during physical design phase. Tuning tools might be triggered when user requirements evolve (new queries/updates, not considering some existing queries), query frequencies change, sizes of tables, materialized views, indexes and partitions increase, etc. To keep data warehouse applications running at high performance, several aspects of physical design should be tuned: buffer pool, allocation of working memory, materialized views, indexes, storage space, horizontal partitioning, vertical partitioning, data placement, etc.

During the data warehouse life cycle, some structures may be added/dropped (e.g., materialized views and indexes), merged (indexes and horizontal partitions) or splitted (e.g., horizontal partitions). For instance, some commercial database systems provide monitoring tools observing the good utilization of indexes. If an index is not used by a workload, it will be dropped. Its storage space might be used for creating another optimization technique. Merging operations deal mainly with indexes and horizontal partitions. They are crucial for data warehouse applications [5,14]. This is because optimization structures are often either too large (for redundant structures) to fit in the available storage, or cause updates to slow down significantly. They are supported by most commercial database systems.

Many commercial database systems offer tools for physical design tuning: "What-If" analysis tool of SQL Server used to facilitate manual tuning. SQL Server proposes a tuning using a relation-based approach. The optimizer can replace a large useful index with smaller, less useful ones. For example, operations that required a single traversal through a complex index may be implemented as the intersection of two traversals through simple indexes. Other transformations include index merging (implementing an index scan of relation B as a full scan through relation A), prefixing (building an index on a; b instead of a; b; c), and the removal of structures. DB2 design advisor tool provides integrated recommendations for indexes, materialized views, shared-nothing partitioning and multidimensional clustering. ORACLE 10G takes as input a workload and a set of optimization candidates for that workload (these candidates are generated by Oracle Automatic Tuning Optimizer) and provides a recommendation for the overall workload.

In academic research work, a tuning tool called AutoPart which combines horizontal and vertical table partitioning to reduce I/O costs for each query by eliminating unnecessary accesses to non-relevant data is proposed [13]. AutoPart recommends the combination of partitioning with a small set of key indexes. A similar work proposed to combine derived horizontal partitioning with bitmap join indexes [1].

Key Applications

The proposed techniques within this paper can be applied in any database applications having the same characteristics (huge tables, complex queries with many join operations and restriction) and requirements of data warehouse (response time). Scientific and statistical database applications are a good example. Historically, the main techniques explored in this paper were proposed and supported in decision support applications. Materialized views and advanced indexing schemes could be easily applied in traditional OLTP applications, when update operations are not important. Horizontal partitioning can also be applied, but moderately. The choice of partitioning attributes is a crucial performance issue. For example, if a database is partitioned based on changing value attributes like Age, the database will be faced with the problem of *instance migration*.

Future Directions

As mentioned in the previous section, physical design and tuning are very crucial decisions for the performance of data warehouse applications. In this section, some of the interesting open issues for physical design and tuning are highlighted:

1. Multi-objective algorithms for indexes: most index selection algorithms have one objective function which represents the query processing cost subject to one constraint representing the storage cost. It will be interesting to propose multi-objective algorithms for selecting indexes. Such formalizations will reduce the query processing and maintenance cost (which is not negligible for indexes). Since there is a strong similarity between materialized views and indexes, an easier way to deal with this problem is to adapt multi-objective algorithms for materialized views to indexes.
2. Incorporating query rewriting using materialized views in selection process: after selection of materialized views, all queries will be rewritten using them. Choosing an optimal rewriting is a difficult problem. It will be interesting to combine the problem of selecting materialized views and the problem of rewriting queries. A simple combination may involve the formalization of materialized view selection subject to time requiring for query rewrite process.
3. Pruning search space of materialized view selection problem: selecting materialized views is an NP-hard problem. To prune search space of this problem, vertical and horizontal partitioning (primary and derived) might be used, because a materialized view may involve selection, projection, join operations.
4. Partition allocation over table spaces: assigning different fragments generated by horizontal partitioning process over various table spaces may be a crucial issue for performance of queries. This problem does not get enough attention from data warehouse research community. This problem is quite similar to data placement studied in distributed and parallel databases areas. It will be interesting to adapt the existing algorithms. Most of these algorithms are static. Tuning of data placement will be recommended since partition usages change, partition might be merged/splitted, etc.
5. Supporting derived horizontal partitioning: Today's commercial database systems support derived horizontal partitioning, where a table is decomposed based on the fragmentation schema of only one table, using referential partitioning [11]. In real data warehouse applications, a fact table may be derived partitioned based on fragmentation schemas of several dimension tables in order to satisfy star join queries requirements. From an industry perspective, this situation is quite unsatisfactory and requires further thought.

OQL

Peter M.D. Gray
University of Aberdeen, Aberdeen, UK

Synonyms

Object query language

Definition

OQL was developed to play the role of SQL for *Object-Oriented Databases*, especially those adhering to the *ODMG Standard* [4] where the language is defined. Unlike SQL, OQL is a functional language, and its operators can be composed to an arbitrary level of nesting within a query provided the query remains type-correct. Fegaras and Maier [8] have shown how OQL expressions have a direct translation into monoid *Comprehensions*.

Optimisation techniques for OQL that exploit its inherent functional nature are discussed in [5,6,8]. OQL has been influential in the development of the SQL3 standard and also the functional core of the XQuery language for XML. Thus optimisation techniques developed for OQL are also applicable to these languages.

Key Points

The fundamental modelling concept of *object identifiers* for entity instances was accepted into the database mainstream in the late 1980s, and the move to using SQL-like syntax for querying such data models followed soon after. Early influential systems were OSQL [2] and *AMOSQL* (q.v.). This resulted in query language proposals for object-oriented databases such as the very influential O2 query language [1] and its successor OQL, which was included in the ODMG Standard [4]. For example, the DAPLEX query

```
FOR EACH S IN STUDENT
  SUCH THAT name(S)="Fred Jones"
      PRINT name(S), age(S);
```

is expressed as follows in OQL, basically by syntactic reordering of the query clauses and using path expressions rather than function application:

```
SELECT S.name, S.age FROM STUDENT S
WHERE S.name="Fred Jones"
```

When restricted to sets, monoid comprehensions are equivalent to set monad comprehensions [3], which capture precisely the nested relational algebra [8]. Most OQL expressions have a direct translation into the monoid calculus. For example, the OQL query

```
SELECT DISTINCT HOTEL.price
FROM HOTEL IN(
  SELECT h
  FROM c IN CITIES, h IN c.hotels
  WHERE c.name="Arlington")
WHERE EXIST r IN HOTEL.rooms:r.bed_num = 3
AND HOTEL.name IN (
  SELECT t.name
  FROM s IN STATES, t IN s.attractions
  WHERE s.name = "Texas" );
```

finds the prices of hotels in Arlington that have rooms with three beds and are also are named after a tourist attraction in Texas. This query is translated into the following monoid comprehension [7]:

```
fold(Union,Empty,
  [ price(h) | c <- Cities; h <- hotels
  (c); name(c) = ''Arlington'';
        fold(Or,False,
        [bednum(r)=3 | r <- rooms(h) ]),
        fold(Or,False,
  [ name(h)=name(t) | s <- States; t <-
  attractions(s);name(s)=''Texas''])])
```

Here, as in Functional Programming

```
  fold(Or,False,[x1,x2, ... xn]) = x1
  Or x2 Or ... xn Or False
```

computes the logical *Or* of a list of boolean values, so it is true only if *some* of them are true. Likewise *fold(Union,Empty,L)* copies the list L into a set without duplicates. Mathematically *fold* implements *monoid* operations with a given *merge* operation and a *zero*.

Orchestration

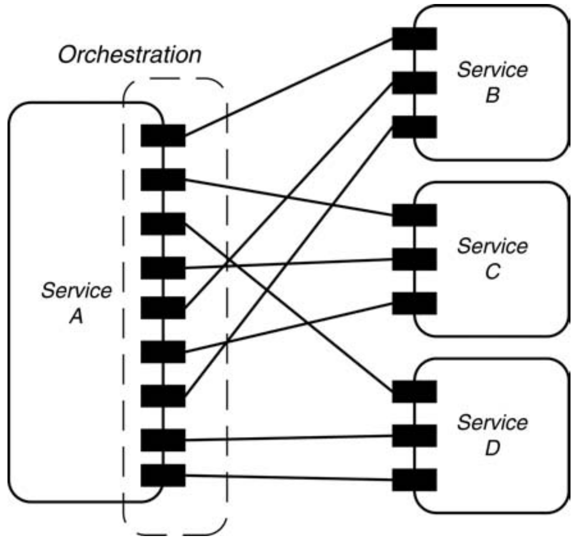
W. M. P. van der Aalst
Eindhoven University of Technology, Eindhoven,
The Netherlands

Definition

In a Service Oriented Architecture (SOA) services are interacting by exchanging messages, i.e., by combining services more complex services are created. Orchestration is concerned with the composition of such services seen from the viewpoint of single service.

Key Points

The terms "orchestration" and "choreography" describe two aspects of integrating services to create business processes [2,3]. The two terms overlap somewhat and the distinction is subject to discussion. Orchestration and choreography can be seen as different "perspectives." Choreography is concerned with the exchange of messages between those services and is often be characterized by analogy "Dancers dance following a global scenario without a single point of control." Orchestration is concerned with the interactions of a single service with its environment. Here an analogy can also be used. In orchestration, there is



Orchestration. Figure 1. Orchestration.

someone, “the conductor”, who tells everybody in the orchestra what to do and makes sure they all play in sync.

Figure 1 illustrates the notion of orchestration. Service A is interacting with other services to create a more complex service. The dashed area shows the focal point of orchestration, i.e., the control-flow related to message exchanges of a single party. Languages such a BPEL are proposed to model and enact such orchestrations [1]. Note that languages like BPEL are very close to traditional workflow languages, i.e., the same types of control-flow patterns need to be supported.

Orchestration often assumes that services have a “buy side” and a “sell side,” i.e., services can be used by other services (“sell side”) and at the same time use services (“buy side”). Orchestration is mainly concerned with the “buy side.” Unlike choreography, there is a single party coordinating the process.

OR-Join

Nathaniel Palmer
Workflow Management Coalition, Hingham,
MA, USA

Synonyms

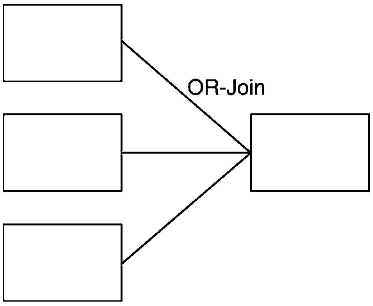
Synchronous join

Definition

The point of convergence within a workflow following alternative, mutually exclusive paths.

Key Points

An OR-Join (Fig. 1) represents a point within a workflow where two or more alternative workflow branches re-converge following an OR-Split into a single common activity as the next step within the workflow. In contrast with an AND-Join, no parallel activity execution has occurred at the join point, therefore no synchronization is required. With an OR-Join a thread of control may arrive at the specific activity via any of several alternative preceding activities.



OR-Join. Figure 1. OR-Join.

OR-Split

Nathaniel Palmer
Workflow Management Coalition, Hingham,
MA, USA

Synonyms

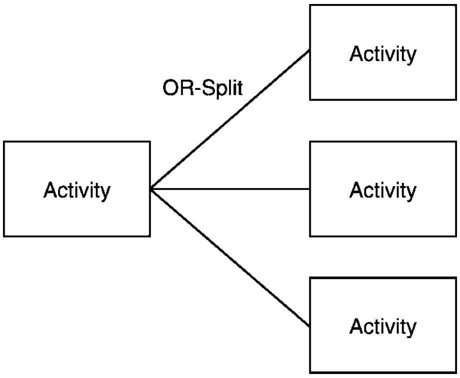
Conditional branching; Conditional routing; Switch; Branch

Definition

A point within the workflow where a single thread of control makes a decision upon which branch to take when encountered with multiple alternative workflow branches.

Key Points

An OR-Split (Fig. 1) establishes alternative and mutually exclusive workflow branches. For example, in a mortgage application, different paths may represent different branches based on conditional logic, such as credit risk or the amount to be barrowed. As paths are mutually exclusive, no parallel execution of activities occur and thus no synchronization is required, so the workflow branching converges with an OR-Join rather than an AND-Join. An OR-Split is conditional and the (single) specific transition to next activity is selected according to the outcome of the Transition Condition(s).



OR-Split. Figure 1. OR-Split.

OSQL

Tore Risch
Uppsala University, Uppsala, Sweden

Definition

OSQL [1,2] is an functional query language and data model similar to Daplex, first implemented in the Iris DBMS [4]. The data model of OSQL is object oriented with three kinds of system entities: objects, types, and functions. A database consists of a set of objects, the objects are classified into types, and functions define the semantics of types. The data model is similar to an ER model with the difference that both entity relationships and attributes are represented as functions and that (multiple) inheritance among entity types is supported. OSQL provide object identifiers (OIDs) as first class objects, and, unlike Daplex, queries can return OIDs in results. Queries are expressed using a SELECT syntax similar to SQL. Derived functions are also defined using select statements similar to functions in SQL-2003.

Key Points

With the OSQL data model a database consists of a set of objects. The objects are classified into subsets by types and each type has an extent consisting of the objects belonging to that type. Type inheritance is supported with the type named OBJECT as most general type. The extent of a type is a subset of the extents of its supertype(s). For example if entity type STUDENT is a subtype of type PERSON then the extent of type STUDENT is also a subset of the extent PERSON. Types are defined dynamically using a CREATE TYPE statement, e.g.,:

```
CREATE TYPE STUDENT SUBTYPE OF PERSON;
```

Functions define relationships among entities and properties of entities. Functions can be stored in the databases, derived in terms of other functions, or be defined as foreign functions implemented in some conventional programming language. Stored functions correspond to tables in relational databases, and derived functions are parameterized views similar to function definitions in SQL-2003.

Queries and derived functions are defined declaratively using a SELECT statement, e.g.,:

```
SELECT NAME(P)
FOR EACH PERSON P
WHERE AGE(P)>20 AND SEX(P) =
``Female'';

CREATE FUNCTION GRANDPARENTS(PERSON
P)-> PERSON
AS SELECT PARENT(PARENT(P));
```

Queries are expressed as constraints over extents. Functions composition allows easy traversal of relationships between entity types. As in Daplex, if a function returns a set of objects (e.g., PARENT) functions applied on it iterate over the elements of the set. This is a form of extended path expressions through function composition.

OSQL was implemented in the Iris DBMS [4] and HP's OpenODB product. The Amos II DBMS [3] uses a modified OSQL language, AmosQL.

Overlay Network

Wojciech Galuba, Sarunas Girdzijauskas
Ecole Polytechnique Fédérale de Lausanne (EPFL),
Lausanne, Switzerland

Definition

An *overlay network* is a communication network constructed on top of an another communication network. The nodes of the overlay network are interconnected with logical connections, which form an *overlay topology*. Two overlay nodes may be connected with a logical connection despite being several hops apart in the underlying network. Overlay networks may define their own *overlay address space* which is used for efficient message routing in the overlay topology.

Key Points

When a distributed application is deployed in a computer network, the individual nodes on which the application is running need to be able to discover and communicate with one another. A solution to this problem is the overlay network. The overlay network interconnects all the application nodes and provides the basic communication primitives such as flooding, random walks or point-to-point overlay message routing and multicast.

Overlay networks are typically deployed on top of the Internet and by far the most common usage is in peer-to-peer systems. For example, Gnutella, an early peer-to-peer file sharing system connects all the peers in an overlay network, each peer shares its files, and files are searched for using query flooding in the overlay network.

Overlay network topologies can be divided into two broad classes: unstructured and structured. Unstructured overlay networks do not construct a globally consistent topology, instead peers choose their neighbor sets independently and in a largely ad-hoc way. In unstructured overlay networks nodes reach the other nodes by message flooding or random walks. Structured overlays define an address space and each of the overlay nodes has a unique address. The addresses are used to construct an overlay topology that enables efficient and scalable messages passing between the overlay nodes. In most of the modern structured overlays the expected number of routing hops scales as $O(log\ N)$ with the network size. Distributed Hash Tables are a specific case of structured overlay networks. Apart from structured and unstructured there also exist hybrid overlays.

Overlay networks are designed to be robust to *churn*, i.e., arrivals and departures of the overlay network nodes to and from the network. As overlay network nodes loose their overlay topology connections, new connections have to be added in their place. In structured overlay networks the additional challenge is to maintain the overlay topology such that the overlay routing remains efficient, i.e., the routing paths are kept short.

Web ontology language

Definition

The Web Ontology Language OWL is a language for defining ontologies on the Web. An OWL Ontology describes a domain in terms of classes, properties and individuals and may include rich descriptions of the characteristics of those objects. OWL ontologies can be used to describe the properties of Web resources. Where earlier representation languages have been used to develop tools and ontologies for specific user-communities in areas such as sciences, health and e-commerce, they were not necessarily designed to be compatible with the

World Wide Web, or more specifically the Semantic Web, as is the case with OWL.

Features of OWL are a collection of expressive operators for concept description including boolean operators (intersection, union and complement), plus explicit quantifiers for properties and relationships; the ability to specify characteristics of properties, such as transitivity or domains and ranges; a well defined semantics facilitating the use of inference and automated reasoning; the use of URIs for naming concepts and ontologies; a mechanism for importing external ontologies; and compatability with the architecture of the World Wide Web, in particular other representation languages such as RDF and RDF Schema.

OWL consists of a suite of World Wide Web Consortium (W3C) Recommendations – six documents published in February 2004 describe Use Cases and Requirements, an Overview of the language, a Guide, Reference, OWL Semantics and a collection of Test Cases [3].

Key Points

Ontology languages allow the representation of ontologies. An ontology "defines a set of representational primitives with which to model a domain of knowledge or discourse" (see Ontology). The definition of an ontology can encompass a wide range of artefacts, from simple word lists, through taxonomies, thesauri and rich logic-based models and there are a corresponding range of languages for their representation.

Standardization of representation languages is a cornerstone of the Semantic Web effort. A standard representation facilitates interoperation – in particular, well-defined, unambiguous *semantics* ensure that applications can agree on the meaning of expressions. OWL is intended to provide that standard representation.

OWL builds on RDF and RDF Schema and adds more vocabulary for describing properties and classes. The design of the language was influenced by a number of factors. Description Logics, Frame-based modeling paradigms, and Web languages RDF and RDF Schema were key inputs, as was earlier work on languages such as OIL and DAML+OIL.

Knowledge Representation in a Web setting introduces particular requirements such as the distribution across many systems; scalability to Web size; compatibility with Web standards for accessibility and internationalization; and openness and extensibility. OWL uses URIs for naming and extends the description framework for the Web provided by RDF to address some of the issues above.

OWL defines three sublanguages: OWL Lite, OWL DL and OWL Full. OWL Full is essentially RDF extended with additional vocabulary, with no restrictions on the way in which that vocabulary is used. OWL DL places restrictions on the way in which the vocabulary can be used in order to define a language for which a number of key reasoning tasks (for example concept satisfiability or subsumption) are decidable. OWL Lite further restricts the expressivity allowed – for example, explicit union or complement are disallowed in OWL Lite. OWL DL and OWL Lite have a model theoretic semantics that corresponds to a Description Logic (DL) [1] and thus facilitate the use of DL reasoners to provide reasoning support for the language [2].

The design of representation languages often involves trade-offs, and there are limitations on what can be expressed using OWL, in particular in OWL-DL. These limitations have been selected primarily to ensure that these language subsets are well-behaved computationally, with decidable procedures for concept satisfiability. For example, OWL does not provide support for general purpose rules, which are seen as an important paradigm in knowledge representation, for example in expert systems or deductive databases. Extensions to OWL are being proposed to cover, among others, rules, query, additional expressivity, metamodeling and fuzzy reasoning.

P/FDM

Peter M.D. Gray
University of Aberdeen, Aberdeen, UK

Definition

P/FDM [5–7] integrated a functional data model with the logic programming language Prolog for general-purpose computation. The data model can be seen as an Entity-Relationship diagram with sub-types, much like a UML Class Diagram. The idea was for the user to be able to define a computation over objects in the diagram, instead of just using it as a schema design aid. Later versions of P/FDM included a graphic interface [2,4] to build queries in DAPLEX syntax by clicking on the diagram and filling in values from menus.

P/FDM was subsequently extended with constraints [3] and with alternative back-ends to remote databases [6], in the spirit of the original MULTIBASE system.

P/FDM is a vehicle to test a system designed on the principle of Data Independence, whereby Functions represent computations that are expressed in a way that is completely independent of data storage (arrays, lists of objects, indexed files etc.). Functions can be sent across the internet and applied to data in a different form, which was very useful for federated data.

Key Points

In P/FDM, the DAPLEX language was deliberately altered from its original specification so that its semantics could be defined by equivalent *Comprehensions* [1]. In particular, simple assignment operations, if present, could only take place within the innermost loop. Based on this, a very successful early optimizer was written in Prolog by Paton, and used in several bioinformatics applications [6,8].

In P/FDM, data independence is ensured by using a small sparse set of built-in predicates *getentity (entity-type, key, instance-variable)* and *getfunctionval (function-name, argument-variable, value-variable).* The first of these predicates requires that abstract entities be identifiable by unique, possibly compound, scalar keys [7]. The keys help with object identity and are very important when accessing or loading bulk data. This is a feature first used in ADAPLEX and EFDM, though P/FDM extends it to allow composed (single-valued) functions, which aids in forming hierarchical keys.

P/FDM queries are written in DAPLEX and translated into Prolog for evaluation. Backtracking in Prolog is used to give the effect of lazy evaluation in a functional programming language, accessing tuples or objects on demand. For example, assuming the following P/FDM declarations:

```
declare student ->> entity
declare name(student) -> string
key_of student is name

declare course ->> entity
declare cname(course) -> string
key_of course is cname
declare attends(student) ->> course
```

to print all the courses attended by Fred Jones, the DAPLEX query is:

```
for each F in student such that name
(F)="Fred Jones"
   for each C in attends(F)
   print(cname(C));
```

which generates the following Prolog:

```
getentity(student,'Fred Jones',F),
getfunctionval(attends,F,C),
getfunctionval(cname,C,N),write(N),
fail; true.
```

Parallel and Distributed Data Warehouses

Todd Eavis
Concordia University, Montreal, QC, Canada

Synonyms

Scalable decision support systems High performance data warehousing

Definition

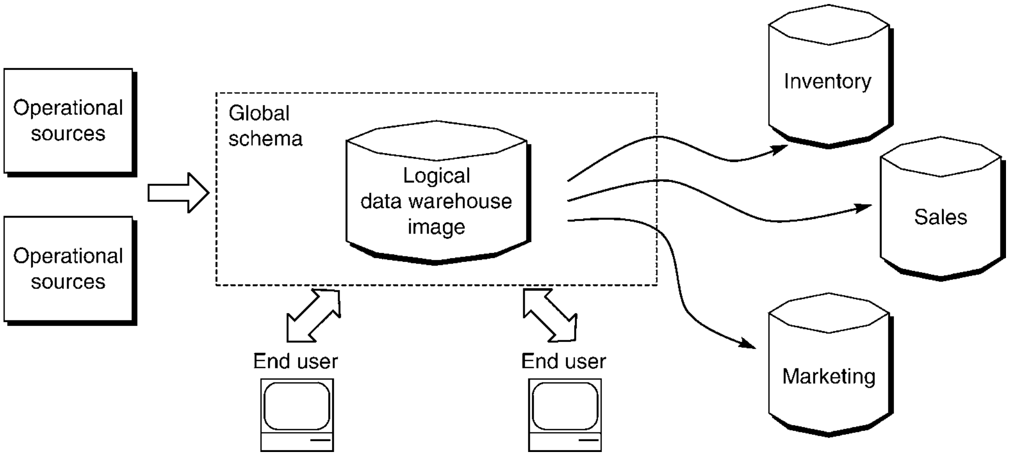
To support the burgeoning data volumes now encountered in decision support environments, *parallel and distributed data warehouses* are being deployed with greater frequency. Having evolved from haphazard and often poorly understood repositories of operational information, the data warehouse itself has become one of the cornerstones of corporate IT architectures. However, as the underlying operational databases grow in size and complexity, so too do the associated data warehouses. In fact, it is not unusual for many corporate or scientific repositories to exceed a terabyte in size, with the largest now reaching 100 TB or more. While processing power has grown significantly during the past decade, the sheer scale of the workload places enormous strain on single CPU data warehousing servers. As a result, some form of data and/or query distribution is often employed in production environments. It is important to note, however, that while contemporary data warehouses are almost always based upon relational DBMS platforms, the unique characteristics and requirements of data warehouse environments often suggest design and optimization choices that are not often employed with general purpose parallelized database systems.

Historical Background

The terms "parallel DW" and "distributed DW" are very often used interchangeably. In practice, however, the distinction between the two has historically been quite significant. Distributed DWs, much like distributed DBs, grew out of a need to place processing logic and data in close proximity to the users who might be utilizing them. In general, multi-location organizations consist of a small number of distinct sites, each typically associated with a subset of the information contained in the global data pool. In the data warehousing context, this has traditionally lead to the development of some form of *federated* architecture. In contrast to monolithic, centralized DWs, federated models are usually constructed as a cooperative coalition of departmental or process specific *data marts*. A simple example is illustrated in Fig. 1. For the most part, design and implementation issues in such environments are similar to those of distributed operational DBMSs [11]. For example, it is important to provide a single transparent conceptual model for the distinct sites and to distribute data so as to reduce the effects of network latency and bandwidth limitations. One unique feature of the distributed data warehouse environment is perhaps the emphasis on integration and consolidation of distributed operational data, a process known in DW terminology as Extract, Transform, and Load (ETL).

With respect to parallelism, research has again been influenced by parallel DBMS projects such as Gamma [3] that were initiated in the mid-to-late 1980s. By the 1990s, it had become clear that commodity-based "shared nothing" databases provided significant advantages over the earlier SMP (Symmetric Multi-Processor) architectures in terms of cost and scalability [4]. Subsequent research therefore focused on partitioning and replication models for the tables of the parallelized DBMS [13]. In general, researchers identified the importance of full *p*-way horizontal striping for large database tables.

Data warehouse researchers have continued to explore the issues related to table partitioning. In addition to complete *p*-way partitioning schemes, full or partial replication (i.e., duplication) of fragments has been investigated [12]. This technique has been further extended by virtualizing partial fragments over



Parallel and Distributed Data Warehouses. Figure 1. A simple federated model illustrating the mapping of a logical global schema on to a series of physically independent data marts.

physically replicated tables [7]. Typically, recent research in the area of table partitioning has exploited the use of "DBMS clusters." Here, rather than constructing a complete, parallel DBMS platform, the parallel system is essentially constructed as a series of commodity DBMS systems, "glued together" with a thin partition-aware wrapper layer.

In addition to the continuation of the traditional partitioning work, a second important theme has been the parallelization of state-of-the-art sequential *data cube* generation methods. The data cube has become the primary abstraction for the multi-dimensional analysis that is central to modern data warehousing systems. Cube parallelization efforts have, in fact, taken two forms, one based upon data that is physically represented as array-based storage [8] and the other based upon relational storage [9,2]. In both cases, the complexity of the algorithm and implementation issues has lead to the development of relatively complete DBMS prototypes.

Foundations

Central to data warehousing systems is a denormalized logical *multi-dimensional model* known as the *Star Schema* (the normalized version is referred to as a Snowflake). A *Star Schema* consists of a single, very large *fact* table housing the measurement records associated with a given organizational process. During query processing, this fact table is joined to one or more *dimension* tables, each consisting of a relatively small number of records that define specific business entities (e.g., customer, product, store). A complete data warehouse typically consists of multiple such *Star Schema* designs.

While the *Star Schema* forms the basis of the relational data warehouse, it can be extremely expensive to query the fact table directly, given that it often consists of tens of millions of records or more. Typically, the basic *Star Schema* is augmented with compact, pre-computed aggregates (called *group-bys* or *cuboids*) that can be queried much more efficiently at run-time. This collection of aggregates is known as the data *cube*. Specifically, for a *d*-dimensional space, $\{A_1, A_2, ..., A_d\}$, the *cube* defines the aggregation of the 2^d unique *dimension* combinations across one or more relevant *measure* attributes. In practice, the generation and manipulation of the data *cube* is often performed by a dedicated *OLAP* (online analytical processing) server that runs on top of the underlying relational data warehouse. While the *OLAP* server may utilize either array-based (MOLAP) or table-based (ROLAP) storage, both provide the same, intuitive multi-dimensional representation for the end user.

Given the enormous size of these new data warehouses, some form of parallelism is often employed in production environments. One option is a "shared everything" architecture. Here, designers would likely employ a CC-NUMA system (Cache Coherent Non Uniform Memory Access) that supports a single global memory pool and some form of single virtual disk

(e.g., a disk array). Such systems have the advantage that they are relatively easy to administer as the hardware transparently performs much of the "magic." That being said, shared everything designs also tend to be quite expensive and have limited scalability in terms of both the CPU count and the number of available disk heads. In terabyte-scale data warehouse environments, either or both of these constraints might represent a serious performance limitation.

For this reason, many vendors and researchers have turned towards distributed, "shared nothing" platforms for high performance database applications. In fact, the characteristics of DW processing environments make such models particulary attractive. The key distinctions between operational and DW processing include:

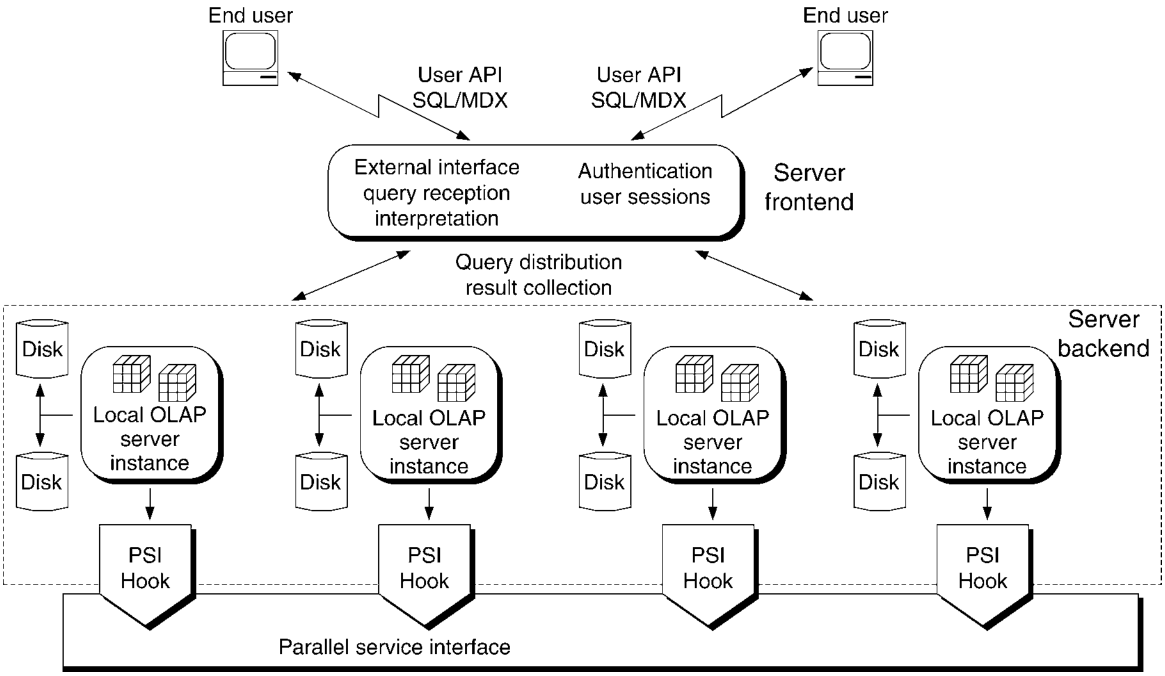
1. Operational systems tend to have high volume query streams. In contrast, DW systems typically process a much smaller number of user queries.
2. Operational queries have *high selectivity*, meaning that they touch relatively few records. Conversely, DW queries are comprehensive in scope, leading to very low selectivity and high I/O and computational load.

Why does this bode well for the use of shared nothing architectures? In large operational environments, high performance can often be achieved through the exploitation of what is often termed a "high throughout engine." Here, improved performance is obtained via *inter-query* parallelism; that is, a stream of small queries is executed concurrently across the parallel/distributed system. However, the low volume/low selectivity combination in DW environments generally argues against the use of inter-query parallelism since such a division of work would likely lead to extensive disk thrashing (i.e., resource conflict). Note, as well, that the use of indexes, a staple in operational systems, is often of relatively little value in DW environments since full table scans are generally more cost effective for low selectivity queries.

As a consequence, the fully distributed, "shared nothing" DBMS model has been particulary attractive for high performance DW practitioners. By partitioning the core fact tables across a large number of independently controlled CPU/disk combinations, shared nothing designs are ideally suited to the exploitation of *intra-query parallelism*. In this case, an individual query q is decomposed and simultaneously executed across the p nodes of the system, with each *partial query* running against approximately $1/p$ records of the partitioned fact table (the small dimension tables are typically replicated on each node). Figure 3b provides a simple example of this technique, contrasting it with the non-partitioned model typically utilized on a single node server (Fig. 3a). Though merging of results may be necessary, it is important to note that while the input partitions may be massive, the output of user-directed analytical DW queries is typically quitesmall. As a result, it should be seen that shared nothing data warehousing excels precisely because it offers tremendous I/O performance while simultaneously requiring only modest inter-node communication [10].

It is against this backdrop that many recent data warehousing partitioning projects have been set. Essentially, there are three forms of DW partitioning. In the first case, the fact tables are physically partitioned in the manner just described. While the performance with this approach can be impressive [15], it is also true that imbalances caused by inherent data skew make effective *a priori* data striping quite challenging. In response, the *virtual* partition model was proposed [1]. Here, as illustrated in Fig. 3c, the fact tables are replicated in full across the nodes of the DBMS cluster. Queries are then decomposed into sub-queries ($1/p$ records per node) that are run against virtual partitions mapped on top of the fully replicated tables. The advantage is that sub-queries may be (i) run against any cluster node and (ii) dynamically migrated to underutilized nodes. The downside is (i) the storage requirement associated with p copies of the primary fact table and (ii) the fact that the commodity DBMS will invoke a full table scan if the partitions are too large. The third partitioning method attempts to combine the best features of the previous methods. In *adaptive virtual partitioning* (AVP) [7], small virtual partitions are layered on top of larger physical partitions. The AVP algorithm dynamically determines the maximum sub-query size that does not invoke a table scan by iteratively probing the commodity DBMS with successively larger queries. The result is a set of re-locatable sub-queries that can generally be answered efficiently without access to the code base of the commodity DBMS systems. A simple illustration is provided in Fig. 3d.

While partitioning is the cornerstone of contemporary high performance data warehouses, it should be clear that such methods represent a sort of "brute



Parallel and Distributed Data Warehouses. Figure 3. Fundamental DW partitioning schemes. (a) Query executed on a single node server that houses a large fact table (T1) and two small dimension tables (T2, T3). (b) Physical partitioning, creating fact table *fragments* (F1, F2). (c) Virtual partitioning on the *clustering attribute* **P** of the replicated fact table. (d) Adaptive virtual partitioning, using fragments and multiple sub-queries.

force" approach to query resolution. Though the response time may indeed represent close to linear speedup as a function of CPU/disk count, the implicit assumption is that full processing of the atomic, transactional data is necessary. This is certainly true for arbitrary or ad-hoc user queries since nothing is known about the possible query format. However, most data warehouses support user interaction through some form of *OLAP* interface. At its core, *OLAP* represents an analytical environment for the intuitive manipulation of the data *cube*. As noted above, there are $O(2^d)$ such views or cuboids. By materializing some (or occasionally all) of these pre-aggregated views, DW/*OLAP* systems can dramatically improve run-time performance on common queries without resorting to massive fact table scans. The trade-off, of course, is that aggregates must be accurately maintained (i.e., updated). In fact, this requirement exerts considerable pressure on the underlying server as data volumes explode in size while, at the same time, update *windows* shrink. It is important to understand, however, that the run-time performance benefit resulting from cube materialization is likely to be significantly larger than the (at best) linear speed-up achieved by a conventional parallel query engine. As such, parallel resources may be more valuable when utilized for the construction and ongoing maintenance of the *OLAP* data structures (e.g., summaries), rather than for brute force query execution.

Because of the extensive computational requirements of *cube* generation in large data warehouses, a number of parallel *cube* construction and querying architectures have in fact been proposed. Note the use of the word "architectures" to indicate comprehensive models that include computation, memory management, and physical storage. In the parallel environment, both array-based (MOLAP) and relational (ROLAP) systems have been explored. With respect to MOLAP parallelism, a distributed memory framework targeting IBM's SP2 was described in [8]. Here, cube construction begins by first equi-partitioning on a single attribute A_1. Using sequential MOLAP techniques, all partial cuboids containing A_1 (exactly $\frac{2^d}{2}$ of the total) are constructed independently on each node. The data set is then re-partitioned on A_2 and the process is repeated. In total, d such rounds are required. The MOLAP mechanism is attractive in the parallel environment as it is well suited to the shared nothing model. Moreover, the parallelized MOLAP cuboids have the potential to provide extremely fast run-time performance (as is generally the case with MOLAP). Having said that, like all MOLAP systems, the sparsity of array-based storage does necessitate complex sparse array compression. In addition, data skew has the potential to generate significant load imbalance during each of the d re-partitioning phases.

Alternatively, parallelism can be exploited in purely relational environments. The cgmCube project, for example, also utilizes state-of-the-art sequential cube construction methods but materializes results in the form of conventional relational tables [2]. Both shared nothing and shared disk platforms are targeted. In this case, the *cube lattice* is physically materialized by first creating a weighted minimum cost spanning tree representation that identifies the most cost effective means by which to materialize all $O(2^d)$ cuboids. Parallelism is supported by decomposing the spanning tree into *p*sub-trees (using a k-min-max graph partitioning algorithm), each of which is computed in its entirety on a single node. The advantage here is that global costing decisions can be employed so as to significantly improve load balancing and to eliminate communication costs (note that the final cuboids can be re-partitioned in any way once the construction algorithm has terminated). Unlike array-based MOLAP systems, ROLAP does not provide implicit indexing, a problem of some significance given that traditional "single dimension" indexes such as the *b-tree* do not work particularly well in multi-dimensional spaces. cgmCube addresses this shortcoming by adding a forest of fully parallelized, multi-dimensional R-tree indexes. Ultimately, cgmCube's algorithmic components are integrated into a fully parallelized server prototype called Sidera that essentially functions as a federation of single node *OLAP* servers [5]. In addition to cube generation and indexing, Sidera adds functionality for caching, selectivity estimation, and the management of *dimensionhierarchies*, as well as fully parallelized sorting and aggregation support. A logical picture of the Sidera server is illustrated in Fig. 3. It should be noted that due to the enormous complexity of parallelized OLAP systems, no direct performance comparison of the MOLAP and ROLAP alternatives has ever been performed.

Finally, one should be aware that commercial parallel DW implementations are also available. Of particular interest in the current context are the dedicated *appliance* style architectures. Here, an integrated, parallel shared nothing hardware/software bundle is tailored specifically to data warehousing workloads and query patterns. Recently, the traditional "high end" DW system provider, Teradata, has been joined by new vendors such as Netezza, DATAllegro, and Greenplum that build upon commodity hardware and open source DBMS software. While each provides proprietary mechanisms for elements such as indexing and partitioning, the DW appliance vendors tend to rely primarily on the aforementioned "brute force" style of parallelism. At present, it does not appear that there is a direct movement of theoretical results from the research community to the industrial sector.

Key Applications

A quick review of the recent database literature indicates that the majority of the current work in high performance databases is actually associated with data warehousing. This should perhaps not be surprising since data warehouses represent some of the largest databases in existence today. In fact, with the emergence of the Internet as a vehicle for both data collection and distribution, one can only expect this trend to continue. So as the *average* size of production DWs pushes past the terabyte limit, parallelism is likely to become an increasingly common theme.

Future Directions

In the short term, one would expect to see continued interest in the exploitation of commodity DBMS systems within loosely federated parallel DBMS clusters. This approach makes a great deal of sense given the considerable maturity of such platforms. Beyond this, OLAP query performance might be further improved by investigating the parallelization of more recent sequential cube methods. The tree-based Dwarf Cube is an obvious target in this regard [14]. We can also expect to see a greater focus on the emerging trend of real time or *near* real time data warehousing, particulary for parallel systems that target large, dynamic data environments.

In the longer term, one possible area for further investigation is the convergence of parallel/distributed data warehouses and the new data centric Grid technologies [6]. To this point in time, the Grid framework has primarily been associated with the concurrent processing of "flat files" rather than highly structured databases. Nevertheless, the Grid model offers interesting opportunities for the distributed, secure, and equitable processing of publicly accessible data repositories.

Experimental Results

Virtually all of the research mentioned in this discussion has relevant experimental evaluations within the associated references. In general, the parallel implementations described above – both partition oriented and OLAP-based – are capable of achieving near linear speedup on contemporary shared nothing parallel systems of 8–32 nodes.

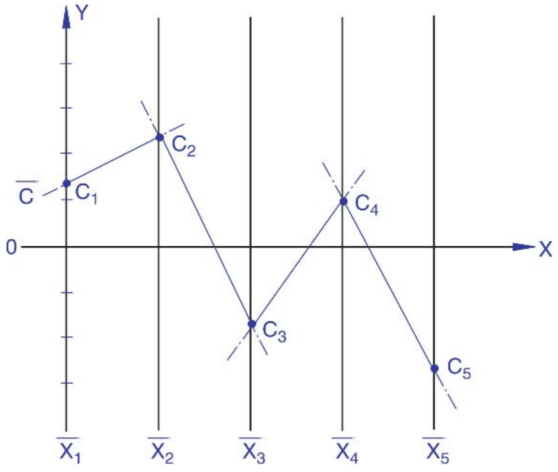
Definition

In the plane with *xy*-Cartesian coordinates N copies of the real line labeled $\bar{X}_1$, $\bar{X}_2$,...,$\bar{X}_N$ are placed equidistant and perpendicular to the *x*-axis. They are the axes of the multidimensional system of *Parallel Coordinates* all having the same positive orientation as the *y*-axis. An N-tuple, N-dimensional point, $C = (c_1, c_2,...,c_N)$ is represented by the polygonal line $\bar{C}$ whose N vertices are at the c_i values on each $\bar{X}_i$-axis as shown in Fig. 1. In this way, a 1–1 correspondence between points in N-dimensional space and polygonal lines with vertices on the parallel axes is established. In principle, a large number of axes can be placed and be seen parallel to each other. The representation of points is deceptively simple and much development with additional ideas is needed to enable the visualization of *multivariate relations* or equivalently multidimensional objects.

A dataset with M items has 2^M subsets anyone of which may be the one wanted. With a good data display the fantastic human pattern-recognition can not only cut great swaths searching through this combinatorial explosion but also extract insights from the visual patterns. These are the core reasons for data visualization. With Parallel Coordinates (abbr. ∥-coords) the search for multivariate relations in high dimensional datasets is transformed into a 2-D pattern recognition problem. A geometric classification algorithm based on ∥-coords is presented and applied to a complex dataset. It has low computational complexity providing the classification rule explicitly and *visually*. The minimal set of variables required to state the rule is found and ordered *optimally* by their predictive value. A visual economic model of a real country is constructed and analyzed to illustrate how multivariate relations can be modeled by means of hypersurfaces. Recent results like viewing *convexity in any dimension* and non-orientability (as in the Möbius strip) provide a prelude of what is on the way.



Parallel Coordinates. Figure 1. The polygonal line $\bar{C}$ represents the N-tuple $C = (c_1, c_2, c_3, c_4, c_5)$.

Historical Background

Legend has it that while constructing a proof, Archimedes was absorbed in a diagram when he was killed by a Roman soldier. “Do not disturb my circles” he pleaded as he was being struck by the sword. Visualization flourished in Geometry and Archimedes’ is the first recorded death in defense of visualization. Visual *interaction* with diagrams is interwoven with testing of conjectures and construction of proofs. The tremendous human *pattern recognition* enables interaction for the extraction of insight from images. This essence of visualization is abstracted and adapted into the general problem-solving process to the extent that, a *mental image* of a problem is formed and at times one says *see* when it is meant *understand*.

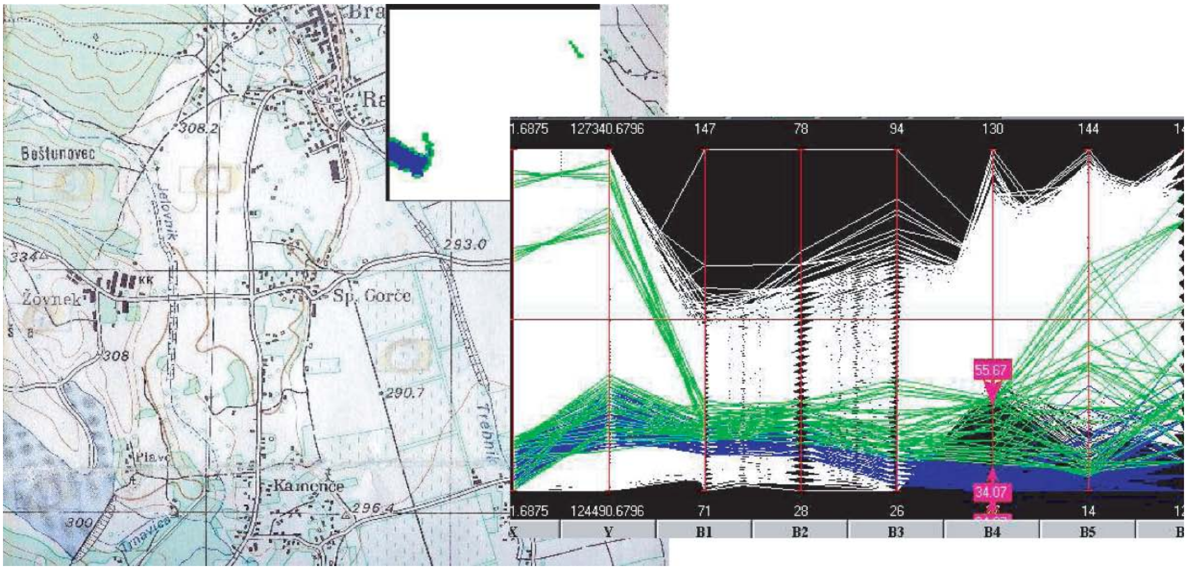
Is there a way to make accurate pictures of multidimensional problems analogous to Descartes coordinate system? What is “sacred” about *orthogonal* axes which use up the plane very fast? After all, in Geometry parallelism rather than orthogonality is the fundamental concept and they are not equivalent for orthogonality requires a prior concept of “angle.” By 1959, while studying Mathematics at the University of Illinois, these thoughts lead to the *multidimensional* coordinate system based on *Parallel Coordinates*. With the encouragement of Professors Cairns and Bourgin (both topologists) basic properties like the *point* ↔ *line* duality were derived. It was not until 1977 when, while teaching a Linear Algebra course, the “challenge” was raised to *show* spaces of dimension higher than 3; parallel coordinates were recalled and their systematic development began. There was early interest and acceptance [6]. The comprehensive report [7] and later [9] layed the foundations of what became the ∥-coords methodology. Collaboration with Dimsdale, (A long-time associate of John von Neuman.) Hurwitz, Boz and Addison ushered to five USA patents (Collision Avoidance Algorithms for Air-Traffic Control, Data Mining and Computer Vision) and applications to Optimization, Process Control [4] and elsewhere. Hurwitz, Adams and later Chomut experimented with multi-query interactive software written in APL for exploratory data analysis (EDA) with ||-coords [5]. There followed [10] on the discovery of structure in data, Gennings et al. [4] on response surfaces based on ||-coords for statistical applications, Wegman using the aforementioned duality promoted the EDA application, Fiorini on Robotics and Hinterberger [14] on comparative multivariate visualization (and earlier on data density analysis). The results of Eickemeyer [2], Hung and Inselberg [5] and Chatterjee were seminal. More recently the work of Ward et al. [15] (Hierachical ||-coords and more), Jones [13] (Optimization), Yang (Association Rules – Databases), Hauser (Categorical Variables and more) and Choi and Heejo Lee (on Intrusion Detection), increased the versatility and sophistication of ||-coords. This list is by no means exhaustive, Shneiderman, Grinstein, Keim, Mihalisin, and others have made significant contributions to data and information visualization.

Foundations

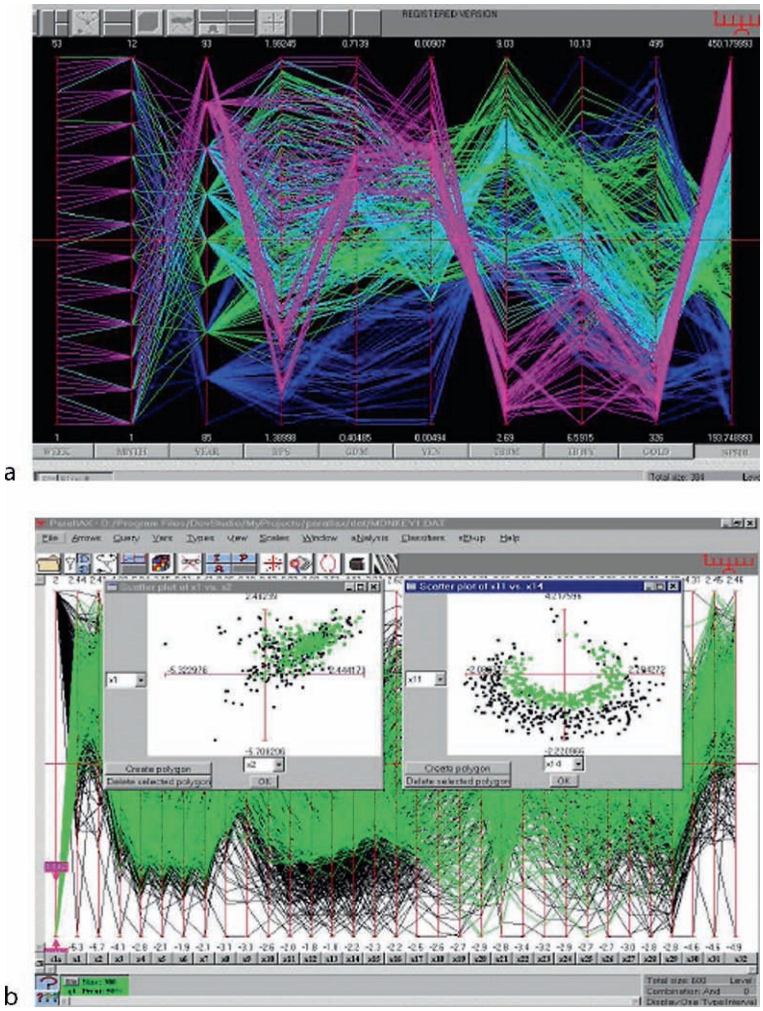
"A picture is worth a thousand words" – But how does one say this with a picture?

The value of data visualization is not seeing "zillions" of objects but rather recognizing *relations* among them. Wonderful successes like Minard's "Napoleon's March to Moscow," Snow's "dot map" and others (see [3]) are *ad hoc* (i.e., one-of-a-kind) and exceptional. Succinct multivariate relations are rarely apparent from *static* displays. With *interactivity* the visual clues in a good data display (*Parallax* MDG's proprietary Data Mining software is used by permission.) can masterfully guide knowledge discovery. Follow up on anything that catches the eyes, gaps, regularities, holes, twists, peaks and valleys, density contrasts like the ones which reveal the water regions in Fig. 2. For the financial data in Fig. 3 (left) *multidimensional contouring* is applied to the axis with *SP500* index values (right) uncovering multivariate relations like high *SP500* low *Gold* and *Interests* correlate with high *Yen* and more. These are examples of two queries and they are others. With Boolean operators compound queries are formed to perform complex tasks. Classification is an important operation in data mining. Powerful geometrical classifiers based on ||-coords [12] have been constructed. An example is shown Fig. 3 (right). The mixing of the two categories is seen on the left plot of the first two parameters. The classifier found the 9 (out of 32) parameters needed to state the rule with 4% error and ordered them according to their predictive value. The two best predictors are plotted on the right showing the separation achieved [12].

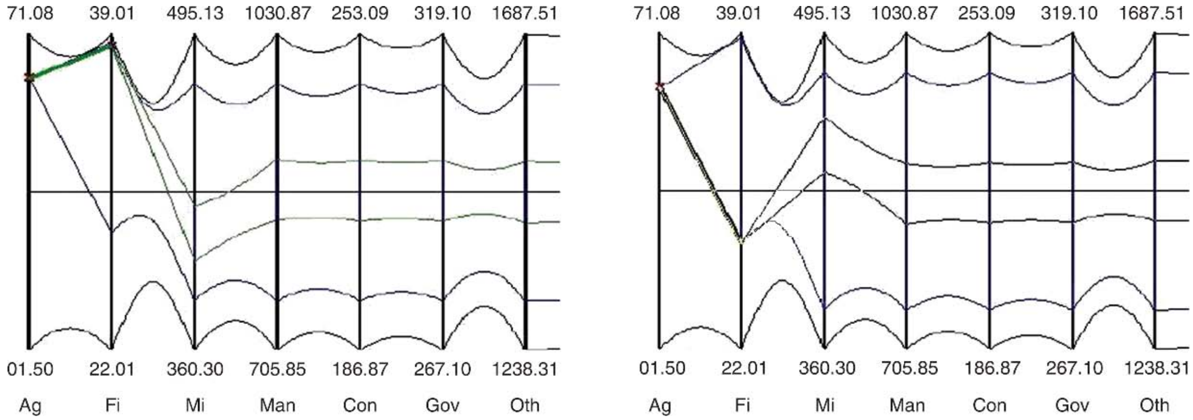
Multivariate relations can be modeled in terms of hypersurfaces – just as a relation between two variables can be represented by a planar region. From a dataset



Parallel Coordinates. Figure 2. Ground emissions measured by satellite on a region of Slovenia (*left*) are displayed on the right. The water and lake's edge are discovered with two queries.

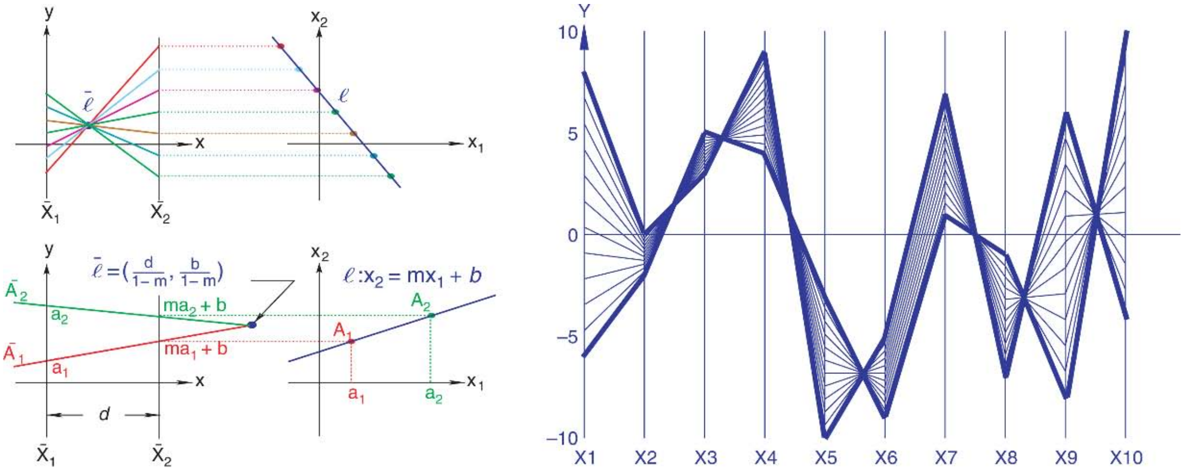


Parallel Coordinates. Figure 3. (a) The *multidimensional-contouring* on financial data reveals multiple interelations. (b) Classification – dataset with 32 parameters and two categories.

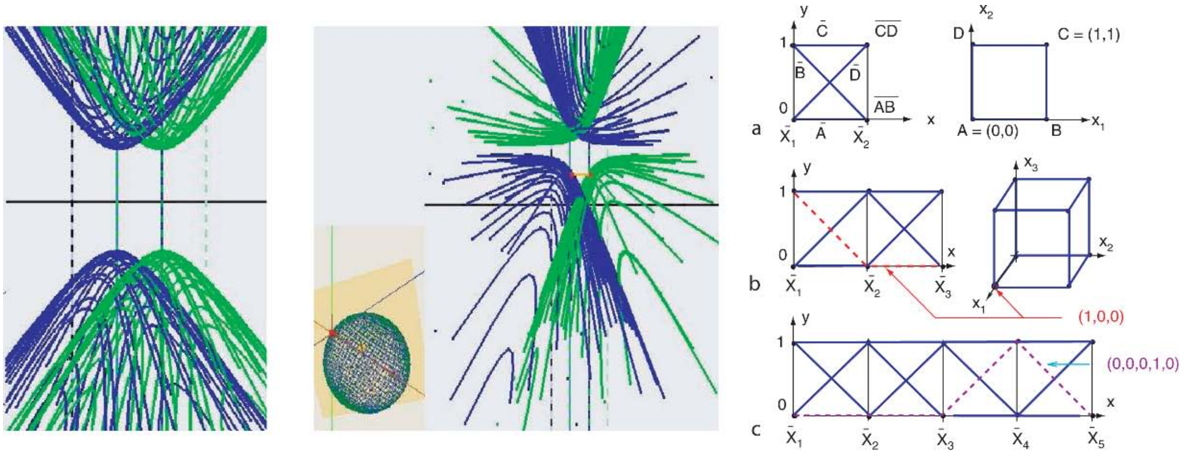


Parallel Coordinates. Figure 4. Hypersurface modeling a country's economy. An interior point represented by a polygonal line depicts a feasible economic policy.

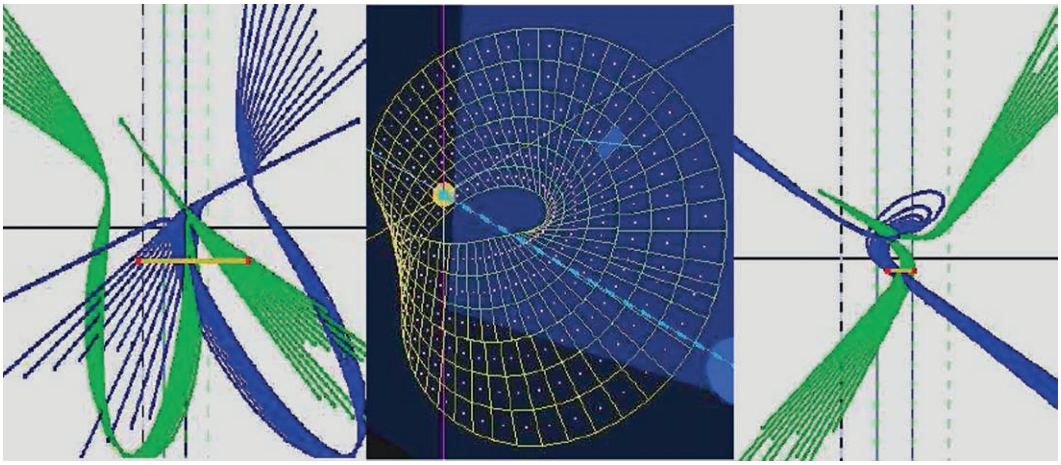
consisting of the outputs of various economic sectors of a real country a visual model of its economy is constructed and shown in Fig. 4 represented by the upper and lower curves. An interior (i.e., a combination of sector outputs) point satisfies all the constraints simultaneously therefore represents a feasible economic policy for that country. Such points can constructed by sequentially choosing variable values within their allowable range. Once a value of the first variable is chosen (in this case the *Agr*icultural output) within its range, the dimensionality of the region is reduced by one. In fact, the upper and lower curves between the second and third axes show the reduced available range of the second variable *Fish*ing and similarly for the remaining variables. Hence the impact of a decision can be seen downstream. In this way it was found that a high value from the available range of *Fish*ing corresponds to very low values of the *Min*ing sector – seen in the right of Fig. 4 and vice versa. This inverse correlation was investigated and found that the two sectors compete for the *same* group of migrating workers. When fishing is doing well, most of them leave the mountains where the mines are located to work on the fishing boats and the reverse. This is an example of ||-coords used for Decision Support and Trade-Off Analysis.



Parallel Coordinates. Figure 5. (*Left*) *point* ↔ *line* duality in 2-D. (*Right*) A N-dimensional line ℓ is represented by $N - 1$ points – the intersections of polygonal representing points of ℓ.



Parallel Coordinates. Figure 6. Convex surfaces represented by $N - 1$ hyperbola-like regions. (left)Sphere in 3-D centered at origin. (*center*) Tranlated sphere *translation* ↔ *rotation* duality (*right*) cube and hypercube in 5-D repeating pattern.



Parallel Coordinates. Figure 7. Möbius strip and its representation for two orientations.

Key Applications

There are numerous others like GIS, Process Control, Trading & Financial Analysis the visualization and analysis of multivariate/multidimensional problems in general.

Future Directions

Though some refer to ‖-coords as a "plot" it is actually *a coordinate system* where the goal, since its inception, is to concentrate N-dimensional relational information into *patterns* the earliest being that N-dimensional lines are represented by $N - 1$ points with *two indices* Fig. 5. Hyperplanes are represented by $N - 1$ points with N indices, and $N - 1$ regions with N indices represent a surface – i.e., the tangent planes enveloping it. Figures 6 and 7 show recent breakthroughs where *convexity in any dimension* and *non-orientability* can be seen. Work is progressing on transforming multivariate relations in datasets into planar patterns completely eliminating display clutter [11].

Parallel Data Placement

Multiprocessor data placement

Definition

Parallel data placement refers to the physical placement of the data in a multiprocessor computer in order to favor parallel data access and yield high-performance. Most of the work on data placement has been done in the context of the shared-nothing architecture. Data placement in a parallel database system exhibits similarities with data fragmentation in distributed databases since fragmentation yields parallelism. However, there is no need to maximize local processing (at each node) since users are not associated with particular nodes and load balancing is much more difficult to achieve in the presence of a large number of nodes.

The main solution for parallel data placement is a variation of horizontal fragmentation, called *partitioning*, which divides database relations into partitions, each stored at a different disk node. There are three basic partitioning strategies: round-robin, hashing, and interval. Furthermore, to improve availability, replication of partitions is needed.

Historical Background

Parallel data placement was proposed in the early 1980s for the first software-oriented parallel database systems. Instead of proposing expensive changes to the disk technology as in database machines with filtering devices, the main idea was to distribute the data onto multiple (smaller) disks and parallelize the I/O bandwidth which could be better consumed by multiple processors.

Data partitioning was first proposed for shared-nothing architectures which are a natural evolution of distributed database architectures. The same basic idea has been also used (with different partitioning strategies) for the Redundant Arrays of Inexpensive Disks (RAID) to build powerful disks out of many smaller ones.

Most of the work in parallel data placement has been done in the context of the relational model with relation partitioning as the main strategy. Extensions have been proposed for object-oriented or semi-structured (XML) data by partitioning collections of objects or elements.

Foundations

Most of the work on data placement has been done in the context of the shared-nothing architecture which is the most general architecture. However, data placement is also important in shared-memory and shared-disk architectures since there can be multiple disks. Thus, the data placement techniques designed for shared-nothing can also be used, sometimes in a simplified form, to other architectures.

Data placement in a parallel database system exhibits similarities with data fragmentation in distributed databases. An obvious similarity is that fragmentation can be used to increase parallelism. In what follows, the terms partitioning and partition are used instead of horizontal fragmentation and horizontal fragment, respectively, to contrast with the alternative approach which clusters all data of each relation at one node. Vertical fragmentation can also be used to increase parallelism and load balancing much as in distributed databases. Another similarity is that queries should be executed as much as possible where the data reside. However, there are two important differences with the distributed database approach. First, there is no need to maximize local processing (at each node) since users are not associated with particular nodes. Second, load balancing is much more difficult to achieve in the presence of a large number of nodes. The main problem is to avoid resource contention, which may result in the entire system thrashing (e.g., one node ends up doing all the work while the others remain idle). Since queries are executed where the data reside, data placement is a critical performance issue.

Data placement must be done to maximize system performance, which can be measured by combining the total amount of work done by the system and the response time of individual queries. Maximizing response time (through intra-query parallelism) may result in increased total work due to communication overhead. For the same reason, inter-query parallelism results in increased total work. On the other hand, clustering all the data necessary to a query minimizes communication and thus the total work done by the system in executing that query. In terms of data placement, the following trade-off exists: maximizing response time or inter-query parallelism leads to partitioning, whereas minimizing the total amount of work leads to clustering. This problem is addressed in distributed databases in a rather static manner. The database administrator is in charge of periodically examining fragment access frequencies, and when necessary, moving and reorganizing fragments.

A solution to data placement is full partitioning, whereby each relation is horizontally fragmented across all the nodes in the system. There are three basic strategies for data partitioning: round-robin, hash, and range partitioning.

1. *Round-robin partitioning* is the simplest strategy, it ensures uniform data distribution. With n partitions, the ith tuple in insertion order is assigned to partition (i mod n). This strategy enables the sequential access to a relation to be done in parallel. However, the direct access to individual tuples, based on a predicate, requires accessing the entire relation.
2. *Hash partitioning* applies a hash function to some attribute which yields the partition number. This strategy allows exact-match queries on the selection attribute to be processed by exactly one node and all other queries to be processed by all the nodes in parallel.
3. *Range partitioning* distributes tuples based on the value intervals (ranges) of some attribute. In addition to supporting exact-match queries as with hashing, it is well-suited for range queries. For instance, a query with a predicate "A between a_1 and a_2 may be processed by the only node(s) containing tuples whose A value is in the range [a_1 and a_2]." However, range partitioning can result in high variation in partition size.

Full partitioning generally yields better performance than clustering relations on a single (possibly very large) disk. Although full partitioning has obvious performance advantages, highly parallel execution may cause a serious performance overhead for complex queries involving joins. Furthermore, full partitioning is not appropriate for small relations that span a few disk blocks. These drawbacks suggest that a compromise between clustering and full partitioning needs to be found.

A solution is to do data placement by variable partitioning, where the degree of partitioning, in other words, the number of nodes over which a relation is partitioned, is a function of the size and access frequency of the relation. This strategy is much more involved than either clustering or full partitioning because changes in data distribution may result in reorganization. For example, a relation initially placed across eight nodes may have its cardinality doubled by subsequent insertions, in which case it should be placed across 16 nodes.

In a highly parallel system with variable partitioning, periodic reorganizations for load balancing are essential and should be frequent unless the workload is fairly static and experiences only a few updates. Such reorganizations should remain transparent to compiled queries that run on the database server. In particular, queries should not be recompiled because of reorganization. Therefore, the compiled queries should remain independent of data location, which may change rapidly. Such independence can be achieved if the run-time system supports associative access to distributed data. This is different from a distributed DBMS, where associative access is achieved at compile time by the query processor using the data directory.

A serious problem in data placement is dealing with skewed data distributions which may lead to non-uniform partitioning and hurt load balancing. Range partitioning is more sensitive to skew than either round-robin or hash partitioning. A solution is to treat non-uniform partitions appropriately, e.g., by further fragmenting large partitions.

Another important function is data replication for high availability. The simple solution is to maintain two copies of the same data, a primary and a backup copy, on two separate nodes. This is the mirrored disks architecture promoted by many computer manufacturers. However, in case of a node failure, the load of the node having the copy may double, thereby hurting load balancing. To avoid this problem, an interesting solution is Teradata's interleaved partitioning which partitions the backup copy on a number of nodes. In failure mode, the load of the primary copy gets balanced among the backup copy nodes. But if two nodes fail, then the relation cannot be accessed thereby hurting availability. Reconstructing the primary copy from its separate backup copies may be costly. In normal mode, maintaining copy consistency may also be costly. A solution to this problem is Gamma's chained partitioning which stores the primary and backup copy on two adjacent nodes. The main idea is that the probability that two adjacent nodes fail is much less than the probability that any two nodes fail. In failure mode, the load of the failed node and the backup nodes are balanced among all remaining nodes by using both primary and backup copy nodes. In addition, maintaining copy consistency is cheaper.

Key Applications

Parallel data placement has been primarily used by parallel database systems on multiprocessor computers. Data partitioning is also used as a basic technique for dealing with very large volumes of data in different environments such as database clusters, data grids, search engines, document management systems, and P2P systems.

Multiprocessor database management

Definition

Parallel database management refers to the management of data in a multiprocessor computer and is done by a parallel database system, i.e., a full-fledge DBMS implemented on a multiprocessor computer. The basic principle employed by parallel DBMS is to partition the data across multiprocessor nodes, in order to increase performance through parallelism and availability through replication. This enables supporting very large databases with very high query or transaction loads.

Parallel database systems can exploit distributed database techniques. In particular, database partitioning is somewhat similar to database fragmentation. Essentially, the solutions for transaction management, i.e., distributed concurrency control, reliability, atomicity, and replication, can be reused. However, the critical issues for parallel database systems are data placement, parallel query processing (including optimization and execution) and load balancing. These issues are much more difficult than in distributed DBMS because the number of nodes may be much higher. Furthermore, the interconnection network of a multiprocessor system provides better opportunities for improving performance than a general-purpose network.

Historical Background

The performance objective of parallel database systems was also that of the database machines in the 1980s. The problem faced by conventional database management on a monoprocessor computer has long been known as "I/O bottleneck," induced by high disk access time. Database machine designers tackled this problem through special-purpose hardware, e.g., by introducing data filtering devices within the disk heads. However, this approach did not succeed because of a poor cost/performance ratio compared to the software solution which can easily benefit from progress in standard hardware technology (processor, RAM, disk). However, the idea of pushing database functions closer to the disk has received renewed interest with the introduction of general-purpose microprocessors in disk controllers, thus leading to intelligent disks.

An important result of database machine research, however, is in the general solution to the I/O bottleneck which can be summarized as increasing the I/O bandwidth through parallelism. If a database is partitioned, e.g., by horizontal fragmentation of the relational tables, across a number *d* of disks, then disk throughput can be increased by accessing the *d* disks in parallel. The same principle has been applied to Redundant Arrays of Inexpensive Disks (RAID) which build a powerful disk with many small disks.

The main memory database solution which maintains the entire database in main memory to avoid disk accesses, is complementary rather than alternative to parallel database systems. In particular, the "memory access bottleneck" induced by high memory access time relative to processor speed can also be tackled using parallel database techniques. In other words, a parallel database system can use main memory database nodes.

Foundations

Parallel database system designers strive to develop software-oriented solutions in order to exploit the various kinds of multiprocessor systems which are now available. This can be achieved by extending distributed database technology, for example, by partitioning the database across multiple disks so that much inter- and intra-query parallelism can be obtained. This can lead to significant improvements in both response time and throughput (number of transactions per time unit).

A parallel database system can be loosely defined as a DBMS implemented on a multiprocessor computer. This definition includes many alternatives ranging from the porting of an existing DBMS, which may require only rewriting the operating system interface routines, to a sophisticated combination of parallel processing and database system functions into a new hardware/software architecture. Thus, there is a trade-off between portability (to several platforms) and efficiency. The sophisticated approach is better able to fully exploit the opportunities offered by a multiprocessor at the expense of portability. Interestingly, this gives different advantages to computer manufacturers and software vendors.

The main objectives of a parallel database system are the following:

High-performance. This can be obtained through several complementary solutions: data-based parallelism, query optimization, and load balancing. Parallelism can increase throughput, using inter-query parallelism, and decrease transaction response times, using intra-query parallelism. Load balancing is the ability of the system to divide a given workload equally among all processors.

Depending on the parallel system architecture, it can be achieved by static physical database design or dynamically at run-time.

High-availability. Because a parallel database system consists of many redundant components, it can well increase data availability and fault-tolerance. Replicating data at several nodes is useful to support failover, a fault-tolerance technique which enables automatic redirection of requests from a failed node to another node which stores a copy of the data, thereby providing nonstop operation.

Extensibility. In a parallel system, accommodating increasing database sizes or increasing performance demands (e.g., throughput) should be easier. Extensibility is the ability of smooth expansion of the system by adding processing and storage power to the system. Ideally, the increase in the configuration of the parallel database system (i.e., more nodes) should speed up existing workloads or scale up to larger databases.

The functions supported by a parallel database system are the same as in a typical DBMS. The differences, though, have to do with implementation of these functions which must now deal with parallelism, data partitioning and replication, and distributed transactions. Depending on the architecture, a processor node can support all (or a subset) of these functions. In the early database machines for instance, some nodes were specialized with hardware to implement some functions, e.g., data filtering.

The way the main hardware elements, i.e., processors, main memory, and disks, are connected (through some interconnection network) has a major impact on the design of a parallel database system. The term processor is used in the general sense of central processing unit (CPU). However, the processor itself can be made of several core processors integrated in a single chip, i.e., a multi-core processor, and perform instruction-level multithread parallelism. But the parallelism being discussed here is much higher-level (query- or operator-level) so processors (e.g., multi-core processors) are simply considered as black-box components accessing other resources (main memory, disk, network). Depending on how main memory or disk is shared, three basic architectures are obtained: shared-memory, shared-disk and shared-nothing.

In the shared-memory architecture, any processor has access to the entire main memory, and thus to all the disks, through the interconnection network. The network is typically very fast (e.g., a high-speed bus or a cross-bar switch) and redundant to avoid any unavailability. All the processors are under the control of a single operating system. Shared-memory makes it easy to build a parallel database system because the operating system deals with load balancing. It is also very efficient since processors can communicate via the main memory. However, the complexity and cost of the interconnection network hurt extensibility which is limited to a few tens of processors. Most parallel database system vendors provide support for shared-memory.

In the shared-disk architecture, any processor has access to any disk unit through the interconnection network but exclusive (non-shared) access to its main memory. Each processor-memory node is under the control of its own copy of the operating system. An important function that is needed is cache coherency which allows different nodes to cache a consistent disk page. This function is hard to support and requires some form of distributed lock management. Shared-disk has better extensibility than shared-memory since the main memory is distributed. However, scalability depends on the efficiency of the cache coherency mechanism. Migrating from a centralized system to shared-disk is relatively straightforward since the data on disk need not be reorganized. Shared-disk is the main architecture used by Oracle for its parallel database system.

The shared-nothing architecture is fully-distributed: each node is made of processor, main memory and disk and communicates with other nodes through the interconnection network.

Similar to shared-disk, each processor-memory-disk node is under the control of its own copy of the operating system. Then, each node can be viewed as a local site (with its own database and software) in a distributed database system. Therefore, most solutions designed for distributed databases such as database fragmentation (called partitioning in parallel databases), distributed transaction management and distributed query processing may be reused. Using a fast interconnection network, it is possible to accommodate large numbers of nodes. The major advantages of shared-nothing over shared-memory or shared-disk are those of distributed systems: relatively low cost, extensibility and availability. However, it is much more complex to manage as physical data portioning is necessary. Shared-nothing has been adopted by the major DBMS vendors (except Oracle) for their high-end parallel database systems.

Various possible combinations of these three basic architectures are possible to obtain different trade-offs between cost, performance, extensibility, availability, etc. Hierarchical architectures typically combine the three architectures using a shared-nothing design where each node can be shared-memory or shared-disk and communicates with other nodes through the interconnection network.

Key Applications

Parallel database systems are used to support very large databases (e.g., tens or hundreds of terabytes). Examples of applications which deal with very large databases are e-commerce, data warehousing, and data mining. Very large databases are typically accessed through high numbers of concurrent transactions (e.g., performing on-line orders on an electronic store) or complex queries (e.g., decision-support queries). The first kind of access is representative of On Line Transaction Processing (OLTP) applications while the second is representative of On Line Analytical Processing (OLAP) applications. Although both OLTP and OLAP can be supported by the same parallel database system (on the same multiprocessor), they are typically separated and supported by different systems to avoid any interference and ease database operation.

Parallel Hash Join, Parallel Merge Join, Parallel Nested Loops Join

Goetz Graefe
Hewlett-Packard Laboratories, Palo Alto, CA, USA

Synonyms

Parallel join algorithms

Definition

These join algorithms are parallel versions of the traditional serial join algorithms. They are designed to exploit multiple processors on a network, within a machine, or even within a single chip.

Key Points

Parallel join algorithms are based on the traditional serial join algorithms, namely (index) nested loops join, merge join, and (hybrid) hash join. The goal of parallel execution is to reduce the input sizes in each processing element, thus reducing the time for query completion even at the expense of increasing overall query execution effort due to data movement. Ideally, parallel join algorithms exhibit linear speed-up and linear scale-up.

Parallel join algorithms are orthogonal to pipelining among join operations in a complex query execution plan. Even a query with a single join can benefit from a parallel join algorithm. The essence of pipelining (and also of "bushy parallelism" in appropriate query execution plans) is to execute different operations with different predicates concurrently, whereas the essence of parallel join algorithms is that a single logical operation exploits multiple processors or processing cores. The conceptual foundations of parallel join algorithms are that database query processing manipulates sets of records, that sets can be divided into disjoint subsets, and that query results based on one record can be computed independently of results based on other records.

Parallel join algorithms apply not only to inner joins but also to semijoins, outer joins, and set operations such as intersection, union, and difference. Thus, they apply to query execution techniques such as index intersection for conjunctive predicates and the star join techniques that are generalizations traditional binary joins.

For a parallel join algorithm, input records are partitioned or replicated such that each result record is produced exactly once. The usual choices are to partition both inputs or to partition one input and to replicate the other. For parallel joins without any equality predicate, the processing elements can be organized in a rectangular grid, one input partitioned over rows of the grid and replicated within each row, and the other join input partitioned over columns of the grid and replicated within each column. These choices mirror schemes in which database records may be stored partitioned or replicated.

Partitioning schemes include range partitioning, hash partitioning, and hybrid schemes such as range partitioning of hash values or hashing (identifiers of) key ranges. For intermediate query results, hash partitioning is simple yet reasonably robust against skewed key distributions.

All of the join algorithms can reduce data transfer efforts using semijoin reduction or its heuristic approximation, bit vector filtering or Bloom filters. Hash join can benefit most obviously due to its separate build and probe phases, with the bit vector filter populated during the build phase and exploited during the probe phase. Merge join can exploit bit vector filtering if the filter can be populated prior to a stop-and-go operation such as sort, and can exploit it with the most gain if the other input also must be processed by an expensive operation such as a sort.

Symmetric partitioning means that both inputs are partitioned. Ideally, the inputs are stored partitioned in such a way that join processing does not incur any cost or delay for partitioning. This is often called "local indexing" or "table partitioning" when it refers to indexes of the same table and "aligned partitioning" when it refers to separate tables. Aligned partitioning often coincides with frequent join operations, foreign key constraints, and complex objects on the conceptual level. The opposites are "global indexing," "index partitioning," and "non-aligned partitioning."

If one of the join inputs is very large, and if the degree of parallelism is only moderate, it might be less expensive to replicate the small input than to partition the large input. An appropriate cost calculation needs to consider record counts, record sizes, communication costs per message or per byte, the available memory allocation for each thread, etc. A first approximation compares the quotient of the two input sizes with the degree of parallelism.

Cost calculation during compile-time query optimization can focus either on the average cost in each of the parallel processing elements or on the maximal cost. The former metric focuses on overall system throughput in multi-user systems, whereas the latter metric focuses on the query elapsed time as perceived by a single user or application.

Partitioned query execution; Partitioning

Definition

Parallel query execution algorithms employ multiple threads that together execute a single query execution plan, with the goal of increased processing bandwidth and decreased response time. Multiple forms of parallelism may be employed in isolation or in combination. Most parallel query execution algorithms are serial algorithms executed in multiple threads, usually with no or only minor adaptations to function correctly or efficiently in the multi-threaded environment.

Historical Background

Set-oriented query languages and the relational algebra have given rise to query optimization and parallel database processing almost from their beginning in the 1970s. They represented a new complexity or liability in database software design as non-procedural languages and physical data independence prevent users from specifying query processing steps and thus require an automatic system component to provide plans for data access and for query execution. At the same time, they created a new opportunity as to prior database systems and their interfaces did permit query rewrite techniques or parallel execution.

The last 30 years have seen many successes and many failures in parallel query execution algorithms. Parallel versions of naïve nested loops join were a failure, because even hardware acceleration cannot compete with well-chosen indexes, whether those are persistent indexes supporting index nested loops join or temporary indexes in form hash tables in hash join. Parallel set operations, including non-indexed selection, join, grouping, and sorting, have been great successes, because they can provide both good speed-up and scale-up. Parallelism is sometimes associated with specific set operations, e.g., hash join instead of all joins, but almost all join algorithms benefit quite similarly if designed and implemented with similar care.

Foundations

In principle, parallel query execution algorithms are traditional sequential algorithms with multiple threads executing different operations or executing the same operation on different data. The relational algebra of sets permits pipelining between operations, partitioning of stored data and of intermediate results, and bushy execution in complex query execution plans. Individual parallel algorithms exploit partitioning but also overcome the issues introduced by partitioning and parallelism.

The value and success of parallel query execution is often expressed as speed-up and scale-up. Speed-up compares execution times of serial and parallel execution for a constant data volume. Linear speed-up is considered ideal; it is achieved if the ratio of execution times is equal to the degree of parallelism. Scale-up compares execution times for a constant ratio of data volume and degree of parallelism. Linear scale-up is considered ideal; it is achieved if the execution times remain constant. There are, however, some effects that permit super-linear speed-up. For example, adding nodes to a parallel database machine increases not only processing bandwidth but also available memory, and might thus turn an external sort into an in-memory sort at a high degree of parallelism.

Pipelining

The pipeline between a producer operation and a consumer operation may pass individual records, value packets, pages, or even runs. Value packets within a sorted stream are defined by equal values in the sort columns. As an example for iterators passing run information, consider a sort operation split into run generation and merging; the pipeline between those two components may pass entire runs at-a-time. In addition to data, the pipeline contents may include control records, e.g., artificially created keys design to advance the merge logic further up in the sequence of operations.

More importantly for multi-threaded query execution, the pipeline between threads may be demand-driven or data-driven. Within each thread, iterators commonly implement demand-driven dataflow, which lend themselves well to joins and other binary operations but not to sharing intermediate results or common sub-expressions, which occur much less frequently than joins in query execution plans. Between threads, data-driven dataflow is commonly regarded superior.

On the other hand, if flow control is implemented, the slower one among producer and consumer dictates the overall pipeline flow, and it might not truly be useful to attempt distinguishing demand- and data-driven dataflow. The important aspect is that some "slack" is created that permits the producer to get ahead of the consumer to some reasonable amount without requiring an excessive amount of buffer space. In general, the quotient of buffer space and bandwidth is equal to the interval that can be smoothed out, i.e., the amount of time the producer may get ahead of the consumer or the consumer may fall behind the producer.

Partitioning

Since pipelining with flow control often leads to consumers throttling producers or the other way around, and since pipelining alone permits only a fairly limited degree of parallelism, it is usually combined with partitioning. Partitioning means that the input into a relational algebra operation is divided into disjoint subsets, which are processed by separate threads or processors.

Many partitioning methods are in common use. The basic partitioning methods are random, round-robin, range, and hash. Both random and round-robin partitioning permit perfect load balancing but do not exploit key values and their importance in relational algebra operations such as joins and duplicate elimination. When random partitioning or round-robin partitioning is applied to stored data, neither queries nor updates can be directed to a single location and instead must be processed in all partitions. Range partitioning assigns key ranges (of the partitioning column) to storage or processing sites. For perfect load balancing, accurate quantile information is required. For intermediate results, quantiles must be estimated during query optimization or during an earlier query execution phase. Hash partitioning applies a hash function to determine storage or processing sites. A suitable hash function can achieve very good load balancing, which is why hash partitioning is sometimes associated with linear speed-up and scale-up. On the other hand, even hash partitioning fails if the data distribution suffers from duplicate skew, i.e., the data contain many duplicate key values.

There are many ways to combine these basic partitioning methods. For example, it may be desirable that small range queries are processed at a one or two sites with little overhead and that large range queries are processed by many or all sites with maximum throughput. To achieve both these effects, many small key ranges can be hashed to storage sites. In other cases, one column may be used to hash data items to sites and another column to hash data items to storage locations within each site. This is just one of many multi-dimensional partitioning methods. Note that partitioning among sites, partitioning within sites, and local organization are orthogonal. The possibilities are endless, and almost each vendor claims to have found a new and superior "secret sauce." The most sophisticated systems even offer partitioning on computed columns or expressions.

Partitioning of stored data usually determines where initial query operations execute, including selection and projection as well as preliminary stages of sorting, duplicate elimination, and "group by" operations. Partitioning of stored data may also interact with high availability consideration, e.g., each data item is hashed to two sites using two hash functions, carefully designed to ensure that no data item is hashed to the same site by both hash functions.

For binary operations, "co-location" of the two inputs permits local execution. These binary operations include inner and outer joins, semijoins including "exists" nested queries, and set operations such as intersection, union, and difference. Set operations after scans of non-clustered indexes are common in query execution plans for complex queries, for ad-hoc queries, and for star joins in relational data warehouses using a star schema. If all indexes for a table or view are partitioned in the same way, both set operations and fetch operations can remain local. On the other hand, there are many situations in which it is advantageous to partition each index on its search columns.

If co-location and local execution are not possible, join input data need to be re-partitioned. In most cases, both inputs are partitioned on the columns participating in the join operation's equality predicate. If one input is much smaller than the other, it may be more efficient to broadcast the small input and not move the large input. In some case, in particular non-equality joins, a combination can be applied. In this technique, the processing sites can be thought of as a rectangular matrix, with one input partitioned among rows and broadcast within rows, and the other input partitioned among columns and broadcast within columns. The essence of all partitioning strategies for binary operations such as joins is to ensure that each pair of input rows that may contribute to the join result "meets" at precisely one processing site.

Bushy Execution

In addition to pipelining and partitioning, a third form of parallel query execution is enabled by bushy query execution plans, as opposed to linear query execution plans. In a linear query execution plan, one input of each binary operation always is a stored table. In a bushy query execution plan, both inputs may be intermediate query results. For example, two sort operations may provide the inputs for a merge join. During the sort operations' input phases, the two sort operations can run in parallel. In more complex query execution plans, numerous operations and plan branches may be active concurrently and independently.

Even the simple example with two sort operations and a merge join suffices to demonstrate the substantial difficulties, however. One problem is finding an appropriate degree of parallelism for each operation or branch. A harder problem is assigning appropriate resources such as memory, disk space and bandwidth, etc. The hardest problem is to ensure that concurrent branches produce their results at the right time. In the example, resources may be wasted if one sort operation finishes before the other, because the former will likely hold on to resources such as memory while waiting for the merge join to need its input and thus for the other sort operation to finish.

Specifics of Parallel Algorithms

In order to keep parallel query execution engines modular, traditional serial query execution algorithms are combined with mechanisms for parallel execution, specifically pipelining and partitioning. The interface between traditional serial query execution operations usually takes the form of iterator. Iterator methods support forward-only scans of intermediate results, rewinding, binding parameters as needed for nested iteration and general predicate evaluation, etc. Iterator instances may recursively invoke their input iterators to implement those methods, and by doing so can execute a very complex query execution plan within a single thread.

Mechanisms for parallel query execution can be encapsulated in a special iterator. This design has been used in a number of research prototypes and commercial database systems. Commonly called the "exchange" operation but also known as "river" or "asynchronous table queue," this iterator encapsulates data transfer and flow control, often provides initialization and teardown of threads and communication paths, and batches records in order to reduce inter-process communication. If parallel execution of nested iteration is desired, both data transfer and flow control must work both from producer to consumer for intermediate query results and from consumer to producer for bindings of correlation columns from outer to inner inputs of nested iteration operations.

As the exchange operation or its equivalent encapsulate the basic mechanisms for parallel query execution, the following only indicates how specific parallel algorithms differ from their serial equivalents.

For parallel sorting, after the input data is partitioned as appropriate, the individual threads of a parallel sort operation usually can work entirely independently. If, however, the query optimizer relies on the sort operation not only for the correct sequence of records but also to avoid the Halloween problem by means of phase separation, the individual threads must coordinate their transition from consuming unsorted input records to producing sorted output records. If one of them produces output too early, it might affect the input set of another thread still consuming input and thus create the Halloween problem.

A similar coordination point exists in parallel hash join. A serial hash join might choose between Grace join, which devotes its first phase entirely to partitioning, and hybrid hash join, which performs some join logic even during its first phase. Multiple threads in a parallel hash join might choose differently, e.g., due to different data volumes. Scheduling other operations within the query execution plan might require, however, that all hash join threads follow the same choice. As for parallel sorting with built-in Halloween protection, such a parallel hash join requires a very brief communication and decision phase.

For parallel hash aggregation and duplicate elimination, a common technique is to run the operation twice, once before and once after data partitioning, in cases in which the input data are not yet partitioned on the grouping columns. The goal is to reduce the number of data records that need to be shipped between threads, processes, and processors. Assuming uniform random distribution of input rows prior to re-partitioning, this goal can be achieved if the average group size, i.e., the ratio of row counts in the input and in the output, exceeds the degree of parallelism. A common name for this technique is "local-global aggregation." The initial, local aggregation may be opportunistic, i.e., it performs as much aggregation as can readily be achieved with the available memory, or it may be complete, i.e., it will spill overflow partitions to disk if required. If network transfer is faster than local disk I/O, overflow partitions may be send to their final destination rather than to a local disk.

Sort-based aggregation and duplicate elimination can benefit from the same ideas. The opportunistic variant performs merely run generation and early duplicate elimination prior to data transfer. The full variant performs complete local sort operations and all aggregation and duplicate elimination prior to the data transfer.

Order-preserving and merging re-partitioning operations may experience a deadlock, assuming flow control or bounded buffers in the data exchange operation. The essence of this deadlock is that producers need to send data in the order produced, whereas consumers need to consume data in the appropriate sort order. For example, if producer 1 has data only for consumer 1, and producer 2 has data only for consumer 2, then consumer 1 waits for data from producer 2 in order to advance its merge logic, yet producer 2 waits for consumer 2 to release flow control, etc. There are several possible solutions for this problem. A typical deadlock avoidance strategy is to let producers send dummy records to all consumers, such that the consumers can advance their merge logic. A typical deadlock resolution strategy is to spill data to disk, effectively going beyond bounded buffers and relaxing flow control.

Parallel nested loops join, index nested loops join, and general nested iteration add further complexity to the data exchange operation. One issue is the number of threads: if the nested operation should run in 4 threads (due to four on-disk partitions, for example) yet the outer operation runs in three threads, will in inner operation actually run in 12 threads? If not, communication and synchronization need careful design, including avoidance or resolution of deadlocks. Moreover, invoking the inner operation for batches of outer correlation values rather than for individual outer rows may reduce communication costs as well as create optimization opportunities in the inner query execution plan.

Another technique to reduce communication costs in all matching operations is bit vector filtering. Sometimes thought to apply only to hash join, it also applies to merge join and nested iteration. If the two inputs for the matching operation are scanned or computed in two separate phases, the first such phase can populate a bit vector filter that the second phase can exploit to eliminate some items without further predicate evaluation and in particular without communication in parallel query execution. The bit vector filter might permit hash collisions or hash collisions might be prevented by some means, typically involving dynamic growth of the bit vector filter. In addition to the actual bit vector filter, it can prove useful to retain information about the minimal and maximal values.

In addition to expensive join and grouping operations, parallel execution and bit vector filtering can benefit set operations such as intersecting lists of row identifiers when exploiting multiple indexes on the same table for a query with a conjunctive predicate. Other index operations include union, difference, and join. Index join sometimes refers to joining indexes of two tables prior to fetching complete rows from either table and sometimes refers to joining indexes from a single table in order to obtain all columns required in a query and to avoid fetching rows one-by-one. Both kinds of index joins can benefit from parallel execution and bit vector filtering.

Some operations, however, cannot exploit parallel execution. The most notable example is a “top” operation, e.g., a query to find the three most productive sales people in the organization. While the “top” operation permits local-global computation with potentially tremendous reduction in serial computation and in communication, the final computation cannot benefit from multiple concurrent threads. An exception to this exception are “top” operations that apply to groups of records, e.g., a query looking for the three most productive sales people in each region.

Some algorithm implementations also exploit local parallelism, independent of parallel execution of the overall query execution plan. Asynchronous I/O (sequential read-ahead, single-page prefetch, and write-behind) are forms of local concurrent execution. Expensive operations, e.g., sort operations, may benefit from multiple threads, e.g., fitting records into a sort operation’s workspace including initialization of a pointer array, sorting and rearranging the pointer array to represent the desired sort order, and forming on-disk runs from pointer arrays already sorted.

Parallel Execution beyond Queries

In addition to query execution, parallelism is also needed for large update operations and, perhaps most importantly, in utilities that scan or modify entire indexes, tables, or databases.

Parallel update operations are required in shared-nothing databases, simply because updates like filters are processed locally at each data site. Otherwise, if all update operations are relatively small, parallel update operations are not required for performance. However, update operations can be large, e.g., in bulk insertion and bulk deletion, also known as load, import, or roll-in and as roll-out.

A parallel update algorithm can follow the partitioning of stored data, it can assign disjoint key ranges within B-tree indexes to separate update threads, or it can assign threads to individual indexes. The latter approach is a special form of index-by-index updates (as opposed to row-by-row updates) as it permits the changes for each index to be sorted like the index for fast modification with read-ahead, etc.

Not only the actual database modifications but also other activities associated with updates can be parallel, including verification of integrity constraints, update propagation to materialized and indexed views, etc. Of course, verification of integrity constraints can be parallel also during definition of new constraints. Definition of new materialized and indexed views creates an opportunity for parallelism both while computing the query defining the view and while loading the query result into the new data structures. Refreshing a view by re-computation is very similar.

In practice, however, the most important parallel operation is probably index creation. High performance index creation is particularly important if online index creation is not supported, i.e., an entire table is read-locked while the index utility scans, sorts, and inserts data. Fortunately, parallel versions of all three of these steps are readily available using standard mechanisms for parallel query execution.

Key Applications

Parallel algorithms for database query execution are used for two reasons. First, if there are more processors than active users, the only means by which these processors can do useful work on behalf of the users are parallel algorithms. Pure pipelining often leads to poor load balancing; thus, partitioning stored data and intermediate results, in particular using hash functions, often permits higher and more reliable speed-up. In the future, many-core processors may well increase the importance of parallel algorithms in database query execution.

Second, the hardware might require parallel algorithm because the database and its data are partitioned across multiple nodes each with its own memory, operating system, etc. If communication is more expensive than immediate data reduction (using selection, projection, and local aggregation), parallel algorithm are required. The future of improvements in processing bandwidth and in communication bandwidth will probably continue to be unbalanced; the current trend towards networked storage over direct-attached storage may reverse, in particular for database systems that support a single-system image over many direct-attached storage devices including management of that storage.

Future Directions

While processor speed kept increasing, the value of parallel query execution has been doubted at times. With hardware development now focusing on many-core processors rather than ever higher clock speeds, there should be no doubt that parallel query execution is required for relational data warehousing and business intelligence. It may be worth noting, however, that parallel utilities such as index creation are more urgently needed by customers with growing data volumes than parallel query execution. Many parallel utilities are implemented using mechanisms shared with parallel query execution, however, such that parallel query technology is needed in any case.

With the emergence of XML and semi-structured data in database type systems, there probably will be growing interest in parallel algorithms for relational algebra extended for unstructured data and graph manipulation. In addition, more data cleaning, data mining, and scientific applications are integrated with databases, and they, too, require parallel execution very similar to parallel query execution. Perhaps the future of parallel query execution is limited by advances in extensible query optimization, such that both together enable deep integration of those parallel algorithm into the query processing framework.

Optimization of parallel query plans

Definition

Parallel query optimization is the process of finding a plan for database queries that employs parallel hardware effectively. The details of this process depend on the types of parallelism supported by the underlying hardware, but the most common method is partitioning of the data across multiple processors.

Historical Background

Most parallel database systems today can trace part of their heritage back to the Gamma project at the University of Wisconsin, Madison in the 1980s – with the exception of the Teradata system, which predates Gamma by several years. Also influential were the GRACE database machine, developed at the University of Tokyo, and work at the Norwegian Institute of Technology, University of Trondheim. These projects did not publish a description of their parallel query optimization algorithms, however. Later projects, like XPRS (University of California, Berkeley) and IBM DB2 Parallel Edition describe that process in more detail.

A simple way of generating parallel query plans is to take the optimal plan produced by a conventional query optimizer and to parallelize it where possible. This may not result in the optimal parallel plan. For example, the chosen join order may require repartitioning of the data, while a slightly different join order might have avoided this costly step. Therefore, most of today's systems integrate parallelism into the optimization phase itself. Different parallel and serial plans are compared on the basis of their estimated cost, and the best plan is selected.

Most optimizer designers of parallel systems chose a very natural extension of non-parallel optimizers. This approach is described in the next section.

Foundations

Most of the parallel database systems use an operator-based model for parallel queries: Traditional relational operators such as join and groupby are employed in a parallel framework, allowing individual CPUs of a parallel system to work on a partition of the data. The task of the query optimizer is to find the right partitioning and degree of parallelism for each step.

With such an operator-based approach, optimizing parallel queries is similar to conventional query optimization, except that a new dimension is added – partitioning.

Extending a non-parallel optimizer to handle parallelism consists of four basic steps: First, the space of semantically correct parallel plans is defined. Second, the optimizer's search algorithm needs to be extended to enumerate a good part of the search space that was defined in the first step. Third, the cost model of the optimizer needs to be able to cost parallel plans such that the best one can be selected. Finally, all these extensions will likely increase the complexity of the optimization algorithm significantly. Heuristics are required to avoid an explosion of the cost of the optimization itself.

The following explores each of these four steps briefly.

Extending Query Plans to Execute in Parallel on Partitioned Data

The optimizer is responsible for generating semantically valid parallel plans. It therefore needs to have a good understanding of and model for parallel operator semantics. This is typically done by assigning a "partitioning" property to each relational operator and by using these properties to constrain the search space to semantically correct query plans. The partitioning property specifies a partitioning scheme (usually hash-based), the partitioning key, and the number of partitions.

In the following, the basic idea behind partitioning properties of a few key relational operators will be discussed.

When a file scan operator is executed in parallel, each parallel instance simply reads a partition of the data. On a shared-nothing system, the partitioning property describes how the data is physically partitioned. On a shared-everything architecture, another way is to let parallel scan operators compete for each block as it is read from disk, achieving a natural load balancing between the parallel operators, with a partitioning property that specifies only the number of partitions, not a partitioning key.

For joins, there are basically two different parallelization strategies. The first is to let each parallel instance join one partition of the first table R with a matching (co-located) partition of the second table S. Both R and S must have a matching partitioning property on the equi-join columns for this case. This is so that for a given row from a partition of R, all its matching rows from S are found in the corresponding partition of S.

The second parallel join algorithm is to join each partition of R with every partition of S or vice-versa. Such joins combine a partitioned table R with a replicated table S or vice versa. This type of parallel join is applicable in nearly all cases, except for full outer joins.

Terms like "co-located nested loop join," "broadcast hash join" or "repartitioned merge join" are used to distinguish these different cases [13].

Semijoins and outer joins can be parallelized as well, with the exception that only the operand requiring special handling can be broadcast. Parallelizing the UNION operator puts no special constraints on the partitioning properties, except what is needed for duplicate elimination.

To increase its choices, the execution engine typically is capable to produce partitioning artificially. This is in most systems implemented by a separate operator, called Exchange [11], Table Queue (DB2), or River [2]. Generally, the exchange operator is the only one that sends data through messages, all other operators process local data and pass their results on in local memory or in a local disk file.

Extending the Search Algorithm to Include Parallel Plans

Almost all query optimizers operate under a principle borrowed from dynamic programming that combines optimal sub-solutions to a larger optimal solution. Sub-solutions are optimal with respect to relevant properties, as described first in [Selinger]. Probably the key aspect of query optimization for parallel queries is that this system of properties can be very elegantly extended to include partitioning properties. Initially only consisting of ordering, with a sort operator to create artificially sorted results, partitioning properties and the exchange operator are now included to create artificially partitioned results.

Extending the properties of query execution plans with partitioning solves the key part of parallel query optimization, namely the problem of enumerating the parallel plans that are possible for a query. The driver for this enumeration are the different ways the other operators can be executed in parallel.

The exchange operator acts as the "enforcer" [11] or "glue" [14] for partitioning.

This extension applies to classical Selinger-style optimizers (e.g., DB2) as well as to rule-based optimizers derived from the Exodus, Volcano and Cascades approaches (e.g., Microsoft SQL Server).

Costing Parallel Query Plans

Executing queries in parallel usually increases the amount of resources consumed, due to communication and synchronization overhead. Parallel execution is therefore not well-suited to minimize the resource cost of queries. Most parallel query optimizers try to minimize the time a query would take if executed in single-user mode on the system. When costing a parallel operator, they therefore compute the cost for a single partition only (assuming that the data is equally distributed over the partitions without skew) and add the cost for needed synchronization. With the goal of keeping the overall query response time low, it is usually not beneficial to reduce the degree of parallelism, therefore the optimizers consider only plans that use all the processing nodes of the system and compare them with a serial plan. The explosion of choices comes with different methods of partitioning and/or replicating data to allow for different types of join execution plans.

Heuristics to Reduce the Number of Parallel Plans Considered

One heuristic, the use of "interesting orders" [Selinger], can be used for partitioning as well. Optimizers with top-down exploration achieve this filtering effect naturally. Without some heuristics, the number of possible partitioning schemes could easily explode. For example, consider a co-located parallel merge join for the query "select * from R join S on R.a = S.a and R.b = S.b and R.c = S.c." Any ordering on a subset of columns (a,b,c), combined with a partitioning on some or all of the columns in this subset would constitute a valid set of properties for the join operator – assuming it is present for both tables R and S. Most implementations of optimizers will heuristically try only a small number of possibilities in this case.

Key Applications

Parallel computers allow database applications to scale, and optimization of parallel queries allows users to write applications without expending effort on parallelizing database queries. Parallel databases are the main application today where automatic parallelization of generic requests is performed successfully.

Future Directions

Challenges for future systems include adaptive systems that learn from poorly parallelized queries and that avoid data skew automatically, as well as automatic advisors and optimizers of physical designs for parallel databases.

Multiprocessor query processing

Definition

Parallel query processing designates the transformation of high-level queries into execution plans that can be efficiently executed in parallel, on a multiprocessor computer. This is achieved by exploiting the way data is placed in parallel and the various execution techniques offered by the parallel database system. As in query processing, the transformation from the query into the execution plan to be executed must be both correct and yield efficient execution. Correctness is obtained by using well-defined mappings in some algebra, e.g., relational algebra, which provides a good abstraction of the execution system. Efficient execution is crucial for high-performance, e.g., good query response time or high query throughput. It is obtained by exploiting efficient parallel execution techniques and query optimization which selects the most efficient parallel execution plan among all equivalent plans.

The main forms of parallelism which can be inferred by high-level queries are inter-query parallelism (several queries executed in parallel) and intra-query parallelism (each query executed in parallel), and within a query, inter- and intra-operator parallelism. These various forms of parallelism are obtained based on how data is placed in the parallel system, i.e., physically on disk or memory. Hence, the term data-based parallelism is communally used. These forms of parallelism can be combined and are exploited by parallel execution techniques.

Historical Background

Parallel query processing had been initiated in the context of database machines in the late 1970's. At that time, parallel processing techniques were already used successfully in scientific computing to improve the response time of numerical applications. However, these techniques are very complex as they typically involve parallelizing compilation which must infer parallelism from programs written in a procedural language, e.g., Fortran or C. Since these programs may be sequential, inferring parallelism to obtain good performance is hard.

With a high-level language like SQL, parallelism is relatively easier to infer. SQL enables programmers to specify what data to access (with predicates) without any detail on how. Thus, this provides the parallel database system much leverage to decide how to access data.

In the context of database machines, parallel query processing was very simple and concentrated on select-project-join queries using brute-force algorithms and special-purpose hardware. As parallel database systems evolved to exploit general-purpose multiprocessors and software-oriented solutions, parallel query processing has become much more complex. Also, the emergence of new applications such as OLAP and data mining translated into new features in SQL which have made parallel query processing more complex.

Compared to distributed query processing (which can also exploit parallelism by executing a query using multiple sites), the main difference is that the parallel system can have many more nodes and a very fast interconnection network. Thus, the execution techniques and execution plans are fairly different.

Foundations

Parallel query processing is the major solution to high-performance management of very large databases. The basic principle is to partition the database across multiple disks or memory nodes so that much inter- and intra-query parallelism can be gained. This can lead to significant improvements in both response time (the time the query takes to be executed and return results) and throughput (number of queries or transactions per time unit). However, decreasing the response time of a complex query through large-scale parallelism may well increase its total time (by additional communication) and hurt throughput as a side-effect. Therefore, it is crucial to optimize and parallelize queries in order to minimize the overhead of parallelism, e.g., by constraining the degree of parallelism for the query.

The performance of a parallel database system should ideally demonstrate two advantages: linear speedup and linear scaleup. *Linear speedup* refers to a linear increase in performance for a constant database size and linear increase in the number of nodes (i.e., processing and storage power). Thus, the addition of computing power should yield proportional increase in performance. *Linear scaleup* refers to a sustained performance for a linear increase in both database size and workload and number of nodes. Furthermore, extending the system should require minimal reorganization of the existing database. Thus, an increase of computing power proportional to the increase in database size and load should yield the same performance. These advantages are ideal since, in practice, increasing the configuration tends to increase the overhead of parallelism (e.g., more communications between nodes, more interference when accessing shared resources, etc.).

Partitioned data placement is the basis for the parallel execution of database queries. Given a parallel system with n nodes (each node may have one or more processors accessing a main memory and disks), each database table T is typically partitioned onto a number of nodes (less or equal to n) so that each node stores a subset of the tuples of T. This corresponds to horizontal fragmentation in distributed databases and similar techniques can be used. However, because there can be many nodes, more scalable techniques are also often used such as round robin or hashing on the placement attribute(s). Furthermore, to improve availability and performance, some partitions (typically those which are accessed more than others) can be replicated.

Given a partitioned database, parallel query execution can exploit two forms of parallelism: inter- and intra-query. *Inter-query parallelism* enables the parallel execution of multiple queries, each at a different node, in order to increase query throughput. This form of parallelism, reminiscent of that used in transaction processing systems, is quite simple since queries need not be parallelized. Thus, incoming queries can simply be dispatched (by a load balancer of the parallel database system) to the nodes which store the data corresponding to the queries. However, this can only work if all the data accessed by a query are stored at the node, or accessible at the node. For instance, in the case of a shared-nothing parallel database system, if a query Q involves data that is partitioned at two different nodes, then either node cannot entirely execute the query. But in the case of a shared disk parallel database system, since all the disks can be accessed from each node, the same query Q could be executed by either node.

A query can be decomposed in a tree of relational operators, where each operator takes data as input (either base data or temporary data) and produces temporary data, with the root operator producing the final result. This decomposition allows for *intra-query parallelism*) which has two forms: inter-operator and intra-operator parallelism. *Inter-operator* parallelism is obtained by executing in parallel several operators of the query on several nodes while with intra-operator parallelism, the same operator is executed by many nodes, each one working on a different partition of the data. For inter-query parallelism, much attention has been devoted to pipelined (or consumer-producer) parallelism which enables consumer operators to start execution as soon they get input data from producer operators. Pipelined executions do not require temporary relations to be materialized, i.e., a tree node corresponding to an operator executed in pipeline is not stored. These two forms of parallelism complement each other well since inter-operator parallelism gets beneficial as the query gets complex (with many operators) while intra-operator parallelism gets beneficial for heavy operators (which access large parts of the data).

To exploit inter- and intra-query parallelism, using database partitioning, parallel algorithms for the execution of relational operators are necessary. Such algorithms must yield a good trade-off between parallelism and communication cost since increasing parallelism involves more communication among nodes. Parallel algorithms for unary operators (e.g., select) are relatively simple as they typically exploit data placement or secondary indices to restrict access to base data. Parallel algorithms for binary operators such as join are much more involved since join can incur much communication. The main algorithms exploit the placement of one of the two relation to reduce communication or artificially create a good data placement using hashing. When there is sufficient main memory to hold one of the two relations (which is a very practical case), the execution of hash-based join can be pipelined across multiple operator nodes, thus increasing performance. Since the intermediate results of the operators can be skewed, parallel algorithms must also deal with load unbalancing, e.g., by redistributing a heavy work at one node to multiple nodes using hashing.

Parallel query optimization is the process of selecting the best parallel execution plan for a query. Compared to distributed query optimization, it focuses on taking advantage of both intra-operator parallelism and inter-operator parallelism. As any query optimizer, a parallel query optimizer can be seen as three components: a search space, a cost model, and a search strategy. Parallel execution plans are abstracted by means of operator trees, which define the order in which the operators are executed. Operator trees are enriched with annotations, which indicate additional execution aspects, such as the algorithm of each operator. An important aspect to be reflected by annotations is that operators are executed in pipeline. The cost model provides the cost functions for parallel operator algorithms.

Key Applications

Parallel query processing has been developed in the context of parallel database systems, with a focus on OLAP applications, where good response time is crucial. Most of the work has been done in the context of the relational model. In order to support new OLAP applications which may access all kinds of data, including unstructured and semi-structured (XML) data, major extensions to parallel query processing are necessary. In particular, techniques from parallel database and information retrieval need to be combined.

Parameterized Complexity of Queries

Christoph Koch
Cornell University, Ithaca, NY, USA

Definition

Parameterized complexity theory is the study of the interaction between the fixing of parameters of input problems and their computational complexity. A central parameterized complexity concept is that of a fixed-parameter tractable (FPT) problem, which captures a strong notion of well-behavedness of a problem under the assumption that parameter values do not grow with input sizes. There is also a solid theory of fixed-parameter intractability, which gives strong evidence that for certain parameterizations of problems, no FPT algorithms can be found.

Historical Background

Fixed-parameter complexity theory is strongly associated with R. Downey and M. Fellows, who did much seminal work in the area (cf. [3,5]). The first fixed-parameter complexity result in the context of database query evaluation was the linear-time query processing algorithm for acyclic conjunctive queries by Yannakakis in 1981 [12], which preceded the development of parameterized complexity theory (cf. also [13]).

Foundations

Fixed-Parameter Tractability

A *parameterized (decision) problem* is a set of pairs (x,k), where x is called the input and k the parameter (an integer). As a convention, $n = ||x||$ will be used to denote the size of the input. A parameterized problem is called strongly uniformly *fixed-parameter tractable* (subsequently, just fixed-parameter tractable, or FPT), if there is a computable integer function f, a constant c, and an algorithm that, given a parameterized problem instance (x, k), decides x in time $O(f(k) \cdot n^c)$.

It is important to note the difference between an algorithm that runs in time $O(n^k)$ and an FPT algorithm. If $k = 10$ and $c = 1$, an algorithm that runs in time $O(f(10) \cdot n)$ is linear (with possibly a large constant), while an $O(n^{10})$ algorithm will not even scale to very moderately sized problem instances.

Consider the *data complexity* of queries [11], i.e., the complexity of evaluating a query on a database if only the database is considered part of the input, while the query is fixed and part of the problem specification. It is well known that quite naive query evaluation techniques can evaluate an arbitrary relational algebra query in time $O(n^k)$, where k is the size of the query (e.g., the number of algebra operators involved). By fixing k, the query evaluation time becomes polynomial, but the $O(n^k)$ time query evaluation technique does not yield a fixed-parameter tractability result. Indeed, such an FPT result is considered unlikely to exist.

For another example, consider the Set Cover problem, a well known combinatorial problem that appears in database problems such as subspace clustering or finding pipelined query plans in stream processors.

A set C is called a *cover* of a set of sets $\mathbf{S}$ if for each $S \in \mathbf{S}$, $S \cap C \neq \emptyset$. The Set Cover problem is defined as follows.

Set Cover
Input: An integer k, a finite set V, and a set $\mathbf{S} \subseteq 2^V$ of subsets of V.
Question: Is there a set C with $|C| \leq$ k such that C is a cover for $\mathbf{S}$?

The Set Cover problem is NP-complete. A naive brute-force algorithm would check for each set $C \subseteq V$ with $|C| \leq k$ whether C is a cover. This algorithm runs in time $O(|V|^k \cdot n)$, which is polynomial in n if k is fixed. However, this is not an FPT algorithm with parameter k because $|V|$ may get arbitrarily large with the input.

Consider the following refined algorithm for Set Cover (cf. [5,8]).

```
$\mathbf{C}_0 := \{\emptyset\}$;
**for** $i = 1$ **to** $k$ **do** $\mathbf{C}_i = \{C \cup \{a\} | C \in \mathbf{C}_{i-1}, a \in S(C)\}$;
**if** at least one element of $\mathbf{C}_k$ is a cover for $\mathbf{S}$ **then**
**output** true;
**else output** false
```

Here, $S(C)$ is a function that returns, in a deterministic way, an element S of $\mathbf{S}$ such that, if this condition can be satisfied by any element of $\mathbf{S}$, $S \cap C \neq \emptyset$. One way of defining $S(C)$ is as

$$S(C) = \begin{cases} \min \mathbf{S}(C) \ldots \mathbf{S}(C) \neq \emptyset \\ \min \mathbf{S} \ldots \text{otherwise.} \end{cases}$$

where $\mathbf{S}(C) = \{S \in \mathbf{S} \mid S \cap C \neq \emptyset\}$ and min returns the smallest element of a subset of **S** with respect to some arbitrary fixed order among the elements of **S** (e.g., the order in which the elements of **S** are stored in memory).

Consider for example $\mathbf{S} = \{\{a, b\},\{a, c\},\{b, d\},\{c, e\}, \{c, f\}\}$ with the elements of **S** ordered as just enumerated. Then, $S(\emptyset) = \{a, b\}$, $\mathbf{C}_1 = \{\{a\},\{b\}\}$, $S(\{a\}) = \{b, d\}$, $\mathrm{S}(\{b\}) = \{a, c\}$, and $\mathbf{C}_2 = \{\{a, b\},\{a, d\},\{b, c\}\}$. Since $\{b, c\}$ is a cover, the algorithm returns true.

It is easy to check that this algorithm runs in time $O(s^k \cdot n)$ where s is the maximum cardinality among the elements of **S**, i.e., $s = \max\{|S| : S \in \mathbf{S}\}$. Thus, Set Cover with parameter $k + s$ (which is not the standard parameterization for Set Cover, which would be k) is FPT. If s is small, this may be a useful algorithm.

Fixed-Parameter Intractability

For a number of parameterized versions of NP-hard problems it can be shown that they are either provably not FPT or not FPT unless P=NP. An example for the former scenario would be EXPTIME Turing machine acceptance (which is EXPTIME-complete) with a dummy parameter that is unrelated to the input. An example of the latter scenario is the satisfiability of CNF formulae whose clauses have no more than k literals, with parameter k. For $k = 3$, this is the 3SAT problem, which is NP-complete. But there are also parameterized problems for which apparently no FPT algorithm exists and for which more subtle hardness arguments based on special complexity classes for parameterized problems have to be developed.

A *fixed-parameter many-one reduction* is a reduction that maps each instance (x, k) of a parameterized problem to an instance (x', k') of another parameterized problem using an FPT algorithm (i.e., in time $O(f(k) \cdot x^c)$), with the additional condition that the size of k' must only depend on k but not on x, such that (x, k) is a yes-instance of the first problem if and only if (x', k') is a yes-instance of the second problem. Closure under such reductions yields robust complexity classes. The class of parameterized problems that are fixed-parameter many-one reducible to problem Π shall be denoted by $[\Pi]^{\text{fpt}}$. A problem in $[\Pi]^{\text{fpt}}$ is called *complete* for $[\Pi]^{\text{fpt}}$ if Π is fixed-parameter many-one reducible to it.

Let $\Gamma_{0,d} = \Delta_{0,d}$ be the class of all propositional formulae constructible from propositional variables using negation and the *binary* operations conjunction $\wedge$ and disjunction $\vee$ such that the maximum expression depth, not taking into account negations, is d. In other words, for any such formula, the maximum number of disjunctions or conjunctions occurring on paths from the root of the expression tree to a leaf is d. Now, $\Gamma_{t,d}$ consists of the formulae of the form $\wedge\ \Phi$, where Φ is a finite subset of $\Delta_{t-1,d}$, and $\Delta_{t,d}$ consists of the formulae of the form $\vee\ \Psi$, where Ψ is a finite subset of $\Gamma_{\mathrm{t-1,d}}$.

A usual way of defining the W hierarchy is in terms of a weighted version of the propositional satisfiability problem. The weight of a truth assignment for the variables of a propositional formula is the number of variables set to true in that truth assignment. The weighted satisfiability problem WSAT($\Gamma_{t,d}$) for the class of formulae $\Gamma_{t,d}$ is as follows: Given a formula $\phi \in \Gamma_{t,d}$ and parameter k, does ϕ have a satisfying assignment of weight k?

The W-hierarchy, for each $t \geq 1$, is defined as

$$W[t] := \underset{d \geq 0}{U} \left[\mathrm{WSAT}(\mathit{\Gamma}_{t,d})\right]^{\text{fpt}}$$

with $W[t] \subseteq W[t+1]$ and is believed to be strict ($W[t] \subsetneq W[t+1]$). For a few examples, natural parameterized versions of Clique and Independent Set are $W[1]$-complete, while parameterized versions of Hitting Set, Dominating Set, and Kernel are $W[2]$-complete (see [5]). These results depend on the choice of parameter, and the standard parameterization is the size of the structure (set) whose existence is to be guessed and verified. The question whether FPT $\neq$ W[1] is the parameterized complexity analogue of the question whether P $\neq$ NP. It remains unproven, but is strongly suspected.

Returning to the evaluation complexity of relational algebra queries with the size of queries as the parameter,

Parameterized Query Evaluation
Input: A Boolean relational calculus query Q and a relational database.
Parameter: The size k of a reasonable representation of Q in bits.
Question: Does Q return true on the input database?

which is known to be $W[1]$-complete [9] already for conjunctive queries (i.e., select-project-join queries) and AW[*]-complete for full relational calculus [4]. AW[*] is a complexity class that subsumes the $W[t]$ classes, for all t, but may contain additional problems.

Further Positive Results on Query Evaluation Complexity

While relational query languages such as relational algebra, calculus, and datalog (a generalization of conjunctive queries) are W[1]-hard and thus unlikely to be fixed-parameter tractable, there are important fragments of these languages that are FPT. Moreover, there are other logics and query languages, specifically on tree- and graph-structured data models, which are FPT with the size of the query as the parameter.

The first FPT result in the context of database query processing was on the evaluation of *acyclic* conjunctive queries by Yannakakis. Consider a Boolean conjunctive query in datalog notation, $q \leftarrow R_1(\vec{y}_1),\ldots,R_k(\vec{y}_k)$. The acyclicity of queries refers to a notion of acyclicity of associated hypergraphs, whose nodes are query variables and whose hyperedges are the sets of variables $\vec{y}_i$ occurring together in an atomic formula of the query. Acyclicity can be defined in a number of ways, such as by a low-complexity algorithm or using guarded logic. An exact definition is beyond the scope of this article, but in the case that all input relations are binary and no atom is of the form $R(y, y)$, the hypergraph is an undirected graph and hypergraph acyclicity coincides with the standard graph-theoretic notion of acyclicity. By exploiting the tree structure of this graph, which describes the necessary joins, and projecting away columns that will not be involved in further joins as early as possible, it is always possible to find a query plan that can be evaluated in time $O(f(k) \cdot n)$ where k is the size of the query – i.e., the problem is fixed-parameter linear.

A Boolean acyclic conjunctive query can be written using just selections and semijoin operations, with a $\pi_\emptyset$ operation on top. If Q_1 and Q_2 are select-semijoin-queries, then $Q_1(x) \ltimes Q_2(x) = \pi_{\mathsf{sch}(Q_1)}(Q_1(x) \bowtie Q_2(x))$ is a subset of $Q_1(x)$ and can be computed in linear time in $|Q_1(x)| + |Q_2(x)|$, where x is the input database. By induction it follows that overall query evaluation is FPT.

Consider the acyclic conjunctive query $\pi_\emptyset\ (R \bowtie S \bowtie T \bowtie U \bowtie V)$ for database schema $R(A,B)$,$S(B,C)$,$T(C,D)$,$U(C,E)$,$V(A,F)$. The hypergraph (here, graph) is acyclic:

The query plan $\pi_\emptyset\ ((R \ltimes V) \ltimes ((S \ltimes \mathbf{T}) \ltimes U))$ admits efficient evaluation.

For nonboolean conjunctive queries, the running time is polynomial of degree c where c is the arity of the query result (which must be considered a true constant rather that a parameter if this is to be considered an FPT result), and clearly, this is optimal because the output size of a query that simply computes the product of the input relations is $\Omega(n^c)$.

The notion of hypergraph acyclicity has been generalized to queries of bounded hypertree-width, which is a measure of how tree-like the query hypergraph is: hypertree-width 1 coincides with hypergraph acyclicity. It was shown in [7] that conjunctive query evaluation with the hypertree-width of the query as the parameter is FPT and that this generalizes in a natural way to relational calculus queries. The fixed-parameter tractability of queries of bounded hypertree-width > 1 (in fact, 2) has been used to explain the polynomial-time complexity of XPath queries [1].

A classical result by Courcelle [2] shows that very powerful queries – in monadic second-order logic, a language that strictly subsumes relational calculus – over databases of bounded tree-width (the exact definition is technical, but in the case that all relations are binary, the condition is bounded tree-width of the (undirected) graph obtained by unioning the relations together) are fixed-parameter linear. Note that in this result the structure of the data is restricted but the structure of queries is not. The special case where the database is a tree with node labels from a finite alphabet is due to Doner, Thatcher and Wright [10]. The algorithm is based on compiling the query into a tree automaton which, once obtained, can be evaluated on the data tree in linear time. Thus, the running time is $O(f(k) + n)$, where k is the size of the query. This is a famous case where f is much worse than singly exponential: f is nonelementary – a tower of twoes $2^{2^{2^{\cdot^{2}}}}$ whose height grows with k. This is apparently necessarily so: Frick and Grohe [6] show that unless $P = NP$, any FPT algorithm for the problem must have a nonelementary f.

Key Applications

Fixed-parameter complexity results can assist designers of data management algorithms in two ways. There is now a large set of positive results for a variety of parameterized versions of NP-hard problems, which may surface in contexts such as query optimization and data mining. For a particular data management problem, it may be known that a particular parameter is always bounded in the problem instances that arise. If the problem is FPT for that parameter, there is an efficient algorithm for solving the problem. Furthermore, FPT results exist for fragments of the relational query languages such as relational algebra as well as for query languages for tree- and graph-structured data.

Conversely, if it is known that a parameterized problem is W[1]-hard, then it is quite hopeless to try to develop an efficient algorithm for solving the parameterized problem; in that case one may look for different acceptable parameterizations or for efficient approximation techniques.

Parametric Data Reduction Techniques

RUI ZHANG
University of Melbourne, Melbourne, VIC, Australia

Definition

A parametric data reduction technique is a data reduction technique that assumes a certain model for the data. The model contains some parameters and the technique fits the data into the model to determine the parameters. Then data reduction can be performed.

Key Points

Parametric data reduction (PDR) techniques is opposite to nonparametric data reduction (NDR) techniques. A model with parameters is used in a PDR technique and therefore some computation is required to determine these parameters, which may be costly. However, if a PDR technique is well-chosen, it may result in much more data reduction than NDR techniques. A representative example is linear regression [3]. Linear regression assumes that the data fall on a straight line, expressed by the following formula

$$Y = a + bX \tag{1}$$

Given a set of points (Assuming two dimensions.) $\{\langle x_1, y_1\rangle, \langle x_2, y_2\rangle, \ldots\}$, parameters a and b in Equation (1) are determined from the points using the least squares criteria. The result is

$$b = \frac{\sum(X - \overline{X})(Y - \overline{Y})}{\sum(X - \overline{X})^2}$$

$$a = \overline{Y} - b\overline{X}$$

where $\overline{X}$ and $\overline{Y}$ are the average values of $x_1, x_2, \ldots$ and $y_1, y_2, \ldots$, respectively. If the data are actually distributed on almost a line, linear regression is a very efficient data reduction technique. Besides the values of a and b, only one dimension of every point is needed to represent the data set. The data volume is reduced by half. However, if the data are not distributed on a line, linear regression will result in large errors.

Other popular PDR techniques include Singular Value Decomposition (SVD) [2] and Discrete Wavelet Transform (DWT). SVD assumes that a matrix is decomposed to the form of $\mathbf{A} = \mathbf{USV}^t$ and $\mathbf{U}, \mathbf{S}, \mathbf{V}$ need to be determined; DWT assumes that a signal is projected to a set of orthogonal basis vectors and the wavelet coefficients need to be determined. A summary of data reduction techniques including PDR techniques can be found in [1].

Partial Replication

Bettina Kemme
McGill University, Montreal, QC, Canada

Definition

A replicated database consists of a set of nodes $\mathcal{N}$ (database servers) and each logical data item x has a physical copy on a subset $\mathcal{N}_x$ of the nodes in $\mathcal{N}$. The replication degree $r_x = |\mathcal{N}_x|$ of a data item is the number of copies it has. Using *full replication*, each logical data item has a copy on each of the nodes, i.e., for each data item x of the database, $\mathcal{N}_x = \mathcal{N}$. Whenever there is at least one data item that does not have copies at all nodes, one refers to a partial replication architecture.

Key Points

Partial Replication can be used for different purposes:

Cluster Replication

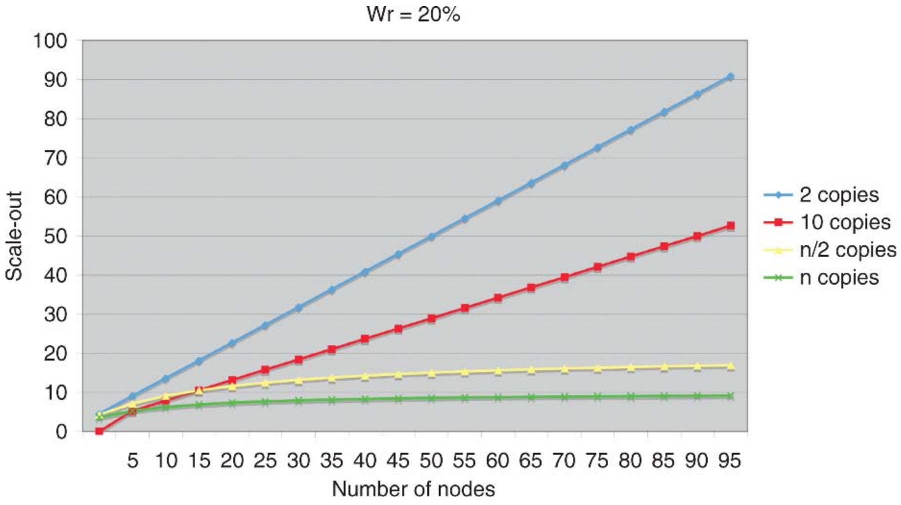
In order to achieve scalability, data can be replicated across nodes residing in a single cluster. Read access to data items can then be distributed across the existing copies. Write operations, however, have to be performed on all copies. The potential for scalability can be best understood by a simple analytical model. It assumes each transaction accesses one data item and has execution cost normalized to one unit. A fraction of *wr* are update transactions. Communication costs and concurrency control issues are ignored. A read-only transaction is executed at any node with a copy of the data item while an update transaction is executed at all nodes. The system consists of n nodes each having the capacity to process C execution units per time unit. There are m data items each having the same replication factor r. The copies are equally distributed across the nodes ($\frac{m*r}{n}$ copies per node). All data items are accessed with the same frequency and requests are equally distributed across all nodes.

If the replicated system can execute l transactions per unit then $(1 - wr) * l$ are read-only transactions executed at one node and $wr * l$ are update transactions executed at r nodes. Thus, the total capacity of the system is used as follows: $n * C = (1 - wr) * l + r * wr * l$. The scale-out is the number of transactions l the replicated system can handle per time divided by the number of transactions a non-replicated system can handle (which is C). Therefore, the scale-out of an n-node system is $\frac{n}{1+(r-1)*wr}$.

Figure 1 shows the scale-out for systems up to 100 nodes with an update load of 10%, and each data item has 2, 10, $n/2$ or n copies. While a constant replication factor provides linear scalability (and the smaller the better), a replication factor that increases with the number of nodes leads to a scalability cealing. Once the saturation point is reached, adding more nodes will not increase the throughput because applying update transactions consumes most of the available resources. More detailed performance models are given in [2,1].

WAN Replication

Replicating data items at different geographical locations is mainly used to provide fast local access to clients of the different regions. Having a data item replicated at a specific location decreases



Partial Replication. Figure 1. Scale-out of partial replication.

communication costs for read operations but increases communication and processing costs for update transactions, and has additional storage costs. Thus, placement algorithms have to decide where to put replicas in order to find a trade-off between the different factors [3].

Challenges

When a transaction executes at a specific node but the node does not have a copy of a requested data item, remote access is necessary. This poses several challenges. First, for update transactions concurrency control becomes more complicated. Second, a location mechanism must be implemented that finds nodes with appropriate data copies. Third, for complex SQL queries, query execution becomes distributed potentially requiring data shipping and advanced operators. Therefore, in practice, data that is often accessed together (within a transaction or query) is co-located. This, however, reduced the flexibility in terms of optimizing load-balancing and update processing.

Path Query

Yuqing Wu
Indiana University, Bloomington, IN, USA

Synonyms

Document path query

Definition

Given a semi-structured data set D, a *path query* identifies nodes of interest by specifying the *path* lead to the nodes and the predicates associated with nodes along the *path*. The *path* is identified by specifying the labels of the nodes to be navigated and structural relationship (parent-child or ancestor-descendant) among the nodes. A predicate can be a path query itself, relative to the node that it is associated with.

Historical Background

Using path information in query processing has been studied in the object-oriented database systems, in which most queries require the traversing from one object to another following object identifiers, in the mid 1990's. The notion of path query, in which the path and predicates along the path are specified as the core of the query, became popular with the growth of the information on the web and the introduction of semi-structured data, especially XML.

Most of the popular query languages for querying XML data, such as XPath [6] and XQuery [4], employ path query as the approach to identify nodes of interest. However, some techniques, such as schema-free XQuery, relax the requirements of specifying the exact path, but rely more heavily on the database management systems to detect the least common ancestors of the keywords specified in the query.

Algebraic research has been fruitful in studying, comparing and characterizing fragments of path queries [2,9], as well as methods and techniques for optimizing and evaluating path queries.

Foundations

Semi-structured data, for example, XML, consists of data entries and containment relationships among the data entries. The data, usually referred to as *a document*, is frequently represented by an ordered node-labeled tree or graph, depending on whether only the containment relationships are treated as first-class relationship, or the id-reference relationships among the data entries are also treated as first-class relationships. The tree representation is more popular:

A *document* D is a 3-tuple (V, Ed, λ), with V the finite set of nodes, $Ed \subseteq V \times V$ a set of parent-child edges, and λ: $V \rightarrow \mathcal{L}$ a node-labeling function into a countably infinite set of labels $\mathcal{L}$.

In addition, even though not always substantial, the ordering among siblings is usually an important feature for nodes in a *document*. The pre-order among the data entries is called the *document order*. Among others, the pre-order is a dominant approach used to identify data entries in a document, while the document is stored in a database system, relational or native.

The aim of the path query is to express the precise requirement of retrieving a set of data entries that satisfy certain value and structural requirements.

The algebraic form of a path query consists of the primitives of $\emptyset$, ε, $\widehat{l}(l \in \mathcal{L})$ for token matching, ↑ and ↓ for upward and downward navigation, and operations $\diamond$ for composition of two algebraic expression $E_1 \diamond E_2$, Π_1 and Π_2 for the first and second projection of an algebraic expression, and set operations $\cap$, $\cup$, and $-$. Given a document $D = (N, Ed, \lambda)$ and a path query E, the path semantics of $E(D)$ is a binary relation:

$$\begin{aligned}
\emptyset(D) &= \emptyset \\
\epsilon(D) &= (n, n) \mid n \in N\} \\
\widehat{l}(D) &= \{(n, n) \mid n \in N \ and \ \lambda(n) = l\} \\
\downarrow(D) &= Ed \\
\uparrow(D) &= Ed^{-1} \\
\Pi_1(E)(D) &= \pi_1(E(D)) \\
\Pi_2(E)(D) &= \pi_2(E(D)) \\
E_1 \diamond E_2(D) &= \pi_{1,4}\sigma_{2=3}(E_1(D) \times E_2(D)) \\
E_1 \cap E_2(D) &= E_1(D) \cap E_2(D) \\
E_1 \cup E_2(D) &= E_1(D) \cup E_2(D) \\
E_1 - E_2(D) &= E_1(D) - E_2(D)
\end{aligned}$$

These primitives and operations identify the path of navigation in a document to reach the resultant data entries.

The $\uparrow^*$ and $\downarrow^*$ are frequently used to identify the ancestor-descendant relationship among data entries along a path:

$$\downarrow^*(D) = \bigcup_{i=0..height(D)} \underbrace{\downarrow \ldots \downarrow}_{i}(D)$$

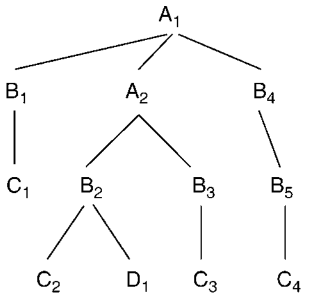
$$\uparrow^*(D) = \bigcup_{i=0..height(D)} \underbrace{\uparrow \ldots \uparrow}_{i}(D)$$

The result of a path query against document D under the *path semantics* is a set of node pairs whose neighborhood data entries and structures satisfy the query expression.

A localized semantics, also called the *node semantics* of a path query Q is to apply the path expression to a document D and a specific node n_0 in the document, such that $Q(D, n_0) = \{n|(n_0, n) \in Q(D)\}$. Usually, the results are presented in a list that honors the *document order*.

For example, assuming document D is represented as a tree structure as shown in Fig. 1, some sample path queries are evaluated as follows:

Path Query	Sample Result
$Q_1 = \downarrow \diamond B$	$Q_1(D) = \{(A_1, B_1), (A_1, B_4), (A_2, B_2), (A_2, B_3), (B_4, B_5)\}$ $Q_1(D, A_1) = \{B_1, B_4\}$
$Q_2 = \Pi_1(\downarrow \diamond \downarrow \diamond C)$	$Q_2(D) = \{(A_1, A_1), (A_2, A_2), (B_4, B_4)\}$ $Q_2(D, A_2) = \{A_2\}$ $Q_2(D, B_4) = \{B_4\}$
$Q_3 = \epsilon \diamond \Pi_1(\downarrow \diamond \downarrow \diamond C) \diamond \downarrow \diamond B \diamond \downarrow$	$Q_3(D) = \{(A_1, C_1), (A_1, B_5), (A_2, C_2), (A_2, D_1), (A_2, C_3), (B_4, C_4)\}$ $Q_3(D, A_1) = \{C_1, B_5\}$ $Q_3(D, B_4) = \{C_4\}$ $Q_3(D, B_2) = \emptyset$
$Q_4 = \uparrow \diamond \Pi_1(\downarrow^* \diamond D) \diamond \Pi_1(\downarrow \diamond \Pi_1(\downarrow \diamond B))$	$Q_4(D) = \{(B_1, A_1), (A_2, A_1), (B_4, A_1)\}$ $Q_4(D, B_1) = \{A_1\}$
$Q_5 = \epsilon \diamond \Pi_1((\downarrow \diamond B) \cup (\uparrow \diamond A)) \diamond \downarrow \diamond \downarrow$	$Q_5(D) = \{(A_2, C_2), (A_2, D_1), (A_2, C_3)\}$ $Q_5(D, A_2) = \{C_2, D_1, C_3\}$



Path Query. Figire 1. A sample semi-structured document presented in a tree structure (subscripts are used to distinguish data entries with the same label).

Path Query and Pattern Tree Matching

Path queries are frequently represented as tree structure, called *pattern trees*, in which nodes (optionally labeled) represents the query requirement on the data entries along the path, and edges (labeled with parent-child or ancestor-descendant relationship) represent the structural requirements among the data entries.

The evaluation of a path query is also called the process of *pattern matching*, which is to find the *witness trees* that consist of data entries that satisfy both the node and structural constraint expressed by the pattern tree.

Path Query Languages

Path query is the core of various query languages for semi-structured data.

XPath [6] is a W3C standard for addressing part of an XML document and for matching and testing whether a node satisfies a pattern. The primary syntactic construct in XPath is the expression, which is evaluated to yield a node set, a boolean value, a number, or a string. The core of the XPath query language is the path query, which is called *location paths* in XPath. Location path consists of relative location paths and absolute location path. A relative location path consists of a sequence of one or more location steps separated by "/". A step is composed from left to right and each step selects a set of nodes relative to a context node, which will in turn serve as the context node for the following step. An absolute location path consists of a leading "/", followed optionally by relative location paths.

XPath, in turn, is the core of other XML query languages and transformation languages, such as XSLT [5] and XQuery [4].

Path Query Evaluation

Even though the way in which the document is stored has great impact on how a path query can be evaluated, some common challenges exist in the evaluation of path queries, comparing to their relational peers, and numerous new operators, optimization techniques and index structures have been proposed to facilitate efficient path query evaluation.

One major characteristic of path query is that the query requirements are expressed not only on data entries, such as the tag (label), attributes, and text values of the entries, but also on the structural relationship among the data entries, which are highlighted by the primitives $\uparrow$ (parent axis), $\downarrow$ (child axis), $\uparrow^*$ (ancestor axis), and $\downarrow^*$ (descendant axis).

Navigation is a natural approach for evaluating a path query. The nagivational approach scans the whole document to verify the query requirement on data entries and the structural relationship among data entries. This approach works more naturally while the document is stored as file, in object-oriented database, or in a native data store. In addition, the nagivational approach is potentially very expensive in cost, especially when the ancestor/descendent axis is involved.

The invention of structural join operator [1,13] and multiple algorithms for efficient computing of structural join advanced the evaluation technique of path queries dramatically. A structural join operation takes two sets of data entries as input and returns pairs of data entries that satisfy the desired structural relationship. The basis of the structural join operation is the pre-order and post-order numbering encoding of data entries in the document. The parent-child relationship is a special case of the ancestor-descendant relationship, in which the nodes that satisfies the desired structural relationship have to be exactly one level apart from each other.

$$(a,b) \in \downarrow^*(D) \Leftrightarrow a_{pre} < b_{pre} \wedge a_{post} > b_{post}$$
$$(a,b) \in \downarrow (D) \Leftrightarrow a_{pre} < b_{pre} \wedge a_{post}$$
$$b_{post} \wedge a_{level} + 1 = b_{level}$$

The structure join operation and various algorithms that support efficient evaluation of the operation enables the evaluation of path queries by decomposition. This approach partitions a path query into twigs that consists of either a node or a pair of nodes with a desired parent-child or ancestor-descendant relationship. The matching of the nodes can be easily evaluated via indices that are similar to value indices in RDB. The structural relationships between node pairs are evaluated by the structural join. Holistic approach has been proposed and widely adopted in answering path queries. This approach uses a chain of linked stacks to compute and represent intermediate results of a path in a compactly fashion.

Path Query Optimization

As any database management system, optimization is a critical step in evaluating path queries.

Syntax based optimization rewrites a path query into a path query in normal format, in pursuit of minimum expression length, minimum number of predicates, and no redundant value and structural requirements. The rewrite may also aim at decomposing a path query into sub-queries that belong to some fragments of path queries that are simpler to answer.

The cost-based optimization relies on the data statistics of the document to be queried, and the cost-model of the physical operators to be employed, to enumerate various physical evaluation plans and choose one with minimum or acceptable estimate performance. This process involves the study of access method selection, query decomposition, cost estimation, etc.

Indices for Path Query Evaluation

Indexing, being one of the most important ingredients in efficient query evaluation, has seen its importance in the context of XML. Over 20 different types of indices have been proposed and have led to significant improvements in the performance of XML query evaluation.

Indices similar to the ones used in RDBs, namely value indices on element tags, attribute names and text values, are first used, together with the structural join algorithms [1,3,10,13], in XML query evaluation. This approach turns out to be simple and efficient, but is not capable of capturing the structural containment relationships native to the XML data.

To directly capture the structural information of XML data, a family of structural indices has been introduced. DataGuide [7] was the first to be proposed, followed by the 1-index [11], which is based on the notion of bi-simulation among nodes in an XML document. These indices can be used to evaluate some path expressions accurately without accessing the original data graph. Milo and Suciu [11] also introduced the 2-index and T-index, based on similarity of pairs (vectors) of nodes. Unfortunately, these and other early structural indices tend to be too large for practical use because they typically maintain too fine-grained structural information about the document. To remedy this, Kaushik et al. introduced the $A(k)$-index which uses a notion of bi-similarity on nodes relativized to paths of length k [8]. This captures localized structural information of a document, and can support path expressions of length up to k. Focusing just on local similarity, the $A(k)$-index can be substantially smaller than the 1-index and others. Several works have investigated maintenance and tuning of the $A(k)$ indices. The $D(k)$-index and $M(k)$-index extend the $A(k)$-index to adapt to query workload. The integrated use of structural and value indices has been explored, and there have also been investigations on covering indices and index selection.

Other directions of XML indexing techniques proposed by researchers include indexing frequent subpatterns, indexing XML tree and queries as sequences, forward and backward index, HOPI index, XR-tree, and encoding-based indices.

Key Applications

Path query is the core concept behind the query languages for semi-structured data. It is also the foundation of path algebra that are used to represent and reason about queries expressed against semi-structured data, especially those focusing on retrieving fragments of the document that satisfy certain value and structural constraints.

Future Directions

Even though the basic idea of the path query has been around for decades, its popularity exploded since XML prevails.

Path query has been adopted as the core of expressing queries again semi-structural data, especially XML. Even though XPath query language has been very stable, new language and language features keep emerging. As to the path query itself, there are on-going study of the sub-languages and the characteristics of such languages, their relationship to each other, the decidability of the queries in these languages, and the complexity of answer the queries.

On the practical side, systems have been developed to answer path queries. Various query evaluation, query optimization and indexing techniques have been proposed to facilitate efficient evaluation of path queries. However, the level of maturity of these techniques are not at the same level as those of relational queries.

In the relational world, the use cases are well understood and various benchmarks have been developed to measure the performance of relational DBMSs. Those of the queries on semi-structured documents are less understood, despite the existence of a few XML benchmarks, such as XMark [12]. In depth research on the usage of path queries and the design and development of benchmarks is yet another promising direction.

Data Sets

Example semi-structured data and queries can be found in benchmarks such as XMark (http://www.xml-benchmark.org), XMach (http://dbs.uni-leipzig.de/en/projekte/XML/XmlBenchmarking.html), and MBench (http://www.eecs.umich.edu/db/mbench).

Pattern-Growth Methods

Hong Cheng[1], Jiawei Han[2]
[1]Chinese University of Hong Kong, Hong Kong, China
[2]University of Illinois-Urbana-Champaign, Urbana, IL, USA

Definition

Pattern-growth is one of several influential frequent pattern mining methodologies, where a pattern (e.g., an itemset, a subsequence, a subtree, or a substructure) is *frequent* if its occurrence frequency in a database is no less than a specified *minimum_support* threshold. The (frequent) pattern-growth method mines the data set in a divide-and-conquer way: It first derives the set of size-1 frequent patterns, and for each pattern *p*, it derives *p*'s projected (or conditional) database by data set partitioning and mines the projected database recursively. Since the data set is decomposed progressively into a set of much smaller, pattern-related projected data sets, the pattern-growth method effectively reduces the search space and leads to high efficiency and scalability.

Historical Background

Frequent itemset mining was first introduced as an essential subtask of association rule mining by Agrawal et al. [1]. A candidate set generation-and-test approach, represented by the Apriori algorithm, was proposed by Agrawal and Srikant [2]. The approach effectively reduces the search space by exploring the *downward closure* property of frequent patterns, i.e., *any subpattern of a frequent pattern is frequent*. Various kinds of refinements of and extensions to this approach were proposed afterwards. However, since the Apriori-like candidate set generation-and-test approach repeatedly scans the whole database and checks the candidates by pattern matching, it is still rather costly.

The pattern-growth approach, represented by the *FP-growth* algorithm, was first proposed by Han, Pei, and Yin [8] for mining frequent itemsets. Since then, the method has been developed in several directions: (i) further enhancement of mining efficiency using refined data structures, such as FP-growth* [6], which uses an array-based implementation of prefix-tree-structure of FP-growth; (ii) mining closed and max patterns [6,13], where a pattern *p* is *closed* if there exists no super-pattern with the same support, and *p* is a *max pattern* if there exists no super-pattern that is frequent; (iii) mining sequential patterns [11] and frequent substructures [14]; and (iv) mining high-dimensional data set [7] and colossal patterns [15], and pattern-based classification [4] and clustering [12]. A comprehensive overview of such extensions is presented in [7].

Foundations

Frequent Itemset Mining

To illustrate the pattern-growth method, the FP-growth method is briefly introduced here that exploits pattern-growth in frequent itemset mining. FP-growth works in a divide-and-conquer way. The first scan of the database derives a list of frequent items in which items are ordered by frequency-descending order (Notice that this particular ordering is not essential, and different ordering schemes can be explored). According to this ordering, the database is compressed into a frequent-pattern tree, or *FP-tree*, which retains the itemset association information.

The FP-tree is mined by starting from each frequent length-1 pattern (as an initial suffix pattern), constructing its *conditional pattern base* (a "subdatabase", which consists of the set of prefix paths in the FP-tree co-occurring with the suffix pattern), then constructing its conditional FP-tree, and performing mining recursively on such a tree. The pattern growth is achieved by the concatenation of the suffix pattern with the frequent patterns generated from a conditional FP-tree. Figure 1 shows an example of a global FP-tree as well as a set of conditional trees and the recursive mining process on top of them. Therefore, the FP-growth algorithm transforms the problem of finding long frequent patterns to searching for shorter ones recursively and then concatenating the suffix.

Sequential Pattern Mining

The pattern-growth philosophy has been extended to sequential pattern mining, where a sequential pattern is a set of (gapped) subsequences that occur frequently in a set of sequences. PrefixSpan, developed by Pei et al. [11], is a typical sequential pattern mining algorithm based on the pattern-growth approach. It works in a divide-and-conquer way, by first scanning the sequence database to derive the set of length-1 sequential patterns. Then each sequential pattern is treated as a prefix and the complete set of sequential patterns can be partitioned into different subsets according to different prefixes. To mine the subsets of sequential patterns, corresponding projected databases are constructed and mined recursively.

Frequent Subgraph Mining

Inspired by the pattern-growth-based frequent itemset and sequential pattern mining algorithms, there are quite a few pattern-growth-based graph pattern mining algorithms developed. Here gSpan [14] is used an example to explain the ideas.

The pattern-growth graph mining algorithm extends a frequent graph by adding a new edge, in every possible position. A potential problem with the edge extension is that the same graph can be discovered many times. gSpan solves this problem by introducing a new lexicographic order among graphs, and maps each graph to a unique minimum DFS code as its canonical label. Based on this lexicographic order, gSpan adopts the pattern-growth philosophy with a *right-most extension* technique, where the only extensions take place on the *right-most path*. A right-most path is the straight path from the starting vertex v_0 to the last vertex v_n, according to a depth-first search on the graph. In Fig. 2, the graph shown in 2a has several potential children with one edge growth, which are shown in 2b–f (assume the darkened vertices constitute the rightmost path). Among them, 2b–d grow from the rightmost vertex while 2e and 2f grow from other vertices on the rightmost path. 2(b.0)–(b.3) are children of 2b, and 2(e.0)–(e.2) are children of 2e. Backward edges can only grow from the rightmost vertex while forward edges can grow from vertices on the rightmost path. The enumeration order of these children is enhanced by the DFS lexicographic order, i.e., it should be in the order of 2b–f.

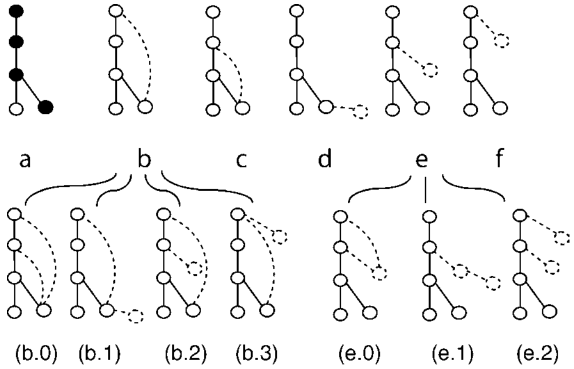
Pattern-Growth Methods. Figure 1. FP-growth mining on conditional FP-trees.



Pattern-Growth Methods. Figure 2. Graph growth with DFS lexicographic order.

With the DFS lexicographic order definition, the frequent subgraph mining is performed in a *DFS Code Tree*. In a DFS Code Tree, each node represents a DFS code. The relation between parent and child node complies with the parent–child relation; the relation among siblings is consistent with the DFS lexicographic order. Figure 3 shows a DFS Code Tree, the nth level nodes contain DFS codes of $(n-1)$-edge graphs. Through depth-first search of the code tree, all the minimum DFS codes of frequent subgraphs can be discovered. That is, all the frequent subgraphs can be discovered in this way. One should note that if in Fig. 3, the dark nodes contain the same graph but different DFS codes, then one of them must not be the minimum code. Therefore, the search space of that sub-branch can be pruned since it does not correspond to a minimum DFS code.

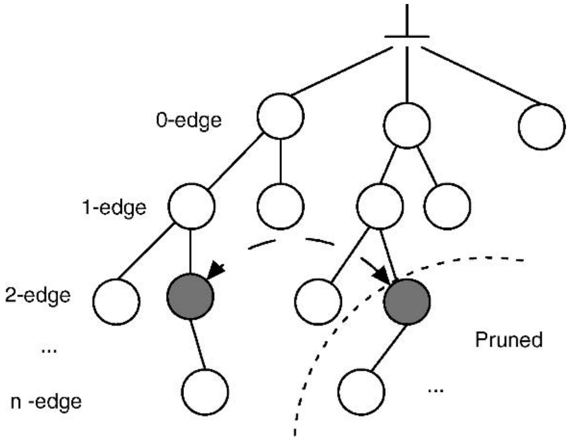
Key Applications

Pattern-growth methods have been used in many tasks that need the mining of frequent patterns, including the discovery of association and correlation relationships among large sets of transactions, event sequences, or complex structures, the discovery of discriminative frequent features for classification and clustering, as well as many other data mining and pattern recognition applications, such as biological data mining.

Future Directions

Mining Approximate or Noise-Tolerant Patterns

Pattern-growth method has been widely applied for efficient mining of precise and complete set of frequent patterns. However, in some real applications, the capacity to accommodate approximation in the mining process has become critical due to inherent noise and



Pattern-Growth Methods. Figure 3. A search space: DFS code tree.

imprecision in complex data sets, for example, gene mutations in genomic DNA sequences, and protein–protein interaction networks. Approximate or noise-tolerant frequent patterns could be the natural choice to handle noise or variations in many applications. Some recent studies proposed new algorithms for mining approximate itemsets [9] and subgraphs [3]. Among them, [9] adopts a candidate generation-and-test approach with the noisy mining model while [3] takes a pattern-growth approach. It is interesting to explore whether pattern-growth method could be naturally applied into a noisy mining model to efficiently discover the approximate or noise-tolerant patterns.

Pattern-Based Classification and Clustering

Frequent patterns have been demonstrated useful in other data mining tasks such as classification [4] and clustering [12], where frequent patterns are used as discriminative classification features and clustering subspaces, respectively. Instead of using the complete set of patterns, usually only a small number of frequent patterns are used in classification and clustering tasks, e.g., the subset of highly discriminative patterns in classification and the subset of frequent patterns with dense regions in clustering. It would be desirable to directly mine the subset of patterns of interests without generating the complete set, for efficiency consideration. To achieve this goal, pruning strategies need to be designed and integrated into the pattern-growth mining methodology to effectively prune the search space which does not yield high-quality patterns. This is a non-trivial task since many quality measures, such as information gain, density, or entropy, are not *anti-monotonic* which is the essential pruning strategy in frequent pattern mining.

Experimental Results

In general, for every proposed method, there is an accompanying experimental evaluation in the corresponding reference. In addition, for frequent itemset mining methods, [5] (The FIMI workshop) provided a detailed and comprehensive experimental evaluation on a large set of benchmark data.

Data Sets

Synthetic Data

A synthetic tree generator can be found at http://www.cs.rpi.edu/∼zaki/software

Real Data

A large collection of real transaction datasets can be found at http://fimi.cs.helsinki.fi/data/. Commonly used real graph data includes AIDS anti-viral screening datasets at http://dtp.nci.nih.gov, and NCI anti-cancer screening datasets at http://pubchem.ncbi.nlm.nih.gov.

URL to Code

The binary codes for FP-growth, PrefixSpan and gSpan are provided by the IlliMine project at http://illimine.cs.uiuc.edu/.

The source codes of FP-growth*, FPClose, and FPMax* [6] are provided by Grahne and Zhu at http://fimi.cs.helsinki.fi/src/fimi06.tgz

Peer Data Management System

Philippe Cudré-Mauroux
Massachussetts Institute of Technology, Cambridge, MA, USA

Synonyms

PDMS; Decentralized data integration system

Definition

A Peer Data Management System (PDMS) is a triple $\mathcal{S} = \langle \mathcal{P}, \mathcal{S}, \mathcal{M} \rangle$ where $\mathcal{P}$ is a set of autonomous peers, $\mathcal{S}$ a set of heterogeneous schemas used by the peers to represent their data, and $\mathcal{M}$ a set of schema mappings, each enabling the reformulation of queries between a given pair of schemas.

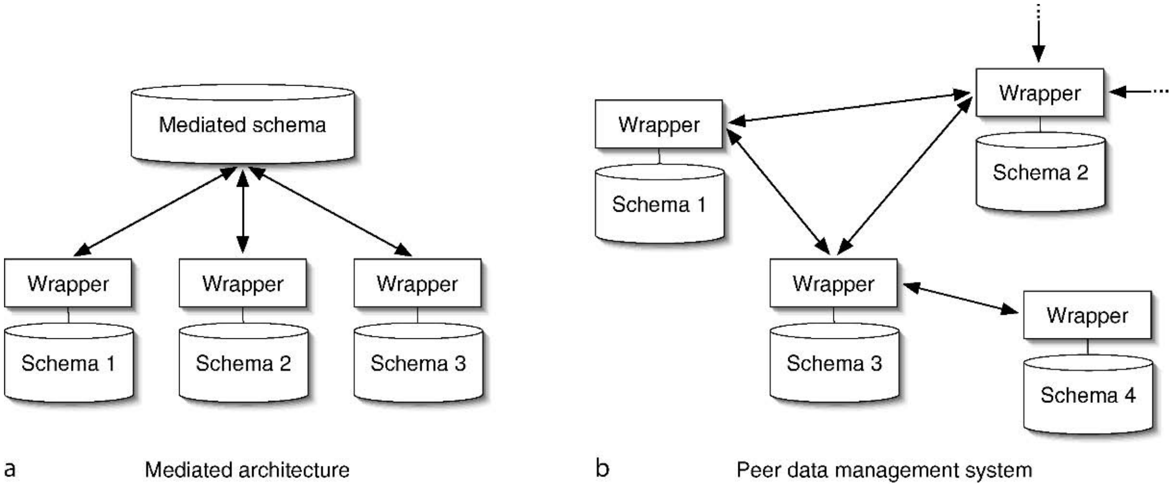
Key Points

A Peer Data Management System (PDMS) is a distributed data integration system providing transparent access to heterogeneous databases without resorting to a centralized logical schema. Instead of imposing a uniform query interface over a mediated schema, PDMSs let the peers define their own schemas and allow for the reformulation of queries through mappings relating pairs of schemas (see Fig. 1). PDMSs typically exploit the schema mappings transitively in order to retrieve results from the entire network.

Compared to centralized data integration systems, PDMSs suggest a scalable, decentralized and easily extensible integration architecture where any peer can contribute data, schemas, and mappings. Peers with new schemas simply need to provide a mapping between their schema and any other schema already used in the system to be part of the network.

The languages used to define the mappings in PDMSs may vary, but are typically derived from GLAV formulae with extensions to support both inclusion and equality mappings. The Piazza system [3] proposes new algorithms to retrieve certain answers in this context. Hyperion [1] is a system focusing on relating data not only at the schema level, but also at the instance level through mapping tables. GridVine [2] provides distributed probabilistic analyses in order to automatically detect mapping inconsistencies in PDMS settings.

PDMSs generally use Peer-to-Peer overlay networks to support their distributed operations. Some use unstructured overlay networks [1,3] to organize the peers into a random graph and use flooding or random walks to contact distant peers. Other PDMSs maintain a decentralized yet structured Peer-to-Peer network [2] to allow any peer to contact any other peer by taking advantage of a distributed index.



Peer Data Management System. Figure 1. Contrary to the mediated architecture (a), Peer Data Management Systems (b) do not impose any form of centralization but consider instead networks of heterogeneous data sources related to each other through pairwise schema mappings.

The lack of global coordination has raised several questions as to the global properties of such systems in the large. In particular, new complex systems perspectives – such as the emergent semantics approach – have been proposed to characterize the global semantics of PDMSs.

Peer to Peer Overlay Networks: Structure, Routing and Maintenance

Wojciech Galuba, Sarunas Girdzijauskas
EPFL, Lausanne, Switzerland

Definition

A peer-to-peer overlay network is a computer network built on top of an existing network, usually the Internet. Peer-to-peer overlay networks enable participating peers to find the other peers not by the IP addresses but by the specific logical identifiers known to all peers. Usually, peer-to-peer overlays have the advantage over the traditional client-server systems because of their scalability and lack of single-point-of-failure. Peer-to-peer overlays are commonly used for file sharing and realtime data streaming.

Historical Background

The rise of the Internet brought the first instances of peer-to-peer overlays like the Domain Name System (DNS), the Simple Mail Transfer Protocol (SMTP), USENET and more recently IPv6, which were needed to facilitate the operation of the Internet itself. These peer-to-peer overlays were intrinsically decentralized and represented symmetric nature of the Internet, where every node in the overlay had equal status and assumed cooperative behavior of the participating peers. The beginning of the file-sharing era and the rise and fall of the first file-sharing peer-to-peer system Napster [9] (2000–2001) paved the way for the second generation of peer-to-peer overlays like Gnutella [5] (2000) and Freenet [4] (2001). The simple protocols and unstructured nature made these networks robust and lacking Napster's drawbacks like single-point-of-failure. Since 2001, these peer-to-peer overlays became extensively popular and accounted for the majority of the Internet traffic. Soon after it was evident that the unstructured nature of Gnutella-like systems is embarrassingly wasteful in bandwidth, more efficient structured overlays appeared, like the Distributed Hash Tables (DHTs), which used the existing resources more effectively (e.g., Chord [13]). Currently, unstructured peer-to-peer overlays are sparsely used, as the most popular peer-to-peer applications for file-sharing and data-streaming (e.g., Skype [12], Kademlia [8], KaZaA [6]) are implemented using structured or hybrid overlay concepts.

Foundations

Taxonomy

There are many features of peer-to-peer overlays, by which they can be characterized and classified [2,11]. However, strict classification is not easy since many features have mutual dependencies on each other, making it difficult to identify the distinct overlay characteristics (e.g., overlay topologies versus routing in overlays). Although every peer-to-peer overlay can differ by many parameters, but each of them will have to have certain network structure with distinctive routing and maintenance algorithms allowing the peer-to-peer application to achieve its purpose. Thus, most commonly, peer-to-peer overlays can be classified by:

1. Purpose of use;
2. Overlay structure;
3. Employed routing mechanisms;
4. Maintenance strategies.

Purpose of Use

Peer-to-peer overlays are used for an efficient and scalable sharing of individual peers' resources among the participating peers. Depending on the type of the resources which are shared, the peer-to-peer overlays can be identified as oriented for:

1. Data-sharing (data storage and retrieval);
2. Bandwidth-sharing (streaming);
3. CPU-sharing (distributed computing).

Data-sharing peer-to-peer overlays can be further categorized by their purpose to perform one or more specific tasks like file-sharing (by-far the most common use of the peer-to-peer overlays), information retrieval (peer-to-peer web search), publish/subscribe services and semantic web applications. The examples of such networks are BitTorrent [3] (file-sharing), YaCy-Peer [14] (web search), etc.

Bandwidth-sharing peer-to-peer overlays to some extent are similar to the data-sharing ones, however, are mainly aimed at the efficient streaming of real-time data over the network. Overlay's ability to find several disjoint paths from source to destination can significantly boost the performance of the data streaming applications. Bandwidth-sharing peer-to-peer overlays are mostly found in peer-to-peer telephony, peer-to-peer video/TV, sensor networks and peer-to-peer publish/subscribe services. Currently Skype [12] is arguably the most prominent peer-to-peer streaming overlay application.

For the computationally intensive tasks, when the CPU resources of a single peer cannot fulfill its needs, a *CPU-sharing* peer-to-peer overlays can provide plenty of CPU resources from the participating idle overlay peers. Currently, only a major scientific experiments employ such strategy for the tasks like simulation of protein folding or analysis of an astronomic radio signals. Although *not* being a pure peer-to-peer overlay, Berkeley Open Infrastructure for Network Computing (BOINC) is very popular among such networks, supporting such distributed computing projects as SETI@home, folding@home, AFRICA@home, etc.

Overlay Structure

Peer-to-peer overlays significantly differ by the topology of the networks which they form. There exist a wide scope of possible overlay instances, ranging from centralized to purely decentralized ones, however, most commonly, three classes of network topology are identified:

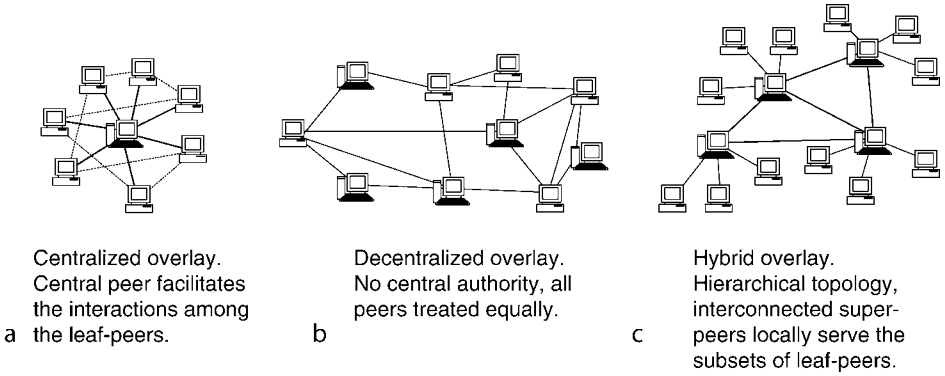
1. Centralized overlays;
2. Decentralized overlays;
3. Hybrid overlays.

Depending on the routing techniques and whether the overlay network was created by some specific rules (deterministically) or in ad hoc fashion (nondeterministically), overlay networks can be also classified into *structured* and *unstructured* peer-to-peer overlays.

Centralized Overlays Peer-to-peer overlays based on *centralized* topologies are pretty efficient since the interaction between peers is facilitated by a central server which stores the global index, deals with the updates in the system, distributes tasks among the peers or quickly responds to the queries and give complete answers to them (Fig. 1(a)). However, not all the purposes of use fit the centralized network overlay model. Centralized overlays usually fail to scale with the increase of the number of participating peers. The centralized component rapidly becomes the performance bottleneck. The existence of a single-point-of-failure (e.g., Napster [9]) also prevents from using centralized overlays for many potential data-sharing applications.

Decentralized Overlays Because of the aforementioned drawbacks, *decentralized* structured and unstructured overlays emerged, which use purely decentralized network model, and do not differ peers as servers or clients, but treat all of them equally – as they were both servers and clients at the same time (Fig. 1(b)). Thus, such peer-to-peer overlays successfully deal with the scalability and can exist without any governing authority.

The simplest decentralized overlays usually are *unstructured*. Unstructured overlay networks typically have arbitrary topology and use flooding based routing among the peers. The distribution of the resources among the peers is completely unrelated to the



a Centralized overlay. Central peer facilitates the interactions among the leaf-peers.

b Decentralized overlay. No central authority, all peers treated equally.

c Hybrid overlay. Hierarchical topology, interconnected super-peers locally serve the subsets of leaf-peers.

Peer to Peer Overlay Networks: Structure, Routing and Maintenance. Figure 1. Examples of peer-to-peer overlays.

network topology. Because of their simplicity, the unstructured overlays are pretty robust to network and peer failures, although are rather inefficient in bandwidth consumption and have poor querying performance.

Structured overlay networks, however, use more efficient routing techniques and the topology of the structured overlays is not arbitrary but typically exhibit Small-World properties, specifically high clusterization and low network diameter. The link establishment among the peers is usually strictly defined by the specific protocols. The topologies can result in various structures like rings, toruses, hypercubes and de-Bruin networks or more loose randomized networks, which do have properties of Small-World networks. A particular instance of structured peer-to-peer overlays is a Distributed Hash Table (DHT) enabling an efficient lookup service, by using a predefined hashing algorithms to assign an ownership for a particular resource (e.g., Chord [13], P-Grid [1], Symphony [7], etc.). In contrast to the traditional Hash Table, the DHTs share the global hashing information among all the participating peers equally and the DHT protocols ensure that any part of a global hash table is easily reachable (usually in logarithmic steps) and there is enough replication to sustain the consistency in the system.

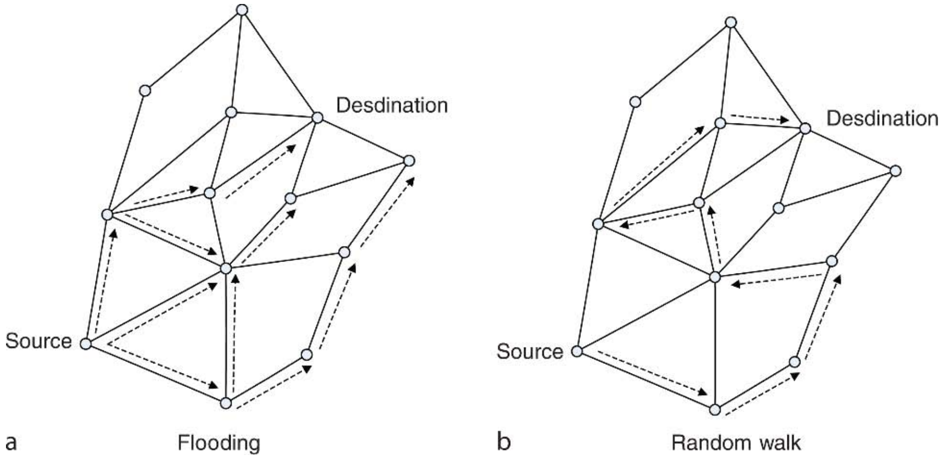
Hybrid Overlays There also exist many *hybrid* peer-to-peer overlays (super-peer systems) which trade-off between different degree of topology centralization and structure flexibility. Hybrid overlays usually use hierarchical network topology consisting of regular peers and super-peers, which act as local servers for the subsets of regular peers (Fig. 1(c)). For example, a hybrid overlay might consist of the super-peers forming a structured network which serves as a backbone for the whole overlay, enabling an efficient communication among the super-peers themselves. Hybrid overlays have advantage over simple centralized networks since the super-peers can be dynamically replaced by regular peers, hence do not constitute single points of failure, but have the benefits of centralized overlays.

Routing

Peer-to-peer overlay networks enable the peers to communicate with one another even if the communicating peers do not know their addresses in the underlying network. For example, in an overlay deployed on the Internet, a peer can communicate with another peer without knowing its IP address. The way it is achieved in the overlays is by *routing* overlay messages. Each overlay message originates at a source and is forwarded by the peers in the overlay until the message reaches one or more destinations. A number of routing schemes have been proposed.

Routing in Unstructured Overlays Unstructured overlay networks use mainly two mechanisms to deliver routed messages: flooding and random walks (Fig. 2). When some peer v receives a flood message from one of its overlay neighbors w, then v forwards the flood message to all of its neighbors except w. When v receives the same flood message again, it is ignored. Eventually the flood reaches all of the destinations.

For example, in Gnutella [10], a file-sharing peer-to-peer system, a peer s that wants to download a file floods the network with queries. If some peer d that has the file desired by s is reached by the query flood, then d sends a response back to s. Flooding consumes a significant amount of network bandwidth. To reduce



Peer to Peer Overlay Networks: Structure, Routing and Maintenance. Figure 2. *Routing in unstructured overlay networks.* The *circles* and *solid lines* represent the overlay topology. The *dashed arrows* illustrate the flow of messages. Peers routing in an unstructured network do not know the exact location of the destinations so they have to either look in all possible directions via flooding or randomly walk to find the destination peer.

it, the flooded messages typically contain a Time-To-Live (TTL) counter included in every message that is decremented whenever the message is forwarded. This limits how far the flood can spread from the source but at the same time lowers the chance of reaching the peer that holds the searched file.

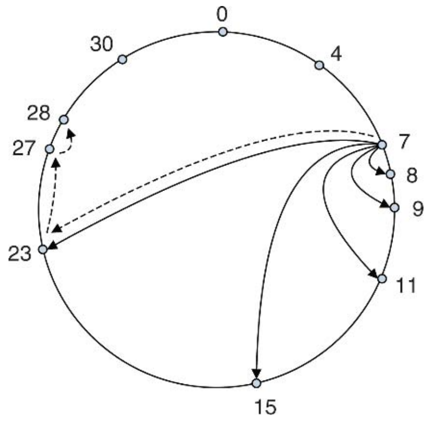
The high bandwidth usage of flooding has led to the design of an alternative routing scheme for unstructured overlay networks: *random walks*. Instead of forwarding a message to all of the neighbors, it is only forwarded to a randomly chosen one. Depending on the network topology random walks provide different guarantees of locating the destination peer(s), however all of the random walk approaches share one disadvantage: a significant and in most cases intolerable delivery latency.

Routing in Structured Overlays As more peers join the overlay network and there are more messages that need to be routed, flooding and random walks quickly reach their scalability limits. This problem has prompted the research on structured overlays.

In structured overlays each peer has a unique and unchanging identifier picked when a peer joins the overlay. The peer identifiers enable efficient routing in the structured overlays. Each routed message has a destination identifier selected from the peer identifier set. Instead of blindly forwarding the message to all neighbors as in the unstructured overlays, a peer in a structured overlay uses the destination identifier to forward the message only to one neighbor. The next hop neighbor is selected to minimize the number of hops to the destination, i.e., the routing is greedy. This selection is made using the *peer identifier distance*.

Most of the modern structured overlays define the notion of distance between any two peer identifiers. For example, in Chord [13] identifiers are selected from the set of integers $[0,2^m - 1]$ and are ordered in a modulo 2^m circle. The distance $d(x, y)$ between two identifiers x and y is defined as the difference between x and y on that identifier circle, i.e., $d(x, y) = (y - x)$ mod 2^m In another overlay, Kademlia [8], the identifiers are 160-bit integers and the distance between two identifiers x and y is defined as their exclusive bitwise OR (XOR) interpreted as an integer, i.e., $d(x, y) = x \oplus y$.

Although the modern structured overlays differ in the details of how they make use of the peer identifiers for routing efficiency, they are all based on the same general *greedy routing* principle. When some peer v receives a message with a given destination identifier it forwards the message to that next hop whose identifier is the closest to the destination identifier. In other words, in every hop the message gets as close as possible to the destination. Routing terminates when TTL is exhausted or one of the peers decides it is the destination for the message. The latter decision is application dependent. For example, in a Distributed Hash Table each peer knows for which hash table keys it is responsible. The key space is mapped onto the peer identifier space in DHTs and the destination identifier of each



Peer to Peer Overlay Networks: Structure, Routing and Maintenance. Figure 3. *Routing in chord.* The *big circle* represents the peer identifier space with IDs in the interval [0,2^5]. The *small circles* are the peers and the number beside them is their ID. Peer 7 is connected (*solid arrows*) to peers with exponentially increasing distance from 7: $7 + 1 = 8, 7 + 2 = 9, 7 + 4 = 11, 7 + 8 = 15, 7 + 16 = 23$. Assume that peer 7 wants to route a message to peer 28. *Dashed arrows* represent the routing path. The peer 23 is the neighbor of 7 that is closest on the ring to the destination 28 and that neighbor is chosen as the first hop for the message. One hop is not enough to reach 28, but the peer 23 brings the message closer to the destination and peer 27 finally delivers it. The greedy routing rule of always selecting such next hop that brings the message as close as possible to its destination is the main building block of all structured overlay networks.

DHT lookup message specifies the hash table key K the lookup is querying for. The lookup message is greedily routed hop by hop from the origin until the message reaches a peer responsible for K. Routing then terminates and the responsible peer sends a lookup response to the origin. The lookup response contains the hash table value stored under the key K.

Maintenance

Peer-to-peer systems are commonly deployed in environments characterized by high dynamicity, peers can depart or join the system at any time. These continuous joins and departures are commonly referred to as *churn*. Instead of gracefully departing from the network peers can also abruptly fail or the network connection with some of its neighbors may be closed. In all of these cases the changes in the routing tables may adversely affect the performance of the system. The overlay topology needs to be *maintained* to guarantee message delivery and routing efficiency.

There are two main approaches to overlay maintenance: proactive and reactive. In *proactive maintenance* peers periodically update their routing tables such that they satisfy the overlay topology invariants. For example, Chord periodically runs a "stabilization" protocol to ensure that every peer is linked to other peers at exponentially increasing distance. This ensures routing efficiency. To ensure message delivery each Chord peer maintains connections to its immediate predecessor and successor on the Chord ring.

In contrast to proactive maintenance, *reactive maintenance* is triggered immediately after the detection of a peer failure or peer departure. The missing entry in the routing table is replaced with a new one by sending a connect request to an appropriate peer.

Failures and departures of peers are detected in two ways: by probing or through usage. In probe-based failure detection each peer continuously runs a ping-response protocol with each of its neighbors. When ping timeouts occur repeatedly the neighbor is considered to be down and is removed from the routing table. In usage-based failure detection when a message is sent to a neighbor but not acknowledged within a timeout, the neighbor is considered to have failed.

The more neighbors a peer must maintain the higher the bandwidth overhead incurred by the maintenance protocol. In modern structured overlays maintenance bandwidth typically scales as $O(\log(N))$ in terms of the network size.

Key Applications

The key applications of peer-to-peer overlay networks include:

1. File-sharing systems, e.g., BitTorrent [3]
2. VoIP (Voice over IP) and VoD (Video on Demand) systems, e.g., Skype [12]
3. Information retrieval, e.g., YaCy-Peer [14]

Peer-To-Peer Content Distribution

Pascal Felber[1], Ernst Biersack[2]
[1]University of Neuchatel, Neuchatel, Switzerland
[2]Eurecom, Sophia Antipolis, France

Synonyms

Cooperative content distribution; Peer-to-peer file sharing

Definition

Peer-to-peer content distribution is an approach for cost-effective distribution of bandwidth-intensive content to large numbers of clients based on *swarming*. Content is split into blocks that are sent to different clients. Thereafter, the clients can directly exchange blocks with one another, in a peer-to-peer manner, without the help of the original server.

Historical Background

Peer-to-peer systems are application-layer networks that directly interconnect users. They have enjoyed a phenomenal success in the last ten years together with the democratization of broadband access. The first disruptive peer-to-peer applications were designed for file sharing (e.g., Napster, Gnutella, KaZaA): they provided users with the means to (i) *search* for content, and (ii) *distribute* content. In the research community, most of the initial focus was on structured peer-to-peer overlays, also known as distributed hash tables (e.g., CAN, Chord). These systems have proved very efficient for *looking up* specific content.

Once users have started exchanging larger files, notably full-length movies, the classical client-server techniques used to transfer files were no longer sufficient and the focus has shifted on developing more scalable mechanisms for content distribution. The first and most emblematic example of peer-to-peer content distribution application is BitTorrent [5]. Its development started in 2001 and it reached widespread popularity in 2003.

BitTorrent is a peer-to-peer application that capitalizes the *bandwidth* of peer nodes to quickly replicate a single large file to a set of clients. The challenge is thus to maximize the speed of replication. The clients involved in a torrent cooperate to replicate the file among each other using *swarming* techniques: the file is broken into fixed size blocks and the clients in a peer set exchange blocks in parallel with one another. BitTorrent only deals with distribution and does not provide any mechanisms for locating content. Several alternatives to BitTorrent have been proposed, but none of them has reached the same level of popularity nor demonstrated sufficient benefits to supersede it.

More recently, some peer-to-peer content distribution systems have been developed specifically for streaming media, such as live television (e.g., PPLive). For such applications, blocks have to be received in order and in time, and clients are only interested in the part of the stream that is being broadcast while they are online.

Foundations

The principle underlying peer-to-peer content distribution is to capitalize the upstream bandwidth of the clients. A user that downloads some content will, at the same time, send part of the content to other peers.

Peer-to-peer content distribution networks are inherently *self-scalable*, in that the bandwidth capacity of the system increases as more peers arrive: each new peer requests service from, but also provides service to, the other peers. The peer-to-peer system can thus spontaneously adapt to the demand by taking advantage of the resources provided by every peer.

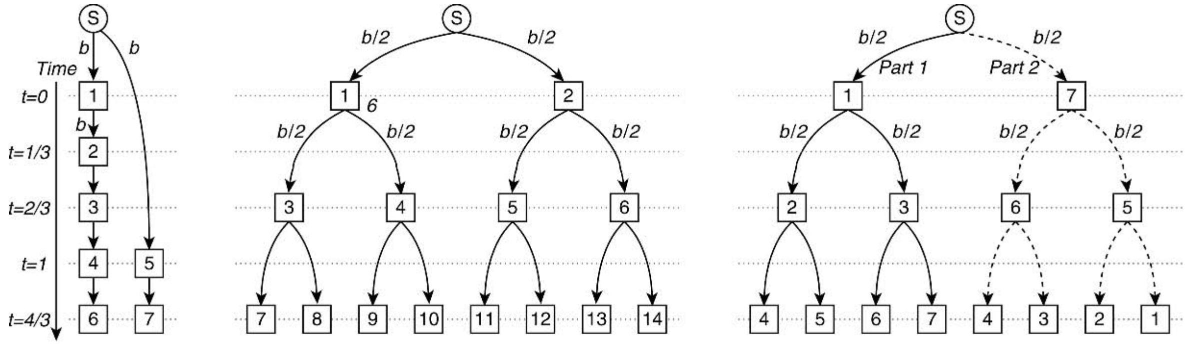
The behavior of each peer in a peer-to-peer content distribution is determined by two factors: (i) the *peer selection strategy* that determines the set of peers a given peer will exchange blocks with and (ii) the *block selection strategy* that determines which blocks will be exchanged. The choice of the peer and the block selection strategy has an important impact on the architecture of the content distribution system. One can distinguish between *structured* and *unstructured* architectures.

Structured architectures organize the peers in a directed acyclic graph such as linear chain or a tree (see Fig. 1). The peer selection is done once for the whole duration of the content distribution. The block selection becomes trivial as each peer simply forwards all the blocks it receives to its children. While structured architectures are easy to understand and model, they are best suitable for content distribution over networks where the bandwidth is homogeneous and nodes stay connected during the whole duration of the content distribution. If these conditions are not met, which is typically the case for the Internet, complex mechanisms are required to make structured approaches work.

Self-organization is the ability of a peer-to-peer network to dynamically determine how to best manage the block exchange as peers join, leave, or fail. Unstructured architectures are self-organizing: they use an underlying mesh structure and build directed graphs through which data is forwarded along several possible paths from the source to each peer. Meshes adapt well to bandwidth fluctuations/heterogeneity and nodes leaving and joining during the transfer at the price of more complex peer and block selection strategies. Since there exist multiple paths for receiving data, each peer must coordinate with its neighbors to avoid receiving the same block multiple times. One such system that uses an unstructured mesh-based approach is BitTorrent, a very popular peer-to-peer system for file distribution.

File Distribution

The BitTorrent protocol makes sensible choices for peer and block selection that are based on a few simple principles. *Peer selection:* first, every peer maintains a limited number of active connections to the other peers that offer the best upload and download rates, thus optimizing bandwidth utilization; second, a peer preferentially sends data to another peer that reciprocally sent data to it, which enforces fairness; third, every peer periodically sends some data to newcomers, so that peers can have an active role in the torrent independent of their arrival time. *Block selection:* a peer requests the block from its neighbors for which the least number of copies exist (rarest first), as rare blocks have a high trading value and can potentially increase the lifetime of the torrent. Maintaining a good



Peer-To-Peer Content Distribution. Figure 1. Evolution of three simple distribution models with time: linear chains (*left*), trees (*center*), and parallel trees (*right*). The nodes in each graph are labeled with the peer number and the edges with the bandwidth allocated for the block transmission. In this example, $C = 3$ and $k = 2$.

diversity of the blocks available in the systems assures that each peer can fully use its upload capacity since it has blocks that its neighbors are interested in.

Despite the simplicity of these design principles and the lack of theoretical foundations to back them when they were introduced, studies [8] have shown they perform exceptionally well in practice. The uplink utilization at the peers is remarkably high, sharing incentives are very effective and resilient to freeriders, and one can observe that peers spontaneously cluster according to their capacity [10].

The choice of the peer and block selection strategy is very important for the good performance of mesh-based systems, because peers can fully use their upload capacity only if the *diversity* of blocks is high, i.e., if they own blocks their neighbors are interested in. Another way to assure that a peer has useful information to transmit to its neighbors is to use *network coding*. In this case, every block that is transmitted is a linear combination of all or a subset of the blocks available at the peer. Since with high probability every such block is unique and contains useful information for the receiving peer, the block selection strategy becomes trivial. Avalanche [6] is a peer-to-peer system for file distribution that uses network coding.

Video Streaming

File distribution systems such as BitTorrent are often used to download files that contain audio or video content. Since the blocks can be downloaded in any order, the consumption of the content cannot start before the download is complete.

In recent years, some peer-to-peer content distribution systems have been developed to support live streaming, where the playback of the content occurs simultaneously with its production. Supporting video streaming is more challenging than file distribution: the users expect that once viewing has started it will be continuous, which means that data must be received in sequence and the rate of data reception must be equal the rate at which data are injected by the source. The architectural variants available for live streaming are the same as for file distribution, namely structured and unstructured approaches.

SplitStream [4] uses a structured architecture and constructs parallel trees, with every peer belonging to all trees. Content is split in multiple layers, each sent along a different tree. As was discussed for the case of file distribution, structured architectures lack flexibility. For this reason, the systems that have been used most widely for video streaming are mesh-based. One can notably mention PPlive [7] that has been used to stream video to tens of thousands of peers.

A robust video streaming system must be able to cope with the heterogeneity of the peers, which can have widely varying download bandwidth. To assure real-time data reception for all clients despite heterogeneity, one can use layered coding: the video is encoded into a base layer and several enhancement layers. While the video cannot be viewed if the base layer is not completely received, the enhancement layer only improve the viewing experience of the video and can be omitted if the download bandwidth is not sufficient.

Many peers are connected via ADSL links that provide much higher download rates than upload rates. A peer-to-peer streaming system is only stable if the aggregate upload rate of the participating peers is at least as high as the aggregate playout rate [9]. In many cases this can only be achieved if there are some peers ("super-peers") that have an upload capacity much higher than the video playout rate [7].

Besides participating in a live streaming event, users may want to watch a video at any point of time, which is referred to as video on demand. While there exist designs for peer-to-peer systems that support video on demand [1], none of these systems has been deployed on a large scale.

Performance Analysis of Distribution Architectures

To evaluate the potential of peer-to-peer file distribution, one can consider very simple distribution models [3] where a server S distributes a file to N peers. The server splits a file into C blocks and serves the file sequentially and infinitely at rate b. The time needed to download the complete file from the server to a *single* peer at rate b is referred to as *one round*.

Consider first a linear chain architecture where the peers are organized in a chain with the server uploading the blocks to the first peer, which in turn uploads the blocks to the second peer and so on (Fig. 1, left). Peers disconnect once they have uploaded the whole file once. The number of peers served in a given number of rounds grows linearly with the number of blocks C, because one can faster engage all peers in the distribution process, and quadratically with the number of rounds t, because the source forks additional chains. Interestingly, when $N/C \ll 1$, the time necessary to serve N peers converges asymptotically to 1.

Consider now a tree architecture where the peers are organized in a tree with an outdegree k (Fig. 1, center). The server serves k peers in parallel, each at rate b/k, and all the peers that are not leaves in the tree in turn upload the blocks to k other peers at rate b/k. This means that it takes k rounds for a peer to download the file and interior nodes upload an amount of data equivalent to k times the size of the file, while leaf nodes do not upload the file at all. The performance of the tree architecture depends on the node degree, and it turns out that for $N/C \leq 1$ the best value is $k = 1$, i.e., a linear chain. For $N/C > 1$ a binary tree is more efficient. Trees with higher degrees are penalized by the higher number of non-contributing leaf nodes.

Finally, consider a forest of k parallel trees, each of which contains all the peers (Fig. 1, right). The server partitions the file into k parts and constructs k spanning trees to distribute each part along a separate tree to all peers. The trees can be built such that each peer is an interior node in at most one tree and a leaf in the remaining $k - 1$ trees. The parallel tree architecture is as efficient as the linear chain when $N/C \ll 1$ and significantly outperforms the other two architectures in other scenarios. The optimal performance is obtained for trees with an outdegree $k = e \approx 3$.

Table 1 summarizes the scaling behavior of the different approaches. One can see that for both the tree and parallel trees architectures, the number of clients served increases exponentially in time and in the number of blocks C.

These performance results are remarkable: with the same amount of effort at the server, distributing the content to N peers using a peer-to-peer architecture can be done in a little more than one round, i.e., it takes just slightly longer than to distribute the file from the server to a single peer. While structured architectures are neither robust nor practical, these performance models still give valuable insights on the asymptotically performance of peer-to-peer content distribution. See [11,2] for studies that take into account other factors such as bandwidth heterogeneity.

Developing performance models for unstructured architectures is much more difficult than for structured ones. Yet, it turns out that the following unstructured architecture, called *Interleave*, is analytically tractable [12]. The performance model for Interleave assumes that all blocks are numbered in increasing order, all peers have the same bandwidth, and the transmission of a block takes one slot. Peer selection is random, while block selection is as follows: in every odd time slot the source and the other peers push the highest numbered block they own to a random peer; in every even time slot each peer requests from a random peer the lowest numbered block that the peer does not yet have. Note that Interleave does not require any peer to exchange information with other peers about the block it already has. As a consequence the protocol will experience some inefficiency as a peer p may ask another peer q for a block that q does not have, or may send to q a block that q already has. It can be shown analytically that with high probability the entire file that consists of C blocks can be distributed to all N peers in a time of $3.2 + \frac{\log N}{C}$. Using simulation the result obtained was $2 + \frac{\log N}{C}$, which is similar to the time required by a structured binary tree (see Table 1). Such good performance is quite astonishing as is indicates that there exist robust mesh-based file distribution schemes that can achieve performance as good as structured architectures.

Key Applications

Peer-to-peer content distribution is a technique to transfer large contents simultaneously to many users.

Peer-To-Peer Content Distribution. Table 1. Performance comparison of three structured distribution models

Architecture	Clients served	Service time	Copies served	Download rate	Upload rate
Linear chain	$C \cdot t^2$	$\frac{1}{2} + \sqrt{\frac{1}{4} + \frac{2 \cdot N}{C}}$	1	b	b (except leaves)
Tree	$k^{(t-k)\frac{C}{k}+1}$	$k + (\lfloor \log_k N \rfloor - 1) \cdot \frac{k}{C}$	k	$1/b$	b (except leaves)
Parallel trees	$k^{(t-1)\frac{C}{k}}$	$1 + \lfloor \log_k N \rfloor \cdot \frac{k}{C}$	1	b	b

Key applications include file sharing systems, live TV, video on demand, or distribution of critical updates.

It also represents a cost-effective alternative to scaling up server architectures. It has notably been used as a way to protect servers from unexpected surges in request traffic, called flash crowds, by replicating popular content on multiple peers.

Future Directions

Peer-to-peer content distribution networks are overlays that typically ignore the underlay, i.e., the underlying IP connectivity. Therefore, such networks generate much unnecessary traffic between Internet service providers.

Another important problem that plagues content distribution networks is the fact that the validity of content cannot be verified until after it is downloaded. The media industry contributes to content pollution in existing networks to deter exchange of copyrighted files.

One can expect video on demand to be an important application domain for peer-to-peer content distribution technology. A major challenge is that users must be able to start watching a movie at any time, as well as suspend it, rewind, skip chapters, etc. (VCR functionality). In these scenarios, there is no such synchronization between the peers as with live streaming.

Peer-to-Peer Data Integration

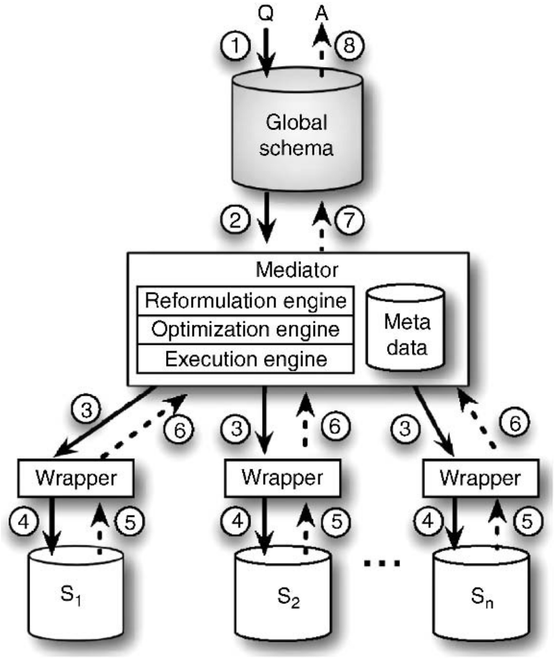
Anastasios Kementsietsidis
IBM T.J. Watson Research Center, Hawthorne,
NY, USA

Definition

Peer-to-Peer data integration lies in the intersection of two popular research topics, namely, Peer-to-Peer systems and Data Integration, and is one of the key topics in the area of *Peer-to-Peer Data Management.* A Peer-to-Peer data integration setting involves a set $\mathcal{P}$ of autonomous, heterogeneous, independently evolving (peer) sources whose pairwise schema or data-level mappings, collectively denoted by $\mathcal{M}$, induce a peer-to-peer network. In this setting, each (peer) source in the network can be queried and act as an *access point* to the data residing in the other network sources. Research in this area focuses on studying the specification and expressiveness of the peer mappings; the corresponding query languages used; algorithms for rewriting queries between peer source schemas; and, to some extent, topics that concern the propagation of updates between peer sources. Key characteristics of the peer-to-peer data integration setting that differentiate it from *traditional* data integration settings and typical Peer-to-Peer systems include (i) the fact that each peer can be full-fledged database; (ii) the lack of centralized control and global schemas; (iii) the need for more diverse set of mapping specifications; and (iv) the need for integration of data across diverse domains.

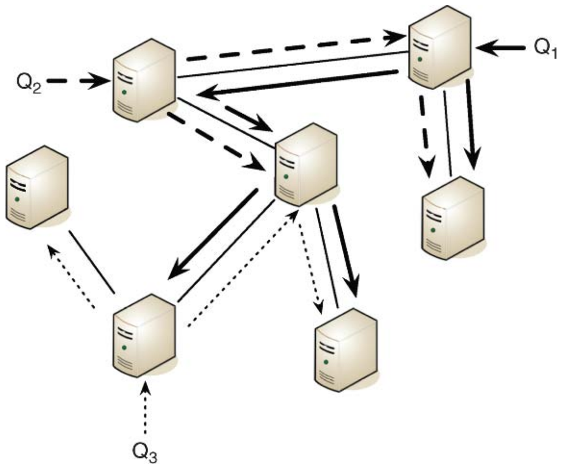
Historical Background

Data integration [11] has been characterized as one of the longest-standing research problems faced by the data management community. A typical data integration setting involves a set $\mathcal{S}$ of sources, a global schema $\mathcal{G}$, and a set $\mathcal{M}$ of mappings between the sources in $\mathcal{S}$ and the global schema $\mathcal{G}$. Figure 1 illustrates such a setting along with the logical steps during query evaluation. Central to the evaluation of queries are the mappings between the global and local schemas (indicated as *Metadata* in the figure). The mappings are used during the rewriting of a user query over the global schema $\mathcal{G}$ to a set of queries over the sources. Two basic approaches have been used to specify the mappings. In a nutshell, in the *Global-as-View* (GAV) approach, the global schema $\mathcal{G}$ is expressed as a view of the set of local schemas $\mathcal{S}$. Main advantage of the GAV approach is the simplicity of the rewriting algorithm. However, a drawback of the approach is that the addition of source in $\mathcal{S}$ results in a revision of the mapping and, in the worst case, a complete re-design of the global schema. In the second approach, called *Local-as-View* (LAV), each source $S_i \in \mathcal{S}$ is expressed as a view over the global schema $\mathcal{G}$. Query rewriting is substantially more involved here, but the approach handles source additions more gracefully.



Peer-to-Peer Data Integration. Figure 1. Typical data integration setting.

Peer-to-peer computing involves an open-ended network of computational peers, where each peer exchanges data and services with a set of other peers, called its *acquaintances*. The peer-to-peer paradigm, initially popularized by file-sharing systems such as Napster [12] and Gnutella [5], offers an alternative to traditional architectures found in distributed systems and the web. Distributed systems are rich in services, but require considerable overhead to launch and have a relatively static, controlled architecture. In contrast, the web offers a dynamic, anyone-to-anyone architecture with minimum startup costs but limited services. Combining the advantages of both architectures, peer-to-peer offers an evolving architecture where peers come and go, choose with whom they interact, and enjoy some traditional distributed services with less startup cost. Figure 2 shows an example of such a system, often referred to in the literature as an *unstructured* peer-to-peer system, to differentiate it from the complementary class of *structured* peer-to-peer systems whose architecture is based on *Distributed Hash Tables* (DHT's). As shown in the figure, mappings in unstructured peer-to-peer system (represented by solid lines) exist between any pair of peers while queries (represented by various line arrows) can be initiated



Peer-to-Peer Data Integration. Figure 2. A Peer-to-Peer system.

at any peer in the system. Furthermore, different queries might involve a different set of peers.

Probably the first works to consider the interaction between database and peer-to-peer systems were the ones by Gribble et al. [6] and Bernstein et al. [3]. The former work focuses on the problem of *data placement*, that is, to find an optimal placement of a set of objects on a peer-to-peer system, under a prespecified query workload, so as to minimize the cost of evaluating the queries. In more detail, the authors consider graph whose nodes correspond to the peers in a peer-to-peer network. Each node is associated with a storage capacity and a query workload. Furthermore, each pair of nodes connected by an edge has an associated data trasfer cost, over this edge. Queries over this network are object lookups and each query has an associated frequency and cost (with the cost being zero, if the query can be served locally in a peer, and a function of the object size and edge transfer cost, if served remotely). In this setting, the main result of this work is that the problem of data placement with optimal cost is NP-complete. The work by Gribble et al. [6] initiated the Piazza System [17] (described in the next section) although the follow-up work in Piazza addresses a setting much closer to data integration. As presented here, the setting in Gribble et al. [6] is more closely related to the one found on the work on DHT's like CAN [15] or Chord [16].

Bernstein et al. [3] is the first work to actually discuss data integration in a peer-to-peer context. The focus in this work is the introduction of the Local Relational Mode (LRM), a model designed specifically for the peer-to-peer setting. Key notions in the model are that of *coordination formulas* and *domain relations*. Much like a mapping in a typical data integration setting, a coordination formula establishes a relationship between the data items stored in acquainted peers. This relationship can be used to express a constraint, like for example, that a particular data item must be stored in either one of three different acquainted peer databases, or it can be used during query answering by expressing, for example, a GAV (LAV) type mapping where the data items returned by query Q_1 in a peer P_1 are contained in those returned by query Q_2 in peer P_2. Since different peers might use different vocabularies to express the same real-world notion, it is the responsibility of domain relations to express the mapping between these vocabularies. For example, a domain relation might be used to map prices expressed in US dollars, in a peer, to those in euro in another peer. The work by Bernstein et al. [3] initiated the Hyperion project [2] the details of which are described in the next section.

Foundations

Important aspects in every peer-to-peer data integration system include (i) the peer joining process and especially the type of mappings used by the system to resolve the heterogeneity of the acquainted peer; (ii) the supported query language and the processing of queries; and (iii) how the system deals with the lack of centralization and the inherent dynamic and unreliable nature of the peer-to-peer setting. Not every system addresses all these aspects and different systems put more emphasis on a different system aspect. The following paragraphs provide an overview of some of the main systems in this area.

In Piazza [17], each peer in the system *exports* a schema which can be one of two kinds: (i) a virtual schema, used for querying and mapping the schemas of its acquainted peers, or (ii) a schema which internally is mapped to actual stored data in the peer. In either case, a peer joining the system establishes GAV or LAV mappings between its export schema and the export schemas of peers that are already part of the system. The creation of such mappings is a complicated process which cannot be fully automated. *Schema matching* techniques are used, both in Piazza and elsewhere, to facilitate their creation. Both the created mappings and the supported query language are expressed in a fragment of XQuery. User queries in this fragment are expressed over the schema of a single peer. The query is answered locally by the peer, if the peer actually stores data, and it is also reformulated to a set of queries over the acquaintances of the current peer. Briefly, the reformulation algorithm combines view unfolding, if a GAV mapping exists between acquainted peers, and an answering queries using views algorithm [7], in the case of LAV mappings. The reformulation algorithm terminates once all the queries that result in from the reformulation refer only to relations that correspond to stored data in peers (and no virtual schemas).

Influenced by the work in the LRM model, in Hyperion [2] two types of mappings are used to support the sharing of information between relational database peers, namely, *mapping expressions* and *mapping tables*. Similar to the GAV/LAV mappings in Piazza (and elsewhere), mapping expressions are schema-level mappings used during query answering for the reformulation of queries between peers. A distinguishing feature of Hyperion, mapping tables [9] are *data-level* mappings that associate the values of acquainted peers (inspired by the domain relations in the LRM model). A mapping table T is a relation over the set of attributes $X \cup Y$, where X and Y are non-empty sets of attributes belonging to two acquainted peers. Each tuple $t \in T$ (whose values might include constants and/or variables) associates the set of values in $t[X]$ to those in $t[Y]$.

While schema matching can still be employed for the creation of mapping expressions, the creation of mapping tables requires the development of specialized techniques. Indeed, the work in [9] formalizes mapping tables as data-level constraints over the sharing of data between peers and illustrates how new mapping tables can be inferred automatically (from existing tables) while establishing an acquaintance between two peers. Due to the dynamic nature of peer-to-peer system, peers are expected to continuously evolve and change their schema (less frequently) and their data (very frequently). This change influences both the existing mapping expressions and the existing mapping tables. As a result, work in the Hyperion project is concerned with how to maintain the existing mappings with emphasis in the frequently updated mapping tables.

In terms of query answering, for the case of mapping expressions, Hyperion relies on techniques similar to the ones developed for Piazza. For the case of mapping tables, Hyperion uses a specialized algorithm to rewrite select-project-join (SPJ) queries between peers, relying only on the use of mapping tables for the rewriting [10]. No algorithm is provided in Hyperion to rewrite queries by combining mapping expressions and tables. However, mapping expressions are used in conjunction with mapping tables in Hyperion for *data coordination* [8]. Indeed, another distinguishing characteristic of Hyperion is that it supports the creation and distributed execution of Event-Condition-Action (ECA) rules over multiple acquainted peer.

The PeerDB [14] system is built on top of a generic peer-to-peer platform, called BestPeer [13]. The BestPeer platform supports two types of peers, namely, a large number of normal (data) peers and a smaller number of *location independent global names lookup (LIGLO)* peers. A LIGLO peer acts as a name server with which every peer in the system registers, when joining, in order to acquire a unique identifier.

Similar to Piazza and Hyperion, in PeerDB, data sharing between heterogeneous peers is achieved in two steps. In the first step, mappings are established between the schemas of the peers. In the second step, the mappings are used to rewrite a query over the schema of one peer to a query over the schema of another. PeerDB has a number of distinguishing characteristics over the previous approaches. First, it differs from the previous systems in that it uses an information retrieval-based technique as a basis for its schema mappings. In more detail, each peer relation and attribute name is associated with a set of descriptive keywords. A mapping between two relations (attributes) that reside on different peers is established if their corresponding descriptive keywords overlap *significantly*. Once a mapping is established, it is used to rewrite a query that refers to one relation into a query that refers to its mapped counterpart. The second distinguishing characteristic of PeerDB is that mappings are established dynamically, at query time. In more detail, PeerDB employs an agent-based technology both during the discovery of schema mappings and during the rewriting of queries. After a user initiates a query over a local peer schema, software agents are responsible for crawling the peer-to-peer network, looking for peers whose schemas can be mapped to the schema where the user query is posed. The agents carry all the necessary functionality to perform the rewriting once such schemas are discovered.

Similar to PeerDB, the GridVine [4] system is built on top its own generic peer-to-peer platform, called P-Grid [1]. However, while the architecture of BestPeer follows the peer/super-peer paradigm, the architecture of P-Grid is that of a structured overlay network. Capitalizing on the efficiency of P-Grid in terms of indexing, routing and load balancing, GridVine builds a semantic mediation layer on top of P-Grid. In this semantic layer, schemas and data are represented as RDF triples, while queries over these triples are expressed as *triple patterns*. A triple pattern query issued at any peer is routed to the peer that can answer the query by using the services of the overlay network (by hashing the constants appearing in the query). In terms of heterogeneity, GridVine employs OWL statements to relate semantically similar schema elements that belong to pairs of schemas. During query evaluation, these mappings are used for the rewriting of queries which are then executed using the overlay network, as described earlier.

Key Applications

Scientific databases, Health informatics databases, Business-to-Business (B2B).

Peer-to-Peer Publish-Subscribe Systems

Peter Triantafillou, Ioannis Aekaterinidis
University of Patras, Rio Patras, Greece

Definition

Publish/Subscribe (a.k.a. pub/sub) software systems constitute a facility for asynchronous filtering of information. Users, consumers of information, present the system with continuous queries, coined *subscriptions*. Sources of data generation (producers) present the system with data-carrying *publication events*. The pub/sub system infrastructure is responsible for (asynchronously) matching the publication events to all relevant subscriptions. Hence, in essence, this infrastructure filters all available information for every user and presents to each user only the information units (s)he has defined as relevant. As such, a pub/sub infrastructure can play a vital role in large-scale data systems, with huge volumes of data, shielding users from the burden of always actively searching for and retrieving relevant information units.

Peer-to-Peer (P2P) systems are software systems, which in fact constitute *overlay* networks, which are built over physical networks, such as the Internet. Their key discriminative feature is the complete decentralized algorithmic and system design, which, in turn, leads to guarantees with respect to system *scalability* in terms of the network size and stored data. In addition, P2P systems are characterized by *self-organization*, being able to withstand high dynamics with respect to network nodes joining and leaving the system while continuing to offer efficient operation.

Pub/sub P2P systems are an attempt to combine these two important technologies. The central aim is to offer facilities for asynchronous matching of continuous user queries to publication events, at very large scales. This entails dealing with large numbers of producers and consumers of information, which are geographically distributed and, also, supporting large publication-event and subscription arrival rates. Coupling pub/sub technology with the P2P paradigm achieves this aim, while introducing the additional benefits of scalability and self-organization into the pub/sub realm.

Historical Background

Publish/subscribe systems have evolved significantly over time, differing on a number of fundamental characteristics. They are classified into two major categories, according to the way subscribers express their interests; the *topic-based* [6,10,16] and the *content-based* [4,5,7,8] systems. Historically, the first systems were topic-based, in which users subscribe to specific topics. All incoming publication events associated with a particular topic are sent to all user subscribers of the topic. This paradigm mimics the way news groups operate. *Content-based* pub/sub systems emerged subsequently, offering users the much-needed ability to express their interests on specific publication events, carrying specific content. Principally, users issue subscriptions which specify predicates over the *values* of a number of well defined attributes. The matching of publication events to subscriptions is performed based on the content (i.e., the values of attributes) being carried by the publication events.

At the turn of the century, related research efforts were maturing and a number of content-based pub/sub systems were already available. Influential examples, with respect to content-based pub/sub systems research, include SIENA [5], Gryphon [4], Le Subscribe [8] and JEDI, [7]. Already, some of this work targeted the challenging issues arising in a distributed system, where publishers and subscribers are geographically distributed [4,5]. Around the same time and in parallel, research related to P2P networks and systems was also maturing. Worthy of special mention are *structured P2P overlay networks*, like Chord [14], Pastry [13], CAN [12], and P-Grid [1]. Several of these networks influenced work on pub/sub systems, especially endeavors aiming to leverage existing P2P networks for providing pub/sub functionality with scalability, efficiency, and self-organization. The Scribe system [6] was a first attempt at providing topic-based pub/sub functionality over the Pastry P2P network. This effort was followed by endeavors to build content-based publish/subscribe systems over P2P networks, [2,3,9,11,15,17].

Foundations

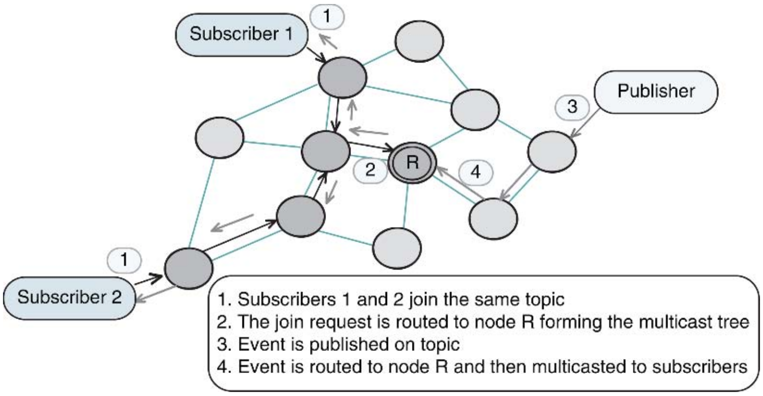
Pub/sub data management represents a significant point of departure compared to traditional data management. In the latter, data items are stored and the system is responsible for appropriate indexing and processing queries and updates issued by users against these data items. In the pub/sub model, it is the users' continuous queries (subscriptions) that are stored and indexed appropriately and the system is responsible for processing data-carrying publication events, matching them to all relevant stored subscriptions.

The fundamental functionality offered by a publish/subscribe system rests on the pillars of subscription processing and publication-event processing and matching. In a P2P environment, all this functionality is based on distributed algorithms that appropriately leverage the P2P network capabilities in order to ensure scalability and efficiency of operation, free of concern for network topology dynamics. The core functionality exported by a P2P network is the so-called *lookup()* function, which receives as input a *key* and returns the network address of the peer node where the data item associated with the key is located. Structured P2P networks, such as those built using *Distributed Hash Tables (DHTs)* (such as [12–14]) can ensure that *lookup()* executes in $O(logN)$ messages, in a network of N nodes, a feature that in essence guarantees scalability and efficiency.

In topic-based publish/subscribe systems, events and subscriptions are associated with specific topics (a.k.a. groups/subjects). A straightforward approach, on which Scribe [6] for example is based for supporting topic-based pub/sub functionality in a P2P environment is to further associate each topic with a *multicast tree*. Topic (and thus multicast tree) creation, involves identifying the node responsible for the tree root, which is determined simply by issuing a *lookup (hash(topic_name))*, using the DHT's hash function. The DHT hash function introduces a randomizing effect when selecting root nodes for different multicast trees. Subscription processing then involves storing the subscription locally at the origin peer node and having that node join the multicast tree. This is basically accomplished by also issuing a *lookup(hash(topic_name))* and creating a path in the multicast tree consisting of all the DHT nodes visited during the execution of the *lookup()* call. Finally, publication-event processing is performed by locating the tree root node (again, using the *lookup ()* function) and sending the publication to it, which it subsequently distributes to the multicast tree. Figure 1 illustrates this process.

The content-based pub/sub model has dominated the area, since it allows for greater user-query expressiveness, resulting in more efficient information filtering. However, this model incurs a much higher complexity. The publication event and subscription schema adopted in this model, defines a set of A attributes (a_i, $1 \leq i \leq A$). Each attribute a_i consists of a name, a type (usually string or numerical), and a value $v(a_i)$. A publication event is defined to be a set of $k < attribute, value >$ pairs ($k \leq A$), while a subscription is defined through an appropriate set of predicates on attributes' values over a subset of the A attributes of the schema. The complexity emerges from the need to support subscriptions with complex predicates. For numerical-typed attributes, the allowable predicates may involve equality, inequality, $\leq, \geq$, and ranges of values. For string-typed attributes, subscribers may define prefix, suffix, sub-string and equality predicates. Fundamentally, solutions in a P2P environment can be classified according to whether they require knowledge of the internal DHT routing state, which is maintained by each DHT node, and its association with additional state that is needed for subscription and publication processing [3,11,15]. A key characteristic in several of these approaches [11,15] is that each node n_1 associates with each other node in its routing table, say n_2, additional state that consists of all subscriptions that n_1 has received from n_2. When a publication event arrives at n_1, it is forwarded to every node n_2 in its routing table only if the publication event matches one of the subscriptions sent to n_1 by n_2.

Approaches that do not belong in this category avoid the maintenance costs associated with the extra,



1. Subscribers 1 and 2 join the same topic
2. The join request is routed to node R forming the multicast tree
3. Event is published on topic
4. Event is routed to node R and then multicasted to subscribers

Peer-to-Peer Publish-Subscribe Systems. Figure 1. Multicast tree construction for event dissemination in topic-based publish/subscribe.

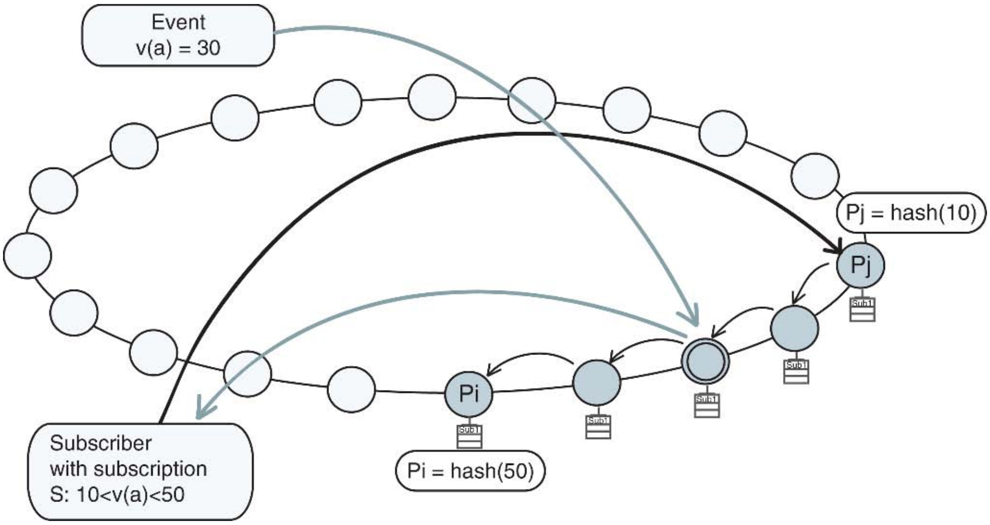
per-node state and enjoy wider applicability as they can be easily integrated with a number of DHTs. Hereafter, the focus is on these approaches, where the content (i.e., the values defined by the predicates) will determine at which peer nodes the subscriptions will be stored. Similarly, the values carried by a publication event will determine which route must be followed within the network so to reach every possible peer node storing a relevant subscription.

Equality predicates can be handled straightforwardly – the basic idea being the following. A subscription s associating with attribute a the value $v(a)$, can be stored simply at the peer node with identifier p, where $p = hash(v(a))$. A publication event e carrying $a = v(a)$, is processed by visiting the peer node $p = hash(v(a))$ and retrieving all locally-stored subscriptions, such as s.

However, for more complex predicates, this is inadequate. At an abstract, high-level view, proposed solutions, albeit very different, share the following characteristics. The node ID namespace is typically associated in solution-specific manners with the value domain of an attribute. A subscription with a complex predicate on an attribute is stored at several nodes, whose IDs depend on the values defined by the subscription's predicate. In other words, a subscription is mapped to a subspace of the node ID namespace. Publications, associating an attribute with a value correspond to a point in the namespace. The node associated with this point, by construction, will be storing all subscriptions whose predicates on this attribute include this event's value. In this way, the *subscription to publication event rendezvous* occurs and in this rendezvous node the event can be matched to all relevant subscriptions.

For concreteness, the basics of the approach adopted in [17] – one of the first to leverage an existing P2P network on top of which to build scalable content-based pub/sub systems – for processing subscriptions with range predicates, is outlined. The approach is simple, requires no additional state maintenance, and no knowledge of the internals of the underlying DHT state. This approach utilizes the Chord DHT [14] in which nodes are arranged in a circular list according to their IDs. However, in [17] specific order-preserving hashing is employed to store subscriptions in the Chord network. That is, when processing subscriptions with values $v(a)_i$ and $v(a)_j$, they are stored at nodes p_i and p_j whose IDs are given by $hash(v(a)_i)$ and $hash(v(a)_j)$, respectively. If $v(a)_j < v(a)_i$, then $p_j < p_i$. An incoming subscription s, identifying a range of values $[v(a)_j, v(a)_i]$ is stored on all nodes in the arc of the ring starting at node $hash(v(a)_j)$ and ending at node $hash(v(a)_i)$. Given this, a publication carrying value $v(a)_k$, with $v(a)_j < v(a)_k < v(a)_i$ will be directed at node $hash(v(a)_k)$ and this node by construction falls on the arc of the ring where the subscription s has been stored. Thus, the matching can be locally performed at this node. Figure 2 illustrates this process.

Finally, the aforementioned discussion has focused on single-attribute (one-dimensional) subscriptions and publications. In general, pub/sub systems involve subscriptions and publications specifying multi-dimensional



Peer-to-Peer Publish-Subscribe Systems. Figure 2. Processing range queries in a content-based pub/sub system.

content. Processing multi-dimensional publication events and subscriptions is a source of additional complexity. In this setting, a publication event *e* will match a subscription *s* if and only if all attributes named by *s* are also named by *e* and the predicates defined by *s* on its attributes are satisfied by the values for these attributes carried by the publication event. A straightforward approach dealing with multi-dimensional events and subscriptions is the following. First, perform the processing as discussed above for each named attribute in the publication event and subscription. Second, for each attribute collect a candidate result set, consisting of the subscriptions being matched only for that attribute of the publication. Lastly, merge and filter the per-attribute candidate result sets into a single result set, by removing those subscriptions in the candidate result sets which have at least one attribute predicate not satisfied by the publication event. Figure 3 illustrates this process.

As these candidate result sets are distributed and can contain very large numbers of subscriptions, the tasks of merging them and filtering subscriptions from them can introduce large overheads. Therefore, multi-dimensional event processing is open to a number of crucial performance optimizations which reveal key trade-offs with respect to network bandwidth overheads, number of required messages, and event-matching latencies [2].

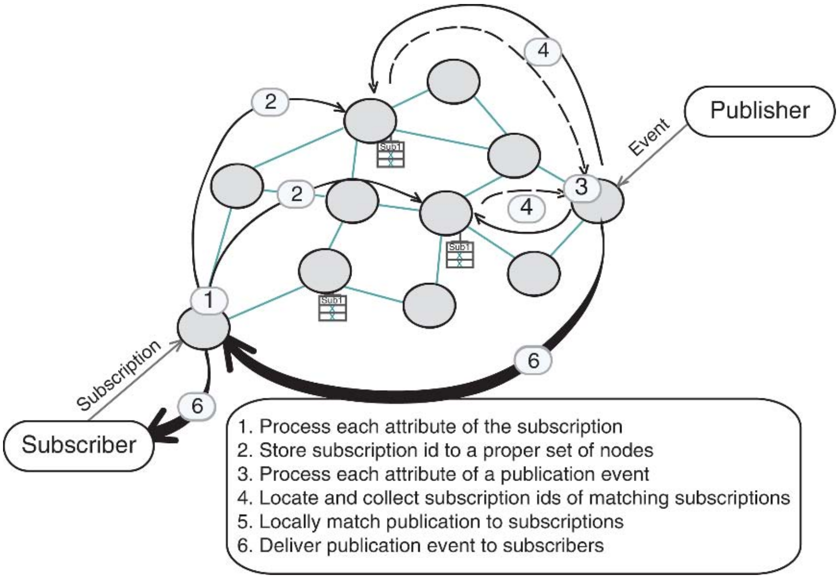
Key Applications

In recent years one notices a proliferation of data-intensive and compute-intensive networked applications aiming for efficiency, scalability, and self-organization. A key characteristic in many such applications is the massive amounts of data of various types and characteristics being generated continuously, from many different sources, at different times, and possibly at very high rates. Users can thus be inundated by the sheer volume of this data and are confronted with severe difficulties in accessing only the typically very small fraction of this data that is of interest to them. Hence, what is very much needed for such applications is an infrastructure that can offer decentralized, scalable, self-organizing asynchronous filtering of this massive information base.

Content-based publish subscribe systems operating in the distributed environment of a P2P overlay network appear as the appropriate infrastructure, and are used to design and implement such applications. A few representative example applications, which also indicate open research and development challenges, are listed below:

(i) *Information Feeds*

A classic example for publish/subscribe application infrastructures are data applications based on information feeds. In these applications publishers can be, for example, news agencies that publish



1. Process each attribute of the subscription
2. Store subscription id to a proper set of nodes
3. Process each attribute of a publication event
4. Locate and collect subscription ids of matching subscriptions
5. Locally match publication to subscriptions
6. Deliver publication event to subscribers

Peer-to-Peer Publish-Subscribe Systems. Figure 3. Multi-dimensional event and subscription processing in content-based P2P publish/subscribe systems.

news articles. Human subscribers declare their interests with proper content-based subscriptions involving numerical-attribute predicates such as date ranges, and string-attribute predicates such as words defining article title prefixes. In general, any RSS feed-like information dissemination system like stock exchange reports falls in this category. The distributed aspects occur when considering large, multi-national news agencies whose computers form a large, geographically-dispersed network. One can even further imagine alliances of such multi-nationals, increasing dramatically the application's scale.

(ii) *Grid Computing*

Consider a farm of computing clusters, each one including a number of computing nodes with heterogeneous characteristics involving, for example, various types of operating systems, hardware specifications, etc. and forming a peer-to-peer computing grid. Each node publishes its characteristics while possible users that wish to execute their programs are interested in specific node attributes (subscriptions) defining for example acceptable CPU speed ranges, minimum memory requirements, desirable operating system versions, etc.

(iii) *Pub/sub and the Web*

The web is of course a massive distributed data repository. Web information systems can be significantly enriched by adopting pub/sub technology. Overlay networks can be created consisting of nodes representing web pages. A pub/sub system over this overlay network can be used, for instance, to inform existing web users of interesting new pages being created, of updates to pages already marked as relevant, etc.

(iv) *Bio-Informatics Applications*

In the area of bioinformatics research, one might imagine a network of research data bases, belonging to specific governmental or private, non-for-profit research institutions, storing results or matching protein sequences and specific sub-sequences. The publishers in this case are the institutions' researchers publishing specific findings and subscribers are researchers inquiring for specific sequences' matching, as defined in their subscriptions.

Experimental Results

Typically, all proposed research solutions are accompanied by independent experimental results. So far the community has not produced widely acceptable general benchmarks, standard data sets, and workloads.

Data Sets

As mentioned, there are no generally-agreed upon real data sets to be used for testing research and development results. Some appropriate data sets are available, however, for some champion pub/sub applications, such as those based on RSS feeds. One example is data made available by the New York Stock Exchange (NYSE) (http://www.nysedata.com/nysedata/default. aspx).

Synonyms

Distributed storage systems; Cooperative storage systems; Wide-area storage systems

Definition

Peer-to-peer (P2P) storage is a paradigm to leverage the combined storage capacity of a network of storage devices (peers) contributed typically by autonomous end-users as a common pool of storage space to store and share content, and is designed to provide persistence and availability of the stored content despite unreliability of the individual autonomous peers in a decentralized environment.

Historical Background

For diverse reasons including fault-tolerance, load-balance or response time, or geographic distribution of end users, distributed data stores have been around for a long while. This includes distributed databases, distributed file systems and *Usenet* servers among others. *Usenet* servers communicated among each other in a peer-to-peer manner, and replicated content.

While some redundancy is necessary for fault tolerance, replicating all content at all peers is a very special case of a peer-to-peer storage system, and is very inefficient. In general, an object is replicated at fewer locations. This leads to the problem of locating the object in the network. Plaxton et al's work on accessing nearby copies in a distributed environment [9] using key based routing is one of the seminal works, which subsequently influenced the design of many peer-to-peer storage systems. Advances in *structured overlay* networks address the problem of object location in a decentralized manner, that is "If an object is in the network, how to find it?" This is important in realizing an efficient decentralized peer-to-peer storage system.

Systems like *OceanStore* [7] aimed at archival storage, *Freenet* [3] for anonymous file sharing and distributed hash table based *DHash* storage layer of *CFS* [5] for a cooperative file system all store data at peers based on key associations determined by the structured overlay. These systems thus have the functionalities of object location and storage coupled together. However, note that locating and storing objects in a peer-to-peer system are in principle independent of each other. One can imagine the routing as a distributed index structure, which can store a pointer to the actual storage location, instead of the object itself. In the file sharing network *Napster*, the storage was peer-to-peer, however the indexing was in fact fully centralized, and very well illustrates the orthogonality of object location and storage issues. So in the rest of this entry the focus will be only on storage.

A critical requirement in a peer-to-peer storage system is to ensure that once a user (application) stores an object, this object should be available and persist in the network, notwithstanding the unreliability of individual peers and membership dynamics (churn) in the peer-to-peer network. This throws open a host of interesting design issues. For resilience, redundancy is essential. Redundancy can be achieved either by replication or using coding techniques, using schemes similar to the *RAID* technique [8]. While coding is in principle storage space efficient for achieving a certain level of resilience, it leads to various kinds of overheads, including computational overhead, and in the context of peer-to-peer systems, communication overhead and even storage overhead to keep track of encoded object fragments, thus making coding mechanisms worthwhile only for relatively larger or rarely accessed objects and applications like archival storage.

Redundancy is lost unless replenished because of departure of peers from the system. Trade-off considerations of redundancy maintenance effort and resilience led to the design of different maintenance strategies [2,6,10].

Note that file sharing systems – early ones like *Napster* and *Gnutella* as well as more recent ones like *Kazaa* and *BitTorrent* – also store and provide access to stored objects. However they are not reliable storage systems. In file sharing networks, users store locally only files they are interested in, and allow others to download the same. However there is no explicit intention to provide a highly available and persistent storage, and hence there are no mechanisms for redundancy management. The design of these systems is often focused on improving the efficiency of search and data transfer, while the content available in the network is considered ephemeral. Nevertheless, popular content may get so widely replicated that it is coincidentally (but not by design) always available.

Foundations

Distributed storage systems have traditionally been managed in a centralized manner, for instance in distributed databases and distributed file systems. The advent of decentralized file sharing networks demonstrated the potential as well as feasibility of decentralized peer-to-peer storage systems composed of autonomous peers. Peer-to-peer storage systems use the combined capacity of the peers to provide storage functionality to end users.

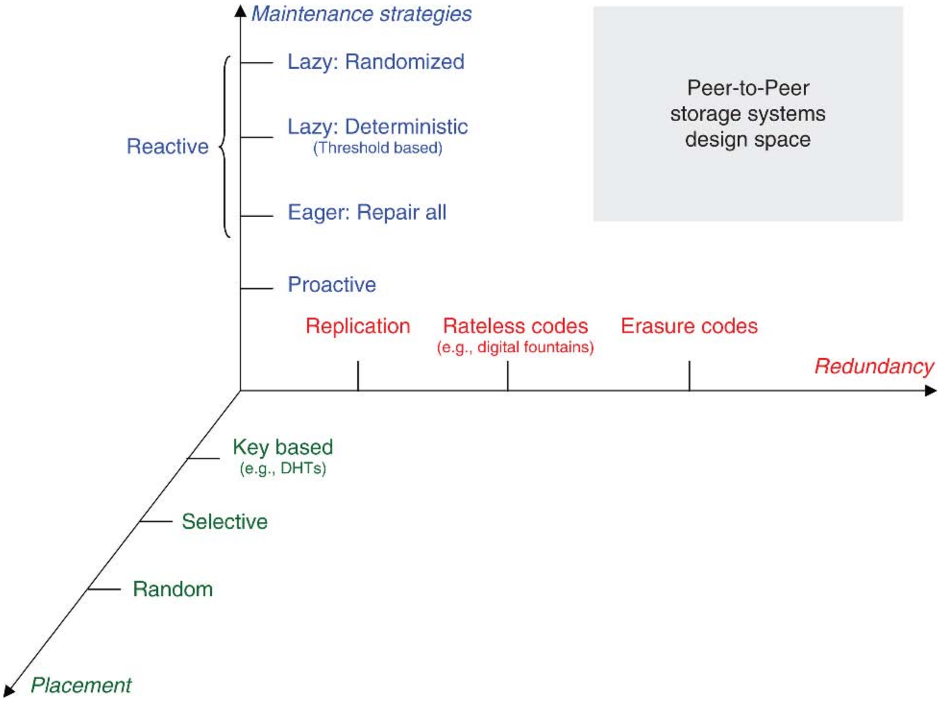
There are several reasons to have such a distributed storage. Multiple users may share and access some stored objects – data, files, etc. Individual users may not have the capacity to store all the objects they wish to access. Furthermore, by storing the same objects at other peers (and reciprocating by storing other users' objects), all peers benefit from an automatic back up service. Against these advantages, the main drawbacks include the unreliability of individual peers, who may leave and re-join autonomously, or even leave permanently, as well as transient communication failures, and delay in accessing objects stored only at a remote peer. Thus the main functionality of peer-to-peer storage systems is to make the distribution of stored objects transparent to the end users, even while users benefit from this distribution.

File sharing networks can be viewed as a special case of a peer-to-peer storage system. However they are not designed to guarantee availability or persistence of stored content, which are essential for a storage system. Resilience and performance in terms of access cost and latency pose some of the crucial challenges in realizing peer-to-peer storage systems.

Resilience of storage systems is measured in terms of two metrics - availability and durability (persistence). Availability of an object within a period of time is essentially the time averaged probability that it is accessible at any random time within that period of time. Durability of an object is the probability that it persists in the system indefinitely (or long enough, depending on the application requirements) under an assumption of a worst case failure scenario.

Consequently, crucial to peer-to-peer storage systems research are some of the following questions: What kind of redundancy is most efficient from various perspectives including storage overhead as well as access and maintenance costs and latency, and implementation complexity? What minimal redundancy is necessary to meet a desired level of resilience? Which maintenance strategy to apply to maintain the necessary redundancy? Which peers to store the redundant blocks in, based possibly on issues like reliability of individual peers, locality and load? The following delves into these. Figure 1 summarizes some of the important design factors.

In a decentralized setting, it is not only essential to ensure that stored objects stay available and persist over time despite changes in the network membership – churn – caused by peers leaving and (re-)joining the network, but also it is important to locate the stored objects efficiently. Some of the early storage systems like *OceanStore* [7] use one of the precursors [9] of contemporary structured overlays to locate objects. The basic idea is to assign to each peer an unique identifier, and also to each object an unique identifier from a same key-space, for instance using a hashing function. Objects are stored at peers which have identifiers closest to the object's identifier. When looking for an object, or the peer(s) at which an object is to be stored, the network of peers is typically searched in a greedy manner, by approaching peers with closer identifiers to the object's key, that is, using *key based routing*. Similar ideas are also used in *Freenet* [3], which aims at



Peer-to-Peer Storage. Figure 1. Some of the important design decisions that need to be taken into consideration when designing and deploying a peer-to-peer storage system.

providing anonymity to its users. Other subsequent storage systems have also followed this approach [5].

This traditional dual use of structured overlays for both routing (indexing) and storage tends to blur the difference between the two, and many people consider the structured overlay (e.g., distributed hash tables) to be the storage system also. In order to identify a full spectrum of design space of peer-to-peer storage systems it is crucial to understand that storage and indexing are actually two different but necessary ingredients for them. Combining these two sometimes simplifies the system architecture and implementation. However, the structured overlay may be used to store only pointers to the actual objects, which are placed using any independent criterion. One may also employ any other kind of directory (for example, *Napster* has a centralized directory) or indexing mechanism instead.

Resilience from Redundancy

Redundancy is essential to achieve resilience. Storage systems realize redundancy by using either replication or error correcting codes (e.g., erasure codes) as discussed next.

Replication Replication, i.e., mirroring, stores the same object on multiple nodes. It is normally efficient when the size of the object is small, or the object is frequently accessed. Note that a large object may still be split in multiple fragments, and each of these fragments will then be replicated.

Erasure codes Erasure codes are a class of error-correcting codes, which can transform a M-fragment object into N ($N > M$) encoded fragments, such that the original object can be reconstructed from any M *out of the N* encoded fragments. This typically leads to a storage overhead slightly more than N/M. The rate of erasure codes r is defined as the fraction of fragments required for decoding, i.e., $r = \frac{M}{N}$. Based on the coding rate, erasure codes can be categorized into two types, fixed-rate codes in which N is limited and r has a fixed value, and rateless codes (for example *Digital Fountains* [4]) in which N is potentially unlimited and r approaches zero (therefore called rateless).

Although replication is sometimes regarded as a special case of erasure codes, a subtle difference exists between them, which has its implications on the maintenance of redundancy. For replication, every reintegrated replica can enhance the object availability. In contrast, for a fixed-rate erasure code, if the reintegrated fragment is identical to one of the existing fragments, it does not improve the availability of the whole object. Even with *M* fragments, one may still not be able to reconstruct the original object, unless the fragments are distinct. The above problem does not occur for rateless codes, in which unique fragments are generated, and thus every reintegrated fragment is useful. In this aspect, replication is more similar to rateless codes, instead of fixed-rate codes.

When accessing an object, if it had been stored in coded fragments, enough fragments need to be accessed first, and then the object needs to be decoded, causing computational and possibly communication overheads. The benefit of coding is that for the same targeted resilience, using coding techniques drastically reduces the storage overhead, alternatively said, for same storage overhead, coding provides a much higher resilience. However, depending on the implementation details, using coding techniques may also lead to additional storage overheads to keep track of the encoded fragments. For frequently accessed objects or small objects, the overheads associated with coding may thus outweigh the benefits.

Because of these considerations, a rule of thumb is small or frequently accessed objects are typically replicated, while large or rarely accessed objects erasure coded. Another option is to use a hybrid approach [11]. Erasure coded fragments are used to achieve high persistence at a low storage overhead. Replication is used for performance.

Maintaining Redundancy

Individual peers may be occasionally unavailable because users go offline, machines fail, or the network gets disconnected. Typically, if there is sufficient redundancy, such *temporary churn* has marginal effect on the availability of a stored object. Furthermore temporary churn does not directly affect long term persistence, since the peers join back, bringing back in the network whatever is stored in them. However, over a period of time, some participating peers may leave the system permanently, in turn leading to permanent loss of redundancy. *Permanent churn* thus makes the system more vulnerable to temporary churn, and unless mitigated, leads to permanent loss of stored objects, thus adversely affecting persistence/durability. So while redundancy provides resilience against temporary churn, maintenance strategies are necessary to restore the lost redundancy and make the system resilient against permanent churn.

Henceforth both coded fragments or replicas will be referred as fragments. The simplest maintenance mechanism is to probe periodically all the peers which are supposed to store redundant fragments of an object, and whenever a probe fails, reactively replenish the redundancy be reintegrating a new suitable redundant fragment. Example storage systems employing this strategy include CFS [5]. This strategy is referred to as an *eager maintenance* strategy. Such an eager reactive (The simultaneous use of the adjectives eager and reactive is admittedly oxymoronic, and is a vestige of the historical development and nomenclature of various maintenance mechanisms.) maintenance mechanism means the system always operates in a state where redundancy level remains constant apart from temporary reduction between repair periods. It has been empirically observed [2] that eager (reactive) maintenance strategy is bandwidth expensive.

A periodic probing and reintegration of all unavailable fragments ignores the fact that many of the fragments are only temporarily unavailable, and will be restored back in the system automatically once the corresponding peers join back. Consequently, a lot of overhead in regenerating and transferring new redundant fragments is avoidable if only the system can wait long enough for some of the absent peers to rejoin. This observation is key to the design of the first lazy repair (reactive) strategy, used in the *TotalRecall* system [2]. All nodes are probed periodically, and repairs are initiated only when less than a certain threshold $T_a > M$ of nodes (and corresponding data) are available. Thus to say, when an object has no more than T_a fragments available in the system, then a repair process for the object is initiated so that at the end of the repair process all *N* fragments are again available. As long as an object has a redundancy more than the parameter T_a, there is no maintenance. This lazy maintenance mechanism saves overheads caused by transient failures. However if the redundancy reduces below this threshold, then it is considered imprudent to further delay repair operations. So once the threshold is breached for an object, *TotalRecall* regenerates all the corresponding unavailable fragments. Thus, this reactive lazy mechanism has a deterministic trigger for initiating repairs.

While saving on bandwidth in comparison to the above mentioned eager reactive maintenance strategy, the threshold based lazy repair strategy suffers from several undesirable effects. First of all, by waiting for the redundancy to fall below a threshold, the system is allowed to degenerate and become more susceptible as compared to other systems which have the same maximum redundancy N. Secondly, while most of the time this approach does not use the bandwidth even if it were available, once the threshold is breached, this approach tries to replenish all the missing fragments at once, thus causing bandwidth spikes. Finally, between the maintenance spikes, as redundancy falls, the available fragments are accessed more frequently, causing access load imbalance, particularly overloading the available peers. Two different works try to address these shortcomings.

A randomized variant of the lazy repair strategy [6] is to probe only a fraction of the stored fragments randomly (uniformly), until a minimal $T_b \geq M$ number of live fragments are detected. Thus a random number $T_b + X$ of probes (determined according to a probability distribution which in turn depends on the actual number of live fragments) will be required to locate T_b live fragments. Then X fragments which were detected to be unavailable are replaced by the system. The beauty of this randomized approach is that the expected value of X adapts with the number of live fragments. If there are fewer live fragments, then X will typically be large, and vice versa. Normally X can be typically much smaller than the total number of unavailable fragments at that instant. As a consequence, the repair process is continuous – thus available bandwidth is used more judiciously, avoiding spikes. The randomized repair process is naturally more aggressive when more redundant fragments are missing, while if very few fragments are missing then there are very few repairs.

While the randomized lazy repair strategy [6] tries to strike a balance between the periodic repair and the threshold based deterministic lazy repair strategies, and as a consequence the bandwidth usage is continuous and smoother, another independent approach [10] makes it an explicit goal to not exceed a bandwidth budget per unit time. Subject to the bandwidth budget per unit time it proactively creates new replicas. In contrast to the previously mentioned approaches all of which react to lost redundancy, the proactive approach does not aim to reduce overall bandwidth usage, but instead tries to ensure that by not exceeding the per unit time maintenance bandwidth budget, a better bandwidth provisioning can be achieved, and thus the maintenance operation does not interfere with applications. Another consequence of this approach is that typically enough redundancy is available to ensure equitable load distribution. However, a maximum redundancy threshold needs to be defined in using such a proactive replication approach to make a judicious use of the storage capacity.

Placement Strategies

A final system design issue is determining the placement strategy to be used to store the objects. One of the most widely used approach is to determine the placement of objects based on keys. In this scheme, all the peers as well as objects are assigned unique keys (e.g., by hashing), and then objects are stored at peers with closest or similar keys. The peers themselves communicate among each other by forming a structured overlay network, and messages are routed based on key similarity (key based routing). Such an object placement strategy can be seen in systems like *CFS* [5], *Oceanstore* [7], *Freenet* [3] and *Tempo* [10] to name a few. This approach essentially combines the storage of the object with the search mechanism.

Alternatively, object placement may be decoupled from the search mechanism, thus giving the systems designer, or even the applications using the storage system much more flexibility in choosing the storage location. This choice may be random (for example, in *TotalRecall* [2]), or based on reliability prediction derived from the history of peers' availability, or based on proximity (locality) from the end users accessing the object, load at peers, or other considerations like storing the object within a specific domain. Furthermore, this choice may be made by the peer-to-peer storage system designer or its administrator, or even independently by the applications and end users using the storage system.

Against this flexibility, the main disadvantage of decoupling storage from search is that one then needs some kind of directory service (potentially realized with a structured overlay) to perform the search functionality. The search provides pointer(s) to the stored object fragments. This creates additional storage and maintenance (of the pointers) overheads. Thus, in contrast to the key based storage approach, there is an additional level of indirection, and the storage system needs to explicitly keep track of any changes, including network level changes like change of peers' network address, unlike the structured overlay (key based storage) approach, where the structured overlay maintenance mechanism takes care of such changes and simplify storage systems design.

Analysis Techniques

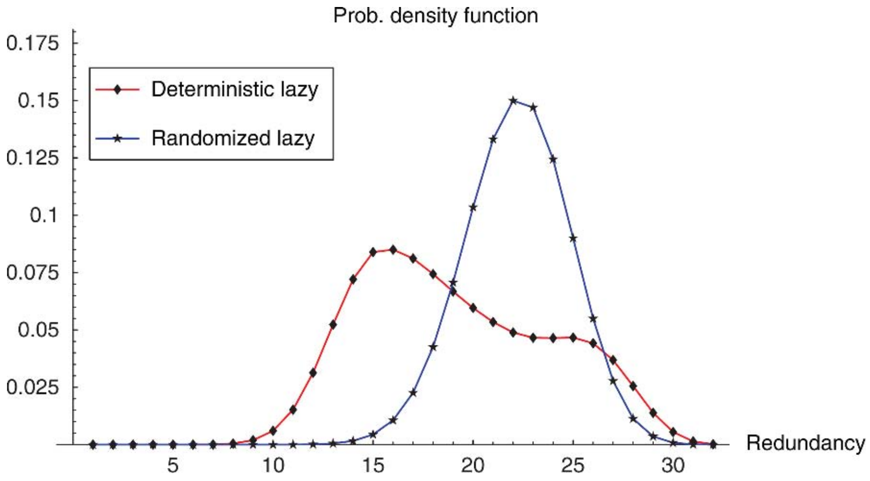
There are several approaches to analyze and study the behavior of peer-to-peer storage systems to better understand and refine its algorithms and design, make better parameter choices and validate its implementation.

Static resilience: Given a certain amount of redundancy, if a certain fraction of the peers are not accessible, either because they left the network, or the machines temporarily crashed, or because of communication problems, one can determine the probability that any specific object will become inaccessible or permanently lost. For example, for pure replication, if there are ρ replicas, and each peer storing a replica is available only p_{on} fraction of the time (randomly and independently from the other peers replicating the object), then the probability of the object becoming unavailable is $(1 - p_{on})^{\rho}$. Such a static resilience analysis gives a system designer a reference for determining an adequate redundancy to tolerate a certain degree of membership dynamics.

Time-evolution: Static resilience does not take into account the combined effect of membership dynamics, which leads to loss of redundancy over time, and repairing strategy, which regenerates redundancy, thus improving the health of the storage system. Given a particular level of network dynamics, the choice of maintenance strategy affects the resilience of the storage system, as well as the overheads incurred. A pragmatic system design thus needs to take into account the combined effect of individual peers' unreliability as well as the specifics of the deployed redundancy maintenance strategy.

Of particular interest is the actual probability distribution of object redundancy under the combined effect of churn and maintenance. This is in contrast to the maximum or average redundancy of objects in the system, based on which static resilience is typically estimated. Objects with smaller actual redundancy at a time instant are more vulnerable to become temporarily unavailable or even permanently lost. Also access to these corresponding objects causes higher load at the peers storing the object fragments or replicas. Finally, more effort and bandwidth is required to restore redundancy for the objects with fewer fragments, thus the maintenance operation witnesses spikes in bandwidth usage. The probability distribution provides a more fine-grained state of the storage system's health, by showing what fraction of all the stored objects are expected to have what level of actual redundancy. Such information can be obtained by studying the time evolution of storage systems [6,12].

For example, Fig. 2 shows the probability density function of the actual redundancy of objects when the



Peer-to-Peer Storage. Figure 2. A snapshot of the probability distribution of the available number of object fragments in the storage system when using (i) Deterministic lazy (reactive) maintenance, (ii) Randomized lazy (reactive) maintenance. An any *8 out-of 32* fragments (rate 0.25) erasure code was used to store the objects. Churn was simulated synthetically, such that online peers could go offline with a probability of 0.2 and offline peers could come back online with a probability of 0.1, such that on an average one third of the peers were online, i.e., $p_{on} = 1/3$. The thresholds T_a and T_b for the two variants of the lazy maintenance strategies were chosen such that the aggregate bandwidth usage for maintenance was the same in both experiments. This figure has been obtained from [6].

deterministic or the randomized lazy maintenance algorithms are used for an otherwise identical specific scenario, that is, same redundancy for objects, same churn level, and algorithm parameters chosen such that total bandwidth usage in both cases are comparable. There is a greater area under the curve corresponding to low redundancy if the deterministic lazy maintenance mechanism is used, in comparison to the case when the randomized variation is used.

Key Applications

Peer-to-peer storage systems have been used to realize traditional applications like file systems [2,5], backup [1] and archival storage [7]. A peer-to-peer backup system has several advantages in comparison to traditional offline backup systems based on secondary storage. It is easier to verify that the backup has indeed worked correctly (in comparison to physical medium like magnetic tapes), and backup as well as maintenance of the backed up data and its restoration whenever necessary can all be completely automated. Furthermore, peer-to-peer storage is not vulnerable to geographically localized catastrophes. This gives large corporations with geographically dispersed offices strong economic incentives to use their employees' desktop computers as a private corporate peer-to-peer storage infrastructure, instead of managing a separate secondary storage based backup. Similarly, individuals can back-up their data by relying on the resource pooled in a public peer-to-peer storage network.

Peer-to-peer storage systems also find use in web proxies for caching, content distribution and file sharing [3] applications. Peer data management systems too rely on an underlying reliable storage service.

Peer-to-Peer System

Wojciech Galuba, Sarunas Girdzijauskas
EPFL, Lausaune, Switzerland

Synonyms

Peer-to-peer network; peer-to-peer overlay

Definition

A peer-to-peer system is a computer network which enables peers to share the network resources, computational power and data storage, without relying on a central authority. Most commonly, peer-to-peer systems form *overlay networks* deployed in the Internet and are used for file sharing, realtime data streaming and computationally intensive tasks.

Key Points

In contrast to client-server systems, peer-to-peer systems consist of interconnected peers of similar capabilities and responsibilities, where the peers can act as both servers and clients. Most commonly, the architecture of the peer-to-peer systems is flat and all peers are assumed to be functionally equal. However, a number of peer-to-peer systems employ hierarchical architecture where some peers (superpeers) act as local servers for the subsets of regular peers. It is also widely accepted in peer-to-peer systems, where some services can be provided by a centralized component, in particular system bootstrapping, authentication etc.

Peer-to-peer systems are designed to be self-organizing and to scale well with the number of participating peers. Each peer contributes a different amount of resources and peer-to-peer systems employ various methods to distribute the load evenly across these resources. Good load balancing is crucial to the scalability of peer-to-peer systems. To account for frequent peer departures and arrivals and to maintain high availability peer-to-peer systems replicate the services and data across several peers for redundancy.

Peer-to-peer systems have a wide range of applications in such areas as the Internet infrastructure (e.g., DNS), file sharing (e.g., Kazaa [3]), communication and data streaming (e.g., Skype [4]), distributed computing (e.g., BOINC [1]), and can even make use of human presence at the participating peers (e.g., Galaxy Zoo project [2]). In addition, the decentralized nature of peer-to-peer systems allows the peer-to-peer applications to be highly resistant to censorship.

High robustness, scalability and lack of the single-point-of-failure make peer-to-peer systems a viable alternative to large client-server systems.

Peer-to-Peer Web Search

Gerhard Weikum
Max-Planck Institute for Informatics, Saarbrücken, Germany

Definition

The peer-to-peer (P2P) computing paradigm is an intriguing alternative to centralized search engines for querying and ranking Web content. In a P2P network with many thousands or millions of computers, every peer can have locally compiled content such as recently visited or thematically gathered Web pages, and can employ its own, potentially personalized search engine on the locally indexed data. In addition, queries can be forwarded to judiciously chosen other peers for collaborative evaluation. Such P2P architectures enable keyword search and result ranking on the network-wide global content. Thus, all peers together form a P2P search engine. Conversely, such P2P architectures could be utilized for scalable, distributed implementations of Web indexing with appropriate partitioning across the nodes of a large server farm.

Historical Background

Peer-to-peer (P2P) systems aim to provide scalable and self-organizing ways of loosely coupling thousands or millions of computers in order to jointly achieve some global functionality [14]. In the last decade, very successful systems of this kind have been built. Most notably, these include *file-sharing networks* such as Gnutella or BitTorrent, and IP telephony like Skype and other collaborative messaging services. They organize peers in so-called *overlay networks* on top of the standard Internet infrastructure, and use various forms of *epidemic dissemination* or distributed data structures like *distributed hash tables (DHTs)* such as Chord or Pastry. The basic functionality that underlies many of these systems is the distributed and dynamic maintenance of a dictionary with efficient support for exact-match key lookups.

Web search requires much richer functionality than exact-match lookups: keyword queries combine multiple dimensions of a very-high-dimensional data space in an ad hoc manner so that standard multi-dimensional indexes are not applicable, and they require ranking of query results based on statistics about local and global keyword frequencies. On the other hand, it seems very natural to build Web search in a P2P manner as the producers and owners of Web pages are widely distributed and autonomous. In fact, the standard approach of crawling the Web for centralized search engines can be seen as rather artificial, but has advantages regarding system management and commercial services such as query-related advertisements.

Approaches to P2P Web search are reminiscent of earlier work on *distributed information retrieval (IR)*, most notably, various kinds of *metasearch engines* where queries are routed to judiciously chosen search providers [15]. However, the P2P setting is much more challenging regarding the enormous scale of the underlying data sources, the dynamics of the system, and the autonomy of the individual peers.

Foundations

Peer-to-peer (P2P) Web search has been studied from two perspectives: *global computing (GC)* and *social computing (SC)*. The GC approaches consider peers that dedicate all their storage and computing resources to the P2P network. The network as a whole emulates a traditional search engine architecture by partitioning a global Web index and assigning partitions and query load to peers. The SC approaches, on the other hand, consider architectures where each peer corresponds to one user, and emphasizes the autonomy of peers, with every peer having full control over its local content and extent of sharing it with other peers. Both GC and SC can be embedded in a server-farm environment with a high-speed physical network or in a geographically distributed environment over the wide-area Internet.

P2P Global Computing for Scalable Search-Engine Functionality

For *indexing the Web*, commercial search engines use large data centers consisting of thousands of low-end computers, carefully designed parallelism and redundancy, and customized software with very low overhead [2]. The key technique to sustain a peak throughput of thousands of queries per second with sub-second response times is *data partitioning*. Index entries – postings that consist of a keyword id, a page id, and a score – are hashed on page id, and each resulting hash partition is assigned to one computer in a very large *cluster* (with hundreds or thousands of nodes). A query with one or more keywords is simply sent to all nodes for parallel evaluation. The load is perfectly balanced across the nodes of the cluster, so that the approach scales up extremely well. For failure resilience, high availability, and higher throughput, an entire cluster is often replicated sufficiently.

The above architecture is distributed, but it is not a P2P approach, for it assumes a fixed, reasonably time-invariant system configuration with a high-speed homogeneous network between nodes. If one tried to carry this design over to a setting with a dynamically varying number of peers that communicate over a high-latency wide-area network, the fine-grained parallelism would probably result in a poor cost/performance ratio. Thus, a geographically distributed architecture for Web indexing needs more sophisticated techniques and is still viewed as a research challenge, but promising work is on its way [1].

The current approaches differ in their ways of partitioning the data across peers, the overlay networks that are employed, their load balancing mechanisms, and their methods for caching and replication, which in turn influences query processing strategies. As for *data partitioning*, three common ways are: hash-partitioning on page ids (documents), hash-partitioning on keywords (terms), or thematic clustering based on page contents or query logs. *Load balancing* needs to counter skewed distributions of both index-list lengths and query popularities for different keywords; many techniques from the distributed computing literature are applicable. *Caching* can consider different granularities like index lists for individual keywords or entire query results, and needs to employ appropriate strategies for cache refreshing and replacement. Finally, efficient algorithms for *distributed top-k query processing* are called for.

P2P Social Computing with Autonomous Peers

In the SC line of work, an architecture is pursued where every peer has a powerful local search engine, with its own crawler, indexer, and query processor. Such a peer can compile its own content from thematically focused crawls and other sources, and make this content available in a P2P overlay network. Search requests issued by a peer can first be executed locally, on the peer's locally indexed content. When the recall of the local search result is unsatisfactory, the query can be forwarded to a small set of other peers that are expected to provide thematically relevant, high-quality and previously unseen results. Deciding on this set of target peers is the *query routing* problem in a P2P search network, also known as *collection selection*. Subsequently, the actual search on the chosen target peers requires efficient algorithms for *top-k query processing*. Search results are then returned by different peers and need to be meaningfully merged, which entails specific problems for *result ranking*. Both query routing and result ranking can build on various forms of *distributed statistics*, computed in a decentralized way and aggregated and disseminated in a scalable P2P manner (using compact synopses such as Bloom filters or hash sketches and leveraging the DHT infrastructure).

Query Routing

A practically viable query routing strategy needs to consider the similarity of peers in terms of their thematic profiles, the overlap of their contents, the potential relevance of a target peer's collection for the given query, and also the costs of network communication and peer-specific processing loads.

Traditionally, the most important measure for assessing the benefit of a candidate target peer for a given query is the estimated relevance of the peer's overall content for the query. This standard IR measure can be estimated frequency statistics over the query's keywords (terms in IR jargon). In conventional, document-oriented IR, these would be term frequencies (tf) within a document and the so-called inverse document frequencies (idf), the reciprocal of the global number of documents that contain a given term. In P2P IR, the estimation is based on the overall content of a peer as a whole. Instead of tf, the *document frequency (df)* of a peer is considered, which is the total number of documents that contain the term and are in the peer's collection; and instead of idf, the *inverse collection frequency (icf)* is considered, which is the reciprocal of the total number of peers that contain (at least one document with) the term. These basic measures are combined into a relevance or query-specific quality score for each candidate peer. There are various models for the combined scores; among the most cited and best performing models are *CORI* [4], based on probabilistic IR, and statistical language models adapted to the setting of P2P collection selection [9]. The Decision-Theoretic Framework (DTF) [11] provides a unified model for incorporating quality measures of this kind as well as various kinds of cost measures.

Selecting peers solely by query relevance, like CORI routing, potentially wastes resources when executing a query on multiple peers with highly overlapping contents. To counter this problem, methods for estimating the overlap of two peers' contents have been developed. These estimates are then factored into an *overlap-aware query routing* [10] method by using a weighted combination of peer quality and overlap (or novelty) as ranking and decision criterion.

Query routing decisions are typically made at query run-time, when the query is issued at some peer. But the above methods involve directory lookups, statistical computations, and multi-hop messages; so it is desirable to precompute preferred routing targets and amortize this information over many queries. A technique for doing this is to encode a similarity-based precomputed binary relation among peers into a *Semantic Overlay Network (SON)* [5]. The routing strategy would then select target peers only or preferably from the SON neighbors of the query initiator.

Search Result Ranking

When a query returns results that have been obtained from different peers, the scores that the peers assign to them are usually not comparable. The reason is that different peers may use different statistics, for example, for estimating the idf value of a term which is crucial for weighting the importance of different query terms, or they may even use completely different IR models. This situation leads to the problem of *result merging*. It is addressed by re-normalizing scores from different peers to make results meaningfully comparable [15]. A variety of such methods exist in the literature, some using only the peer-specific scores and some aggregated measures about peers (e.g., the total number of documents per peer), some using sampling-based techniques, and some using approaches that first reconstruct the necessary global statistics (e.g., global document frequencies for each term) for optimal re-normalization of scores.

Web search ranking usually also considers the query-independent authority of pages as derived from link analysis, and a P2P network is a natural habitat for such "social ratings". *Link analysis* algorithms such as PageRank are centralized algorithms with very high memory demand. Executing them in a distributed manner would allow scaling up to even larger link graphs, by utilizing the aggregated memory of a P2P system. Various decentralized methods have been developed to this end, including a general solution to the spectral analysis of graphs and matrices [8], which underlies the PageRank computation.

Most of these methods assume that the underlying Web graph can be nicely partitioned among peers. In contrast, a P2P system with autonomous peers faces a situation where the Web pages and links that are known to the individual peers are not necessarily disjoint. The JXP algorithm [12] computes global authority measures such as PageRank in a decentralized and scalable P2P manner, when the Web graph is spread across autonomous peers and peers' local graph fragments overlap arbitrarily, and peers are (a priori) unaware of other peers' fragments. The scores computed by JXP provably converge to the same values that would be obtained by a centralized PageRank computation on the full Web graph. These kinds of algorithms seem to be highly relevant also for analyzing authority and reputation measures in large-scale social networks.

Key Applications

The technology for P2P Web search has many potential applications, ranging from keyword search on the Web or in blogs, possibly in a personalized manner and exploiting social-network affinities among users, all the way to more "semantic" search capabilities in large enterprises, scholarly communities, federations of digital libraries, and distributed Internet archives. The latter may include searching XML, RDF, or multimedia data as well as providing temporal querying and other forms of enhanced search capabilities. With richer functionality, centralized systems face scalability bottlenecks, whereas decentralized approaches can leverage the fact that the underlying information is naturally distributed at a large scale.

Future Directions

Today, there is still no P2P Web search system that would scale anywhere near the sizes of the major commercial search engines. But as the Web continues to grow, search functionality is becoming richer (e.g., by personalization), and workloads are becoming much more demanding, the P2P paradigm is likely to gain more momentum for Web applications. Currently, there is a variety of research prototypes (e.g., [3,6,7,13]), including some that offer open-source software.

Performance Analysis of Transaction Processing Systems

ALEXANDER THOMASIAN
Thomasian and Associates, Pleasantville, NY, USA

Synonyms

Queueing analysis; Probabilistic analysis; Cache performance; Storage systems; Concurrency control

Definition

The performance of *transaction (txn) processing (TP)* systems and more generally *database management systems (DBMSs)* is measured on operational systems, prototypes, and benchmarks. Probabilistic and queueing analyses have been used to gain insight into TP system performance, but also to develop capacity planning tools. The following is considered: (i) queueing analysis of processors and disks, (ii) *queueing network models (QNMs)* of computer systems, (iii) techniques to estimate the database buffers miss rate, (iv) factors affecting RAID performance, (v) *concurrency control (CC)* methods for high data contention TP systems and their analyses.

Historical Background

Early performance studies of TP were concerned with processor or *central processing unit (CPU)* scheduling. *Queueing network models – QNMs* were developed in the 1970s to estimate delays at active computer system resources, i.e., CPU and disks. The effect of passive resources, such as the memory size constraint, was later incorporated into capacity planning tools for TP systems [5]. The *Transaction Processing Council's (TPC's)* debit–credit benchmark in 1985 compares the performance of TP systems using their throughput at which a certain txn response time is reached (http://www.tpc.org). Buffer/cache management policies in processors, databases, and disk controllers have been studied since the 1970s. Coherence issues of CPU caches in multiprocessors and database buffers in shared disk systems gained importance in 1980s. Magnetic disks invented in 1950s have a significantly improved capacity and transfer rate, but not random access time. This led to the proposal and analysis of numerous disk arm scheduling policies. The 1988 *Redundant Array of Independent Disks (RAID)* classification provided renewed impetus to improve the performance and reliability of storage systems [1]. Shared-everything, -disk, and -nothing computer organizations have limitations for high-performance TP and DBMS applications, i.e., the first two pose cache coherence problems and shared-nothing systems are susceptible to processing time skew. (For example, there is a twofold increase with exponentially distributed processing times at four nodes, since $\sum_{i=1}^{4} 1/i = 2.08$.) CC has limited effect on TP performance in modern DBMSs, but this was not so in early relational DBMSs with coarse granularity locking, therefore many CC methods were proposed and evaluated [10].

Foundations

CPU Scheduling. Processing of txns at the CPU has been modeled by an M/G/1 queueing model, which consists of a *First-Come, First-Served (FCFS)* queue and a single server [4]. M stands for Poisson arrivals with rate λ, G stands for a general service time distribution with $\overline{x^i}$ as the *i*th moment. The server utilization is $\rho = \lambda\overline{x} < 1$, the mean waiting time at the queue is $W_{M/G/1} = \lambda\overline{x^2}/(2(1-\rho))$, and the mean response time $R = W_{M/G/1} + \overline{x}$ [4]. M/M/1 is a special case of M/G/1 with an exponential service time distribution with $\overline{x^2} = 2(\overline{x})^2$, so that the mean of the exponentially distributed response time is $R_1 = \overline{x}/(1-\rho)$. M/M/m has m servers, hence $\rho = \lambda\overline{x}/m$. For $m = 2$ there is $R_2 = \overline{x}/(1-\rho^2)$ (for $m > 2$ see [4]). For a single-server which is twice as fast as the previous servers: $R_3 = (\overline{x}/2)/(1-\rho)$. The same ρ is maintained in the three systems with R_i, $1 \leq i \leq 3$, by setting the arrival rate to 2λ, but utilizing two M/M/1 queues with uniform routing in the first case, so that the total processing capacity is 2μ in all three cases. There is $R_1 > R_2 > R_3$, where the first inequality reflects the resource sharing advantage of a shared queue, while the second inequality reflects the advantage associated with a single fast server when service times are not highly variable [4]. For K fork-join requests initiated at K M/M/1 queues the expected value of the maximum of K response times is: $R_k^{max} = H_K R$, where $H_K = \sum_{k=1}^{K} 1/k$ is the Harmonic sum. The components of a fork-join request are correlated, so that $R_2^{F/J} < R_k^{max}$, e.g., $R_2^{F/J} = (1.5 - \rho/8)R < R_2^{max}$. An approximate expression for $R_k^{F/J}$ for $K > 2$ has been used in the analysis of RAID5 disk arrays. With two txn classes the response time for the more urgent (class 1) txns can be improved by processing them at a higher priority than less urgent (class 2) txns. The arrival rates are λ_1 and λ_2 and the *i*th moments of service time are $\overline{x_1^i}$ and $\overline{x_2^i}$, respectively. With preemptive priorities and a negligible preemption overhead, class 1 txns are processed without being affected by class 2 txns. With non-preemptive priorities $W_1 = W_0 / (1 - \rho_1)$ and $W_2 = W_0 / ((1 - \rho_1)(1 - \rho))$, where $\rho_j = \lambda_j\overline{x}_j$, $j = 1{,}2$ and $W_0 = \frac{1}{2}\sum_{j=1}^{2} \lambda_j\overline{x_j^2}$ is the remaining processing time of txns at the CPU [4]. Note that W_1 is only affected by ρ_1, but not $\rho = \rho_1 + \rho_2$. Kleinrock's *conservation law* states that the improvement in waiting time of one txn class is at the cost of the other, so that the weighted sum of waiting times remains constant: $\sum_{j=1}^{2} \rho_j W_j = W_0/(1-\rho)$. Preemptive (resp. non-preemptive) priorities are applicable to CPU (resp. disk) scheduling.

Queueing Network Models – QNMs

In *open QNMs* there are txn arrivals and departures, while in a *closed QNM* a completed txn is immediately replaced by a new txn, so that the number of txns remains fixed at N. Txns are processed at $K > 1$ nodes, where each node is a single or multiserver queueing system. The QNM of a computer system may be organized as the *Central Server Model (CSM)*, with the CPU the central server and the disks as peripheral servers. Txns arrive at the CPU (node 1), access one of the $K-1$ disks with probability p_k, $2 \le k \le K$, return to the CPU for additional processing, and leave the system after CPU processing with probability p_1, so that $\sum_{k=1}^{K} p_k = 1$. The transition probability matrix yields the mean number of visits to the nodes: i.e., $v_1 = 1/p_1$ and $v_k = p_k/p_1, 2 \le k \le K$. QNMs satisfying the BCMP theorem allow four types of nodes, most notably exponential service times at single- or multi-server queues with FCFS scheduling and nodes with an infinite number of servers [4,5]. The steady-state probability $Pr[n_1,n_2,...,n_K]$ in such QNMs can be expressed in product-form and their performance metrics computed efficiently. Approximation techniques or simulation can be applied otherwise.

The mean residence times at the nodes of an open product-form QNM can be obtained separately. With an external arrival rate Λ, the arrival rate to node k is $\lambda_k = v_k \Lambda$, its utilization $\rho_k = \lambda_k \overline{x}_k / m_k$, where $\overline{x}_k$ is its mean service time and m_k is the number of its servers. The service demand or the total txn processing time at a node k is given as $D_k = v_k \overline{x}_k$, $1 \le k \le K$, so that alternatively $\rho_k = \Lambda D_k$. The mean txn residence time at node k is $r_k = \overline{x}_k/(1-\rho_k^{m_k})$, $1 \le k \le K$ with $m_k \le 2$. The mean txn response time is $R = \sum_{j=1}^{K} v_k r_k$ and the mean number of txns at the system following Little's result is the product of the arrival rate and the mean response time: $\overline{N} = \Lambda R$ [4,5]. $\overline{N}$ can be used to estimate the degree of txn concurrency or *Multiprogramming Level (MPL)* and the memory size requirements for TP.

Closed QNMs can be analyzed via the convolution or the *mean value analysis – MVA* algorithm [4,5]. The MVA *arrival theorem* states that in a closed QNM with n txns the mean queue-length at node k at an arrival instant, is that of a closed system with $n-1$ txns, i.e., $A_k(n) = Q_k(n-1)$ [5]. The mean queue-length includes the request at the server, whose mean residual service time is the same as its service time due to the memoryless property of the exponential distribution: $\overline{x'}_k = \overline{x^2}_k/(2\overline{x}_k) = 2(\overline{x}_k)^2/(2\overline{x}_k) = \overline{x}_k$ [4]. The mean residence time at node k for v_k visits is $R_k(n) = v_k r_k(n) = v_k \overline{x}_k [1 + Q_k(n-1)] = D_k[1 + Q_k(n-1)]$.

MVA Algorithm for Closed QNM with Single Servers.

```
Input parameters: N (MPL), K (number of nodes), $D_k$, $1 \le k \le K$ (mean service demands).
for $k = 1$ to $K$ do $Q_k(0) = 0$ (initialize queuelengths at $n = 0$)
for $n = 1$ to $N$ do {(vary the number of txns)
for $k = 1$ to $K$ do {(vary the node index)
        if delay server $R_k(n) = D_k$ (no queueing at "infinite servers")
        if single server $R_k(n) = D_k[1 + Q_k(n-1)]$}
$R(N) = \sum_{k=1}^{K} R_k(n)$ (txn residence time)
$X(n) = n/R(n)$ (txn throughput using Little's result)
for $k = 1$ to $K$ do $Q_k(n) = X(n)R_k(n)$ (mean queue-length at the nodes, Little's result) }
```

The convolution algorithm applied to single-server queues computes $G(0 : N)$, after the initialization $G(0) = 1$ and $G(n) = 0$, $n \neq 0$, as: $G(n) = G(n) + D_k G(n-1)$, $1 \le n \le N$, $1 \le k \le K$, so that $X(N) = G(N-1)/G(N)$. Compared to MVA the order of the iterations on n and k are reversed. Given that $\sum_{k=1}^{K} D_k$ =constant, the throughput of a closed QNM is maximized when the service demands at all the nodes are equal. Due to symmetry $Q_k(N) = (N-1)/K$, so that $R(N) = KD(1 + (N-1)/K) = (N + K - 1)D$. Next, consider Poisson arrivals to a QNM with a maximum degree of concurrency M due to limited memory size. For $n < M$ arriving txns are activated immediately and otherwise enqueued at a FCFS memory queue. A hierarchical solution method is applicable in this case [5]. The lower level model yields the throughput characteristic of the closed QNM: $X(n)$, $1 \le n \le M$. Additional txns waiting in the memory queue do not contribute to throughput, so that $X(n) = X(M)$, $n > M$. A birth-death model is used at the higher level, with the state n denoting the number of txns at the system. The arrival rate at all states is Λ and the completion rate at state n is $X(n)$, $n \ge 1$. The probability that there are n txns in the system is: $P_n = \Lambda P_{n-1}/X(n)$, $n \ge 1$. The normalization condition $\sum_{n \ge 0} P_n = 1$ yields P_0 and hence $P_n, \forall n > 0$. The mean number of txns at the computer system, mean number of txns at the memory queue, and the mean number of activated txns is: $\overline{N} = \sum_{n>0} nP_n$, $\overline{N}_B = \sum_{n>M}(n-M)P_n$, and $\overline{N}_A = \sum_{n>0} min(n,M)P_n$. The mean txn response time, mean waiting time at the memory queue, and the mean residence time at the computer system are, respectively: $R = \overline{N}/\Lambda$, $W_M = \overline{N}_B/\Lambda$, and $R_A = \overline{N}_A/\Lambda$. $\overline{N} = \overline{N}_B + \overline{N}_A$, so $R = W_M + R_A$. The throughput characteristic $X(n)$, $n \geq 1$ vs. n (without an MPL constraint) is a convex function, which reaches an asymptotic value $min\{m_k/D_k, \forall k\}$. The node with the smallest throughput is the bottleneck resource, since it determines the maximum system throughput Λ_{max}. The throughput may drop due to thrashing in an overloaded virtual memory system [5] or due to excessive lock contention with the standard locking method.

Buffer Miss Rate (BMR)

BMR is applicable to the various levels of the memory hierarchy. Misses at the database buffer and disk controller cache result in disk accesses, which significantly degrade the performance of TP systems. BMR is affected by the buffer size, the replacement policy, and the workload. Analyses of replacement policies, such as FIFO, LRU, and CLOCK, using Markov chain modeling are based on the *Independent Reference Model (IRM)*. (http://www.informatik.uni-trier.de/~ley/db/dbimpl/buffer.html.) Data streams can also be characterized by stack depth and the hierarchical reuse or fractal models. Trace-driven simulation is a straightforward technique for evaluating the performance of buffer management policies, which can be used for calibrating empirical formulas. A recent top-down analysis derives an equation for the number of page faults (n) vs. memory size (M) [9]. M_0 and M^* are the min and max M that are sufficient and necessary. n^* is the number of cold memory misses, i.e., misses starting with an empty buffer. The parameters vary with program behavior and replacement policy.

$$n = \frac{1}{2}[H + \sqrt{H^2 - 4}](n^* + n_0) - n_0,$$
$$H = 1 + \frac{M^* - M_0}{M - M_0}, M \leq M^*.$$

Performance Analysis of Storage Systems

RAID performance is improved by striping and caching. Striping eliminates disk access skew by partitioning large datasets into fixed size *stripe units (SUs)*, which are allocated in round-robin manner across all disks [1]. The RAID controller cache complementing the database buffer in main memory is partially *nonvolatile storage (NVS)* and is used for *fast writes*, which are as reliable as writing to disk. Disk writes can be deferred and processed at a lower priority than reads, since read response times affect txn response time. Dirty data blocks in NVS are possibly overwritten several times, before they are destaged or written to disk. This eliminates unnecessary disk accesses. Applying disk scheduling to batched destaging of multiple blocks leads to higher disk access efficiency. Both effects can be captured by trace analysis [15].

RAID1 or disk mirroring, which predates the RAID classification, replicates data on two disks to achieve fault-tolerance. A data block can be read from either disk, but both copies should be eventually updated. Disk bandwidth can be saved by writing modified blocks to NVS first. The doubling of data access bandwidth is beneficial in view of increasing disk capacities, but an even further improvement in bandwidth can be attained by judicious routing of requests. When one of mirrored disks fails the read load on the surviving disk is doubled, but a smaller load increase can be attained with *interleaved declustering*, which replicates the contents of one disk on the other $n - 1$ disks of the cluster, so that the read load increase is $n/(n - 1)$ [13].

Erasure coding in RAID5 and RAID6 uses one and two check disks to protect against single and double disk failures, respectively [1]. RAID5 uses parity coding, so that the check SU is the *exclusive-OR (XOR)* of the remaining SUs in the same stripe or row. RAID6 uses Reed-Solomon or specialized parity codes to protect two disks out of N. The updating of a data block requires the corresponding check block(s) to be computed and updated. If the old copies of data and check blocks are not cached, four (resp. six) disk accesses are required for RAID5 (resp. RAID6), this is therefore referred to as the *small write penalty* [1]. Check SUs are placed in repeating left-to-right diagonals to balance the load for updating the check blocks. When one of the N disks fails, RAID5 continues its operation in degraded mode, by reconstructing missing blocks of the broken disk on demand as follows. The controller issues a fork-join request to the $N - 1$ corresponding blocks on surviving disks and these blocks are XORed to reconstruct the missing block. The read load on surviving disks is doubled, but the load increase for write requests is smaller. The *clustered RAID* paradigm reduces the disk load in degraded mode by using a parity group size $G < N$, so that the increase in read load is $\alpha = (G-1)/(N-1) < 1$ [1]. The RAID5 rebuild process reconstructs the contents of a failed disk track-by-track on a spare disk, by reading successive tracks from surviving disks, XORing all corresponding tracks to reconstruct a missing track, and writing it on the spare disk [15]. Distributed sparing distributes the spare areas among $N + 1$ disks. so that the bandwidth of the spare disk is not wasted [15]. The *vacationing server method (VSM)* starts reading tracks from disks when they become idle, so the rebuild process does not affect the disk load. No new tracks are read after there is an external arrival, but the reading of the current track is completed. The increase in mean disk waiting time over M/G/1 is the mean residual time to read a track: $W_{VSM} = W_{M/G/1} + \overline{x'}_{track}$ [4]. RAID6 deals with the possibility of unsuccessful rebuild, when unreadable sectors or *latent sector failures – LSFs* are encountered during the rebuild process or to cope with rare two disk failures.

Mean disk response time with FCFS disk scheduling can be obtained using the M/G/1 queuing model [4]. Random disk accesses incur a seek, latency or rotational delay (half a rotation time for small blocks), and transfer time (negligible for small blocks). One has $x_{disk} = x_{seek} + x_{latency} + x_{xfer}$. The moments of disk access time can be obtained under various assumptions, e.g., all disk cylinders are accessed uniformly. A significant reduction in disk response time is possible via the *Shortest Access Time First (SATF)* policy [14]. Given n random disk requests, the disk access time drops as $n^{1/5}$, e.g., $n = 32$ halves the access time with respect to FCFS.

Performance Analysis of Concurrency Control Methods

Performance degradation due to CC is in the form of txn blocking and restarts. The *standard locking* method is based on the strict *two-phase locking (2PL)* method [3], i.e., locks are requested on demand and held to completion, at which point the txn commits, releasing all of its locks. Locks are also released when a txn is aborted to resolve deadlocks or other reasons [3]. Restart-oriented locking methods and *optimistic CC (OCC)* methods are also discussed.

Standard Locking

Consider an abstract model of standard locking [12]. There are M txns in a closed system. A txn of size k has $k + 1$ steps with mean duration s, so that the mean txn residence time with no lock contention is: $r_k = (k + 1)s$. A lock is requested at the end of the first k steps and all locks are released at the end of the k + 1st step, i.e., strict 2PL, so that lock requests are uniformly distributed over the lifetime of a txn. The mean number of locks held by a txn is the ratio of the time–space of the number of locks held by a txn and r_k, which is an approximation to R_k at lower levels of lock contention, which yields: $\overline{L}_k \approx k/2$. Assuming that all lock requests are exclusive and are uniformly distributed over the D objects in the database, the probability of lock conflict is: $P_c(k) \approx (M-1)\overline{L}_k/D$. When the fraction of shared lock requests is f_S, the analysis can proceed as if all the lock requests are exclusive with an effective database size $D_{eff} = D/(1 - f_S^2)$ [8]. The probability that a txn encounters a lock conflict for $P_c(k) \ll 1$ can be used to obtain the probability of a two-way deadlock [3]:

$$P_w(k) = 1 - (1 - P_c(k))^k \approx kP_c(k) \approx \frac{(M-1)k^2}{2D}.$$

$$\begin{aligned} P_{D(2)}(k) &= \frac{1}{M-1} Pr[T_1 \rightarrow T_2] Pr[T_2 \rightarrow T_1] \\ &= \frac{(P_w(k))^2}{M-1} \approx \frac{(M-1)k^4}{4D^2}. \end{aligned}$$

A two-way deadlock can only occur if txn T_A requests a lock held by txn T_B, which is blocked because of its previous lock conflict with T_A. Multiway deadlocks are much less common and are ignored [3]. We obtain the mean blocking delay of a txn with respect to an active txn holding the requested lock ($W_k^{(1)}$) by noting that the probability of lock conflict increases with the number of locks held by the txn (j) and that there are ($k - j$) remaining steps each with mean duration ($s + u$) [10,11]:

$$\begin{aligned} W_k^{(1)} &\approx \sum_{j=1}^{k} \frac{2j}{k(k+1)} [(k-j)(s+u)] \\ &\quad + s' = \frac{k-1}{3}[r+u] + s'. \end{aligned}$$

$u = P_c(k)W_k$ is the mean blocking time per step, where W_k is the mean waiting time per lock conflict, and s' is the remaining processing time of a step. Since deadlocks are rare, the mean txn response time only takes into account txn blocking time due to lock conflicts: $R_k \approx (k + 1)s + kP_c(k)W_k$. The fraction of txn blocking time per lock conflict with an active txn is $A = W_k^{(1)}/R_k \approx 1/3$. A more accurate expression for two-way deadlocks as verified by simulation is: $P'_{D(2)}(k) \approx AP_{D(2)}(k) = P_{D(2)}(k)/3$ [16]. Next consider K txn classes in a closed system, so that a completed txn is replaced by a class k txn with frequency $f_k, \sum_{k=1}^{K} f_k = 1$. The mean response time over all txn classes is: $R = (K_1 + 1)s + K_1 P_c W$, where $K_i = \sum_{k \geq 0} k^i f_i$ is the ith moment of txn size. The mean number of txns in class k is $\overline{M}_k = MR_k f_k / R$ (the summation $\sum_{k=1}^{K}$ yields M on both sides). Given that $\overline{M}_k = M(k+1) f_k / (K_1 + 1) \approx M k f_k / K_1$, the mean number of locks held per txn is then:

$$\overline{L} = \frac{1}{M} \sum_{k=1}^{K} \overline{L}_k \overline{M}_k \approx \frac{1}{M} \sum_{k=1}^{K} \frac{k}{2} \overline{M}_k$$
$$\approx \frac{1}{2K_1} \sum_{k=1}^{K} k^2 f_k = \frac{K_2}{2K_1}.$$

Similarly to fixed size txns $P_c \approx (M-1)\overline{L}/D$ and the expression for $P_{D(2)}$ is given in [16,12]. Both P_c and $P_{D(2)}$ are affected by the variability of txn sizes, e.g., for a truncated geometric distribution there is a twofold and tenfold increase with respect to fixed txn sizes, respectively [16]. W_1 for variable txn sizes can be obtained as the expected value of $W_1(k)$ over all txn sizes. The normalized value for W_1 is [10,11]:

$$A = \frac{W_1}{R} \approx \frac{K_3 - K_1}{3K_1(K_2 + K_1)}.$$

Denote the fraction of blocked txns with β and ignore the difference in the number of locks held by active and blocked txns. The probability that a txn has a lock conflict with an active txn at level $i = 0$ (resp. has a lock conflict with a txn blocked at level $i = 1$) is $1 - \beta$ (resp. β) and the mean blocking time is W_1 (resp. $W_2 = 1.5 W_1$). The expression for W_2 relies on the fact that at the random instant when the lock conflict occurs the active txn in the waits-for-graph is halfway to its completion. Generally, the probability that a txn is blocked at level i is: $P_b(i) \approx \beta^{i-1}, i > 1$ and $P_b(1) = 1 - \beta - \beta^2 - \beta^3 \ldots$. The mean waiting time at level $i > 1$ is $W_i \approx (i - 0.5) W_1$, which is motivated by the expression for W_2. The mean blocking time is a weighted sum of delays incurred by txns blocked at different levels:

$$W = \sum_{i \geq 1} P_b(i) W_i = W_1 [1 - \sum_{i \geq 1} \beta^i + \sum_{i > 1} (i - 0.5) \beta^{i-1}].$$

Let $\overline{M}_A$ and $\overline{M}_B$ denote the mean number of active and blocked txns, so that $\overline{M}_A + \overline{M}_B = M$. The fraction of blocked txns is $\beta = \overline{M}_B / M$. Dividing $\overline{M}_B$ and M by the system throughput yields $\beta = K_1 P_c W/R$. Multiplying both sides of the above equation by $K_1 P_c / R$ yields β on the left hand side and $\alpha = K_1 P_c W_1 / R = AK_1 P_c$ on the right hand side. Note that α is the product of the mean number of lock conflicts per txn and the normalized waiting time with respect to active txns. It follows: $\beta = \alpha(1 + 0.5\beta + 1.5\beta^2 + 2.5\beta^3 + \ldots)$. A closed-form expression for β can be obtained by noting that $\beta < 1$ and assuming that the series is infinite:

$$f(\beta) = \beta^3 - (1.5\alpha + 2)\beta^2 + (1.5\alpha + 1)\beta - \alpha = 0.$$

Plotting $f(\beta)$ vs. β it is observed that the cubic equation has three roots $0 \leq \beta_1 < \beta_2 \leq 1$ and $\beta_3 \geq 1$ for $\alpha \leq \alpha^* = 0.226$, which makes its discriminant $f(\alpha) = \alpha^3 + \frac{4}{5}\alpha^2 + \frac{28}{15}\alpha - \frac{64}{135} < 0$ (http://en.wikipedia.org/wiki/Cubic_equation.), and a single root $\beta_3 > 1$ for $\alpha > \alpha^*$. *The single parameter α determines the level of lock contention for the standard locking and its critical value α^* determines the onset of thrashing*. The smallest root β_1 for $\alpha \leq \alpha^*$ determines $\overline{M}_A = M(1 - \beta_1)$, which increases with M, but drops after a maximum value is achieved. This is because of a snowball effect that blocked txns cause further txn blocking. Given the throughput characteristic $X(n)$, $n \geq 1$ with no lock contention, the throughput of a TP system when $\overline{M}_A$ is non-integer is: $X(\overline{M}_A) = (\lceil \overline{M}_A \rceil - \overline{M}_A) \quad X(\lfloor \overline{M}_A \rfloor) + (\overline{M}_A - \lfloor \overline{M}_A \rfloor) X(\lceil \overline{M}_A \rceil)$. The analysis for txns with variable step durations uses iteration to estimate ρ, which is the ratio of the number locks held by blocked and active txns. It is shown in [12] that the critical value of ρ matches the *conflict ratio* parameter in [17], which is the ratio of the number of locks held by all and active txns.

Restart-Oriented Locking Methods

Performance degradation in standard locking is mainly caused by txn blocking. Txn aborts and restarts to resolve deadlocks have little effect on performance, because deadlocks are rare. Restart-oriented locking methods follow the strict 2PL paradigm, but txns encountering lock conflicts are restarted to increase the degree of txn concurrency, so that a higher txn throughput can be attained. This is beneficial for high lock contention TP systems with excess processing capacity, but in hardware resource bound systems this may result in performance degradation with respect to standard locking. Since active txns are not guaranteed to complete successfully and commit, txn throughput cannot be expressed as $X(\overline{M}_A)$, as in the case of standard locking. The *Running Priority* (RP) method aborts txn T_B in the waits-for-graph $T_A \rightarrow T_B \rightarrow T_C$, when T_A has a lock conflict with T_B [2]. Similarly T_B which is already blocking T_A is aborted when it is blocked requesting a lock held by T_C. In effect RP increases the degree of txn concurrency even if the restart of an aborted txn is delayed. The no-waiting [8] and cautious waiting methods abort and restart a txn encountering a lock conflict with an active and blocked txn, respectively. There is no benefit, since the restarted txn will encounter the same lock conflict as before. The *Wait Depth Limited* (WDL) method measures txn progress by its length (L), which in [2] is approximated by the number of locks that it holds in a lock contention bound system, while attained CPU time would be a concern otherwise. WDL differs from RP in that it attempts to minimize wasted processing by not restarting txns holding many locks or txns nearing completion. This requires a priori knowledge of txn's locking requirements. For example, if T_A which is blocking another txn has a lock conflict with T_B, then if $L(T_A) < L(T_B)$ then abort T_A, else abort T_B [2]. The superior performance of WDL over RP and especially standard locking has been shown via random-number-driven (Monte-Carlo) simulation in [2], but also trace-driven simulation in [17]. RP and WDL attempt to attain *essential blocking*, i.e., allowing a txn to be blocked only by active txns and not requesting a lock until it is required. Immediately restarting an aborted txn may result in *cyclic restarts* or *livelocks*, which should be prevented to reduce wasted processing and to ensure timely txn completion. *Restart waiting* delays the restart of an aborted txn until *all* conflicting txns are completed [2]. Conflict avoidance delays with random duration are a less reliable method to prevent cyclic restarts.

Restart-oriented methods are analyzed using a Markov chain model in [11], while flow-diagrams are utilized in the analysis of the no-waiting method in [8]. Active (resp. blocked) states correspond to S_{2j}, $0 \leq j \leq k$ (resp. S_{2j+1}, $0 \leq j \leq k-1$). For example, in the case of the no-waiting policy there is a transition forward when there is no lock conflict: $S_{2j} \rightarrow S_{2j+2}$, $0 \leq j \leq k-1$, otherwise the txn is aborted: $S_{2j} \rightarrow S_0$. The state equilibrium equations for the Markov chain yield the steady-state probabilities π_i, $0 \leq i \leq 2k$. The mean number of visits v_i to S_i can be similarly obtained by noting that $v_{2k} = 1$, which is the state at which the txn commits. Given that h_i denotes the mean holding time at S_i, then $\pi_i = v_i h_i / \sum_{j=0}^{2k} v_j h_j$, $0 \leq i \leq 2k$. The mean number of txn restarts is given by $v_0 - 1$. A shortcoming of the analytic approach is that requested locks are implicitly resampled.

Optimistic Concurrency Control

A txn starting its execution first copies all objects required for its processing into its private workspace [6]. To ensure serializability after completing its processing, the txn undergoes validation to ascertain that none of the copied objects was modified by another txn after it was read. If validation is successful the txn commits and otherwise it is immediately restarted. Given that the k objects updated by txns are uniformly distributed over a database of size D, the probability of data conflict between two txns of size k is: $\psi = 1 - (1 - k/D)^k \approx k^2/D$. The completion rate of successfully validated txns is $p\mu s(M)$, where p is the probability of successful validation, μ is the completion rate of txns, and $s(M)$ takes into account the hardware resource contention due to multiprogramming. A txn with processing time x will require $xM/s(M)$ time units to complete. It observes the commits of other txns as a Poisson process with rate $\lambda = (1 - 1/M)p\mu s(M)$. Txns encountering data conflict with rate $\gamma = \lambda\psi$, fail their validation with probability $q = 1 - e^{-\gamma xM/s(M)}$. The number of txn executions in the system follows a geometric distribution $P_j = q(1-q)^{j-1}$, $j \geq 1$ with a mean $\overline{J} = 1/q = e^{\gamma xM/s(M)}$. The system efficiency p can be expressed as the ratio of the mean execution time of a txn without and with data contention, i.e., with the possibility of restarts due to failed validation:

$$p = \frac{E[xM/s(M)]}{E[(xM/s(M))e^{\gamma xM/s(M)}]} = \frac{\int_0^\infty xe^{-\mu x}dx}{\int_0^\infty xe^{(\gamma M/s(M)-\mu)x}dx}$$
$$= [1-(M-1)\psi p)]^2.$$

The equation yields one acceptable root $p = [1+2(M-1)\psi - \sqrt{1+4(M-1)\psi}]/[2(M-1)^2\psi^2] < 1$, provided $\gamma M/s(M) < \mu$ and the integral in the denominator converges. The txn execution time is not resampled in this analysis, because resampling processing times results in a mix of completed txns which is shorter than original. Shorter txns have a higher probability of successful validation and resampling results in overestimating performance. This analysis in [6] is that of the OCC *silent* [7] or *die* method [2], which is inefficient in that a conflicted txn is allowed to execute to the end, at which point it is restarted. The analysis in [6] also considers *static* data access, i.e., all objects are accessed at the beginning of execution, while *dynamic* or *on-demand* data access is more realistic. The OCC *broadcast* or *kill* method aborts a txn as soon as a conflict is detected. The analysis of the static/silent method in [6] is extended to the other three cases in [7]. The distribution of txn processing time affects performance and in a system with multiple txn sizes the wasted processing is mainly due to lengthy txns [7]. This is due the *quadratic effect* that the probability that a txn encounters a data conflict increases with the number of objects it accesses (k) and its processing time, which is also proportional to k [2]. While the optimistic die method seems to be less efficient than the optimistic kill method, this is not the case when due to buffer misses txns make disk accesses. It is advantageous then to allow a conflicted txn to run to its completion to prime the database buffer with all the objects required for its re-execution in a second processing phase. In *two-phase processing* txns in the second execution phase have a much shorter processing time, since disk accesses are not required, provided *access invariance* prevails, i.e., a restarted txn accesses the same set of objects as it did in its first execution phase [2]. The second execution phase may use the optimistic kill method or even lock preclaiming which ensures that the txn will not be restarted. In general we have multiphase processing methods with different CC methods with increasing strengths, e.g., locking vs. OCC. WDL and RP restart-oriented locking methods outperform two-phase methods [2]. The analysis in [7] can be extended to take into account the variability in txn processing times and the use of different CC methods across txn phases.

Conclusion

There is a need for methodologies combining analytic models, simulation, and trace analysis to explore the effectiveness of new computer organizations for TP, since it is expensive to build realistic prototypes for experimentation. An abstract model of a standard locking system is analyzed here to provide an understanding of the thrashing phenomenon in standard locking. It is shown that a single parameter α determines the level of lock contention with a critical value, which determines the onset of thrashing. Restart-oriented locking methods selectively abort txns to increase the degree of txn concurrency and reduce the level of lock contention, by disallowing txns to wait for the completion of already blocked txns. Two-phase processing methods reduce the data contention level in TP systems with access invariance, by lowering the holding time of database objects. Both methods require excess processing capacity to cope with the additional processing when txns are restarted.

Performance Monitoring Tools

Philippe Bonnet[1], Dennis Shasha[2]
[1]University of Copenhagen, Copenhagen, Denmark
[2]New York University, New York, NY, USA

Definition

Performance monitoring tools denote the utilities and programs that give access to database server internals.

Historical Background

Relational database systems have had to prove their performance from the outset [1]. Tools to measure their performance have therefore been present in early versions of most major systems.

Foundations

Performance Monitoring tools are useful in finding out how queries are being serviced, and how the underlying resources are being used. In this entry, the characteristics of the most relevant types of tools are described.

Event Monitor

Event monitors capture the aggregate resources associated to a given event (e.g., query execution, deadlock, session) and report the collected data when the event completes. Event monitors should have low overhead as the collected data is usually accumulated in performance counters that are updated as a side effect of the operations monitored (e.g., CPU usage, IO issued, locks collected during query execution) and only accessed once the event has completed.

Event monitors are useful to identify the queries that consume most resources and should require the attention of the database tuner.

Query Plan Explainer

Query plan explainers display the execution plan chosen by the query optimizer for a given query. Explainers represent a query plan, either in textual form or graphically, as a tree whose leaves are base tables and internal nodes are access methods and relational operators. The nodes are possibly annotated with relevant properties (e.g., cardinality, estimated cost).

Query plan explainers are useful to check that the optimizer relies on updated statistics to generate a query execution plan, to check that indexes are used as intended, or to find out whether costly operators are inserted against the programmer's better judgment.

Profiler

There are two types of profilers:

1. Time-based profilers address the question: *how is the time spent*? A time-based profiler logs the time spent in the different components of the database system and presents the time spent processing as well as the time spent waiting for resources.
2. Counter-based profilers address the question: *how are resources used*? A counter-based profiler uses counters to monitor the resources used during execution and presents either database-wide or system-wide aggregate counters.

Profilers might incur high running cost because of the overhead of logging a potentially large number of actions. Profilers are most useful to understand the behavior of critical queries.

Key Applications

Database management system developers need performance monitoring tools to make sure that their system is performing well. Database administrators need performance monitoring tools to make sure that their database instance is performing as well as possible.

Period-Stamped Temporal Models

NIKOS A. LORENTZOS
Agricultural University of Athens, Athens, Greece

Synonyms

Interval-based temporal models

Definition

A period-stamped temporal model is a *temporal data model* for the management of data in which time has the form of a *time period*.

Historical Background

There are applications that require the recording and management not only of data but also of the time during which this data is valid (*valid time*). A typical example is the data maintained by pension and life insurance organizations in order to determine the benefits for which a person qualifies. Similarly, such organizations have to record their financial obligations at various times in the future.

There are also sensitive applications, in which it is important to record not only the data but also the time at which this data was either recorded in the database or deleted or updated (*transaction time*). This time is recorded automatically by the Database Management System (DBMS) and it cannot be modified by the user.

Finally, there are applications in which both data, valid time, and transaction time need be recorded.

A data model for the management of data and also of either valid time or transaction time is a *temporal data model*. If time has the form of a *time period* the model is a *period-stamped data model*.

In the case of the relational model, data and time are recorded in a relation. A relation to record data and valid time is a *valid time* relation. A relation to record data and transaction time is a *transaction time* relation. Finally, a relation to record data, valid time and transaction time is a *bitemporal relation*.

In spite of the interest for the management of temporal data, there are many practical problems, which cannot be supported directly by the use of a conventional DBMS. As a consequence, much programming is required in order to support such applications. Hence, the satisfaction of actual user requirements necessitated the definition of a period-stamped temporal model. The bulk of research, on the definition of such a model, appeared in the 1980's, at a time when computers became powerful enough to process large volumes of data.

Foundations

Problems related to the management of temporal data are depicted next. The illustration is restricted to the relational model, in particular to the management of valid time relations. Note, however, that relevant problems can be identified in the management of transaction time relations whereas the management of bitermporal relations is much more complicated.

Examples Illustrating Inadequacy of Conventional Models to Support Time Period

Figure 1 shows SALARY, a valid time relation that records salary histories. The notation "d_number," for values recorded in attributes Begin and End,

Salary

Name	Amount	Begin	End
Alex	100	d100	d299
Alex	150	d300	d499
Alex	150	d800	d999
John	100	d200	d899

Period-Stamped Temporal Models. Figure 1. Example of a valid time relation.

represents a point in time, which is of a date-time data type. For example, d100 could represent "January 1, 2007." The interpretation of the first tuple is that Alex earned 100 on each of the dates in the *time period* [d100, d299], i.e., on each of the dates d100, d101,..., d299. Then the amount earned was 150 for each of the dates in [d300, d499].

Contrary to the simple representation of a valid time relation, a conventional DBMS lacks the functionality required for the management of such relations. This is illustrated below by a number of examples.

Data insertion: If the tuple (Alex, 150, d400, d799) is inserted into SALARY, it will be recorded in addition to the other tuples. In this case, however, SALARY will contain duplicate data for Alex's payment on the dates d400, d401,...,d499, since this data is already recorded in the second tuple of the relation. Moreover, the query, to return *the time at which Alex's salary became 150*, if not formulated carefully, will return three dates, d300, d400 and d800 whereas the correct answer should be d300. To avoid such problems, it would be appropriate for the newly inserted tuple to be combined with the second and third tuple for Alex into a single one, (Alex, 150, d300, d999), i.e., tuples with identical data for attributes Name and Amount (*value equivalence*), which have either *overlapping* or *adjacent* time periods, to coalesce into a single time period (*temporal coalescing*).

Key: Declaring the primary key of SALARY, to be a multi-attribute key of Name and Amount, will not disallow the recording of the tuple (Alex, 200, d400, d799). As a result, SALARY will contain conflicting data, since its second tuple will be showing that Alex's payment is 150 for each of the dates d400, d401,...,d499 whereas, from the newly inserted tuple, it will also be shown that, for these dates, this payment is 200. Hence, in the case of a conventional DBMS, special integrity constraints have to be defined for every relation like SALARY.

Data deletion: Assuming that John's payment for the dates d400, d401,...,d799 was recorded by mistake and has to be deleted, the last tuple of SALARY has to be replaced by two tuples, (John, 100, d200, d399) and (John, 100, d800, d899).

Data update: Assuming that John's payment for dates d400, d401,...,d799 has to be corrected to be 150, the last tuple of SALARY has to be replaced by three tuples, (John, 100, d200, d399), (John, 150, d400, d799) and (John, 100, d800, d899).

Data projection: The query "*for every employee, list the time during which he is paid*," requires a projection on attributes Name, Begin, End. This will generate four tuples. In practice, however, a *temporal coalescing* of the time periods recorded in SALARY is also required in order to obtain the correct result, consisting of only three tuples, (Alex, d100, d499), (Alex, d800, d999) and (John, d200, d899).

Since a conventional DBMS lacks the functionality illustrated above, special code has to be written to handle correctly all the cases described. This limitation gave rise to research on the definition of a temporal data model. Many of the research efforts led to proposals for the definition of various period-stamped data models.

Common Characteristics of Period-Stamped Data Models

The majority of researchers adopted the principle that a temporal data model should be a minimal extension of the conventional relational data model. The most common characteristics of these approaches are outlined below.

A period-stamped, valid time relation always has two types of attributes: The first type consists of one or more ordinary attributes of a conventional relation. These attributes are termed *explicit* by some authors. Valid time itself is not considered to be data, it is considered as being *orthogonal* to data. Hence, the second type consists of special attributes to record valid time. These attributes are often termed *implicit* and can be system-assigned by default. Some approaches consider one pair of such attributes, to record the Begin and End of valid time periods. The valid time recorded in them is usually assumed to represent a time period of the form [Begin, End], i.e., an interval closed on both sides. It is said that the data recorded in the explicit attributes is *stamped* by the time recorded in the implicit attributes.

According to the concepts discussed above, the explicit attributes of the relation in Fig. 1 are Name and Amount and the implicit attributes are Begin and End. The first tuple of the relation is (Alex, 100) and it is *stamped* by the time period [d100, d299].

Some approaches define a *time period* data type; therefore they consider only one implicit attribute. In such approaches, the equivalent scheme for the relation in Fig. 1 is SALARY (Name, Amount, Period).

Since valid time is not considered to be data, it cannot be part of the primary key of a relation. Hence, Name is designated as the primary key of SALARY, i.e., it matches the primary key of an ordinary relation.

In all the approaches, valid time is considered to be discrete. Hence, the time period [d100, d299] is interpreted as consisting of the dates d100, d101,...,d299. Various *temporal granularities* can be declared by the user, depending on the application.

Temporal Algebras, *Temporal Query Languages* or Temporal Calculi are proposed in various approaches. The functionality of the operations of the conventional relational model is revised accordingly, so as to overcome the problems illustrated earlier. Appropriate predicates are also defined, applicable to time periods, which can be used in selection operations. In some approaches additional operations are defined to capture temporal functionality that cannot be achieved by simply extending existing languages. In general, an implicit *temporal coalescing* takes place in all the temporal operations introduced.

Most of the proposed models in the literature support the valid time property over past, present and future time periods.

Desired Behavior of Period-Stamped Data Models

Given the above limitations, new problems have to be faced by the proposed period-stamped models. The most interesting of them are illustrated next by making use of relation SALARY in Fig. 1.

Data projection: The query "*list all the employees ever paid*" requires a projection of SALARY on Name. Such an operation normally yields a relation R with tuples (Alex), (John). Given however that R lacks implicit attributes, it gives rise to the question whether it is an appropriate response. To overcome this problem, in some approaches projection is defined to yield, after a *temporal coalescing*, the rows (Alex, d100, d499), (Alex, d800, d999) and (John, d200, d899). Notice however that, in this case, the result matches exactly that of another query, "*for every employee, list the time during which he is paid.*"

Stamp projection: Since time is not data, some special operation, to project only on time, may be necessary. For example, the answer to the query "*give the time during which at least one employee was paid*" should consist of one row, (d100, d999). Given however that this result lacks explicit attributes, it is necessary to determine whether it is appropriate to allow time stamp projection without explicit attributes. Similar questions arise in the case of projections of only one of the two implicit attributes.

Association of data in distinct relations: Such an association requires the use of the Cartesian product operation. For an illustration, consider also the relation in Fig. 2, which is used to record the history of employee assignments to departments. Then a Cartesian product of SALARY with ASSIGNMENT seems to yield a relation with two pairs of Begin and End time stamps, one pair from each relation. Clearly this is not a correct period-stamped relation. The same is also true for a join operation. As a consequence, some researchers avoid defining Cartesian product and restrict to the definition of a *temporal join* operation. This operation yields relation R, in Fig. 3, with a single pair of implicit attributes.

Literature Overview

The characteristics of individual approaches are outlined below. Unless otherwise specified, a point-stamped valid time relation, in the approach under discussion, is that of Fig. 1.

Jones and Mason [1] define LEGOL, a language for the management of period-stamped, valid time relations. It is an early, yet incomplete piece of work.

Ben-Zvi defines a model for the management of period-stamped, bitermporal relations ([14], Chap. 8). One more attribute is used, to record the time at which a tuple is deleted. Sets of time periods are also

Assignment

John	100	Food	d200	d899

Period-Stamped Temporal Models. Figure 3. Result of a temporal join operation.

considered, consisting of mutually disjoint periods. Some SQL extension is provided, too. It is also an early and incomplete piece of work.

Snodgrass defines a QUEL extension, for the management of valid time, transaction time and bitemporal relations [9]. Data may alternatively be stamped by time points (*point-stamped temporal models*). Time may not be specified for the primary key. Formal semantics are provided. A tuple calculus and a relational algebra are defined in [14], Chap. 6.

Navathe and Ahmed propose an SQL extension for period-stamped valid time relations ([14], Chap. 4, [5,6]). In this approach, the primary key of the relation in Fig. 1 is <Name, Begin>. The definition of the primary key of a relation, in conjunction with the definition of a *Time Normal Form*, enables temporal coalescing. One variation of the select operation takes as argument a time period value. A *moving window* operation enables a temporary *split* of the time stamps of all the tuples into time periods of a fixed size, and the subsequent application of aggregate functions on the data that are associated with these fixed size periods.

Lorentzos and Johnson define a relational algebra for the management of either period-stamped or point-stamped valid time data [3,2]. It is also shown that there are practical considerations for having relations with more than one valid time. A period data type is later defined in [14], Chap. 3. A generic period data type is defined in [14], Chap. 3, and in [4], enabling the use of periods of numbers and strings. Such periods can be used for the management of non-valid time relations which, however, require a functionality identical with that of period-stamped, valid time relations. The operations of the conventional relational model are not revised but two new algebraic operations are defined. Time is treated as data. As such, it may participate in the primary key [4]. In [14], Chap. 3, and in [4], it is shown that there are applications in which a *temporal coalescing* should be disallowed. An SQL extension is also defined in [4].

Sarda defines a relational algebra in [7] and an SQL extension for valid time relations in [14], Chap. 5, and in [8]. A time period data type is also defined in [7]. Data may alternatively be stamped by time points. Time may not be specified for the primary key. The operations of the conventional relational model are not revised but, as reported in [14], if time is projected out, the result relation is not a correct valid time relation. Similarly, the result returned by the Cartesian product operation is considered not to be a correct period-stamped relation. Two additional relational algebra operations are also defined, functionally equivalent with those defined by Lorentzos.

TSQL2 is a consensus temporal SQL2 extension for the management of either period or point-stamped valid time relations, transaction time relations and bitermporal relations. It is complemented by the definition of a relational algebra.

All the previous approaches incorporate time at the tuple level (*tuple time-stamping*). Contrary to these, Tansel incorporates time at the attribute level (*attribute time-stamping*) [10]. Hence, to record the history of salaries and of assignment to departments, it suffices to consider a relation like that shown in Fig. 4, in place of the two distinct relations in Figs. 1 and 2. The relation consists of two tuples, one for Alex and another for John. Time periods are open for the End time. One exception is the case where the end point of a time period equals *now*, in which case the period is closed (see for example Fig. 4, the assignment of Alex to the Food department). Therefore, data valid in the future is not supported.

The approach considers four types of attributes, *atomic* (Name, in Fig. 4), *set valued* (e.g., to record data such as {Alex, Tom}), *triplet valued* (e.g., to record data such as <[d100, d300), 100>) and *set triplet valued* (Salary and Department, in Fig. 4). The operations of the relevant conventional model are revised accordingly. Four additional operations are defined, which enable transformations between relations with different types of attributes. A QUEL extension is defined in [11]. The approach in [10] is extended in [14], Chap. 7, and in [12], to a nested model, incorporating the well-known nest and unnest operations. A Calculus and Algebra are also defined. The approach in [12] is extended in [13], in order to support nested bitemporal relations, in which valid and transaction time are incorporated at the attribute level.

Employee

Name	Salary	Department
Alex	{<[d100, d300), 100> <[d300, d500), 150> <[d800, d1000), 150>}	{<[d100, d200), Shoe> <[d300, now], Food>}
John	{<[d200, d900), 100>}	{<[d200, d900), Food>}

Period-Stamped Temporal Models. Figure 4. A relation in Tansel's approach.

Key Applications

There are many applications that necessitate the management of period-stamped and, more generally, temporal data. Some examples are the following.

Period-stamped, valid time relations can be used by pension and life insurance organizations in order to determine the benefits a person qualifies for. Such relations are also needed for these organizations to record their financial obligations at various times in the future.

Similarly, period-stamped, transaction time relations can be used in sensitive applications, to enable tracing the content of the database and evaluate some decision taken in the past, with respect to the content of the database at that time.

Future Directions

Given the practical interest of period-stamped data, and given the many differences between different approaches, it will be useful to agree on and develop a standard model by an international organization, such as ISO.

Further research is necessary for the management of period-stamped geographical data and for the definition of a nested period-stamped data model.

Personalized search

Definition

For a given query, a personalized Web search can provide different search results for different users or organize search results differently for each user, based upon their interests, preferences, and information needs. Personalized web search differs from generic web search, which returns identical research results to all users for identical queries, regardless of varied user interests and information needs.

Historical Background

Web search engines have made enormous contributions to the web and society. They make finding information on the web quick and easy. However, they are far from optimal. A major deficiency of generic search engines is that they follow the "one size fits all" model and are not adaptable to individual users. This is typically shown in cases such as these:

1. Different users have different backgrounds and interests. They may have completely different information needs and goals when providing exactly the same query. For example, a biologist may issue "mouse" to get information about rodents, while programmers may use the same query to find information about computer peripherals. When such a query is issued, generic search engines will return a list of documents on different topics. It takes time for a user to choose which information he/she really wants, and this makes the user feel less satisfied. Queries like "mouse" are usually called ambiguous queries. Statistics has shown that the vast majority of queries are short and ambiguous. Generic web search usually fails to provide optimal results for ambiguous queries.
2. Users are not static. User information needs may change over time. Indeed, users will have different needs at different times based on current circumstances. For example, a user may use "mouse" to find information about rodents when the user is viewing television news about a plague, but would want to find information about computer mouse products when purchasing a new computer. Generic search engines are unable to distinguish between such cases.

Personalized web search is considered a promising solution to address these problems, since it can provide different search results based upon the preferences and information needs of users. It exploits user information and search context in learning to which sense a query refers. Consider the query "mouse" mentioned above: Personalized web search can disambiguate the query by gathering the following user information:

1. The user is a computer programmer, not a biologist.
2. The user has just input a query "keyboard," but not "biology" or "genome." Before entering this query, the user had just viewed a web page with many words related to computer mouse, such as "computing," "input device," and "keyboard."

Foundations

User Profiling

To provide personalized search results to users, personalized web search maintains a user profile for each individual. A user profile stores approximations of user tastes, interests and preferences. It is generated and updated by exploiting user-related information. Such information may include:

1. Demographic and geographical information, including age, gender, education, language, country, address, interest areas, and other information;
2. Search history, including previous queries and clicked documents. User browsing behavior when

viewing a page, such as dwelling time, mouse click, mouse movement, scrolling, printing, and bookmarking, is another important element of user interest.

3. Other user documents, such as bookmarks, favorite web sites, visited pages, and emails. Teevan et al. [15] and Chirita et al. [1] demonstrate that external user data stored in a user client is useful to personalize individual search results.

User information can be specified by the user (explicitly collecting) or can be automatically learnt from a user's historical activities (implicitly collecting). As the vast majority of users are reluctant to provide any explicit feedback on search results and their interests, many works on personalized web search focus on how to automatically learn user preferences without involving any direct user efforts [6,8,9,10,13]. Collected user information is processed and organized as a user profile in a certain structure, depending on the need of personalization algorithm. This can be completed by creating vectors of URLs/domains, keywords, topic categories, tensors, or the like.

A user profile can usually aggregate a user's history information and represent the user's *long-term* interests (information needs). Some work has investigated whether such a long-term user profile is ineffective in some cases. Consider the second case that was described in the historical background section: a user will have different needs at different times based on circumstances. In such situations, personalization based on a user's long-term interests may not provide a satisfying performance, because similar results could be returned. Some work [10] has considered the use of a user's active context to represent *short-term* information needs. Search context is incorporated into the user profile, or is constructed as a separate short-term user model/profile and is used in helping infer a user's information needs.

Personalized Search Based on Content Analysis

Personalized web search can be achieved by checking content similarity between web pages and user profiles.

Some work has represented user interests with topical categories. User's topical interests are either explicitly specified by users themselves, or can be automatically learned by classifying implicit user data. Search results are filtered or re-ranked by checking the similarity of topics between search results and user profiles. In some work [2,8], a user profile is structured as a concept/topic hierarchy. User-issued queries and user-selected snippets/documents are categorized into concept hierarchies that are accumulated to generate a user profile. When the user issues a query, each returned snippet/document is also classified. The documents are re-ranked based upon how well the document categories match user interest profiles. Chirita et al. [2] use the ODP (Open Directory Project, http://www.dmoz.org/) hierarchy to implement personalized search. User favorite topics nodes are manually specified in the ODP hierarchy. Each document is categorized into one or several topic nodes in the same ODP hierarchy. The distances between the user topic nodes and the document topic nodes are then used to re-rank search results.

Some other work uses lists of keywords (bags of words) to represent user interests. In [13], a user profile is built as a vector of distinct terms and is constructed by aggregating past user click history. The cosine similarity between the user profile vector and the feature vector of returned web pages are used to re-rank results. Shen et al. [10] first use language modeling to mine immediate search contextual and implicit feedback information. The approach selects appropriate terms from related preceding queries and corresponding search results to expand the current query. In a query session, the viewed document summaries are used to immediately re-rank documents that have not yet been seen by the user. Teevan et al. [15] and Chirita et al. [1] exploit rich models of user interests, built from both search-related information, and other information about the user. This includes documents and emails the user has read and created. In [6], keywords are associated with categories and thus user profiles are represented by a hierarchical category tree based on keywords categories.

Personalized Web Search Based on Hyperlink Analysis

Most generic web search approaches rank importance of documents based on the linkage structure of the web. An intuitive approach of personalized web search is to adapt these algorithms to compute personalized importance of documents. A large group of these works focuses on personalized PageRank. PageRank, proposed by Page and Brin [7], is a popular link analysis algorithm used in web search. The fundamental motivation underlying PageRank is the recursive notion that important pages are those linked-to by many important pages. This recursive notion can be formalized by the "random surfer" model [7] on the directed web graph G. A directed edge $<p, q>$ exists in G if page p has a hyperlink to page q. Let $O(p)$ be the outdegree of web page p in G. $O(p)$ is equivalent to number of web pages that linked by page p. Let $\mathbf{A}$ be the matrix corresponding to the web graph G, where $A_{ij} = 1/O(j)$ if page j links to page i, and $A_{ij} = 0$ otherwise. In the random surfer model, when a surfer visits page p, he/she keeps clicking outlinks at random with probability (1-c), and jumps to a random web page with probability c. c is called teleportation constraint or damping factor. The PageRank of a page p is defined as the probability that the surfer visited page p. Iterative computation of PageRank is done as the following equation:

$$\boldsymbol{v}^{k+1} = (1 - c)\ \boldsymbol{A}\boldsymbol{v}^{k} + c\boldsymbol{u} \tag{1}$$

Here, $\boldsymbol{u}$ is defined as a preference vector, where $|\boldsymbol{u}| = 1$ and $u(i)$ denotes the amount of preference for page i when the surfer jumps to a random web page i. The global PageRank vector is computed when there is no particular preference on any pages, i.e., $\boldsymbol{u} = [1/n,...,1/n]^T$. By setting variant preference to web pages, a PageRank vector with personalized views of web page importance is generated. It recursively favors pages with high preference, and pages linked by high-preference page. This PageRank vector is called a *personalized PageRank vector* (*PPV*). To accomplish personalized web search, a personalized PageRank is computed for each user based upon the user's preference. For example, web pages in the user's bookmarks are set higher preferences in $\boldsymbol{u}$. Rankings of the user's search results can be biased according to the user's Personalized PageRank vector instead of the global PageRank.

Unfortunately, computing a PageRank vector usually requires multiple scans of the web graph [7], which makes it impossible to carry out online in response to a user query. Furthermore, when a large number of users employ a search engine, it is impossible to compute and store so many personalized PageRank vectors offline. Many later works [4,5] make efforts to reduce the computation and storage cost of personalized PageRank vectors. Jeh and Widom [5] support the concept that a user's preference set is a sub-set of a set of hub pages H, selected as those of greater interest for personalization. For each hub page p in H, setting the preference to 1 for page p and 0 for other pages, the corresponding personalized PageRank vector is called a basis hub vector. The authors decompose each basis hub vector in two parts: hub skeleton vector and partial vector. Hub skeleton vector represents common interrelationships between hub vectors, and is computed offline. Each partial vector for a hub page p represents the part of p's hub vector unique to itself. Partial vector can be computed at construction-time efficiently. Finally, a personalized PageRank vector can be expressed as a linear combination of a set of basis hub vectors, and is computed at query time efficiently. Experiments show that the approach is feasible when size of hub set $> 10^4$.

Haveliwala [4] use personalized PageRank to enable "topic-sensitive" web search. The approach precomputes k personalized PageRank vectors using k topics, e.g., the 16 top level topics of the Open Directory. For each topic i, a preference vector $\boldsymbol{u}_\mathbf{i}$ is generated. $(u_i)_j$ represents the confidence that web page j is classified into topic i. A PPV is computed base upon preference vector $\boldsymbol{u}_\mathbf{i}$. The k personalized PageRank vectors are combined at query time, using the context of the query to compute the appropriate topic weights. The experiments concluded that the use of personalized PageRank scores can improve web search, but the number of personalized PageRank vectors used was limited due to the computational requirements. In fact, this approach modulates the rankings based on the topic of the query and query context, rather than for truly "personalizing" the rankings to a specific individual. Qiu and Cho [9] develop a method to automatically estimate a user's topic preferences based on Topic-Sensitive PageRank scores of the user's past clicked pages. The topic preferences are then used to bias future search results.

Community-based Personalized Web Search

In most of the above personalized search strategies, each user has a distinct profile and the profile is used to personalize search results for the user. There are also some approaches that personalize search results for the preferences of a community of like-minded users. These approaches are called community-based personalized web search or collaborative web search. In a community-based personalized web search, when a user issues a query, search histories of users who have similar interests to the user are used to filter or re-rank search results. For example, documents that have been selected for the target query or similar queries by the community are re-ranked higher in the results list. Sugiyama et al. [13] use a modified collaborative filtering algorithm to constructed user profiles to accomplish personalized search. Sun et al. [14] proposed a novel method named CubeSVD to apply personalized web search by analyzing correlations among users, queries, and web pages in clickthrough data. Smyth et al. [12] show that collaborative web search can be efficient in many search scenarios when natural communities of searchers can be identified.

Server-Side and Client-Side Implement

Personalized web search can be implemented on either server side (in the search engine) or client side (in the user's computer or a personalization agent).

For server-side personalization, user profiles are built, updated, and stored on the search engine side. User information is directly incorporated into the ranking process, or is used to help process initial search results. The advantage of this architecture is that the search engine can use all of its resources, for example link structure of the whole web, in its personalization algorithm. Also, the personalization algorithm can be easily adapted without any client efforts. This architecture is adopted by some general search engines such as Google Personalized Search. The disadvantage of this architecture is that it brings high storage and computation costs when millions of users are using the search engine, and it also raises privacy concerns when information about users is stored on the server.

For client-side personalization, user information is collected and stored on the client side (in the user's computer or a personalization agent), usually by installing a client software or plug-in on a user's computer. In client side, not only the user's search behavior but also his contextual activities (e.g., web pages viewed before) and personal information (e.g., emails, documents, and bookmarks) could be incorporated into the user profile. This allows the construction of a much richer user model for personalization. Privacy concerns are also reduced since the user profile is strictly stored and used on the client side. Another benefit is that the overhead in computation and storage for personalization can be distributed among the clients. A main drawback of personalization on the client side is that the personalization algorithm cannot use some knowledge that is only available on the server side (e.g., PageRank score of a result document). Furthermore, due to the limits of network bandwidth, the client can usually only process limited top results.

Challenges of Personalized Search

Despite the attractiveness of personalized search, there is no large-scale use of personalized search services currently. Personalized web search faces several challenges that retard its real-world large-scale applications:

1. Privacy is an issue. Personalized web search, especially server-side implement, requires collecting and aggregating a lot of user information including query and clickthrough history. A user profile can reveal a large amount of private user information, such as hobbies, vocation, income level, and political inclination, which is clearly a serious concern for users [11]. This could make many people nervous and feel afraid to use personalized search engines. A personalized web search will be not well-received until it handles the privacy problem well.
2. It is really hard to infer user information needs accurately. Users are not static. They may randomly search for something which they are not interested in. They even search for other people sometimes. User search histories inevitably contain noise that is irrelevant or even harmful to current search. This may make personalization strategies unstable.
3. Queries should not be handled in the same manner with regard to personalization. Personalized search may have little effect on some queries. Some work [1,2,3] investigates whether current web search ranking might be sufficient for clear/unambiguous queries and thus personalization is unnecessary. Dou et al. [3] reveal that personalized search has little effect on queries with high user selection consistency. A specific personalized search also has different effectiveness for different queries. It even hurts search accuracy under some situations. For example, topical interest-based personalization, which leads to better performance for the query "mouse," is ineffective for the query "free mp3 download." Actually, relevant documents for query "free mp3 download" are mostly classified into the same topic categories and topical interest-based personalization has no way to filter out desired documents. Dou et al. [3] also reveal that topical interest-based personalized search methods are difficult to deploy in a real world search engine. They improve search performance for some queries, but they may hurt search performance for additional queries.

Key Applications

Personalized web search is considered a promising solution to improve the performance of generic web search. Currently, Google and other web search engines are trying to do personalized search.

Experimental Results

Experimental results have shown that personalized web search can indeed improve performance of web search. Detailed experimental results can be found in the corresponding reference for each presented method. Dou et al. [3] propose a personalized web search evaluation framework based upon large-scale query logs.

Petri Nets

W. M. P. van der Aalst
Eindhoven University of Technology, Eindhoven,
The Netherlands

Synonyms

Place transition nets; Condition event nets; Colored nets

Definition

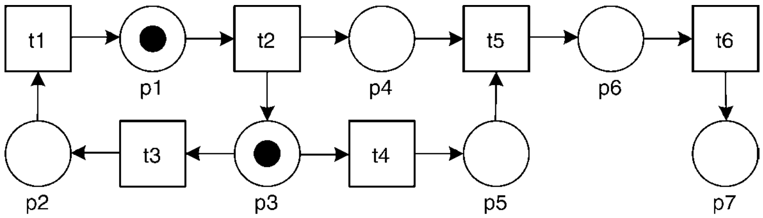
The Petri net formalism provides a graphical but also formal language which is appropriate for modeling systems and processes with concurrency and resource sharing. It was introduced in the beginning of the 1960's by Carl Adam Petri and was the first formalism to adequately describe concurrency. The classical Petri net is a directed bipartite graph with two node types called *places* and *transitions*. The nodes are connected via directed *arcs*. Places are represented by circles and transitions by rectangles. The network structure of the Petri net is static. However, places may contain tokens and the distribution of tokens of places may change as described in the *firing rule*. Petri nets have formal semantics and allow for all kinds of analysis. Moreover, due to the strong theoretical foundation much is known about the properties of different subclasses of Petri nets. Petri nets have been extended in many different application domains, e.g., workflow management systems, flexible manufacturing, embedded systems, communication protocols, web services, asynchronous circuits, etc. Moreover, many modeling languages have been influenced by Petri nets (e.g., UML) and have been mapped onto Petri nets for analysis purposes (e.g., BPEL, BPMN, etc.). The classical Petri net has been extended to allow for the modeling of complex systems, e.g., so called "colors" have been added to model data, timestamps have been added to model time, and hierarchy concepts have been proposed to structure large models. The resulting models are called a *high-level Petri nets.*

Historical Background

Petri started his scientific career with his dissertation "Communication with Automata" [7], which he submitted to the Science Faculty of Darmstadt Technical University in July, 1961. He defended his thesis there in June, 1962 [8]. Petri's dissertation has been quoted frequently, but the Petri net formalism as it is known today emerged later. However, the fundamental idea that asynchronous systems are more powerful than synchronous systems was already present. Petri nets as they are used today first appeared in Petri's talk "Fundamentals on the description of discrete processes" at the Third Colloquium on Automata Theory in Hannover in 1965. Using a simple graphical representation consisting of two types of nodes (places and transitions), Petri was able to describe processes exhibiting concurrency and possibly infinitely many states. Figure 1 shows a simple Petri net consisting of six transitions and seven places. The black dots in places *p1* and *p3* denote tokens and are used to represent the initial state. Despite the addition of concurrency, various properties are decidable for Petri nets which are not decidable for Turing machines (e.g., reachability, liveness, boundedness, etc.).

Initially the focus was on understanding concurrency through Petri nets and little emphasis was put on practical applications. This changed over time and Petri nets were used more and more in all kinds of applications. A nice example is the work on office information systems in the late seventies and early eighties. People like Skip Ellis, Anatol Holt, and Michael Zisman worked on information systems which were driven by explicit process models. It is interesting to see that the three pioneers in this area independently used Petri-net variants to model office procedures. The ideas of these people resulted in all kinds of workflow management systems and today most of the workflow management systems use a notation close to Petri nets [1]. Petri nets have been used in many other application domains ranging from embedded systems and asynchronous circuits to flexible manufacturing, communication protocols, and web services. Petri nets also influenced the development of many languages ranging from process calculi to more application oriented languages such as UML, EPCs, etc.

The classical Petri net allows for the modeling of states, events, conditions, synchronization, parallelism, choice, and iteration. However, Petri nets describing real processes tend to be complex and extremely large.



Petri Nets. Figure 1. A Petri nets consisting of six transitions and seven places.

Moreover, the classical Petri net does not allow for the modeling of data and time. To solve these problems, many extensions have been proposed. Three well-known extensions of the basic Petri net model are: (1) the extension with *color* to model data, (2) the extension with *time*, and (3) the extension with *hierarchy* to structure large models. A Petri net extended with color, time, and hierarchy is called a *high-level Petri net* [2]. Using high-level Petri nets it is much easier to describe complex systems and processes. However, analysis of high-level Petri net other than simulation is often intractable.

Foundations

The classical Petri net is a directed bipartite graph consisting of *places* and *transitions* connected via directed *arcs*. Connections between two nodes of the same type are not allowed. Places are represented by circles and transitions by rectangles as shown in Fig. 1.

A *Petri net* is formally defined by a triple (P, T, F):

1. P is a finite set of *places*,
2. T is a finite set of *transitions* $(P \cap T = \emptyset)$,
3. $F \subseteq (P \times T) \cup (T \times P)$ is a set of *arcs* (flow relation)

A place p is called an *input place* of a transition t iff there exists a directed arc from p to t. Place p is called an *output place* of transition t iff there exists a directed arc from t to p. The notation $\bullet t$ is used to denote the set of input places for a transition t. The notations $t\bullet$, $\bullet p$ and $p\bullet$ have similar meanings, e.g., $p\bullet$ is the set of transitions sharing p as an input place. In Fig. 1 transition *t2* has one input place (*p1*) and two output places (*p3* and *p4*).

At any time a place contains zero or more *tokens*, drawn as black dots. The *state*, often referred to as marking, is the distribution of tokens over places, i.e., $M \in P \to \mathrm{IN}$. A state is represented as follows: $1p_1 + 2p_2 + 1p_3 + 0p_4$ is the state with one token in place p_1, two tokens in p_2, one token in p_3 and no tokens in p_4. The notation $p_1 + 2p_2 + p_3$ can also be used represent this state. To compare states a partial ordering is defined. For any two states M_1 and M_2, $M_1 \leq M_2$ iff for all $p \in P$: $M_1(p) \leq M_2(p)$.

The number of tokens may change during the execution of the net. Transitions are the active components in a Petri net: they change the state of the net according to the following *firing rule*:

1. A transition t is said to be *enabled* iff each input place p of t contains at least one token.
2. An enabled transition may *fire*. If transition t fires, then t *consumes* one token from each input place p of t and *produces* one token for each output place p of t.

The initial marking shown in Fig. 1 is *p1* + *p3*. In this marking, *t2*, *t3*, and *t4* are enabled. Firing *t2*, results in the state 2*p3* + *p4*. Firing *t3*, results in the state *p1* + *p2*. Firing *t4*, results in the state *p1* + *p5*. Note that firing *t3* disables *t4* and vice versa, i.e., there is a non-deterministic choice between *t3* and *t4*. However, *t2* can fire independently from *t3* and *t4* because it is in parallel.

Given a Petri net (P, T, F) and a state M_1, the following notations are used:

1. $M_1 \xrightarrow{t} M_2$: transition t is enabled in state M_1 and firing t in M_1 results in state M_2
2. $M_1 \rightarrow M_2$: there is a transition t such that $M_1 \xrightarrow{t} M_2$
3. $M_1 \xrightarrow{\sigma} M_n$: the firing sequence $\sigma = t_1 t_2 t_3 ... t_{n-1}$ leads from state M_1 to state M_n via a (possibly empty) set of intermediate states $M_2,...M_{n-1}$, i.e., $M_1 \xrightarrow{t_1} M_2 \xrightarrow{t_2} \ldots \xrightarrow{t_{n-1}} M_n$

A state M_n is called *reachable* from M_1 (notation $M_1 \xrightarrow{*} M_n$) iff there is a firing sequence σ such that $M_1 \xrightarrow{\sigma} M_n$. Note that the empty firing sequence is also allowed, i.e., $M_1 \xrightarrow{*} M_1$.

(PN, M) is used to denote a Petri net PN with an initial state M. A state M' is a *reachable state* of (PN, M) iff $M_1 \xrightarrow{*} M'$.

The marked Petri net shown in Fig. 1 has an unbounded number of states. Note that the sequence *t2 t3 t1* can be repeated over and over again. In each cycle an additional token is put in place *p4*.

In the remainder, some standard properties for Petri nets are defined [3,4]. First, properties related to the dynamics of a Petri net are defined. Then some structural properties are given.

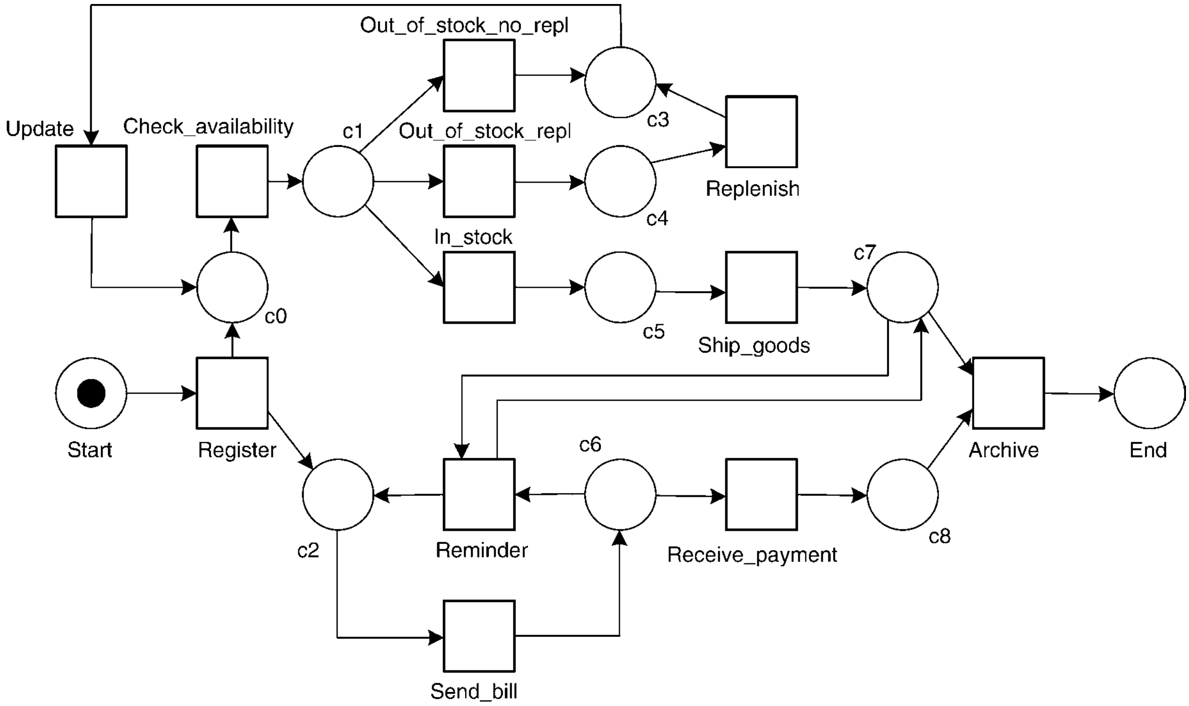
A Petri net (PN, M) is *live* iff, for every reachable state M' and every transition t there is a state M' reachable from M' which enables t. Note that the marked Petri net shown in Fig. 1 is not live. After firing *t4* twice, it becomes impossible to execute any of the first three transitions. A Petri net is *structurally live* if there exists an initial state such that the net is live. Figure 1 is also not structurally live.

A Petri net (PN, M) is *bounded* iff for each place p there is a natural number n such that for every reachable state the number of tokens in p is less

P

than *n*. The net is safe iff for each place the maximum number of tokens does not exceed 1. As indicated before, the marked Petri net shown in Fig. 1 is not bounded because the number of tokens in *p4* can exceed any number. A Petri net is *structurally bounded* if the net is bounded for any initially state.

Figure 2 shows a more meaningful example of a Petri net. In fact it models the workflow related to some ordering process and the transitions correspond to tasks. The token in *start* corresponds to an order. Task *register* is represented by a transition bearing the same name. From a routing point of view it acts as a so-called AND-split (two outgoing arcs) and is enabled in the state shown. If a person executes this task, the token is removed from place *start* and two tokens are produced: one for *c0* and one for *c2*. Then, in parallel, two tasks are enabled: *check_availability* and *send_bill*. Depending on the eagerness of the workers executing these two tasks either *check_availability* or *send_bill* is executed first. Suppose *check_availability* is executed first. Based on the outcome of this task a choice is made. This is reflected by the fact that three arcs are leaving *c1*. If the ordered goods are available, they can be shipped, i.e., firing *in_stock* enables task *ship_goods*. If they are not available, either a replenishment order is issued or not. Firing *out_of_stock_repl* enables task *replenish*. Firing *out_of_stock_no_repl* skips task *replenish*. Note that *check_availability*, place *c1* and the three transitions *in_stock*, *out_of_stock_repl*, and *out_of_ stock_no_repl* together form a so-called OR-split: As a result of this construct one token is produced for either *c3*, *c4*, or *c5*. Suppose that not all ordered goods are available, but the appropriate replenishment orders were already issued. A token is produced for *c3* and task *update* becomes enabled. Suppose that at this point in time task *send_bill* is executed, resulting in the state with a token in *c3* and *c6*. The token in *c6* is input for two tasks. However, only one of these tasks can be executed and in this state only *receive_payment* is enabled. Task *receive_payment* can be executed the moment the payment is received. Task *reminder* is an AND-join/AND-split and is blocked until the bill is sent and the goods have been shipped. However, it is only possible to send a reminder if the goods have actually been shipped. Assume that in the state with a token in *c3* and *c6* task *update* is executed. This task does not require human involvement and is triggered by a message of the warehouse indicating that relevant goods have arrived. Again *check_availability* is enabled. Suppose that this task is executed and the result is



Petri Nets. Figure 2. A workflow expressed in terms of a Petri net.

positive, i.e., the path via *in_stock* is taken. In the resulting state *ship_goods* can be executed. Now there is a token in *c6* and *c7* thus enabling task *reminder*. Executing task *reminder* enables the task *send_bill* for the second time. A new copy of the bill is sent with the appropriate text. It is possible to send several reminders by alternating *reminder* and *send_bill*. However, assume that after the first loop the customer pays resulting in a state with a token in *c7* and *c8*. In this state, the AND-join *archive* is enabled and executing this task results in the final state with a token in *end*.

The marked Petri net shown in Fig. 2 is bounded but not live. In fact the model is safe because there are never two tokens in the same place.

Reachability, liveness, and boundedness can be decided for any classical Petri net. For example, it is possible to construct the so-called coverability graph. However, this may be quite inefficient. Fortunately, more efficient techniques are available for different subclasses of Petri nets. Some of these subclasses are listed below.

A Petri net is a *free-choice Petri net* [5]. iff, for every two transitions t_1 and t_2, $\bullet t_1 \cap \bullet t_2 \neq \emptyset$ implies $\bullet t_1 = \bullet t_2$. Figure 1 is free-choice but Fig. 2 is not. Figure 2 is not free-choice because of the two arcs between *c7* and *reminder*. Many properties of free-choice nets can be exploited in their analysis. For example, the combination of liveness and boundedness can be decided in polynomial time.

A Petri net is *state machine* iff each transition has exactly one input and one output place. A Petri net is *marked graph* iff each place has exactly one input and one output transition. Both state machines and marked graphs are examples of free-choice nets and can be analyzed efficiently.

A Petri net $PN = (P, T, F)$ is a WF-net (Workflow net, [1,6]) if and only if:

1. There is one source place $i \in P$ such that $\bullet i = \emptyset$.
2. There is one sink place $o \in P$ such that $o\bullet = \emptyset$.
3. Every node $x \in P \cup T$ is on a path from i to o.

The class of WF-net has been extensively studied because of its applications in workflow management processes and other case-driven processes. Clearly, Fig. 2 is a WF-net while Fig. 1 is not.

For a WF-net with one token on the source place i it is interesting to know whether the net will always terminate properly with a token in the sink place o. This corresponds to the so-called *soundness property*. Soundness can be expressed in terms of liveness and boundedness. If the sink place o is connected to the source place i using some transition $t*$, the so-called short-circuited net is obtained. The original WF-net is sound if and only if the corresponding short-circuited net is live and bounded. This result can be exploited in the analysis of complex workflows.

Key Applications

Workflow Management

Petri nets are used for the modeling, analysis, and enactment of workflows. Many workflow languages have a graphical representation close to Petri nets. Moreover, today's workflow engines use mechanisms comparable to using tokens and the firing rule.

Discrete/Flexible Manufacturing

Traditionally, there have been may applications of Petri nets in manufacturing. The models are used to analyze the manufacturing process in detail, e.g., to find deadlocks or to analyze the performance.

Communication Protocols

Different protocols have been modeled using Petri nets. Various errors have been discovered by verifying established protocols using Petri-net-based analysis techniques.

Embedded Systems

The interactions between hardware and software in embedded systems (e.g., copiers, cars, mobile phones, etc.) may result in all kinds of problems. Therefore, Petri nets are used to model and analyze such systems.

Physical Clock

Curtis Dyreson
Utah State University, Logan UT, USA

Synonyms

Clock

Definition

A *physical clock* is a physical process coupled with a method of measuring that process to record the passage of time. For instance, the rotation of the Earth measured in *solar days* is a physical clock. Most physical clocks are based on cyclic processes (such as a celestial rotation). One or more physical clocks are used to establish a *time-line clock* for a temporal database.

Key Points

Every concrete time is a measurement of some physical clock. For instance a wind-up watch provides the time "now" by measuring the rate at which a coiled, wound spring unwinds. A physical clock is limited by the durability and regularity of the underlying physical process that it measures, so to provide a clock for every instant in a time-line for a temporal database several physical clocks might be needed. For instance a clock based on the rotation of the Earth will (likely be) limited as current models predict the Earth will eventually be gravitationally drawn into the Sun. The modifier "physical" distinguishes this kind of clock from other kinds of clocks in an application, in particular a "time-line" clock. Atomic clocks, which are a kind of physical clock, provide the measurements for International Atomic Time (TAI).

Physical Database Design for Relational Databases

Sam S Lightstone
IBM Canada Ltd., Markham, ON, Canada

Synonyms

Database design; Database materialization; Database implementation; Table design; Table normalization; Indexing; Clustering; Multidimensional clustering; Range partitioning; Materialized views; Materialized query tables

Definition

Physical database design represents the materialization of a database into an actual system. While logical design can be performed independently of the eventual database platform, many physical database attributes depend on the specifics and semantics of the target DBMS. Physical design is performed in two stages:

1. Conversion of the logical design into table definitions (often performed by an application developer): includes pre-deployment design, table definitions, normalization, primary and foreign key relationships, and basic indexing.

2. Post deployment physical database design (often performed by a database administrator): includes improving performance, reducing I/O, and streamlining administration tasks.

Generally speaking, physical database design covers those aspects of database design that impact the actual structure of the database on disk. Stage 1 is variably referred to in the industry as an aspect of *logical database design* or *physical database design*. It is known as *logical database design* in the sense that it can be designed independent of the data server or the particular DBMS used. It is also often performed by the same people who perform the early requirements building and entity relationship modeling. Conversely, it is also called *physical database design* in the sense that it affects the physical structure of the database and its implementation. For the sake of this entry, the latter assumption is used, and it is therefore included as part of *physical database design*.

Although it is possible to perform logical design independently of the physical platform and knowledge of database software that will eventually be used, many physical database design tasks depend on the specifics and semantics of the target DBMS (software and hardware). The major tasks of physical database design include: table normalization, table denomalization, indexing, clustering, multidimensional clustering (MDC), range partitioning, hash partitioning, shared nothing partitioning (hash), materialized views (MVs), memory allocation, database storage topology, and database storage object allocation.

Historical Background

Physical database design is as old as database research. Specifically, if this question is limited to relational databases, the first systems were prototyped in the early 1970's. The most elementary problems of physical database design are those of table normalization and index selection. The relational model for databases was first proposed in 1970 by E.F Codd at IBM. The first relational databases using SQL and B+-tree was IBM's System R, in 1976 and the INGRES database at the University of California, Berkeley. The B+-tree, the most commonly-used indexing storage structure for user designed indexes, was first described in the paper *Organization and Maintenance of Large Ordered Indices* by Rudolf Bayer and Edward M. McCreight. While System R was a research prototype, commercialization followed with products by IBM (DB2 – DB2 and Informix are trademarks or registered trademark of International Business Machines Corporation in the United States, other countries, or both. Oracle is a trademarks or registered trademark of Oracle Corporation in the United States, other countries, or both. Other company, product, or service names may be trademarks or service marks of others.) and Oracle around 1980. INGRES also became commercial and was followed by POSTGRES which was incorporated into Informix. Prior to these relational systems, other data models for databases had been used, such as IMS which uses a hierarchical storage model and dominated industrial practice between 1967 and 1980. These pre-relational systems also had unique physical database design challenges.

As relational database systems advanced, new techniques were introduced to help improve operational efficiency, and reduce I/O by partitioning, distributing, and/or better indexing data. All of these innovations, while improving the capabilities and potential for databases, expanded the scope of physical database design increasing the number of design choices and therefore the complexity of optimizing database structures. Though the 1980's and 1990's were dominated by the introduction of new physical database design capabilities, it can also be said that the years since have been dominated by efforts to simplify the process through automation, best practices, or deploying pre-configured "database appliances".

Foundations

The vast majority of physical database design tasks have the primary goal of reducing I/O consumption at runtime for query processing. However, to a lesser degree there are physical design aspects that help improve administrative efficiency by reducing the granularity of backup and restore operations (as in the case of range partitioning), or by improving the efficiency of mass insertion or deletion of data (so called "roll-in" and "roll-out" of data) as in the case of range partitioning. Some features can help reduce CPU or network consumption as in the case of memory tuning for heaps associated with these resources (such as the compiled SQL statement cache found in many commercial database server products).

Infrastructure Mechanics

Indexing schemes typically exploit tree-based structures or hash methods to provide fast access to data, with B+-trees being the dominant strategy. Range partitioning and clustering methods are based on grouping strategies to physically cluster like or similar data nearby on disk in order to reduce I/O. Hash partitioning methods hash data horizontally across storage objects so that processing can be performed on records associated with the different hash partitioning by different CPUs, providing parallel processing efficiencies. MVs are based on the strategy of pre-computation, so that results are available either in full or in part when needed without scanning and calculation. Considerable literature has been published on strategies to match the information within the MV at query compilation time to the queries requiring them, which is non trivial except in cases where the incoming query is an exact match to the MV.

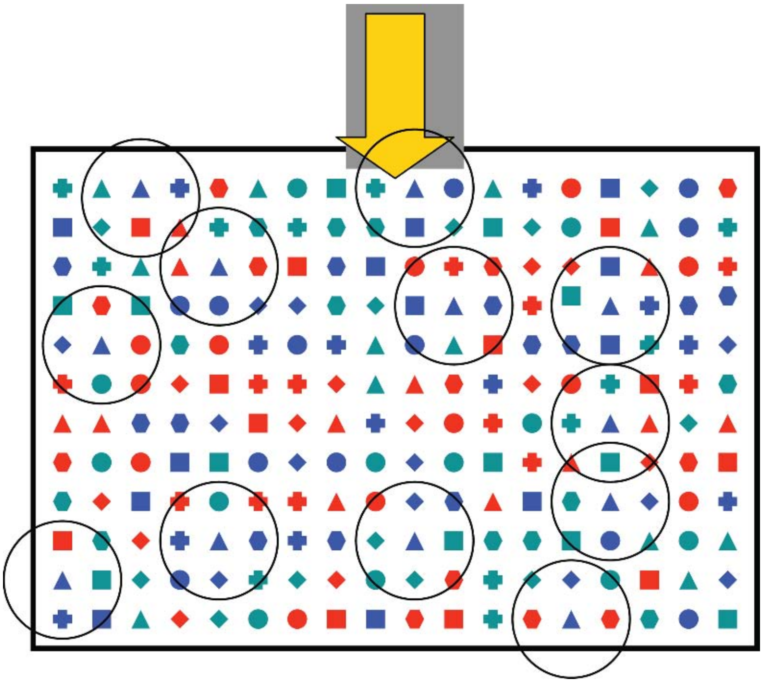
The full breadth of physical database design is beyond the scope of this entry, so this discussion touches only on major aspects.

Design Choices

Physical database design, as performed by end users, has not yet been codified into a scientifically based strategy, and remains as much an art as a science. Typical strategies include cost-benefit analysis of applying various design features. Trial-and-error is still a significant part of the design process. For query processing, indexing is the first design feature considered, and the design process can generally explore the columns used in query predicates within the workload. Range partitioning is generally designed around date fields (by month or by quarter) for roll-in and roll-out processing, and backup granularity. Hash partitioning typically focuses on a unique key or near-unique key in order to efficiently distribute records across CPUs without skew. Data clustering strategies typically focus on columns used in range predicates, or in equality clauses that have high cardinality results sets in order to place similar data that are likely to be jointly required for query resolution physically nearby one another on disk.

Combining Physical Design Choices

Figure 1 shows a conceptual illustration of data stored in one large physical object without any specific treatment of the data, so that the data is unsorted, unclustered, unpartitioned, and not indexed. Data of different characteristics is illustrated by the different colored shapes that appear in the set. One can consider a query that was interested in data represented by the



Physical Database Design for Relational Databases. Figure 1. Data of various attributes, stored in a single monolithic table. (image courtesy of K. Beck at IBM) blue triangles in the image, which appear scattered throughout the object. A full data scan of the set would be required to find and fetch these data.

Figure 2 shows a database with the same data as Fig. 1, which has been carefully designed to exploit a number of physical database design features in combination, such as indexing, range partitioning, MVs, MDC, and hash partitioning. In this new configuration a query for the data represented by the blue triangles is not only clustered in order to perform minimal IO, but the clearly indexed and can be distributed across several CPUs due to hash partitioning. Aggregation on the data can be precomputed and stored in the MV as well.

Other Physical Database Design Techniques

1. Other indexing mechanisms: hash index, bitmap index
   - These indexing strategies use hash functions, or bitmaps to index data that is typically slow changing. Bitmap indexes are favors for data with low cardinality (i.e., few distinct values).
2. Physical design for XML data
   - Semi-structured databases, like XML databases, require alternate indexing strategies.
3. Indexing for Information Retrieval
   - Text indexing is often based on an “inverted tree” index method.
4. Storage and object layout
   - Data placement on disk is affects the efficiency of storage and retrieval. Particularly important when some data has very different frequency or urgency of access than others.
5. Page and block size for I/O efficiency
   - Size of the storage pages, and the blocking levels (number of pages) used during I/O dramatically affect I/O efficiency, where random access favors smaller blocking and while sequential access favors large blocking.
6. Memory configuration and management
   - Complex design choice in the distribution of memory for caching, sorting, hashing, locking, tat typically has large impact on the efficiency of a database, especially if any key memory

consumer is constrained. Since memory is a fixed resource, the distribution of memory is a zero sum game (i.e., adding memory for one purpose requires reducing it for another)

7. Distributed database design
   - Distributed databases require complex design choices for data placement and choice of access (particularly where the distributed database includes redundancy, providing choices for which node to access).
8. Shared nothing partitioning
   - Shared nothing partitioning, common in data warehousing, hash partitions data across CPUs (and/or server) to achieve parallel processing over large volumes of data. The choice of hashing key is non trivial. However, in a shared nothing architecture, queries over each hash bucket later need to be shipped and merged since each node (or partition) is assumed to be distinct.
9. Hash partitioned tables
   - Hash partitioning within a server, can divide process of a query across CPUs, while still allowing the efficiencies of shared memory processing within a server.

Key Applications

Lifecycle Differences

It is important to distinguish between physical database design tasks performed during application development, versus those performed following deployment by an administrator.

During application development, the application designer performs logical database design and derives from it a physical design of the database. The physical design assigns typing to the elements of the entities in the database. This phase also designs the database tables, including normalization. Indices are defined, most commonly on primary and foreign keys. Views (non-materialized) are created to abstract the physical implementation away from the application as much as possible and to improve security of the system by controlling access to the data by the logical definition of the views, rather than by the physical structures of the storage.

Following deployment of the database, physical design continues, usually conducted by a database administrator. The design tasks here focus on performance tuning, or performance problem alleviation. Common tasks include the selection of secondary indexes, clustering, MDC, and range partitioning.

A common problem in database application development is that the application designer is forced to develop the database application using small samples of data. DBAs face design challenges when trying to optimize data access for applications that operate over large data sets, which the application designers themselves did not have access to when performing the initial application and database design.

Another key difference between the database design tasks performed at application development time and those following deployment relate to the physical resources of the database server. In most cases the properties of the database server – number and speed of CPUs, CPU-cores, disks, memory, bus bandwidth, etc – are unknown during application development. For applications that are deployed to possibly many sites or many customers there can be many different eventual target servers. Thus physical design qualities of the database that depend on the server's characteristics are inherently the role of the DBA to design. These include data placement and storage topology, memory allocation, and to a lesser degree clustering choices.

The design tasks performed by the DBA occur frequently with the deployment of new applications, application upgrades, or due to the evolution of the data set.

Application Domains

Different application domains require different physical design techniques. The section below highlights the two largest categories of application domains, namely Online Transaction processing (OLTP) and Decision Support Systems (DSS).

OLTP/ERP. Such applications deal with small numbers of records per transaction, and are commonly subject to extremely high concurrency rates. Key physical design characteristics include: (i) Small storage page sizes; (ii) Highly normalized data; (iii) Use of clustering indices or single-dimension MDC to enforce clustering of data; (iv) Memory allocation is heavily used for data caching (bufferpools), and to a lesser degree for caching compiled SQL statements. Memory work area for sorting, hash joins, etc, has considerably reduced demand in this space; (v) Due to the small selectivity of the transactions, the use of range partitioning, MDC with high dimensionality, and view materialization are not heavily used.

Decision Support, Data Warehousing and OLAP. These applications are characterized by large numbers of records accessed for aggregation, cubing etc. Table scans are common, and the workloads often include a high percentage of ad-hoc unpredictable queries, which can not be explicitly optimized for. Key physical design considerations here include: (i) Larger page size and storage blocking to increase the efficiency of scans and prefetching; (ii) Data may be stored in 3NF or Star Schema; (iii) Use of clustering is extremely common, especially long date and geography dimensions; (iv) Range partitioning is heavily used for roll-in and roll-out of data within the warehouse. This is almost always performed along a date dimension (such as by month or by quarter); (v) Memory allocation is complex in these environments. Data caching remains dominant, however, the common occurrence of sorting and hashing in these workloads places increased demand on work memory for these operations. The low concurrency characteristics of these workloads (compared to OLTP systems) place a reduced demand on memory for locking and caching of compiled statements.

Future Directions

The powerful capabilities of modern RDBMSs add complexity and have given rise to an entire professional domain of experts, known as Database Administrators (DBAs), to manage these systems. The problem is not unique to RDBMSs, but is ubiquitous in Information Technology today. Some have called this explosive growth of complexity "creeping featurism". In fact many companies now spend more money recruiting administrators to manage their technology than the money they have spent on the technology itself. One of the key roles of such DBAs is in the development and refinement of physical database design, to achieve "tuning" of the database.

The only real viable long term strategic solution is to develop systems that manage themselves. Such systems are called "self-managing" or "autonomic" systems. Several research efforts have focused on such self-designing database systems, working on problems such as:

1. What-if analysis reusing a database's native query optimizer to explore hypothetical design choices over a real or synthetic workload.
2. Data sampling and statistical analysis to explore the impact of design choices on data distribution and density, or conversely to assess the suitability of target data for design attributes.

Physical Layer Tuning

Philippe Bonnet, Dennis Shasha
University of Copenhagen, Copenhagen, Denmark
New York University, New York, NY, USA

Definition

Tuning the physical layer entails choosing and configuring the underlying hardware and operating system to improve the performance of a database system running a given set of applications.

Historical Background

Ultimately, a database management system runs on processor and memory chips as well as secondary devices such as flash memory and disks. Trying to use those physical resources in the best way possible has been a problem since the first databases were available. Many researchers have noticed that disk capacity has been less of an issue than disk speed (or aggregate bandwidth from an entire disk array). Main memory size has always been a critical factor, because accesses to main memory are so much faster than accesses to disk. Processor speed has been important in applications that mix sophisticated computation with data access (for example in financial analysis), such computations are often handled outside the database server. New technologies have improved the capacity and speed of processors, memory, and disks, but memory is still vastly faster than disk (and somewhat faster than flash memory), so certain tuning principles will remain true.

Foundations

Hardware Tuning

Hardware tuning essentially consists of picking the hardware components on which the database management server is run. The goal is to design a balanced system [2].

Each processing unit consists of one or more processors, one or more disks, and some memory. Assuming a n-GIPS (billion instructions per second) processor, disks will be the bottleneck for on-line transaction-processing applications until the processor is attached to around 30n disks (counting 500,000 instructions per random IO issued by the database system and 70 random IOs per second). Each transaction spends far more time waiting for head movement on disk than in the processor.

Decision-support queries, by contrast, often entail massive scans of a table. In theory, an n-GIPS processor is saturated when connected to n/4 disks (counting 500,000 instruction per sequential IO and 8,000 IO per second, considering 50 MB/second per disk and 64 KB per IO). In practice, the system bus might become the bottleneck. Thus, decision-support sites may need fewer disks per processor than transaction-processing sites for the purposes of matching aggregate disk bandwidth to processor speed. The numbers change when disks are implemented using flash memory, but the principle remains the same.

Operating System Tuning

Tuning the operating system primarily consists of providing an efficient input/output (IO) subsystem to the database server. A database server can issue buffered or unbuffered IO using the file system, or it can issue IO on raw disks thus bypassing the file system. Raw disks offer control and performance to the database system at the cost of a very low level of abstraction. The file system, on the other hand, provides a high level of abstraction, at the cost of decreased performance and double buffering. Further, IO is either synchronous or asynchronous. A synchronous IO forces the thread that issued the issuing thread to block until the IO is complete. Asynchronous IO allows the database server to issue concurrent IO requests on multiple files. Modern operating system such as Linux or Windows, provide database servers with direct asynchronous IO, that provide file abstraction and efficient IO scheduling at a low overhead. Note that out-of-the-box, a database system will most likely be configured to use standard buffered IO and thus needs to be tuned to use direct asynchronous IO.

As noted above, if one could eliminate the overhead caused by seeks and rotational delay, the aggregate bandwidth could increase by a factor of 10–100. Making this possible requires laying out the data to be read sequentially along disk tracks. Recognizing the advantage of sequential reads on properly laid-out data, most database systems encourage administrators to lay out tables in relatively large *extents* (consecutive portions of disk). Having a few large extents is a good idea for tables that are scanned frequently or (like database recovery logs or history files) are written sequentially. Large extents, then, are a necessary condition for good performance, but not sufficient, particularly for history files. Consider, for example, the scenario in which a database log is laid out on a disk in a few large extents, but another hot table is also on that disk. The accesses to the hot table may entail a seek from the last page of the log; the next access to the log will entail another seek. So, much of the gain of large extents will be lost. For this reason, each log or history file should be the only hot file on its disk, unless the disk makes use of a large RAM cache to buffer the updates to each history file.

When accesses to a file are entirely random (as is the case in on-line transaction processing), seeks cannot be avoided. But placement can still minimize their cost, since seek time is roughly proportional to a constant plus the square root of the seek distance.

The operating system also allows to control the thread model used by the database server and to assign priorities to the different database server threads (and processes). The goal is to favor low latency requests (log writes), ensure fairness among database clients while avoiding starvation. This has several pitfalls however as discussed in [3] below.

Key Applications

A database system depends on the underlying hardware and operating system. Tuning the physical layer is thus a necessary step when deploying any database application.

Pipeline

Ryan Johnson
Carnegie Mellon University, Pittsburg, PA, USA

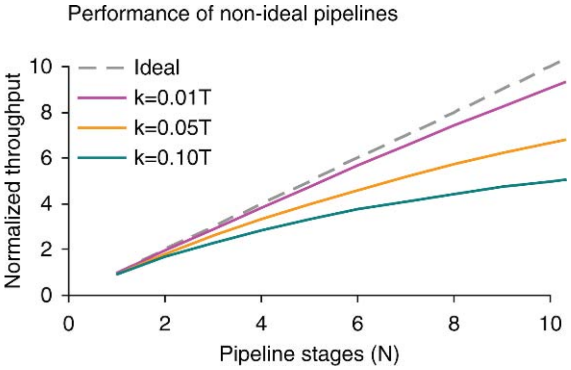
Definition

Pipelining is a performance-enhancing technique which breaks a job into multiple overlapping pieces of work assigned to *pipeline stages*. Each pipeline stage operates in parallel, receiving inputs from a previous stage and passing intermediate results to the next. A pipeline with N stages can accommodate up to N in-progress jobs at a time. A well-designed pipeline requires only a fraction of the resources needed to achieve the same throughput with non-pipelined execution. A *balanced* pipeline, which distributes processing time evenly between all stages, can produce N results during the time it would have taken to process a single job all at once; unbalanced pipelines do not perform nearly as well. Pipelining also provides a secondary benefit of allowing each pipeline stage to specialize for its particular task, potentially making the combined stages both faster and less expensive than the non-pipelined server. Factory assembly lines leverage pipelining to great effect, allowing N specialized workers to achieve far higher throughput than N general purpose workers, while requiring less training per worker and fewer resources overall. The impressive throughput and efficiency pipelining provides make it a useful tool in both hardware and software design. Database systems often improve performance of query processing by executing query plans in pipelined fashion. Pipelining is a form of parallel dataflow execution.

Key Points

Suppose a non-pipelined server requires T time units and R resources to process a job all at once. The server's *latency* (time to process a job start-to-finish) and *occupancy* (time until it can accept more work) are both T. In contrast, a pipelined server with N stages ideally provides latency and occupancy of T' $\leq$ T and T'/N time units, respectively, while consuming R + ε resources. Because peak throughput is the reciprocal of the server's occupancy, pipelined execution potentially provides an N-fold increase in throughput over non-pipelined execution. When plenty of work is available, an initially empty pipeline *fills* or *ramps up* over a period of T' time units to reach peak operating capacity with N in-progress jobs. The pipeline must *stall* any time the first pipeline stage becomes ready and no new jobs are available. Stalls propagate through the pipeline as *bubbles* and reduce throughput by leaving stages idle.

Ideal pipelines assume that (i) the job can be broken into N pieces requiring no more than T/N time units each (possibly less due to gains from specialization), and that (ii) passing work between stages imposes no extra overhead. In practice, pipelines usually have non-negligible stage overhead and tend to be unbalanced, with a *bottleneck stage* that runs slower than the others. Real pipelines therefore have occupancy and latency of T/N + k and T + kN, where k is the total extra delay imposed by imbalance and overhead. Pipeline bubbles, unbalanced stages, and



Pipeline. Figure 1. Impact of unbalanced pipelines and pipelining overhead for as pipeline depth varies. Normalized throughput is equal to 1/(T/N + k)/T. Note that just 1% overhead (and/or imbalance) costs 10% ideal throughput in a 10-stage pipeline.

overhead all become more severe for *deep* pipelines containing many stages, and limit the useful depth of any pipeline. Figure 1 illustrates how even small values of k reduce peak throughput from the ideal as a pipeline gets deeper.

Pipelining

Evaggelia Pitoura
University of Ioannina, Ioannina, Greece

Definition

The query execution engine operates on an execution plan produced during query processing which typically is a physical operator graph whose edges specify the dataflow among the operators. There are two basic alternatives for evaluating the execution plan: materialization and pipelining. With materialized evaluation, the results of each operator are created (materialized) and stored in disk and then used as input for the evaluation of the next operator. With pipelining, the results of an operator are passed along as input to the next operator, before the first operator completes its execution. In general, pipelining improves the efficiency of query evaluation by reducing the number of temporary files that are produced.

Key Points

The output of query optimization is an execution plan or operator tree. The execution plan can be thought of as a dataflow graph where the nodes correspond to the physical operators and the edges represent the data flow among these physical operators. The query execution engine is responsible for the execution of this plan. The engine provides generic implementations of all physical operators that take as input one or more data streams and produce one output data stream.

In most database systems, each operator supports an *iterator* interface that allows a parent operator to get the results from its children one tuple at a time. The iterator interface supports *pipelining*, since tuples produced as output by a child operator can be fed as input to their parent in the operator tree, even before the child operator has finished its execution. The alternative would be *materialized evaluation*, in which each operator would fully complete its operation and write its results to disk before the next operator starts execution. By reducing the number of intermediate results written to disk, pipelining improves the efficiency of query evaluation. However, not all physical operators can use pipelining efficiently. For instance, merge-join cannot exploit pipelining in general, since it requires both its input relations to be sorted and it is not possible to sort a relation until all its tuples are available.

Pipelines can be executed in one of two ways: demand-driven or producer-driven. In a *demand-driven* or *demand-pull* pipeline, an operator computes the next tuple or tuples to be returned after receiving a corresponding request from its parent operator. In a *producer-driven* or *push* pipeline, operators do not wait for requests to produce tuples, instead, they generate output tuples eagerly and put them in their output buffers until the buffers become full. Demand-driven pipelining is more common, since it is easier to implement. It also allows for the whole plan to be executed by a single process or thread.

Point-in-Time Copy

Kenichi Wada
Hitachi Limited, Tokyo, Japan

Synonyms

Snapshot; PiT copy

Definition

A point-in-time copy is a copy of original data as it appeared at a point in time. In a conventional backup operation, users often create a PiT Copy, while an application is in quiescing, to make the PiT Copy a consistent copy of original data.

Key Points

There are two popular implementation techniques for creating PiT Copies inside a storage system: split mirror and copy on write.

Split mirror is a technique for replicating the original data at a point in time. In some implementations, a storage system replicates the original data, and when users create the PiT Copy, a storage system splits the replication. Copy on Write (CoW) is a technique for capturing data changes to storage and creating a PiT Copy after specifying the point in time. In some implementations, when users create the PiT Copy, a storage system creates its image with both the original data and the modified data.

Techniques for creating PiT Copies have a tradeoff between occupied storage capacity and performance. A PiT Copy created by split mirror occupies as much storage as the original data, but a PiT Copy by CoW usually occupies less storage. On the other hand, CoW usually has more time for accessing the copy source and creating PiT Copies than split mirror.

Point-Stamped Temporal Models

David Toman
University of Waterloo, Waterloo, ON, Canada

Point-based temporal models

Definition

Point-stamped temporal data models associate database objects with time instants, *indivisible* elements drawn from an underlying time domain. Such an association usually indicates that the information represented by the database object in question is *valid* (i.e., believed to be true by the database) at that particular time instant. The time instant is then called the *timestamp* of the object.

Historical Background

Associating time-dependent data with time instants has been used in sciences, in particular in physics, at least since Isaac Newton's development of classical mechanics: time is commonly modeled as a two-way infinite and continuous linear order of indivisible time instants (often with distance defined as well). Similarly, in many areas of computer science, ranging from protocol specifications to program verification to model checking, discrete point-based timestamps play an essential role. In database systems (and in AI), however, the requirement of *finite* and compact representation has often lead to the use of more complex timestamps, such as intervals. This is particularly common when information about *durations* is stored in a database (in AI, such timestamps are called *fluents*). However, Chomicki [2] has shown that many of these approaches are simply compact representations of large and potentially infinite sets of time instants associated with a particular fact and that, at the conceptual level, the underlying information is often better understood as being timestamped by time instants.

Foundations

Temporal data models are typically defined as extensions of standard non-temporal data models that provide means for representation and manipulation of time-dependent data. Temporal extensions of the relational model accomplish this by relativizing *truth*, i.e., the sets of facts the database believes to be true in the modeled reality, with respect to elements of the time domain. These elements are then called the timestamps of the facts and, intuitively, specify *at which times* the associated facts are true. In the case of point-stamped temporal models, these elements are indivisible time instants drawn from an appropriate time domain.

The main ideas are outlined in a setting in which the time domain is an unbounded countably infinite linear order of *time instants*. Moreover, while the main focus is on *temporal extensions of the relational model*, most of the issues arise in other data models as well, and admit similar solutions.

Timestamps and Database Objects

The choice of timestamps is orthogonal to other choices that define the flavor and properties of the resulting temporal data model, in particular:

1. To the decision of *what database objects the timestamps are attached to*, and
2. To the decision of *how many timestamps* (per such object) are used.

First to explore is the choice of objects to be timestamped. Intuitively, timestamps should only be attached to objects that actually *capture* information in the underlying data model, indicating that the particular (piece of) information is valid for that timestamp. In the relational model these are *tuples* and their membership in *relations*. Thus, the two principal choices are as follows:

The Snapshot Model. Temporal databases in the *snapshot model* are formally defined as mappings from the time domain T to (the class of) standard relational databases with a particular fixed schema ρ. In the case of a linearly ordered time domain, such a temporal database can be viewed as a time-indexed sequence of standard relational databases, commonly called *snapshots*. Note that such a sequence is not necessarily discrete or finite: that depends on the choice of the underlying time domain. Intuitively, to capture the fact that, in a snapshot temporal database D, a relationship r holds among uninterpreted constants $a_1,...,a_k$ at time t it must be the case that $r(a_1,...,a_k)$ holds in $D(t)$, where $D(t)$ is a standard relational instance, the snapshot of D at time t; this statement is denoted by writing $r^{D(t)}(a_1,...,a_k)$.

These structures, in the area of *modal logics*, are called *Kripke structures* in which worlds are described by relational databases and where the time domain serves as the accessibility relation.

The Timestamp Model. Temporal databases in the *timestamp model* are defined in terms of temporal relations, relations whose schemas are extended with an additional attribute ranging over the time domain. This attribute is commonly referred to as the *timestamp attribute* or simply *timestamp*.

More formally, a relational symbol R is a *timestamped extension* of a symbol $r \in \rho$ if it contains all attributes of r and a single additional attribute t of the temporal sort (without loss of generality, assuming that it is always the first attribute). A *timestamp temporal database* D is then a first-order structure $D = \{R_1^D,...,R_k^D\}$ consisting of the interpretations (instances) for all the temporal extensions R_i of r_i in ρ. The instances R_i^D are called *temporal relations*. Similarly to the snapshot case, there is no restriction on the number of timestamps (i.e., the cardinality of the set of timestamps) in such instances; issues connected with the actual finite representation of these relations are addressed below. However, the relation

$$\{a_1,...,a_k : (t, a_1, ..., a_k) \in R_i^D\},$$

a snapshot of R at t, must be finite for every timestamp $t \in T$.

It is easy to see that snapshot and timestamp temporal models are simply different views of the same (isomorphic) sets of facts and thus represent the same class of temporal databases. Formally, a snapshot temporal database D corresponds to a timestamp temporal database D' (and vice versa) as follows:

$$\forall t.\forall x_1,...,x_k.r^{D(t)}(x_1,...,x_k) \;\Leftrightarrow\; R^{D'}(t, x_1,...,x_k),$$

where r and R are a relation in the schema of D and its temporal extension in the schema of D', respectively. This correspondence makes the two models interchangeable. Hence, for temporal queries formulated in query languages such as Temporal Relational Calculus (TRC) or First-order Temporal Logic (FOTL), these two models of point-stamped temporal databases can be used interchangeably.

The Parametric Model. Several temporal data models propose to use time-dependent *unary functions* as attribute values of tuples in temporal relations. These models are called *parametric models* or *attribute timestamped models*. As unary functions can be represented by binary relations (e.g., with the first attribute being the timestamp and the second attribute the value of the function for that timestamp), these models are examples of nested, non-first normal form models [4,5]. Moreover, if the implicit grouping of tuples in such relations is accidental or in the presence of appropriate keys, a first-normal form representation can be obtained by unfolding, similarly to the case of the nested relational model. The transformation is then defined by:

$$R := \{(t, f_1(t),..., f_k(t)) \mid (f_1,...,f_k) \in R^P, t \in T\},$$

where R is a timestamp relation corresponding to the parametric relation R^P. Note also that if a varying number of tuples is to be modeled in this model, *partial functions* must be used in R^P; then, however, tuples can become only partially defined for a given time instant, and therefore additional conditions must be enforced. This makes the model quite cumbersome to use, in particular when compared to the snapshot and timestamp models. Many of these difficulties originate from associating timestamps with *uninterpreted constants* that, in the relational model, *do not* carry any information on their own.

Multiple Atomic Timestamps

The second issue that arises is the question of *how many* timestamps are attached to database objects. So far single-dimensional temporal databases were considered, i.e., where each database object was associated with a single timestamp. The intuition behind such models is that *validity* of data is determined by a single time instant. In the case of the timestamp model, this translates to the fact that temporal relations were allowed only a single (often *distinguished*) temporal attribute. However, there are two natural reasons to relax this requirement and to allow multiple timestamps to be associated with database objects (i.e., multiple timestamp attributes to appear in schemas of relations, either explicitly or implicitly). There are two cases to consider:

Models with a fixed number of timestamp attributes. In many cases data modeling requires attaching several timestamps to database objects. Intuitively, a particular piece of information can be associated with, e.g., a timestamp for which the information is *valid* in the modeled world and another timestamp that states when the information is *recorded* in the database. Hence, every object has two timestamps. The resulting data model is called the bitemporal model [6] and the timestamps are called valid time and transaction time, respectively. Similarly, one can envision temporal models with three (or any fixed number) of *distinguished temporal attributes* – attributes with a predetermined interpretation – that are *common to all temporal relation schemas*. Temporal data models with an apriori *fixed* number of timestamp attributes can still be equivalently represented using the snapshot and the timestamp approaches. In the snapshot case, database instances are indexed by fixed tuples of time instants. Hence the bitemporal model can be seen as a two-dimensional plane of relational instances. The timestamp model simply adds an appropriate number of (distinguished) attributes to the timestamp extensions of relational schemes.

Models with a varying number of timestamp attributes. While most of the data modeling techniques require only a fixed number of timestamp attributes in schemas of temporal relations, it is often convenient to allow arbitrary number of timestamp attributes to be associated with a database object. This leads to allowing temporal data models without limits on the number of timestamp attributes in schemas of temporal relations. In such models, time dependencies are captured by explicit (user-defined) attributes ranging over the time domain. For a varying number of timestamps, only the *timestamp* view of the temporal data model makes sense.

Fixed-dimensional temporal data models are appealing as they commonly provide an additional built-in *interpretation* for timestamps, e.g., the valid time timestamp always states that the information is *true* in the world at that particular time. Temporal data models with varying, user-defined timestamps do not posses this additional interpretation, and the exact meaning of the timestamps depends on how the world is modeled by the associated attributes (similarly to the standard relational case). However, there is another need for models with varying and unbounded number of timestamp attributes: for temporal query languages based on temporal relational calculus, there cannot be an equivalent temporal relational algebra defined over any of the fixed-dimensional temporal data models (see the entry on Temporal Logic in Database Query Languages or [7,8] for details).

Sets of Timestamps: Compact Representation

The point-stamped temporal data models and the associated temporal query languages provide an excellent vehicle for defining a precise semantics of queries and for studying their properties. However, in *practical applications* an additional hurdle has to be overcome: a naive storage of point-stamped temporal relations, either in the timestamp or in the snapshot model, is often not possible (as the instances of the relations can be infinite, e.g., sets of time instants that represent bounded durations are infinite when a *dense time domain* is used) or impractical (the number of instants is very large). For these and other reasons, many temporal data models associate database objects with *sets* of time instants rather than with single individual time instants.

Temporal models that use complex timestamps, such as intervals, no longer appear to be point-stamped – or in the first normal form (1NF). However, Chomicki [2] has shown that in many cases these complex objects are merely compact representations of a possibly large or even infinite number of time instants associated with a particular fact. The most common approach along these lines is to attach timestamps in the form of *intervals* to facts that persist over time. For example, the temporal relation **WorksFor** in Fig. 1 can be compactly (and finitely) represented by the relation:

$$\mathbf{WorksFor}' = \{([2001, 2002], \mathrm{John}, \mathrm{IBM}),\\ ([2004, \infty], \mathrm{John}, \mathrm{Microsoft})\}.$$

Note that such an *interval encoding* is not unique and multiple snapshot equivalent representations can exist. For single-dimensional temporal relations, uniqueness

of the representation can be achieved using temporal coalescing. However, it is not clear that meaningful, canonical ways of defining coalescing for multidimensional temporal relations, including bitemporal relations, exist [3].

On the other hand, the use of temporal coalescing and other set-oriented operations on interval timestamps, such as intersection of timestamps in temporal joins, indicates that the interval timestamps are indeed solely a representation tool for point-stamped relations: these operations cannot be used in a model that associates truth with the intervals themselves as there is no clear way to do so for the intervals that result from such operations, e.g., it is unclear – from a conceptual point of view – what facts should be associated with an intersection of two intervals *without* implicitly assuming that facts associated with the original two intervals hold *for all time points contained in those two intervals*, or at least for certain sub-intervals.

The choice of *intervals* to compactly represent adjacent timestamps originates from the structure of the temporal domain: intervals are the only (convex) one-dimensional sets that can be defined by (first-order) formulas in the language of linear order. For more structured time domains, however, the repertoire of encodings for sets of timestamps can be richer, e.g., using formulas describing *periodic sets*, etc., as compact timestamps.

Query Languages and Integrity Constraints

Point-stamped data models support point-based temporal query languages that are commonly based on extensions of the relational calculus (first-order logic). The two principal extensions are as follows:

1. First-order Temporal Logic: a language with an implicit access to timestamps using temporal connectives and
2. Temporal Relational Calculus: a two-sorted logic with variables and quantifiers explicitly ranging over the time domain.

These languages are the counterparts of the snapshot and timestamp models. However, unlike the data models that are equivalent in their expressiveness, the second language is strictly more expressive than the first [1,8]. Temporal integrity constraints can also be conveniently expressed in these languages [3].

Key Applications

Point-based temporal data models serve as the underlying data model for most abstract temporal query languages.

Polytransactions

George Karabatis
University of Maryland, Baltimore County (UMBC),
Baltimore, MD, USA

Definition

A polytransaction $T^{+}$is a transitive closure of a transaction T submitted to an Interdependent Data Management System (a type of a multidatabase system which enforces dependencies among related data objects). The transitive closure is computed with respect to an Interdatabase Dependency Schema (IDS) consisting of a collection of data dependency descriptors (D^3s), which specify the dependencies between data objects.

Key Points

Data objects in multiple (possibly distributed and/or heterogeneous) systems which form dependencies among them are called *interdependent data*. These dependencies are identified through *data dependency descriptors* (D^3s). A D^3 specifies the relationships between source and target objects including how much inconsistency can be tolerated between them before it is necessary to restore it, and the actions to take to maintain consistency when it reaches intolerable levels. All these D^3s together form an *Interdatabase Dependency Schema* (IDS) [3].

When a source object in a D^3 is updated, the consistency between itself and the target object in the same D^3 may be violated beyond allowable levels. Then, a system-generated transaction updates the target object to maintain consistency. The updated target object may participate as source in another D^3, therefore a series of related transactions may execute to maintain consistency. These related transactions form a transaction tree called a *polytransaction* [3,1,2].

A polytransaction tree contains nodes (corresponding to its component transactions), and edges (identifying the "execution mode" between the parent and children transactions) and is determined as follows. For each D^3_ε IDS containing a source object updated by T, and in need to restore consistency with its target object, a new node is added corresponding to a new transaction T' (child of T). The operations of T' which restore consistency are the actions specified in the D^3.

Execution modes: A child transaction is *coupled* if the parent transaction must wait until the child transaction completes before proceeding further. It is *decoupled* otherwise. Also, a coupled transaction is *vital* (the parent transaction must fail if the child fails), or *nonvital* (the parent transaction survives the failure of a child).

Positive Relational Algebra

Cristina Sirangelo
University of Edinburgh, Edinburgh, UK

Synonyms

SPJRU-Algebra; SPCU-Algebra

Definition

Positive relational algebra is the fragment of relational algebra which excludes the difference operator. Relational algebra queries are expressions defining mappings from database instances of an input database schema to an output relation. In particular a positive relational algebra query over a database schema τ is one of the following expressions, each one with an associated set of attributes:

- A constant relation over a set of attributes U is a positive relational algebra query with associated set of attributes U;
- If $R(U)$ is a relation schema in τ, the relation symbol R is a positive relational algebra query with associated set of attributes U;
- If Q and Q' are positive relational algebra queries with sets of attributes U and U' respectively, the following are positive relational algebra queries:
  - The *selection* $\sigma_{A=B}(Q)$ or $\sigma_{A=c}(Q)$, with set of attributes U, where A and B are attributes in U, and c is a constant value;
  - The *projection* $\pi_X(Q)$, with set of attributes X, where $X \subseteq U$;
  - The *natural join* $Q \bowtie Q'$, with set of attributes $U \cup U'$;
  - The *renaming* $\rho_{U \to W}(Q)$, with set of attributes W;
  - The *union* $Q \cup Q'$, in the case that $U = U'$, with associated set of attributes U.

The semantics of a positive relational algebra query on a database instance I of schema τ is a relation instance defined as follows: the semantics of a constant relation is the relation itself; the semantics of a relation symbol R of τ is the value of R in I; the semantics of selection, projection, natural join, renaming and union expressions above, is defined according to the semantics of the corresponding operator on inputs given by the semantics of Q and Q'.

Key Points

The basic operators of the positive relational algebra are a non-redundant set: by removing any of these operators the set of expressible query mappings would be reduced. Moreover they allow the simulation of other operators. Among these, the intersection $R_1 \cap R_2$ of two relations over the same set of attributes can be simulated as $R_1 \bowtie R_2$; the generalized selection whose condition is a positive boolean combination of equality atoms can be simulated using composition and union of primitive selection operators; consequently also the theta-join, with the same restriction on the join condition, and the equijoin can be simulated.

An example of positive relational algebra query over a database schema consisting of relation schemas *Students*(*student-number, student-name*) and *Exams* (*course-number, student-number, grade*), is the expression $\pi_{student-name}(Students \bowtie \sigma_{grade\ =\ A}(Exams))$. It returns the names of the students that have passed at least one exam with grade A.

The positive relational algebra is equivalent (in that it expresses the same query mappings) to other query languages such as *unions of conjunctive queries* in safe relational calculus, and *nonrecursive datalog* with one target predicate.

In the absence of attribute names, the basic operators of positive relational algebra are $\{\sigma, \pi, \times, \cup\}$. The positive relational algebra without names turns out to be equivalent to the positive relational algebra with names and thus equivalent to the other above mentioned query paradigms.

Post-Randomization Method

▶ PRAM

PRAM

Josep Domingo-Ferrer
Universitat Rovira i Virgili, Tarragona, Catalonia

Synonyms

Post-randomization method

Definition

The Post-RAndomization Method (PRAM) is a probabilistic, perturbative masking method for disclosure protection of categorical microdata. In the masked file, the scores on some categorical attributes for certain records in the original file are changed to a different score according to a prescribed probability mechanism, namely a Markov matrix. The Markov approach makes PRAM very general, because it encompasses noise addition, data suppression and data recoding.

Key Points

The PRAM matrix contains a row for each possible value of each attribute to be protected. This rules out using the method for continuous data. PRAM was invented by Gouweleeuw et al. [1]. The information loss and disclosure risk in data masked with PRAM largely depend on the choice of the Markov matrix and are still (open) research topics [2].

Precision

Ethan Zhang[1,2], Yi Zhang[2]
[1]University of California-Santa Cruz, Santa Cruz, CA, USA
[2]Yahoo! Inc., Santa Clara, CA, USA

Definition

Precision measures the accuracy of an information retrieval (IR) system. More precisely, precision is the fraction of retrieved documents that are relevant. Consider a test document collection and an information need Q. Let R be the set of documents in the collection that are relevant to Q. Assume an IR system processes the information need Q and retrieves a document set A. Let $|R_a|$ denote the number of documents that are in both R and A. Further let $|R|$ and $|A|$ be the numbers of documents in R and A, respectively. The *precision* of the IR system for Q is defined as $P = |R_a| / |A|$.

Key Points

Precision and recall are the most frequently used and basic retrieval performance measures. Many other standard performance metrics are based on the two concepts.

Precision and Recall

Ben Carterette
University of Massachusetts Amherst, Amherst, MA, USA

Synonyms

Positive predictive value; Sensitivity; False negative rate

Definition

Recall measures the ability of a search engine or retrieval system to locate relevant material in its index. *Precision* measures its ability to not rank nonrelevant material. With everything above rank cut-off n considered "retrieved" and everything below considered "not retrieved," precision and recall can be stated mathematically as:

$$\text{precision} = \frac{|\text{retrieved \& relevant at rank } n|}{|\text{retrieved at rank } n|}$$

$$\text{recall} = \frac{|\text{retrieved \& relevant at rank } n|}{|\text{relevant}|}$$

Key Points

Precision and recall are the traditional metrics for retrieval system performance evaluation, and nearly all other performance measures can be seen as either precision-based, recall-based, or a combination of the two.

There is a trade-off between precision and recall: as more is done to bring more relevant results into a ranking, increasing recall, inevitably nonrelevavnt results will be captured as well, decreasing precision. This can be seen in precision-recall curves, which plot precision against recall while varying rank cut-off n.

		Condition	
		True	False
Prediction	True	True Positive	False Positive
	False	False Negative	True Negative

Precision and recall are not limited to information retrieval; they can be defined more formally on any 2 × 2 contingency table. For the table precision is True Positives divided by True Positives + False Positives and recall is True Positives divided by True Positives + False Negatives. In medical literature, precision is known as *positive predictive value* and recall as *sensitivity*; in the statistics literature, recall is equivalent to the *power* (or 1 − Type II error rate) of a hypothesis test (precision has no analogue).

Precision at n

Nick Craswell
Microsoft Research Cambridge, Cambridge, UK

Synonyms

P@n

Definition

In an information retrieval system that retrieves a ranked list, the top-n documents are the first n in the ranking. Precision at n is the proportion of the top-n documents that are relevant.

Key Points

If r relevant documents have been retrieved at rank n, then:

$$\text{Precision at n} = \frac{r}{n}$$

The value of n can be chosen based on an assumption about how many documents the user will view. In Web search a results page typically contains ten results, so n = 10 is a natural choice. However, not all users will use the scrollbar and look at the full top ten list. In a typical setup the user may only see the first five results before scrolling, suggesting Precision at 5 as a measure of the initial set seen by users. It is the document at rank 1 that gets most user attention, because this is the document that users view first, suggesting the use of Precision at 1 (which is equivalent to Success at 1).

It is possible to calculate precision at a later cutoff, although precision gives equal weight to every result in the list. For example, when calculating precision at 1,000 the 1,000th document is as important as the 1st, whereas users of a ranked retrieval system are likely to consider the 1st document most important. Other information retrieval measures place a greater emphasis on early ranks, such as Mean Average Precision and Mean Reciprocal Rank.

In set-based retrieval, where there is no ranking, the precision of a retrieved set of size n can still be calculated, as r/n.

In order to calculate precision at n it is only necessary to obtain relevance judgments for the top-n documents, unlike recall, which can only be measured if the complete set of relevant documents has been identified.

Precision-Oriented Effectiveness Measures

NICK CRASWELL
Microsoft Research Cambridge, Cambridge, UK

Definition

Precision-oriented evaluation in information retrieval considers the relevance of the top *n* search results, for small *n* and using a set of relevance judgments that need not be complete. Such "shallow" evaluation is consistent with a user who only cares about the top-ranked documents. Relaxing the requirement of identifying all relevant documents for every query means that certain measures, such as recall at *n*, cannot be applied. However, it also allows evaluation on a very large corpus, where employing human relevance assessors to find the complete relevant set for each query would be too expensive. Both aspects of precision-oriented evaluation, the shallow viewing of results and the large corpus, are associated with Web search, where search results are typically a top-10 and the corpus may contain tens of billions of documents.

Historical Background

The Cranfield II experiments in 1963 were a landmark effort in information retrieval evaluation [3]. A test collection comprising 1,440 documents, 225 queries and relevance judgments was created. Because the document set was small, it was possible to judge the relevance of every document for each query. Using complete relevance judgments it is possible to evaluate precision, the proportion of retrieved documents that are relevant, and recall, the proportion of relevant documents that are retrieved. The test collection is reusable, in that it is possible to run a new retrieval experiment using existing queries and relevance judgments, without encountering any unjudged document in the search results.

Judging all documents for every query does not scale well with corpus size, and becomes untenable even with tens of thousands of documents. The best-known solution to this problem is the pooling method, as introduced in the Text Retrieval Conference (TREC) in 1991 [5]. Under pooling, the top-n documents are merged from a large number of systems. This pool of documents does not necessarily contain all relevant documents. However, if a sufficient variety of top-n lists are merged, for a large enough n, the pool will contain the majority of the relevant documents. After judging the pool, the set of relevance judgments can be thought of as "sufficiently complete" to be reusable. In other words, a new retrieval experiment may retrieve unjudged documents, but these can be assumed to be irrelevant since almost all the relevant documents have already been identified.

Most TREC experiments have resulted in test collections where the pools are sufficiently complete for reuse. However, for the largest TREC corpora, it is unlikely that the full relevant set has been identified, or could be identified due to practical limitations in the judging resources [4]. In such cases it is possible to judge with shallow pools, for example judging the top 20 documents and using a precision-oriented measure. Since the full relevant set has not been discovered, it is not straightforward to measure recall, or use any measure that relies on knowing the size of the relevant set. The test collection may not be reusable.

Foundations

To understand precision-oriented evaluation, it is useful to revisit the fundamental measures of information retrieval, precision and recall. If there are *R* known relevant documents, and *r* of them have been retrieved at rank n, then:

$$\text{Precision at n} = \frac{\mathrm{r}}{\mathrm{n}}$$

$$\text{Recall at n} = \frac{\mathrm{r}}{\mathrm{R}}$$

For a given cutoff n, these are just different ways of normalizing r. If r increases, because a new retrieval system retrieves a better set of *n* documents, both precision and recall improve.

One aspect of precision-oriented evaluation is where not all relevant documents have been identified, so R is unknown. In such a case it is not straightforward to estimate recall, which depends on knowledge of R. However, if the top n documents have been judged, it is possible to accurately measure precision.

Another aspect of precision-oriented evaluation is shallow evaluation. At an early cutoff (small n) few relevant documents will have been retrieved (small r), but precision may still be quite high. By contrast, recall might be low, particularly if R is much higher than r and n. In a standard precision-recall curve, which shows precision and recall at multiple cutoffs, precision-oriented evaluation considers the left-hand end of the curve. Precision-oriented evaluation models a user who does not need to see all relevant documents and is impatient, unwilling to look deep into the ranking.

Some experiments have both shallow evaluation and incomplete judgments, for example the TREC Very Large Collection Track [4] judged with a pool depth of 20, to measure Precision at 20. Metrics such as Precision at n, Success at n, Mean Reciprocal Rank and Average Precision at n have been applied in such settings. More details about these metrics can be found from the corresponding entries in this encyclopedia.

In other experiments, judgments may be incomplete or evaluation shallow, but not both. In those cases, it is not clear that the evaluation should be called precision-oriented. It is possible to evaluate with a recall-oriented measure using incomplete judgments, via measures such as bpref and inferred AP [1,6]. It is also possible to perform shallow evaluation with complete judgments, particularly in cases with very few relevant documents such as known item search. In a setting where R tends to be between 1 and 10, a metric such as R-Precision could be thought of as precision-oriented.

Key Applications

Web search is probably the most well-known application where precision-oriented evaluation is used. Users do not often look deep into the results list, so evaluation that concentrates on shallow ranks is appropriate. In addition, the document collection is so large, that it is difficult to be sure that all good answers for a query have been identified. The exception is where a user has a very focused need, for example navigational search, where only a single document is required. Even then the web is volatile, with documents being created, modified and deleted without warning, so it is necessary to perform careful maintenance of a query set. For queries with multiple correct answers, it is usual to calculate precision-oriented measures, and very difficult to estimate recall.

Data Sets

Data sets for precision-oriented evaluation, and Information Retrieval experimentation in general, are available from the National Institute of Standards and Technology, in the Text Retrieval Conference (TREC) series [5]. TREC experiments typically involve hundreds of thousands of documents or more, and 50 or more query topics.

Structured Text Retrieval Tasks

Definition

Presenting structured text retrieval results refers to the fact that, in structured text retrieval, results are not independent and a judgment on their relevance needs to take their presentation into account. For example, HTML/XML/SGML documents contain a range of nested sub-trees that are fully contained in their ancestor elements. As a result, structured text retrieval should make explicit the assumptions on how the retrieval results are to be presented. Four of the main assumptions to be addressed are the following. First, the *unit of retrieval* assumption: is there a designated retrieval unit (such as the document or root node of the structured document) or can every sub-tree be retrieved in principle? Second, the *overlap* assumption: may retrieval results contain text or content already part of other retrieval results (such as a full article and one of its individual paragraphs)? Third, the *context* assumption: can results from the same structured document be interleaved with results from other structured documents? Fourth, the *display* assumption: is a retrieval result (say a document sub-tree corresponding to a paragraph) presented as an autonomous unit of text, or as an entry-point within a structured document?

Historical Background

Although similar considerations play an important role in the design of user interfaces (see, for example, [6]), this entry will focus on the underlying principles of the different structured text retrieval tasks. Structured text retrieval dates back, at least, to the early days of passage retrieval [14]. Early passage retrieval approaches have been using either the document structure (sentences, paragraphs, sections, etc.), or arbitrary text windows of fixed length. The early experimental results primarily confirmed the effectiveness of passage-level evidence for boosting document retrieval. The use of document structure derived from SGML mark-up was pioneered by [20], studying adhoc SGML element retrieval. Probabilistic indexing approaches for databases have been studied even earlier [4], allowing to rank results based on vague queries. Adhoc XML element retrieval and best entry point retrieval was studied in the Focus project [3,10].

The main thrust in recent years is the initiative for the evaluation of XML retrieval [7]. The retrieval task descriptions heavily evolved during the different years. Initially, in 2002, INEX studied adhoc XML element retrieval for keyword (Content-Only) and structured (Content-And-Structure) queries with the goal to "retrieve the most specific relevant document components" [5, p. 2]. This generic adhoc XML element retrieval task was continued at INEX 2003 [9, p. 200] and at INEX 2004 [12, p. 237], asking for "components that are most specific and most exhaustive with respect to the topic of request." Ongoing discussion, and vivid disagreement, on the interpretation of generic adhoc XML element retrieval task prompted the introduction of three different retrieval strategies at INEX 2005 [11, pp. 385–386]: *Thorough* aims to find all highly exhaustive and specific elements (roughly corresponding to the earlier INEX task); *Focussed* aims to find the most specific and exhaustive element in path (no overlapping results); and *Fetch and browse* aims to first identify relevant articles, and then to find the most specific and exhaustive elements within the fetched articles (results grouped by article). These different adhoc XML element retrieval tasks have been continued and further explicated at INEX 2006 [1], with the Fetch and browse task refined to: *Relevant in Context* aims to retrieve a set of non-overlapping relevant elements per article; and *Best in Context* aims to retrieve, per article, a single best entry point to read its relevant content. At INEX 2007 three tasks are continued: Focused, Relevant in Context, and Best in Context, but liberalized to arbitrary passages [2].

Foundations

The way in which retrieval results are presented to users, is always a crucial factor determining the success or failure of an operational retrieval system. However, within the Cranfield/TREC tradition of evaluating document retrieval systems it is unproblematic to abstract away from presentation issues and analyze retrieval effectiveness by regarding retrieved documents as atomic and independent results. In structured text retrieval, the situation is different, and there is a need to make explicit some of the assumptions underlying the retrieval task since these have an impact on what is regarded as a "relevant" retrieval result.

First, the *unit of retrieval* assumption: is there a designated retrieval unit (such as the document or root node of the structured document) or can every sub-tree be retrieved in principle? Rather than treating documents as atomic, structured documents have internal document structure that allows any logical unit of them to be retrieved. For example, in case of a textual document where the layout structure is marked up, it is possible to retrieve sections, paragraphs, or still the whole article if its completely devoted to the topic of request. Figure 1 contains a screen-shot of a XML element retrieval system that retrieves a ranked list of XML elements.

Second, the *overlap* assumption: may retrieval results contain text or content already part of other retrieval results (such as a full article and one of its individual paragraphs)? Interactive experiments at INEX 2004 [17] clearly revealed that test persons disliked a ranked list of element results that overlap in whole or part in their content. Hence, if the retrieval tasks should reflect a scenario in which the ranked elements are directly displayed to an end-user, retrieval results should be disjoint.

Third, the *context* assumption: can results from the same structured document be interleaved with results from other structured documents? A further finding of the interactive experiments at INEX 2004 [17] is that test persons prefer results from the same document be grouped together. Figure 2 contains a screen-shot of a XML element retrieval system that retrieves XML elements displayed in document order in their article's context.

Presenting Structured Text Retrieval Results. Figure 2. Displaying structured text retrieval results within article context (reproduced from [15]).

Fourth, the *display* assumption: is a retrieval result (say a document sub-tree corresponding to a paragraph) presented as an autonomous unit of text, or as an entry-point within a structured document? A decision on the relevance of a particular document component crucially depends on whether it will be presented as an isolated excerpt, or within its original context. In the first case, the component should be fully self-contained: it should not only contain the relevant information (say, for example, a description of an algorithm) but also establish that this information is, indeed, satisfying the topic of request (for example, that the algorithm is the fastest way to lexicographically sort a list, if that were the topic of request). This is related to linguistics, where there is a common distinction between the context (or topic/theme: that what is being talked about), and the information (or comment/rheme/focus: that what is being said). If results are to be presented in their document context, the link to the topic of request can be taken for granted and only the sought information can be regarded as relevant. If results are to be presented out of context, both the information and its relation to the topic of request are needed to establish the relevance of a document component.

Table 1 shows how the different structured text retrieval tasks are based on different underlying assumptions. For traditional document or article retrieval, there is a fixed unit of retrieval and assumptions on overlap, context, or display do not apply. For the generic adhoc element retrieval task (INEX 2002–2004) or Thorough (INEX 2005–2006), any document

Presenting Structured Text Retrieval Results. Table 1. Structured text retrieval tasks

	Unit of retrieval	Overlap	Context	Display
Article retrieval	Whole article	–	–	–
Thorough	Arbitrary element	Allowed	Scattered	Elements
Focussed/Focused	Arbitrary element	Non-overlapping	Scattered	Elements/Passages
Fetch and browse	Arbitrary element	Allowed	List per article	Elements
Relevant in context	Arbitrary element	Non-overlapping	Set per article	Elements/Passages
Best in context	Arbitrary element	Non-overlapping	One result per article	Starting point

component can be retrieved, and there are no restrictions on overlap, context, or display. Basically, the task is system-biased, reflecting the ability of the retrieval engine to estimate the relevance of individual document components, for example for further processing methods. For Focussed/Focused (INEX 2005–2007), a ranked list of non-overlapping document components is asked for, with no restrictions on context or display. This task reflects a scenario where a ranked-list of document components is directly presented to the searcher. For Fetch and browse (INEX 2005), retrieval results from the same structured document need to be returned consecutive, with no restriction on overlap or display. This results in a tasks resembling on the one hand traditional document retrieval, whilst on the other hand providing deep-linking to relevant document components. The same holds for Relevant in context (INEX 2006–2007), where there is an unranked set of now non-overlapping elements per article, reflecting results to be presented in document order. Finally, Best in context (INEX 2006–2007) explicitly asks for a single best entry point into the article (so non-overlapping and non-scattered articles by definition). This scenario captures a "relative" notion of relevance, where users desire access to the best information, rather than all relevant information.

These different retrieval tasks lead to different evaluations of what systems and techniques are effective for structured text retrieval. Although these tasks are not unrelated, for example, the generic Thorough task (capturing the ability of a system to estimate the relevance of an element) can be use as input for further processing for the other tasks, each of these different retrieval tasks is capturing a different aspect of structured text. The retrieval tasks bring in elements from the task context in which they are to be applied, either in a end-user setting or system setting. As a result, the richer descriptions of the task's context and underlying assumptions are resonating more closely with actual real-world applications [19]. Bringing task-specific elements into information retrieval benchmark testing has been identified as one of the main research directions for further enhancing information access in general [18].

Key Applications

Structured text retrieval has the potential to improve information access by giving more direct access to the relevant information inside documents. As [14, p. 49] put it:

- Large collections of full-text documents are now commonly used in automated information retrieval. When the stored document texts are long, the retrieval of complete documents may not be in the users' best interest. In such circumstances, efficient and effective retrieval results may be obtained by using passage retrieval strategies designed to retrieve text excerpts of varying size in response to statements of user interest.

Structured document retrieval is becoming increasingly important in all areas of information retrieval, the application to full-text book searching is obvious and such commercial systems already exist [19].

Future Directions

Improving information access by formulating retrieval tasks that capture interesting aspects of real-world structured text searching is an ongoing open problem. There has been a series of workshops addressing open problems, including real-world applications, the unit of retrieval, tasks and measures, and the problem of overlap [18].

The traditional picture of IR takes as input a document collection and a query, and gives as output a ranked list of documents. In the retrieval task, there no distinction between the hit list (communicating the ranked list) and the actual result documents. Where structured document retrieval is going beyond a linear ranked list of results, at least conceptually, interesting new research questions present themselves. By presenting related results from the same article, like in Fig. 2, the hit-list becomes a query-biased summary of the discourse structure of the retrieved article. [16] conduct experiments on the level of detail desired by searchers. Evaluation of such a system seems to require taking both retrieval effectiveness and document summarization aspects into account.

Data Sets

Notable data-sets are:

1. The *Shakespeare test collection* used in the Focus project 2000–2001 [3].
2. The *IEEE Computer Society collection* used at INEX 2002–2004 [7].
3. The expanded *IEEE Computer Society collection* used at INEX 2005 [7].
4. The *Wikipedia XML Corpus* used at INEX 2006–2007 [7].

Clustering index; Sparse index

Definition

A tree-based index is called a *primary index* if its order is the same as the order of the file which it indexes Consider a relation *R* with some numeric attribute *A* taking values over an (ordered) domain *D*. Assume that relation *R* has been physically stored as an *ordered* file, following the order of the values of attribute *A*. Furthermore, assume that a tree-based index (e.g., B +-tree) has been created on attribute *A*. Then this index is primary.

Key Points

Tree-based indices are built on numeric attributes and maintain an order among the indexed search-key values. They are further categorized by whether their search-key ordering is the same with the file's physical order (if any). Note that a file may or may not be ordered. Ordered is a file whose records are stored in pages according to the order of the values of an attribute. Obviously, a file can have at most a single such order since it is physically stored once. For example, if the *Employee* relation is ordered according to the *name* attribute, the values in the other attributes will not be in order. A file stored without any order is called an unordered file or heap. If the search-key of a tree-based index is the same as the ordering attribute of a (ordered) file then the index is called *primary*. An index built on any non-ordering attribute of a file is called *secondary*.

Note that a primary index also controls the physical placement of the data records in a file. Since such an index also clusters the values of the file, the term *clustering* index has alternatively been used. In contrast, the order in the leaf pages of a secondary index is not the same as the order of the records in the file. Hence, a secondary index (also called *non-clustering*) needs an extra level of indirection, namely, a pointer to the actual position of a record with a given value in the relation file. In other words, a secondary index only clusters references to records (in the form of <value, pointer> fields), but *not* the records themselves. This extra indirection from a leaf page of a secondary index to the actual position of a record in a file has important subsequences on optimization. Consider for example a secondary index (B + -tree) on the *ssn* attribute of the *Employee* relation (which assume is ordered by the *name* attribute). A query that asks for the salaries of employees with *ssn* in the range *[x,y]* can facilitate the B + -tree on *ssn* to retrieve references to all records in the query range. Assume there are 1,000 such *ssn* values in the *Employee* file. Since the actual *Employee* records must be retrieved (so as to report their salaries), each such reference needs to be materialized by possibly a separate page I/O (since the actual records can be in different pages of the *Employee* file). If instead the file was ordered on the *ssn* attribute, the B + -tree on *ssn* would have clustered (as primary index) the *Employee* records on *ssn*, and thus the 1,000 records that need to be retrieved would be located within few pages.

In practice, the search-key of a primary index is usually the file's primary key, however this is not necessary. That is, primary indexes need not be on the primary keys of relations. (In the above example, it was first assumed that the *Employee* file is ordered according to the *name* attribute and not according to the primary key *ssn* attribute). A relation can have several indices, on different search-keys; among them, at most one is primary (clustering) index and the rest are secondary ones.

Principal Component Analysis

Heng Tao Shen
The University of Queensland, Brisbane, QLD, Australia

Synonyms

PCA

Definition

Principal components analysis (PCA) is a linear technique used to reduce a high-dimensional dataset to a lower dimensional representations for analysis and indexing. For a dataset P in D-dimensional space with its principal component set Φ, given a point p∈P, its projection on the lower d-dimensional subspace can be defined as: p. Φ_d, where Φ_d represents the matrix containing 1st to d^{th} largest principal components in Φ and $d < D$.

Key Points

PCA finds a low-dimensional embedding of the data points that best preserves their variance as measured in the high-dimensional input space [1]. It identifies the directions that best preserve the associated variances of the data points while minimize "least-squares" (Euclidean) error measured by analyzing data covariance matrix. The first principal component is the eigenvector corresponding to the largest eigenvalue of the dataset's co-variance matrix, the second component corresponds to the eigenvector with the second largest eigenvalue and so on. The chosen principal components form the lower dimensional subspace of interest. Typically, the top *d* principal components are selected since they carry the most information of original data. The lower dimensional representation for a point is then generated by multiplying the data point with the selected principal components. PCA makes a stringent assumption of orthogonality to make it amenable to linearity.

PCA has been widely used in many applications for exploratory data analysis and compression, making predictive models, indexing, information retrieval, etc.

Privacy

Patrick C. K. Hung[1], Vivying S. Y. Cheng[2]
[1]University of Ontario Institute of Technology, Oshawa, ON, Canada
[2]Hong Kong University of Science and Technology, Hong Kong, China

Definition

Privacy helps to establish personal autonomy and create individualism. Privacy is a state or condition of limited access to a person (e.g., client). In particular, information privacy relates to an individual's right to determine how, when, and to what extent information about the self will be released to another person or to an organization.

Key Points

With the rising occurrence of information privacy violations, people have begun to take interest in how, when, and where their personal information is being used. People usually interchange the concepts of security with privacy. In fact, they are essentially two different concepts used to protect data. In general, security involves the use of cryptographic tools to protect information in terms of confidentiality, availability, and access control and integrity enforcement. Privacy mainly focuses on the ability of keeping data away from public access, and the way to protect it according to the individual rights.

There are various definitions of privacy in the literature. Some researchers describe confidentiality as privacy, while some regard privacy as an aspect different from using cryptographic tools. Anderson [1] defined privacy as secrecy for benefit of the individual, and confidentiality as secrecy for the benefit of the organization. Alternatively, privacy can also be described by the ability to have control over the collection, storage, access, communication, manipulation and disposition of data. Privacy is also referred as the right for individuals to determine for themselves when, how, and to what extent information about them is communicated to others. As Westin [2] notes,

> ▶ *No definition [of privacy]. . . is possible, because [those] issues are fundamentally matters of values, interests and power.*

It can be said that privacy is a much broader concept than security; privacy protection is based on security protection. Security may enable privacy protection from authorized access, but security alone cannot provide privacy.

To enhance the privacy protection of personal information, legislative schemas and practice guidelines have been proposed by different organizations such as the Health Insurance Portability and Accountability Act (HIPAA) in the United States of America (USA) and the European Union (EU) Data Protection Act. These legislations and requirements can be abstracted as access control policies or rules to serve as a privacy foundation to control access to personal information.

Privacy Measures

▶ Privacy Metrics

Privacy Metrics

Chris Clifton
Purdue University, West Lafayette, IN, USA

Synonyms

Privacy measures

Definition

Measures to determine the susceptibility of data or a dataset to revealing private information. Measures include ability to link private data to an individual, the level of detail or correctness of sensitive information, background information needed to determine private information, etc.

Historical Background

Legal definitions of privacy are generally based on the concept of *Individually Identifiable Data*. Unfortunately, this concept does not have a clear meaning in the context of many database privacy technologies. The official statistics (census) community has long been concerned with measures for privacy, particularly in the contexts of microdata sets (datasets that represent real data, but obscured in ways to protect privacy) and tabular datasets. Measures have largely been based on the probability that a specific value belongs to a given individual, given the disclosed data. As technologies have been developed to anonymize and analyze private data, measures have been developed to quantify the potential for disclosure of private information by those techniques. In 2001, Samarati and Sweeney published papers on k-anonymity as a measure of individual identifiability, leading to considerable research in anonymity measures. At the same time, the rise in privacy-preserving data mining techniques lead to measures based on the ability to estimate values from disclosed data. As of this writing, this field is still open, with many competing measures, often tied to specific anonymization, analysis, or privacy protection techniques.

Foundations

There have been two distinct approaches to measuring privacy, or more specifically probability of disclosure. The first is measuring anonymity. k-anonymity states that any released data item must be linked to at least k individuals with equal probability. It builds on a concept of *Quasi-Identifier QI*: a quasi-identifier is information that an adversary can use to link a released data record to an individual. Formally,

k-Anonymity [8] A given table T^* is said to satisfy k-anonymity if and only if each sequence of values in $T^*[QI_{T^*}]$ appears at least k times in T^*.

While simple to compute, k-anonymity does not by itself guarantee that sensitive data is protected. As first pointed out in [7], if all k values with the same quasi-identifiers also have the same value for a sensitive attribute, k-anonymity can be met while still revealing the sensitive value for an attribute to an adversary. k-anonymity can be extended to deal with this issue:

ℓ-Diversity Principle [4] A $q^\star$-block is ℓ-diverse if contains at least ℓ "well-represented" values for the sensitive attribute S. A table is ℓ-diverse if every $q^\star$-block is ℓ-diverse.

This still does not resolve the issue, as real values may have skewed distributions; a particular rare value may be "well-represented" by occurring in only one $q^\star$-block, identifying the individuals represented in that block as having an unusually high probability of possessing that rare value. A further refinement is:

The t-closeness Principle [3] An equivalence class is said to have t-closeness if the distance between the distribution of a sensitive attribute in this class and the distribution of the attribute in the whole table is no more than a threshold t. A table is said to have t-closeness if all equivalence classes have t-closeness.

A challenge with any of these metrics is choosing appropriate values for k. Achieving a suitably low risk of disclosure may require a high value of k to protect particularly easy to identify individuals, resulting little specificity (and thus low value) in the anonymized dataset. This leads to a second set of metrics for anonymity, measuring not privacy but the fidelity of the disclosed data. These are typically based on the levels of generalization required to achieve a given level of anonymization, but as yet it isn't clear how well they relate to actual data utility (see [6]).

An alternative is to measure specifically the risk of identifying individuals, as with

δ-Presence[6] Given an external public table P, and a private table T, *δ-presence* holds for a generalization $T^\star$ of T, with $\delta = (\delta_{min}, \delta_{max})$ if

$$\delta_{min} \leq \mathcal{P}(t \in T \mid T^*) \leq \delta_{max} \qquad \forall\ t \in P.$$

The above approaches measure the ability of an adversary to link a data item to a specific individual. An alternative is to measure the ability to estimate sensitive data for an individual, once such linkage is performed. In [2], the assumption was that individuals provided sensitive data directly to the data analyst; the link between data and individual was thus known. Instead, the sensitive data is distorted to prevent the analyst from knowing values for an individual. This leads to a metric based on bounding the knowledge gained by an adversary from seeing the (distorted) sensitive value. The metric in [2] was based on two things: an interval and confidence level. If the analyst can determine that a value lies within the range $[x_1, x_2]$ with c% confidence, then the privacy at that confidence level is $x_2 - x_1$.

This measure raises two issues. First (as with ℓ-diversity), it relies on two numbers. This increases the difficulty of using it in practice. Second, as pointed out in [1], knowledge of the distribution of the original data (acquired by the analyst from the distorted dataset) may allow tightening of the bounds. They propose a measure based on the *differential entropy* of a random variable. The differential entropy $h(A)$ is a measure of the uncertainty inherent in A. Their metric for privacy is $2^{h(A)}$. Specifically, when adding noise from a random variable A, the privacy is:

$$\Pi(A) = 2^{-\int_{\Omega_A} f_A(a) log_2 f_A(a) da}$$

where Ω_A is the domain of A. This metric has several nice features. It is intuitively satisfying for simple cases. For noise generated from A, a uniformly distributed random variable between 0 and a, $\Pi(A) = a$. Thus this privacy metric is exactly the width of the unknown region. Furthermore, if a sequence of random variables A_i converges to B, then $\Pi(A_i)$ converges to $\Pi(B)$. For most random variables, e.g., a gaussian, the notion of width of the unknown region does not make sense. However, by calculating Π for such random variables, the above properties can be used to make the case that the privacy is equivalent to having no knowledge of the value except that it is within a region of width Π. This gives an intuitively satisfying way of comparing the privacy of different methods of adding random noise.

The authors extend this definition to *conditional privacy*, capturing the possibility that the inherent privacy from obscuring data may be reduced by what can be learned from a collection. The conditional privacy $\Pi(A|B)$ follows from the definition of conditional entropy:

$$\Pi(A|B) = 2^{-\int_{\Omega_{A,B}} f_{A,B}(a,b) log_2 f_{A|B=b}(a) dadb}$$

They show how this can be applied to measure the actual privacy after reconstructing distributions of the original data to improve the accuracy of decision trees build on the obscured data [1,2].

Another use of this metric is to evaluate the inherent loss of privacy caused by data mining results. The use of conditional privacy enables estimating how much privacy is lost by knowing the data mining results, even with a "perfect" privacy-preserving technique such as secure multiparty computation. The literature has not yet addressed this issue; the assumption has generally been that the data mining results do not of themselves violate privacy.

Numerous other metrics have been proposed; the above give a representative view of the approaches and challenges faced in measuring privacy.

Key Applications

Primary applications are in aggregate analysis of privacy-sensitive data, such as individual health-care, personal preference, or financial information. Direct access to individual data is typically a confidentiality and access control issue; access to data is either allowed or it is not. Privacy measures come into play when individual data is analyzed as part of a broader study, where the end result is not solely for the benefit of the individuals whose data was used. (e.g., Studies of demographics or medical research.) Privacy laws typically control the use of data when not specifically to complete a transaction on behalf of the individual; measures are thus needed to show that privacy is maintained.

Future Directions

One approach is measures that correlate with legal and regulatory standards (e.g., the HIPAA safe harbor rules). Perhaps more promising as a research direction is risk-based measures such as δ-presence [5]. Location data (as from mobile devices) also poses new issues; European Community rules specifically discuss protection of location, but it is not clear to what extent existing measures can be applied. Another need is measures that adjust for differences in individual privacy needs, e.g., protecting outliers.

Privacy Policies and Preferences

Patrick C. K. Hung, Yi Zheng, Stephanie Chow
University of Ontario Institute of Technology, Oshawa, ON, Canada

Definition

Privacy policies describe an enterprise's data practices, what information is collected from individuals (subjects), what the information (objects) will be used for, whether the enterprise provides access to the information, who the recipients are of any result generated from the information, how long the information will be retained, and who will be informed in the event of a dispute. A subject releases his or her data to the custody of an enterprise while consenting to the set of purposes for which the data may be used. The subject can express his or her preferences in a set of preference-rules to make decisions regarding the acceptability of privacy policies.

Historical Background

People have been concerned with privacy policies and preferences for more than 200 years. For example, the Hippocratic Oath was written as a guideline of medical ethics for doctors in respect to a patient's health condition, and states as follows: "*Whatsoever things I see or hear concerning the life of men, in my attendance on the sick or even apart there from, which ought not to be noised abroad, I will keep silence thereon, counting such things to be sacred secrets*." Privacy policies and preferences are often expressed in natural language to specify or regulate how a system or an organization is to preserve privacy. In response to privacy policy and preference violations, many countries have enacted legislation to protect privacy for individuals. There are also different legislations for different industry sectors. For example, in the financial sector the Gramm-Leach-Bliley Act (GLB Act) of the U.S. requires banks to implement security programs to protect customer information; in the healthcare sector the Health Insurance Portability and Accountability Act (HIPAA) of the U.S. sets an American national standard to protect and enhance the rights of consumers, clients, and patients to control how their health information is used and disclosed. Similarly, the Personal Information Protection and Electronic Documents Act (PIPEDA) of Canada sets out ground rules for how private sector organizations may collect, use, or disclose personal information in the course of commercial activities. Failing to comply with these legislations, in their respective countries, may lead to civil and/or criminal penalties and/or imprisonment. In addition to the penalties, organizations may even suffer the loss of reputation and goodwill when the non-compliance of legislation is publicized. Looking at the above factors, it is evident that the privacy legislations have forced a widespread impact on the privacy policies and preferences.

Foundations

One can imagine that information privacy is usually concerned with the confidentiality of information. Threats to information privacy can come from insiders and from the outsiders in each enterprise. Privacy control is usually not concerned with individual subjects. Privacy policies are often expressed in natural language to specify or regulate how a system or an enterprise is to preserve privacy. Here are the principles of information privacy protection:

- Principle 1: Data-level security protection principle
  - Principle 1.1: Personal information shall be protected by security safeguards in a secure way such that data confidentiality, integrity, and availability can be achieved.
  - Principle 1.2: In needs to be accurate, complete, and up-to-date. The correction of inaccurate information should be allowed for maintaining data quality.
- Principle 2: Communication-level security protection principle
  - Principle 2.1: Information shall be transported in a secure way that data confidentiality and authentication of users/systems/services are achieved.
  - Principle 2.2: Data integrity must be maintained during the transmission in the communication channel.
- Principle 3: Consent requirement principle
  - Principle 3.1: Consent must be given by the owner of the information for the collection, disclosure, use, and retention of his/her information.
  - Principle 3.2: Owners of information should be allowed to review, control, and setup restrictions to their information on collection, usage, disclosure, and retention.

Principle 3 includes four limitations to specify how personal information can be released upon request:

- *Limitation on Collection*: The collection of personal information shall be limited to specific legitimate purposes of collection only.
- *Limitation on Disclosure*: The owner of information should be able to make special restrictions on the disclosure of his/her own information.
- *Limitation on Use*: The use of personal information shall be identified as legitimate use by the services provider and/or the owner of information.
- *Limitation on Retention*: Personal information shall be retained for only as long as the purpose for which it is used.

A subject releases his or her data to the custody of an enterprise while consenting to the set of purposes for which the data may be used. The subject can express his or her preferences in a set of preference-rules to make decisions regarding the acceptability of privacy policies. Preference assumes a real or imagined choice between alternatives and the possibility of rank ordering of these alternatives in a privacy policy. Privacy preferences are formally expressed by a set of rules and should preferably be captured through an interface. Subjects who are aware of how their personally identifiable information is being used, collected or disclosed can better understand how to protect it. Personally Identifiable Information (PII) includes information that identifies and individual and information that an organization may be able to identify. This includes, but is not limited to a subject's name, address, telephone number, social insurance number and credit card number(s). Among the most sensitive PII are medical and financial records.

Key Applications

In many instances, subjects do not have the knowledge or understanding of how his or her PII is being used, collected or disclosed, nor what privacy preferences are available. The adoption of information technology and the Internet have further added to this complexity. Even the most common daily transactions such as Internet browsing, grocery shopping and online banking increase the exposure and vulnerability of threats to information privacy. In response to these threats, and concerns surrounding data integrity, security, online privacy and confidentiality, professional services firms have begun to expand their service lines to include third-party enforcement programs. Seals, or other easily distinguishable symbols, are issued to enterprises whose privacy policies and procedures have been concluded to be in compliance with its governing board(s). The purposes of third-party enforcement programs are three-fold: (i) to build consumer trust; (ii) to educate subjects of their privacy preferences; and (iii) to develop a complaint resolution mechanism. Here are the three major procedures of enforcing privacy policies in an organization:

- Building consumer trust
  - There exists a natural conflict of interest between organization and subject.
  - Subject is absent from the development of privacy policy.
  - Independent review of an organization's compliance with governing board(s) adds reliability and credibility.
- Educate subjects of their privacy preferences
  - Promote awareness of privacy issues and how to get in contact with privacy coordinator.
  - If for any reason a subject's PII is required for another purpose from when it was collected, it is the enterprise's responsibility to obtain additional consent.
  - At a minimum, the enterprise is to inform the subject of the circumstance and provide an opportunity for the subject to opt out of such a use.
- Complaint resolution mechanism
  - Organizations rewarded a seal of validation are required to provide subjects a method to resolve any problems or discuss any complaints.
  - Complaint resolution process should be easily accessible and comprehendible.

In order to stand apart from industry rivals, companies strive to obtain a competitive advantage. As an organization, it is advantageous to be knowledgeable of the external risks associated affecting the protection of a subject's privacy. Participants of third-party enforcement programs are continuously monitored for adaptability to legislative frameworks and threats to privacy compliance.

Privacy technologies have been researched for a period of time. For example, the Platform for Privacy Preferences Project (P3P) working group at World Wide Web Consortium (W3C) develops the P3P specification for enabling Web sites to express their privacy practices in a standard and machine-readable XML format. P3P user agents allow users to automatically be informed of site practices and to automate decision-making based on the Web sites' privacy practices. In addition, P3P also provides a language called P3P Preference Exchange Language 1.0 (APPEL1.0) that is used to express the user's preferences for making automated or semi-automated decisions regarding the acceptability of machine-readable privacy policies from P3P enabled Web sites. It provides a base schema for the data collected and a vocabulary to express purposes, the recipients, and the retention policy. Although it captures common elements of privacy policies, sites may have to provide further explanations in human-readable policies.

Furthermore, WS-Privacy has been mentioned in industry for a period of time for defining subject privacy preferences and organizational privacy practice statements for Web services. At this minute, the WS-Privacy specification has not been released to public yet. Then, the Enterprise Privacy Authorization Language (EPAL) technical specification is used to formalize privacy authorizations for actual enforcement within an intra- or inter- enterprise for business-to-business privacy control. On the other hand, the XACML is a general- purpose access control policy language used to describe policy and access control decision request/response [11]. Though XACML has drafted a privacy policy profile document [12], the current XACML framework can not handle the privacy enforcement.

One of the most significant privacy technologies is the IBM Tivoli Privacy Manager for e-business. This privacy middleware technology converts privacy policy and data-handling rules from applications and IT systems to P3P format. The future development will include the integration of privacy technologies into some specific Web-based applications like in healthcare sector (e.g., Microsoft Healthvault and Google Health Portal), especially in light of recent changes in health privacy legislative environment.

PETs

Definition

Privacy-Enhancing Technologies (PETs) can be defined as technologies that are enforcing privacy principles in order to protect and enhance the privacy of users of information technology (IT) and/or of individuals about whom personal data are processed (the so-called data subjects). Privacy principles that PETs are enforcing can be derived from internationally acknowledged privacy guidelines or legislation, such as the OECD Privacy Guidelines [10] and the EU Data Protection Directive 95/46/EC [7]. One fundamental privacy principal that serves as the foundation for the Privacy-Enhancing Technologies that are aiming at providing *anonymity*, *pseudonymity*, or *unobservability* for users and/or other data subjects, is the privacy principles of data minimization. It requires that the collection of personally identifiable data should be minimized (and if possible avoided), because obviously privacy is best protected if no personal data at all (or at least as little data as possible) is collected or processed. Further important privacy principles addressed by other PETs are the informed consent by data subjects (as a prerequisite for making data processing legitimate), transparency (i.e., openness) of data processing, and appropriate technical security means for protecting the confidentiality, integrity and availability personal data.

Historical Background

IT security technologies for protecting the confidentiality, integrity and availability of (personal) data, such as *access control*, have been developed and researched since the beginning of computing – *data encryption* as a technique for protecting the confidentiality of data has been used since ancient times. *Inference controls* for protecting the data of individuals stored in statistical databases (e.g., medical databases) have been elaborated since the 1970's.

Most of the fundamental anonymity technology concepts were introduced by David Chaum in the 1980's (see: [3,4,2]). The term "Privacy-Enhancing Technologies" was first introduced in 1995 in a report on data minimization technologies, which was jointly published by the Dutch Registratiekamer and the Information and Privacy Commissioner in Ontario with the title "Privacy-Enhancing Technologies: The path to Anonymity" [13]. Since then, further research and development has been done in data minimization technologies (e.g., [12,14]), and areas such as privacy policies [9,10] and privacy enhancing identity management [11].

Privacy as an expression of the rights of self-determination and human dignity is considered a core value in democratic societies and is recognized either explicitly or implicitly as a fundamental human right by most constitutions of democratic societies. However, in the network society, individuals are increasingly at risk that all their communications, transactions and movements can be monitored and profiled. Profiles collected at various sites can be easily combined, aggregated and retained without time limitations and without the individuals' knowledge or consent. Research and development of PETs have been motivated by the vision to provide technical means allowing individuals to retain control over their personal spheres, i.e., to protect their privacy in the electronic information age.

Foundations

Privacy-Enhancing Technologies can basically be divided into:

1. The class of PETs for minimizing or avoiding identifiable data for users and/or other data subjects.
2. The class of PETs for safeguarding lawful and privacy-friendly personal data processing.
3. PETs that are a combination of the two aforementioned PET classes.

PETs for Minimizing or Avoiding Personally Identifiable Data

To the class PETs that are minimizing or eliminating personally identifiable data of data subjects (that are not acting as users) belong *inference controls* in statistical databases. In general-purpose database systems (e.g., medical databases), some users (e.g., physicians) need to access personal data attributes, while other user (e.g., researchers) only need to access a personal database by statistical queries. Thus, access control mechanisms should allow certain users to access data in anonymous form by performing only statistical queries. However, by correlating different statistics (i.e., by launching so-called tracker attacks), a user may succeed in deducing confidential information about some individual. *Inference controls* in statistical databases shall ensure that the statistics released by the database do not lead to the disclosure of any confidential personal data.

PETs that are minimizing/avoiding identifiable data of users, and that are thereby providing *anonymity*, *pseudonymity*, and/or *unobservability*, can be divided dependent on whether data is minimized on communication level or on application level. Examples for anonymous communication schemes for achieving sender anonymity are DC-nets [4], Mix-nets [2] or Crowds [14], where the latter two ones will be presented in more detail below.

With DC-nets, the fact that someone is sending a message is hidden by a one-time pad encryption, which means that DC-nets can offer *perfect sender anonymity* (in the information-theoretic sense). By the use of message broadcast and implicit addresses (i.e., by the use of an attribute which allows only the addressee to recognize that the message is addressed to him, e.g., the message is public-key encrypted and the addressee is the only one who can successfully decrypt it with his secret key), it also provides *receiver and relationship anonymity.*

Another example for a protocol providing receiver anonymity is private information retrieval [2], which assures that a powerful attacker is not able to find out what information another user has requested (i.e., who has received certain information). The goal is to request exactly one datum that is stored in a remote memory cell of a server without revealing which datum is requested.

Mix Nets The technique of a Mix network, which was originally introduced by David Chaum [4], realizes unlinkability of a sender and recipient (*relationship anonymity*), as well as, *sender anonymity* against the recipient, and optionally *recipient anonymity* (via so-called anonymous return addresses, which is however not elaborated further here).

A mix is a special network station, which collects and stores incoming messages, discards repeats, changes their appearance by encryption, and outputs them in a different order, and by this hides the relation between incoming and outgoing messages. If a sender of a message uses one mix for forwarding a message to a recipient on his behalf, the relation between sender and recipient is hidden from everybody but the mix and the sender of the message. This means also that the recipient only learns that the message was sent to him by the mix, but he does not know the identity of the real sender. However, if only one mix is used, this mix can in detail learn and potentially profile who is communicating with whom. To improve security, a message is sent over a mix net, which consists of a chain of independent mixes. The sender must perform cryptographic operations inverse to those of the mix, because the recipient must be able to read the message. A global attacker, who can monitor all communication lines, should in principle only be able to trace a message through the mix network, if he has the cooperation of all mix nodes on the path or if he can break the cryptographic operations. Thus, in order to ensure unlinkability of sender and recipient, at least one mix in the chain has to be trustworthy.

Assume that Alice wants to send anonymously a message msg to recipient Bob (which could be encrypted with Bob's public key for providing also message secrecy). Alice chooses a mix sequence Mix_1, Mix_2,..., Mix_m (In Fig. 1, Alice chooses m = 3 Mixes). Let for simplicity Mix_{m+1} denote the recipient (Bob). Each Mix_i with address A_i has initially chosen a key pair (c_i, d_i), where c_i is a public key of Mix_i and d_i is its private key. Let z_i be a random string.

Alice recursively creates the following encrypted messages, where M_i is the message that Mix_i will receive:

$$M_{m+1} = \mathrm{msg}$$

$$M_i = c_i(z_i, A_{i+1}, M_{i+1}) \quad \text{for } i = 1,\ldots, m,$$

i.e., she adds one layer of public key encryption to the message in reverse order to the sequence of mixes in the chain. She then sends the result M_1 to Mix_1.

Each Mix_i decrypts the incoming message $M_i = c_i(z_i, A_{i+1}, M_{i+1})$ with its private key d_i, discards the random string z_i, and finds the address A_{i+1} of the next mix Mix_{i+1} in the chain and the message M_{i+1}, which it forwards to Mix_{i+1}. The random string z_i is needed, because otherwise an attacker could again, by

Privacy-Enhancing Technologies. Figure 1. Mix-network with a chain of three mixes.

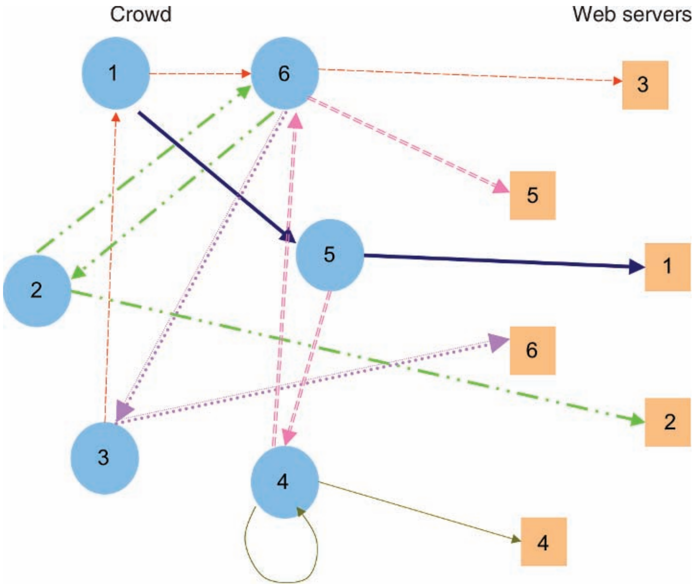
encrypting an outgoing message from a mix with the public key of the mix and comparing the result with the former inputs to the mix, succeed to relate an input to its output (i.e., he would be able to trace the message flow through the mix). Besides *anonymity* protection, mix nets can also provide *unobservability*, if dummy messages (i.e., meaningless messages) are sent out by the participants in order to hide information about if and when meaningful messages were sent.

Attacks on mix nets and possible countermeasures have been discussed in [8].

Mix-nets have first been developed for anonymous email applications. Later the Mix-net concept has been used for establishing anonymous bi-directional real-time communication. One example for distributed overlay networks designed to anonymize real-time, bidirectional TCP-based communications is Onion Routing, in which the sender's proxy constructs an onion which encapsulates a route to the responder (e.g., Web server). An Onion is an object with layers of public key encryption, which is used to produce anonymous bi-directional virtual circuit between communication partners (in Mix nets layered public key encryption are also used to build up a path) and to distribute symmetric keys to the nodes on the path. The sender's proxy constructs an onion which encapsulates a route to the responder. Faster symmetric encryption with the symmetric keys that were distributed to the nodes on the path with the help of the Onion is used for data communication via the virtual path once it has been established.

Crowds Reiter and Rubin developed Crowds – a system based on the idea that users can make anonymous Web transactions when they blend into a "crowd" [14]. A crowd is a geographically diverse group that performs Web transactions on behalf of its members. Each crowd member runs a process on his local machine called "jondo." Once started, the jondo engages in a protocol to join the crowd, during which it is informed of the other current crowd members and in which the other crowd members are informed of the new jondo's membership. Besides, the user configures his browser to employ the local jondo as a proxy for all network services. Thus all http requests are directly sent to the jondo rather than to the end Web-server and the jondo forwards the request to a randomly chosen crowd member. Whenever a crowd member receives a request from another jondo in the crowd, it makes a random choice to forward the request to another crowd member with a probability $p_f > ½$ or to submit the request to the end Web server to which the request was destined. Figure 2 shows a possible set of virtual paths that are created according to the Crowds protocol.

The server's reply is sent backward along the path, with each jondo sending it to its predecessor on the



Privacy-Enhancing Technologies. Figure 2. Paths in a crowd, where for each path the initiator (sender) and web server are labeled the same [14].

path. All communication between jondos is encrypted by a cryptographic key shared between the jondos involved.

Crowds provides sender anonymity against the end Web-server, since the end server obtains no information regarding who initiated any given request (each Crowds member is equally "suspicious"). Second, since a jondo on the path cannot distinguish whether its predecessor on the path initiated the request or is forwarding it, no jondo on the path can learn the initiator of a request. Since all communication between jondos is encrypted, Crowds also offers receiver anonymity against a local eavesdropper (e.g., local gateway administrator) that can observe the communication involving the user's machine unless the originator of the request ends up submitting the request itself. (However, the probability that an originator submits its own request decreases as the crowd size increases).

Crowds enables very efficient implementations that typically outperforms mixes that uses layered encryption techniques. However, in contrast to mix-nets, crowds cannot protect against global attackers.

PETs for anonymous or pseudonymous applications/transactions can be implemented on top of anonymous communication protocols. Examples are anonymous E-cash protocols based on *blind signatures* [3], as well as anonymous credential systems (such as Idemix [1]), which can be used to implement for instance anonymous or pseudonymous access control, e-health or e-government, and other anonymous or pseudonymous applications.

PETs for Safeguarding Lawful and Privacy-Friendly Personal Data Processing

It is not always possible to avoid the processing of personal data. Public authorities, health care providers, employers are example of organizations that still need to process personal data about their citizens, patients, employers for various legitimate reasons. If personal data are collected and processed, legal privacy requirements need to be fulfilled. The class of PETs described in this section comprises technologies that enforce legal privacy requirements in order to safeguard the lawful processing of personal data. The driving principles behind these types of PETs can also be found in data protection legislation, such as the EU Data Protection Directive 95/46/EC, which requires that controllers implement security measures which are appropriate to the risks presented for personal data in storage or transmission, with a view to protecting personal data against accidental loss, alteration, unauthorized access and against all other unlawful forms of processing.

Examples of technologies belonging to this class of PETs include classical security technologies, such as *data encryption* or *access control*, which protects the confidentiality and integrity of personal data. Other examples are technologies for stating or enforcing privacy policies: The Platform for Privacy Preferences Protocol (P3P) [6] increases transparency for the end users by informing them about the privacy policies of web sites and can hence be used to enforce the legal principles and requirement (e.g., according to Art.10 EU Data Protection Directive 95/46/EC) to inform data subjects about the purpose of data processing, identity of the controller, retention period, etc. Privacy policy models (such as the privacy model presented in [8]) can technically enforce privacy requirements such as purpose binding, and privacy policy languages, such as the Enterprise Privacy Authorization Language EPAL [9], can be used to encode and to enforce more complex enterprise privacy policies within and across organizations.

PETs that are a Combination of the Two Aforementioned PET Classes

The third class of PETs comprises technologies that are combining PETs of class 1 and class 2. An example is provided by privacy-enhancing identity management technologies as the ones that have been developed within the EU FP6 project PRIME (Privacy and Identity Management for Europe) [11]. Identity Management (IDM) subsumes all functionalities that support the use of multiple identities by the identity owner (user-side IDM) and by those parties with whom the owner interacts (services-side IDM). The PRIME project addresses privacy-enhancing IDM to support strong privacy by particularly avoiding or reducing identification and by technically enforcing informational self-determination.

PRIME is based on the principle that design must start from maximum privacy. Therefore, with the help of anonymous communication technologies and anonymous credential protocols, a priori all interactions are anonymous, and individuals can chose pseudonyms to link different interactions to each other, bind attributes and capabilities to pseudonyms and can establish end-to-end secure channels between pseudonyms. Whether or not interactions are linked to each other or to a certain pseudonym is under the individual's control. For this, PRIME tools allow individuals to act under different pseudonyms with respect to communication partners, roles or activities. Policy management tools are helping them to define and negotiate privacy policies with services sides regulating who has the right to do what with one's personal data under which circumstances. Those policies are enforced at the receiving end, and there is enough evidence, so that users can actually trust in this enforcement. Transparency tools allow users to be informed about who has received what personal data related to them, and to trace personal data being passed on, and include online functions for exercising their rights to object to data processing or to rectify, block, delete data (see also [11] for more information).

Key Applications

As illustrated above, PETs can be applied in all kinds of application areas of IT, in which personal data is or can be collected or processed.

Privacy-Preserving Data Mining

CHRIS CLIFTON
Purdue University, West Lafayette, IN, USA

Definition

Data Mining techniques that use specialized approaches to protect against the disclosure of private information may involve anonymizing private data, distorting sensitive values, encrypting data, or other means to ensure that sensitive data is protected.

Historical Background

The field of privacy-preserving data mining began in 2000 with two papers of that name[1,4]. Both papers addressed construction of decision trees, approximating the ID3 algorithm while limiting disclosure of data. While the problems appeared similar on the surface, the fundamental difference in privacy constraints shows the complexity of this field. In [1], the assumption was that individuals were providing their own data to a common server, and added noise to sensitive values to protect privacy. The key to the technique was to discover the original distribution of the data, enabling successful construction of the decision tree. In [4], the data was presumed to be divided between two (or a small number) of parties, and cryptographic *Secure Multiparty Computation* techniques are used to construct the decision tree without any site disclosing the actual data values it holds.

A third approach to privacy-preserving data mining, *Data Transformation*, was introduced in [5]. The idea behind this approach is to transform the data space (e.g., using techniques such as Random Projection) so that data items can no longer be tied to individuals, but sufficient information is preserved to enable data mining.

Research in the field has largely been directed toward:

- Supporting more data mining tasks and algorithms (e.g., clustering, classification, outlier detection)
- Different privacy constraints (e.g., *vertically partitioned* and *horizontally partitioned* data)

Techniques provide varying levels of privacy guarantees, data mining result accuracy, and run-time performance.

Foundations

There are several factors that must be identified in developing or choosing a privacy-preserving data mining approach. The first is the source of and privacy constraints on the data. In some cases, data is held by a relatively small number of trusted parties, such as credit reporting bureaus, insurance companies, or government agencies. The challenge is that while these parties are allowed to use the data for their own purposes, privacy constraints prevent them from disclosing the data to others.

Secure Multiparty Computation Methods address this problem, allowing a data mining model to be constructed from the distributed data using cryptographic approaches that prevent disclosure of the individual data items between the parties. The key components of such a method are the algorithm, which uses cryptographic computations to duplicate a distributed data mining algorithm without disclosing data from any site, and a proof that disclosure is controlled. Typically such proofs use a simulation argument, showing that given the final result, a party can simulate the messages received in running the protocol (thus showing that no valuable information was disclosed other than that inherent in the result.)

When data is more widely distributed, such as individuals providing their data to a server for use in data mining, *Data Transformation Methods* and *Data Perturbation* come into play. Data transformation methods modify the data so that the original values are lost, but important information (e.g., distances) is preserved. A typical example of transformation is dimensionality reduction, for example random projection [3]. Typically the providers of data must agree on a transformation, then transform their data and send it to a central data collector / data miner. Details of the transformation are kept secret from the data miner. In many cases, the transformation is individualized or constructed collaboratively in a way that protects against collusion. Such techniques require specialized versions of data mining algorithms to mine the transformed data. The techniques also involve a proof; in this case, showing the difficulty/impossibility of reversing the transformation, or the amount of background knowledge required to do so.

Data Perturbation is similar in that individuals modify their data before providing it to a central data warehouse. The differences is that data perturbation techniques add noise, while preserving the structure of the original data. The key to these techniques is specialized data mining algorithms that can utilize knowledge of the distribution of the noise, along with the noisy data, to obtain better results than mining on the noisy data alone. These approaches typically reconstruct the data *distribution*, then use this to guide the data mining, rather than mining the data directly. As the goal of most data mining is to obtain models that generalize well, models consistent with the distribution of the data are likely to have good accuracy. In addition to the reconstruction algorithm, data perturbation methods need a measure of the privacy provided; as data is not completely hidden, it is important to be able to measure the tradeoff between privacy and model accuracy.

Once the data privacy constraints are understood and a general approach is chosen, the next step is to develop an algorithm for the data mining model to be built. Privacy-preserving data mining algorithms typically replicate the results of traditional data mining algorithms, and have been developed for many of the standard machine learning approaches.

Key Applications

Privacy-preserving data mining has application wherever data mining is applied to data about individuals. Examples include recommender systems, medical studies, intelligence, and social network analysis. In addition, this technology can be useful for sharing sensitive corporate information, for example in supply chain management [2].

As an example, Figure 1 shows a scenario evaluating an Algorithm developed to identify terrorist organization financial patterns. To evaluate this, it is necessary to compare real financial records to see how many are identified by the algorithm. An outlier detection algorithm could be used to determine if the space identified by the algorithm reflects a cluster of "normal" financial patterns or just a few outliers, but accessing real financial records is problematic. Using the secure multiparty computation technique in [6], it is possible to identify the number of items in the vicinity of "Tom Terrorist" without revealing either the identity or specific values of any of the items. This gives us the result sought without exposing private data.

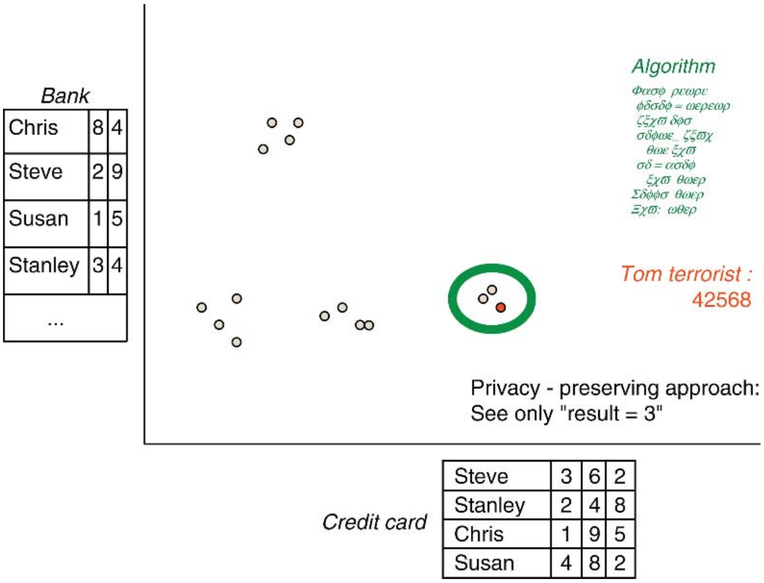
Future Directions

The main factors limiting adoption of this technology are:

1. The difficulty of doing exploratory data analysis. Privacy-preserving data mining techniques require that the data mining task to be performed be known without seeing the data.
2. Privacy standards and definitions. Current privacy regulations do not make it clear if this technology is either necessary or sufficient. Further work is needed to establish technically meaningful definitions of privacy.
3. Cost/performance. Many of these techniques are expensive in either computational power, their effect on result quality, and perhaps most important the cost of implementing a solution for a particular task.

Ongoing work is addressing these issues. Applications in corporate collaboration using corporate-sensitive data is likely to lead commercialization, as cost/benefit tradeoffs are easier to evaluate than with personal private data.

The field is closely related to *inference control in statistical databases* and *statistical disclosure limitation*; these fields have extensively studied the privacy risks inherent in releasing data under various types of perturbation and transformation. The key difference with privacy-preserving data mining is that the specific use of the data is assumed to be known. This allows methods that drastically distort the data, keeping only specific information intact rather than trying to preserve general statistical properties. The success of statistical disclosure limitation provides a good historical



Privacy-Preserving Data Mining. Figure 1. Using a privacy-preserving outlier detection algorithm to determine if an algorithm isolates terrorist behavior.

framework for the adoption of privacy-preserving data mining.

Uncertain databases

Definition

A probabilistic database is a database in which every tuple t belongs to the database with some probability $\mathbf{P}(t)$; when $\mathbf{P}(t) = 1$ then the tuple is certain to belong to the database; when $0 < \mathbf{P}(t) < 1$ then it belongs to the database only with some probability; when $\mathbf{P}(t) = 0$ then the tuple is certain not to belong to the database, and it is not necessary to bother representing it. A traditional (deterministic) database corresponds to the case when $\mathbf{P}(t) = 1$ for all tuples t. Tuples with $\mathbf{P}(t) > 0$ are called *possible tuples*. In addition to indicating the probabilities for all tuples, a probabilistic database must also indicate somehow how the tuples are correlated. In the simplest cases the tuples are declared to be either independent (when $\mathbf{P}(t_1 t_2) = \mathbf{P}(t_1 t_2)$), or exclusive (or disjoint, when $\mathbf{P}(t_1 t_2) = 0$).

Historical Background

Extensions of databases to handle probabilistic data have been considered since the 1980s. In 1992, Barbara, Garcia-Molina, and Porter [6] developed a probabilistic data model that is an extension of the relational data model, in which relations have deterministic keys, and non-key attributes that are stohastic. They also introduced probabilistic analogs to the relational algebraic operators, later called *extensional operators*. Queries were restricted to return all deterministic keys of relations mentioned in the query body. Efforts to remove this restriction on queries lead to several extensions. In 1997, Lakshmanan, Leone, Ross, and Subrahmanian [19] modified the query semantics and proposed that probabilities be combined by user-defined *strategies*. In 1997, Fuhr and Roellke [17] proposed an alternative way to compute the correct semantics for all queries, using *intensional semantics*, by which every tuple in the query answer is annotated with a propositional formula called *event expression*: a general-purpose probabilistic inference algorithm can be used to compute the tuple's probability from the event expression, but this is known to be expensive in general. Dalvi and Suciu in 2004 [12] showed that some queries can be computed efficiently using extensional operators if these are ordered carefully, to ensure that they are applied correctly: a plan consisting of correctly applied operators is called a *safe plan*. Not all queries admit a safe plan, but those that do not admit one can be shown to be #P-hard, thus they cannot be evaluated efficiently unless $P = NP$. Recent systems for managing probabilistic or incomplete databases include Trio [8,24], MystiQ [20], and MayBMS [4].

Foundations

For an illustration, consider the probabilistic database in Fig. 1. It has three tables, of which `Product`^{p} and `Customer`^{p} are probabilistic and `Order`^{p} is deterministic. `Product`^{p} contains three products; their names and their prices are known, but their color and shape are unknown. For example `Gizmo` may be have `color` = `red` and `shape` = `oval` with probability $p_1 = 0.25$, or may have `color` = `blue` and `shape` = `square` with probability $p_2 = 0.75$ respectively. `Camera` has three possible combinations of `color` and `shape`, and `IPod` has two. In other words, for every product in the database, the values for `color` and `shape`, are not known, but instead there is a probability space over their values. Each color-shape combination should exclude the others, so $p_1 + p_2 \leq 1$, $p_3 + p_4 + p_5 \leq 1$ and $p_6 + p_7 \leq 1$, holds for our table. When the sum is strictly less than one then that product may not occur in the table at all: for example `Camera` may be missing from the table with probability 1-p_3-p_4-p_5.

Representation and Smantics

A popular representation of a probabilistic database consists of a regular database with two additional pieces of information: for each probabilistic table a distinguished attribute **P** is designated as the probability attribute, and a set of attributes is designated as *possible worlds key*. The key is interpreted as follows. If two tuples have the same values of the key attributes, then they are exclusive, i.e., only one of them may actually occur in the database. Otherwise, if the values of their key attributes differ then the tuples are independent. Tuples from different tables are always assumed to be independent. Figure 2a illustrates such a representation. Here the attribute **P** is designated as the probability attribute, and the two attributes `prod` and `price` are the possible worlds key. There are seven possible tuples, but at most three of them may actually occur in the database, because the first two are exclusive tuples, the next three are exclusive, and the last two are exclusive.

Tuples with the same possible worlds key are sometimes called *xor-tuples* or *x-tuples*. The entire set of such tuples is called a *maybe tuple*. The three `Camera`

`Product`^{P}

Prod	Price	Color	Shape	P
Gizmo	20	red	oval	$p_1 = 0.25$
		blue	square	$p_2 = 0.75$

b **P**(Product$_3$) = $p_1(1{-}p_3{-}p_4{-}p_5)p_6$

Probabilistic Databases. Figure 2. A representation of a probabilistic table (a): it shows the probability of each tuple, and the key of the possible worlds: if two tuples share the same key values then they are exclusive, otherwise they are independent. Three possible worlds (b).

tuples in Fig. 2a are x-tuples, and together they form one maybe-tuple.

The semantics of a probabilistic database is a probability space over *possible worlds*. Product^p has 16 possible worlds, since there are two choices for Gizmo, four for Camera (including removing Camera altogether) and two for IPod. Figure 2b illustrates three of these sixteen possible worlds and their probabilities.

Query Evaluation

The semantics of a query q on a probabilistic database is defined as follows. Consider all possible worlds of the probabilistic database: each such world is a standard, deterministic database. Evaluate q on each possible world, using the standard semantics of a query on a deterministic database. Any tuple that is an answer to the query in some possible world is called a *possible answer tuple*. The *probability of a possible answer tuple* is defined as the sum of the probabilities of all worlds where the tuple is an answer. The semantics of the query is the set of possible answer tuples together with their probabilities.

A central problem in probabilistic databases is query evaluation. It is infeasible to enumerate all possible worlds, because their number is exponential is the size of the database. There are two approaches to query evaluation: extending relational algebra operators to manipulate probabilities explicitly, or using a general-purpose probabilistic inference algorithm. The first approach is rather similar to standard query processing, and is quite efficient: the declarative SQL query is translated into a relational algebra plan, called an *extensional plan*, then this plan is executed. We illustrate this below. However not all queries admit correct extensional plans. Those that do not admit such plans require a more expensive, general-purpose probabilistic inference, which have been studied in the context of knowledge representation systems and are not be discussed here.

The three main extensional operators on the three queries are illustrated in Fig. 3, then show how to combine them for more complex queries. The left column in the figure shows the queries in SQL syntax, the right column shows the same queries in datalog notation. In datalog, underline the variables that occur in the key positions. The first query, Q_1, asks for all the oval products in the database, and it returns two possible answer tuples:

prod	price	P
Gizmo	20	p_1
Camera	80	$p_3 + p_5$

For example the probability of the possible answer tuple Gizmo is the sum of the probabilities of the

```
Q1  : SELECT DISTINCT prod, price
      FROM Product^P                          Q1(x,y) : -     Product^P(x,y,'oval',z)
      WHERE shape = 'oval'

Q2  : SELECT DISTINCT city
      FROM Customer^P                         Q2(y)   : -     Customer^P(x,y)

Q3  : SELECT DISTINCT*
      FROM Product^P, Order, Customer^P       Q3(*)   : -     Product^P(x,y,z),
      WHERE Product^P.prod = Order.prod                       Order(x,y,u)
      and Product^P.price = Order.price                       Customer^P(u,v)
      and Order.cust = Customer^P.cust
```

Probabilistic Databases. Figure 3. Three simple queries, expressed in SQL and in datalog.

8 possible worlds for `Product` (out of 16) where `Gizmo` appears as `oval`, and this turns out (after simplifications) to be p_1. These probabilities can be computed without enumerating all possible worlds, directly from the table in Fig. 2a by the following process: (i) Select all rows with `shape='oval'`, (ii) project on `prod`, `price`, and **P** (the probability), (iii) eliminate duplicates, by replacing their probabilities with the sum, because they are disjoint events. The latter two steps are called a disjoint project:

Disjoint Project, $\pi_{\bar{A}}{}^{pD}$ If k tuples with probabilities $p_1,\ldots,p_k$ have the same value, $\bar{a}$, for their $\bar{A}$ attributes, then the disjoint project will associated the tuple $\bar{a}$ with the probability $p_1 + \ldots + p_k$. The disjoint project is correctly applied if any two tuples that share the same values of the $\bar{A}$ attributes are disjoint events.

Q_1 can therefore be computed by the following plan:

$$Q_1 = \pi^{pD}_{\texttt{prod,price}}(\sigma_{\texttt{shape='oval'}}(\texttt{Product}^p))$$

$\pi^{pD}_{\texttt{prod,price}}$ is correctly applied, because any two tuples in $\texttt{Product}^{\mathrm{P}}$ that have the same `prod` and `price` are disjoint events.

Query Q_2 in Fig. 3 asks for all cities in the `Customer` table, and its answer is:

city	P
New York	q_1
Boston	$1-(1-q_2)(1-q_4)$
Seattle	$1-(1-q_3)(1-q_5)$

This answer can also be obtained by a projection with a duplicate elimination, but now the probabilities p_1, p_2, p_3,... of duplicate values are replaced with $1 - (1 - p_1)(1 - p_2)(1 - p_3)\ldots$, since in this case all duplicate occurrences of the same city are independent. This is called an independent project:

Independent Project, $\pi^{pI}_{\bar{A}}$ If k tuples with probabilities $p_1,\ldots,p_k$ have the same value, $\bar{a}$, for their $\bar{A}$ attributes, then the independent project will associated the tuple $\bar{a}$ with the probability $1 - (1 - \mathrm{p}_1)(1 - p_2)\ldots(1 - p_\mathrm{k})$. The independent project is correctly applied if any two tuples that share the same values of the $\bar{A}$ attributes are independent events.

Thus, the disjoint project and the independent project compute the same set of tuples, but with different probabilities: the former assumes disjoint probabilistic events, where $\mathbf{P}(t \vee t') = \mathbf{P}(t) + \mathbf{P}(t')$, while the second assumes independent probabilistic events, where $\mathbf{P}(t \vee t') = 1 - (1 - \mathbf{P}(t))(1 - \mathbf{P}(t'))$. Continuing our example, the following plan computes Q_2: $Q_2 = \pi^{pI}_{\texttt{city}}(\texttt{Customer}^{\mathrm{P}})$. Here $\pi^{pI}_{\texttt{city}}$ is correctly applied because any two tuples in $\texttt{Customer}^{\mathrm{P}}$ that have the same `city` are independent events.

Query Q_3 in Fig. 3 illustrates the use of a join, and its answer is:

prod	price	color	shape	cust	city	P
Gizmo	20	red	oval	Sue	New York	p_1q_1
Gizmo	20	red	oval	Sue	Boston	p_1q_2
Gizmo	20	red	oval	Sue	Seattle	p_1q_3
Gizmo	20	blue	square	Sue	New York	p_2q_1
...	...					

It can be computed by modifying the join operator to multiply the probabilities of the input tables:

Join, $\bowtie^p$ Whenever it joins two tuples with probabilities p_1 and p_2, it sets the probability of the resulting tuple to be p_1p_2.

A plan for Q_3 is: $Q_3 = \texttt{Product} \bowtie^{p} \texttt{Order} \bowtie^{p} \texttt{Customer}$.

Extensional operators can be combined to form an extensional plan. A plan is called *safe* if each operator is applied correctly. It is possible to illustrate with the following probabilistic database schema:

$\texttt{Product}^p(\underline{\texttt{prod, price}}, \texttt{color, shape})$
$\texttt{Order}^p(\underline{\texttt{prod, price, cust}})$

Both tables are probabilistic. The following query finds all colors of products ordered by the customer named Sue:

$$Q_4(c) : -\texttt{Product}^p(\underline{x, y}, c, s), \texttt{Order}^p(\underline{x, y, Sue})$$

Q_4 admits the following safe plan:

$$Q_4 = \Pi^{pI}_{\texttt{color}}(\Pi^{pD}_{\texttt{prod,price,color}}(\texttt{Product}^p) \bowtie^p \sigma_{\texttt{cust='Sue'}}(\texttt{Order}^p))$$

This is safe because $\Pi^{pD}_{\texttt{prod,price,color}}$ combines only disjoint tuples, while Π^{pI}_{color} combines only independent tuples. Similarly, the join operators combines independent tuples, since the left operand consists of tuples combined from the $\texttt{Product}^p$ table while the right operand consists of tuples from the $\texttt{order}^p$ table.

In contrast, the following plan is not safe:

$$\Pi^{pI}_{\text{color}}(\texttt{Product}^p \bowtie^p \sigma_{\texttt{cust='Sue'}}(\texttt{Order}^p))$$

because the outermost projection Π^{I}_{color} will combine tuples that are not independent: there may be two or more distinct tuples in the join $\texttt{Product}^p \bowtie^p \texttt{Order}^p$ that have the same $\texttt{Product}^p$ tuple, hence they are not independent.

Some queries do not admit any safe plans at all. Figure 4 illustrates three queries that are known not to admit any safe plan. All three are boolean queries, i.e., they return either "true" or nothing, but they still have a probabilistic semantics, and it is necessary to compute the probability of the answer "true." No combination of extensional operators result in a safe plan for any of these queries. For example $\pi^{pI}_{\emptyset}(\texttt{R} \bowtie \texttt{S} \bowtie \texttt{T})$ is an incorrect plan for H_1, because two distinct rows in $\texttt{R} \bowtie \texttt{S} \bowtie \texttt{T}$ may share the same tuple in R, hence they are not necessarily independent events. In fact it has been shown that the complexity of each of these three queries is #P-hard, hence there is no polynomial time algorithm for computing their probabilities unless $P = NP$.

Key Applications

Probabilistic databases are design to allow uncertain data to be managed directly by a relational database system. Several types of applications have been considered.

In *Information Extraction* the goal is to extract structured data from a collection of unstructured text documents. Examples include address segmentation, citation extraction, extractions for comparison shopping, hotels, restaurant guides, etc. The schema is given in advance by the user, and the extractor is tailored to that specific schema. All approaches to extraction are imprecise, and most often can associate a probability score to each item extracted. A probabilistic database allows these probability scores to be stored natively.

In *Fuzzy Object Matching* the problem is to reconcile objects from two collections that have used different naming conventions. This is a central problem in data cleaning and data integration, and has also been called record linkage, or de-duplication. The basic approach is to compute some similarity score between pairs of objects, usually by starting from string similarity scores on their attributes then combining these

```
Schema: R(A),S(A,B), T(B)
H1: SELECT DISTINCT 'true' AS A          H1  : - R(x),S(x,y),T(y)
    FROM R, S, T
    WHERE R.A = S.A and S.B = T.B

Schema: R(A,B), S(B)
H2: SELECT DISTINCT 'true' AS A          H2  : - R(x,y),S(y)
    FROM R, S
    WHERE R.B = S.B

Schema: R(A,B), S(A, B)
H3: SELECT DISTINCT 'true' AS A          H3  : - R(x,y),S(x,y)
    FROM R, S
    WHERE R.A = S.A and R.B = S.B
```

Probabilistic Databases. Figure 4. Three queries that do not admit safe plans, and that are known to be #P-complete.

scores into a global score for the pair of objects. Thus, the result of fuzzy object matching is inherently probabilistic. In traditional data cleaning it needs to be determinized somehow, e.g., by comparing the similarity score with a threshold and classifying each pair of object into a *match*, a *non-match*, and a *maybe-match*. A probabilistic database allows users to keep the similarity scores natively.

Other applications include: management of sensor data and of RFID data, probabilistic data integration, probabilistic schema matches, and flexible query interfaces.

Definition

Information retrieval (IR) systems aim to retrieve relevant documents while not retrieving non-relevant ones. This can be viewed as the foundation and justification of the binary independence retrieval (BIR) model, which proposes to base the ranking of documents on the division of the probability of relevance and non-relevance.

For a set r of relevant documents, and a set $\bar{r}$ of non-relevant documents, the BIR model defines the following term weight and retrieval status value (RSV) for a document-query pair "d, q":

$$\mathrm{birw}(t, r, \bar{r}) := \frac{P(t|r) \cdot P(\bar{t}|\bar{r})}{P(t|\bar{r}) \cdot P(\bar{t}|r)} \qquad (1)$$

$$\mathrm{RSV}_{\mathrm{BIR}}(d, q, r, \bar{r}) := \sum_{t \in d \cap q} \log \mathrm{birw}(t, r, \bar{r}) \qquad (2)$$

Here, $P(t|r)$ is the probability that term t occurs in the relevant documents, and $P(t|\bar{r})$ is the respective probability for term t in non-relevant documents.

There are two ways to estimate the term probabilities: (I_1) $P(t|r) := \frac{r_t}{R}$ and $P(t|\bar{r}) := \frac{n_t}{N}$, or (I_2) $P(t|r) := \frac{r_t}{R}$ and $P(t|\bar{r}) := \frac{n_t - r_t}{N - R}$. R denotes the number of relevant documents, and N denotes the number of all documents; r_t denotes the number of relevant documents containing term t, and n_t denotes the respective number of all documents. I_1 assumes term independence in the relevant documents and in *all* documents; I_2 assumes term independence in the relevant documents and in the *non-relevant* documents.

Given the two independence assumptions, and given the option to consider term presence only, there are four forms/variations of the BIR term weight. Further, the BIR model proposes a technique for dealing with missing relevance, where a zero probability problem needs to be avoided. The definitions given next show the case referred to as F4 where I_2 is assumed and term absence is considered. The constant 0.5 caters for missing relevance data.

$$\mathrm{birw}_{+0.5}(t, r, \bar{r}) := \frac{(r_t + 0.5)/(R - r_t + 0.5)}{(n_t - r_t + 0.5)/(N - R - (n_t - r_t) + 0.5)} \qquad (3)$$

$$\mathrm{RSV}_{\mathrm{BIR,\,F4}}(d, q, r, \bar{r}) := \sum_{t \in d \cap q} \log \mathrm{birw}_{+0.5}(t, r, \bar{r}) \qquad (4)$$

The derivation of the term weight and the retrieval status value is to be found in the scientific fundamentals of this entry.

Historical Background

The paper [10] on "Relevance Weighting of Search Terms" proposed what became known as the probabilistic retrieval model, binary independence retrieval model, or RSJ (initials of the authors) model.

Closely related is the "The Probability Ranking Principle in IR" [8] to justify that a ranking based on the probability of relevance is an optimal ranking, since the ranking minimises the costs for browsing the ranking.

Reference [2] on "Using Probabilistic Models of Document Retrieval without Relevance Information" investigated the generalisation for missing relevance, and [4] contributed "An Evaluation of Feedback in Document Retrieval using Co-occurrence Data."

Foundations

Derivation of the BIR Model

Derivations of the BIR model can be found in [6], [3] (pp. 21–31), and [5] (pp. 167–175).

The BIR model is derived from the odds of the probability of relevance:

$$O(r|d, q) := \frac{P(r|d, q)}{P(\bar{r}|d, q)} = \frac{P(r|d, q)}{\mathrm{I} - P(r|d, q)} \qquad (5)$$

Here, $P(r|d, q)$ is the probability that the event relevant (r) occurs for a given document-query pair. $P(\bar{r}|d, q)$ is the respective probability for non-relevant.

The derivation of the BIR model can be represented in six steps:

1. Bayes theorem and reduction of $O(r|d, q)$.
2. Representation of d as a vector $\vec{x}$ of binary term features (the binary term features are "term does occur" and "term does not occur").
3. Independence assumption for features.
4. Split product over features into two products: a product for term presence, and a product for term absence.
5. Non-query term assumption: if non-query terms occur with the same frequency in relevant and non-relevant documents, then they do not affect the ranking.
6. Rewrite the expression to obtain a compact form.

Bayes Theorem To estimate the unknown probability $P(r|d, q)$, the theorem of Bayes is applied:

$$P(r|d,q) := \frac{P(r|d,q)}{P(d,q)} = \frac{P(d|r,q)\cdot P(r|q)\cdot P(q)}{P\,(d,q)} \tag{6}$$

For $O(r|d, q)$, the probabilities $P(q)$ and $P(d, q)$ drop out. With respect to the ranking of documents, the factor $\frac{P(r|q)}{P(\bar{r}|q)}$ has no effect, since it is document-independent. Thus, the ranking of documents is based on the following ranking equivalence:

$$O(r|d,q) \overset{rank}{=} \frac{P(d|r,q)}{P(d|\bar{r},q)} \tag{7}$$

Binary Feature Vector $\vec{x}$ The next step concerns the representation and decomposition of the document d. For this, the BIR model assumes that d is a vector of binary features; this vector is denoted $\vec{x} = (x_1,\ldots,x_n)$. Each x_i corresponds to a term t_i, and for all x_i, $x_i = 1$ if term is present, and $x_i = 0$ if term is absent.

Independence Assumption Next, the BIR model assumes that the binary features are independent. This leads to the following equation for $P(d|r, q)$:

$$P(d|r,q) = P(\vec{x}|r,q) = \prod_{x_i} P(x_i|r,q) \tag{8}$$

The equation for $P(d|\bar{r}, q)$ is accordingly.

Product Split The product over all features is split into two products: one product for term presence ($x_i = 1$), and one for absence ($x_i = 0$).

$$P(d|r,q) = \left[\prod_{x_i=1} P(x_i|r,q)\right]\cdot\left[\prod_{x_i=0} P(x_i|r,q)\right] \tag{9}$$

Since $x_i = 1$ corresponds to "term occurs," and $x_i = 0$ corresponds to "term does not occur," the next equation replaces x_i by the term event t, where t means "term occurs."

$$P(d|r,q) = \left[\prod_{t\in d} P(t|r,q)\right]\cdot\left[\prod_{t\notin d} P(\bar{t}|r,q)\right] \tag{10}$$

In classical literature [10,6], the symbols p_i and q_i are employed instead of $P(t|r, q)$ and $P(\bar{t}|r, q)$; however, since the probabilities are more explicit, and avoid a confusion of query (q) and absence of term (q_i), and facilitate to relate the BIR model to other retrieval modes, the probabilistic notion is chosen here, while keeping in mind that $P(t|r, q)$ refers to the binary feature of term t.

Non-Query Term Assumption For all non-query terms, it is assumed that their frequency in relevant documents is equal to their frequency in non-relevant documents, i.e., $\forall t \notin q : P(t|r, q) = P(t|\bar{r}, q)$. This leads to a reduction of the product, i.e., the non-query terms are dropped.

$$\frac{P(d|r,q)}{P(d|\bar{r},q)} = \left[\prod_{t\in d\cap q} \frac{P(t|r,q)}{P(t|\bar{r},q)}\right]\cdot\left[\prod_{t\in q\setminus d} \frac{P(\bar{t}|r,q)}{P(\bar{t}|\bar{r},q)}\right] \tag{11}$$

This assumption corresponds to $\frac{P(t|r,q)}{P(t|\bar{r},q)} = 1$, and the more general assumption is $\frac{P(t|r,q)}{P(t|\bar{r},q)} = c$, where c is a constant.

Rewriting to Achieve Compact Form Finally, a rewriting leads to a compact form. The rewriting is based on the following equation:

$$1.0 = \prod_{t\in d\cap q}\left[\frac{P(\bar{t}|\bar{r},q)}{P(\bar{t}|r,q)}\cdot\frac{P(\bar{t}|r,q)}{P(\bar{t}|\bar{r},q)}\right] \tag{12}$$

Equation 11 is multiplied with this 1.0. This fills up the right product over query-only terms to a product over all query terms; then, this product is document-independent, and it can be dropped for ranking purpose, as the next equations illustrate.

$$O(r|d,q) = \left[\prod_{t \in d \cap q} \frac{P(t|r,q)}{P(t|\bar{r},q)}\right] \cdot \left[\prod_{t \in q \setminus d} \frac{P(\bar{t}|r,q)}{P(\bar{t}|\bar{r},q)}\right] \cdot$$
$$\left[\prod_{t \in d \cap q} \frac{P(\bar{t}|\bar{r},q)}{P(\bar{t}|r,q)} \cdot \frac{P(\bar{t}|r,q)}{P(\bar{t}|\bar{r},q)}\right]$$
$$\overset{rank}{=} \prod_{t \in d \cap q} \frac{P(t|r,q) \cdot P(\bar{t}|\bar{r},q)}{P(t|\bar{r},q) \cdot P(\bar{t}|r,q)} \tag{13}$$

The fractional expression is referred to as the BIR term weight, where either the above form or the logarithm of it may be viewed as the term weight. The following definition follows the first approach, and the logarithm is applied to the term weight in the definition of $\mathrm{RSV}_{\mathrm{BIR}}$.

$$\mathrm{birw}(t,r,\bar{r}) := \frac{P(t|r,q) \cdot P(\bar{t}|\bar{r},q)}{P(t|\bar{r},q) \cdot P(\bar{t}|r,q)} \tag{14}$$

$$\mathrm{RSV}_{\mathrm{BIR}}(d,q,r,\bar{r}) := \sum_{t \in d \cap q} \log \mathrm{birw}(t,r,\bar{r}) \tag{15}$$

The BIR weight is greater than 1.0 for *good* terms, i.e., good terms occur more frequently in relevant documents than in non-relevant documents. For $P(t|r,q) = P(t|\bar{r},q)$, the BIR weight is 1.0; thus, such terms have no effect on the ranking. For *poor terms*, the BIR weight is less than 1.0; thus, poor terms have a negative effect on the $\mathrm{RSV}_{\mathrm{BIR}}$.

Alternative Derivation An alternative, shorter derivation is shown next. The abbreviations $p_i := P(x_i = 1|r)$ and $q_i := P(x_i = 1|\bar{r})$ are applied, and the document probabilities are expressed as follows:

$$\frac{P(d|r)}{P(d|\bar{r})} = \prod_i \frac{p_i^{x_i} \cdot (1-p_i)^{1-x_i}}{q_i^{x_i} \cdot (1-q_i)^{1-x_i}} \tag{16}$$

The exponent $x_i = 1$ selects the probability p_i that the term occurs, and $x_i = 0$ selects the probability $(1 - p_i)$ that the term does not occur. Resolving the exponent $1 - x_i$ leads to the next equation and ranking equivalence.

$$\frac{P(d|r)}{P(d|\bar{r})} = \left[\prod_i \left(\frac{p_i}{1-p_i} \cdot \frac{1-q_i}{q_i}\right)^{x_i}\right] \cdot \prod_i \frac{1-p_i}{1-q_i} \tag{17}$$

$$\overset{rank}{=} \prod_{t \in d \cap q} \mathrm{birw}(t,r,\bar{r}) \tag{18}$$

The right product ($\prod_i \frac{1-p_i}{1-q_i}$ in 17) is constant, and therefore does not affect the ranking. Since $x_i = 0$ for non-document terms, the first product reduces to $x_i = 1$ in d. With $p_i = q_i$ for non-query terms, the product reduces to $x_i = 1$ in d and q, i.e., the product is over $t \in d \cap q$.

Estimation of Term Probabilities

For describing the estimation of term probabilities, the following notation is employed:

Traditional notation	Event-based notation	Comment
r_t	$n_D(t, r)$	Number of relevant documents with term t
R	$N_D(r)$	Number of relevant documents
n_t	$n_D(t, c)$	Number of documents with term t in the collection c
N	$N_D(c)$	Number of documents in the collection c
p_t	$P_D(t\|r)$	Term probability in relevant documents
q_t	$P_D(t\|\bar{r})$	term probability in non-relevant documents

The notation comprises the traditional symbols, and it shows an alternative, namely an event-based notation. The event-based notation is explicit regarding the event-space (D for documents). Therefore, it is applicable in a dual way to document-based and location-based event spaces. Also, events such as a document, a collection, and any set of documents (relevant, non-relevant, retrieved, all) can be referred to systematically.

The estimates of the term probabilities are given next:

Traditional notation	Event-based notation	Comment
$p_t = \frac{r_t}{R}$	$P_D(t\|r) = \frac{n_D(t,r)}{N_D(r)}$	Probability of term in relevant
$q_t = \begin{cases} \frac{n_t}{N} & I_1 \\ \frac{n_t - r_t}{N-R} & I_2 \end{cases}$	$P_D(t\|\bar{r}) = \begin{cases} \frac{n_D(t,c)}{N_D(c)} & I_1 \\ \frac{n_D(t,c)-n_D(t,r)}{N_D(c)-N_D(r)} & I_2 \end{cases}$	Probability of term in non-relevant assumptions I_1 and I_2

The I_2 assumption and the consideration of term absence lead to the following equation for the BIR term weight:

$$\mathrm{birw}(t, r, \bar{r}) = \frac{r_t/(R - r_t)}{(n_t - r_t)/(N - R - (n_t - r_t))} \tag{19}$$

The next section groups the variations of the term weight.

Variations of the BIR Term Weight

[10] introduced four variations (forms) of the term weights: the four variations (referred to as F1, F2, F3, and F4) follow from the two estimates for $P(t|\bar{r})$, and whether or not term absence is considered.

Assumption	Term absence	Variation	Term Weight
I_1	no	F1	$\frac{r_t/R}{n_t/N}$
I_2	no	F2	$\frac{r_t/R}{(n_t-r_t)/(N-R)}$
I_1	yes	F3	$\frac{r_t/(R-r_t)}{n_t/(N-n_t)}$
I_2	yes	F4	$\frac{r_t/(R-r_t)}{(n_t-r_t)/(N-R-(n_t-r_t))}$

For further reading, the BIR term weights are summarised in [3], page 27. The variations form a comprehensive mathematical coverage; F4 is the prime choice.

Solving the Zero Probability Problem

The BIR term weight is not defined for missing relevance; $R = r_t = 0$ leads to a division by zero. Therefore, [10] proposes to add constants to the frequency counts:

$$\mathrm{birw}_{+0.5}(t, r, \bar{r}) := \frac{(r_t + 0.5)/(R - r_t + 0.5)}{(n_t - r_t + 0.5)/(N - R - (n_t - r_t) + 0.5)} \tag{20}$$

The subscript +0.5 in $\mathrm{birw}_{+0.5}(t, r, \bar{r})$ marks this term weight to be different from the bare term weight $\mathrm{birw}(t, r, \bar{r})$ in 19; $\mathrm{birw}_{+0.5}(t, r, \bar{r})$ is also referred to as $\mathrm{rsj}(t, r, \bar{r})$. What is the explanation underlying this zero-probability "fix"?

To reach an explanation, insert $r_t + 0.5$ for each r_t, and insert $R + 1$ for each R. This corresponds to assuming that there is a *virtual* document that is relevant, and each term occurs in *half* of the relevant documents, i.e., $p_t = 0.5$. The virtual document is retrieved, i.e., $n_t + 1$. Finally, this requires to assume $N + 2$ documents, which corresponds to assuming that there are two virtual documents, one of which is relevant. The next equation illustrates the explanation via virtual documents:

$$\mathrm{birw}_{+0.5}(t, r, \bar{r}) := \frac{(r_t + 0.5)/(R + 1 - (r_t + 0.5))}{((n_t + 1) - (r_t + 0.5))/((N + 2) - (R + 1) - ((n_t + 1) - (r_t + 0.5)))} \tag{21}$$

This expanded form reduces to 20.

From a more general point of view, the estimate $P(t|r) := \frac{r_t + k}{R + K}$ is applied to cover the case for missing relevance, where $\frac{k}{K} = 0.5$, and $k = 0.5$, and $K = 1$, for $\mathrm{birw}_{+0.5}$. This formulation reminds of the Laplace law of succession. Since the notion of "half of a relevant document" has no intuition, the number of virtual documents could be scaled to four rather than two [13]. This leads to: $N + 4$, $n_t + 2$, $R + 2$, $r_t + 1$. Then, the BIR weight is as follows:

$$\mathrm{birw}_{+1}(t, r, \bar{r}) := \frac{(r_t + 1)/(R - r_t + 1)}{(n_t - r_t + 1)/(N - R - (n_t - r_t) + 1)} \tag{22}$$

Relationship between the BIR Model, IDF, and BM25

The BIR model can be viewed as a theoretical argument to support IDF-based retrieval.

[2] proposes for missing relevance to assume that for all term, $P(t|r)$ is the same. This leads to a co-ordination level component in the retrieval function:

$$\sum_{t \in d \cap q} \log \frac{P(t|r)}{1 - P(t|r)} + \sum_{t \in d \cap q} - \log \frac{P(t|\bar{r})}{1 - P(t|\bar{r})}$$

The left component expresses the co-ordination level match. For large N and $N >> n_t$, the right component is similar to the IDF component. i.e., $\sum_{t \in d \cap q} - \log \frac{n_t}{N - n_t} \approx \sum_{t \in d \cap q} idf(t, c)$. [11] investigates how these assumptions are affected in the case of little relevance information.

[9] reviews the relationship of the BIR model and IDF, and theoretical arguments for IDF. The relationship between BIR and IDF is based on the definition $idf(t, c) := -\log P_D(t|c)$ and the estimation of the BIR probability $P(t|\bar{r})$. By assuming

$P(t|\bar{r}) = P_D(t|c)$, the relationship is established, i.e., *idf* $(t, c) = -\log P(t|\bar{r})$.

[13] builds on this relationship and shows a fully *idf*-based formulation of the BIR term weight:

$$\log \text{birw}(t, r, \bar{r}) = \log \frac{P(t|r) \,.\, P(\bar{t}|\bar{r})}{P(t|\bar{r}) \,.\, P(\bar{t}|r)} \qquad (23)$$

$$= idf(t, \bar{r}) - idf(t, r) + idf(\bar{t}, r) - idf(\bar{t}, \bar{r}) \qquad (24)$$

$$\approx idf(t, c) - idf(t, r) + idf(\bar{t}, r) - idf(\bar{t}, c) \qquad (25)$$

This linear combination of *idf* values underlines the issue that the collection *c* is much larger than the set *r* of relevant documents ($|c| >> |r|$), and therefore the maximum-likelihood estimates may be not comparable, and may need to be normalised [13].

Ignoring the negated term events (dropping the term absence, see section 1, variations of BIR term weight) leads to the following simplified term weight:

$$\log \frac{P(t|r)}{P(t|\bar{r})} = idf(t, \bar{r}) - idf(t, r) \approx \\ idf(t, c) - idf(t, r) \qquad (26)$$

The formulation shows that the term weight is $idf(t, c)$, if $idf(t, r) = 0$. The latter is the case for terms that occur in *all* relevant documents, i.e., $P(t|r) = 1$. Therefore, from this simplified form of the BIR model, *idf*-based retrieval assumes $P(t|r) = 1$. On the other hand, the full formulation (25) assumes $idf(t, r) = idf(\bar{t}, r)$, i.e., $P(t|r) = 0.5$, for missing relevance.

Regarding BM25, the BIR term weight is in BM25 what IDF is in TF-IDF, i.e., in BM25, a TF-component is multiplied with the BIR F4 term weight, whereas in basic TF-IDF, a TF-component is multiplied with the IDF term weight.

Key Applications

The BIR model is applied to incorporate relevance feedback data into document ranking; this model has become a key foundation of retrieval models. In 2004, the BIR model served as a foundation for a probabilistic ranking of tuples for database queries [1].

Probabilistic Spatial Queries

Imprecise spatial queries

Definition

An uncertain item is defined as a range-limited probability density function (pdf) in a multi-dimensional space, which can model the uncertainty of location, sensor and biological data. Given a set of uncertain items, a probabilistic spatial query returns results augmented with probabilistic guarantees for the validity of answers. The impreciseness of query answers is an inherent property of these applications due to data uncertainty, unlike the techniques for approximate processing that trade accuracy for performance. New query definitions, processing and indexing techniques are required to handle these queries.

Historical Background

Data uncertainty is an inherent property in a number of important and emerging applications. Consider, for example, a habitat monitoring system used in scientific applications, where data such as temperature, humidity, and wind speed are acquired from a sensor network. Due to physical imperfection of the sensor hardware, the data obtained are often inaccurate [9]. Moreover, a sensor cannot report its value at every point in time, and so the system can only obtain data samples at discrete time instants. As another example, in the Global-Positioning System (GPS), the location collected from the GPS-enabled devices (e.g., PDAs) also has measurement and sampling error [16,14]. The location data transmitted to the system may further encounter some network delay. In biometric databases, the attribute values of the feature vectors stored are not exact [1]. Hence, the data collected in these applications are often imprecise, inaccurate, and stale.

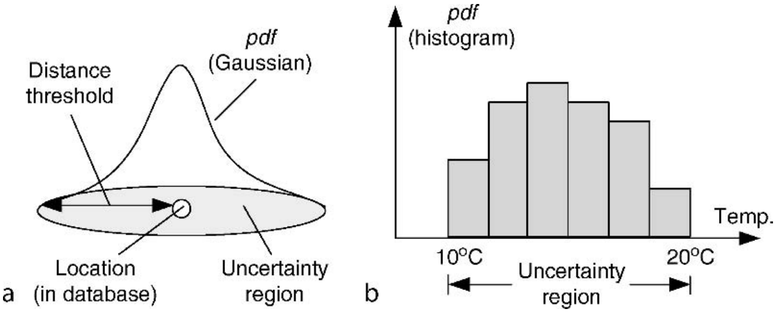
Services or queries that base their decisions on these data can produce erroneous results. There is thus a need to manage these data errors more carefully. In particular, the idea of *probabilistic spatial queries* (PSQ in short), which is a variant of spatial queries that handle data uncertainty, has been recently proposed. The main idea of a PSQ is to consider the models of the data uncertainty (instead of just the data value reported), and augment probabilistic guarantees to the query results. For example, a traditional query asking who is the nearest neighbor of a given point q can tell the user that John is the answer, while a PSQ informs the user that John has a probability of 0.8 of being the closest to q. The probabilities reflect the degree of correctness of query results, thereby facilitating the system to produce a more confident decision.

In this entry, the recent research efforts on PSQ will be summarized. Specifically, the details of how a PSQ can be classified will be discussed. Then, the issues of evaluating and indexing different types of PSQ in a large database will be addressed.

Foundations

Spatial Uncertainty Models To understand a PSQ, it is important to first discuss a commonly-used model of data uncertainty. This model assumes that the actual data value is located within a closed region, called the *uncertainty region*. In this region, a non-zero probability density function (*pdf*) of the value is defined, where the integration of pdf inside the region is equal to one. The cumulative density function (*cdf*) of the item is also provided. In an LBS, a normalized Gaussian pdf is used to model the measurement error of a location stored in a database [16,14] (Fig. 1a). The uncertainty region is a circular area, with a radius called the "distance threshold"; the newest location is reported to the system when it deviates from the old one by more than this threshold (Fig. 1a). Gaussian distributions are also used to model values of a feature vector in biometric databases [1]. Figure 1b shows the histogram of temperature values in a geographical area observed in a week. The pdf, represented as a histogram, is an arbitrary distribution between 10 and 20°C.

A logical formulation of queries for this kind of uncertainty model has been recently studied in [12,15].



Probabilistic Spatial Queries. Figure 1. Location and sensor uncertainty.

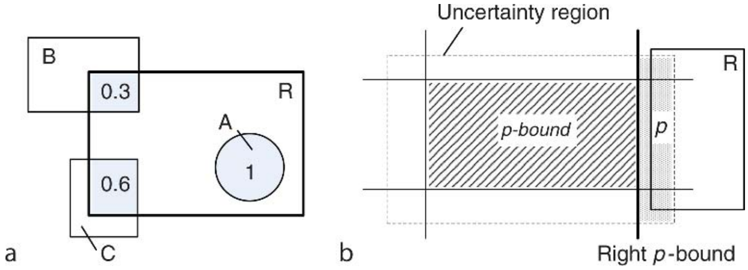
Other variants have also been proposed. In [11], piecewise linear functions are used to approximate the cdf of an uncertain item. Sometimes, point samples are derived from an item's pdf [10,13]. In the *existential uncertainty model*, every object is represented by the value in the space, as well as the probability that this object exists [8]. With these modified models, it is possible to develop fast processing techniques for PSQs.

Query Classification Given the spatial uncertainty model, the semantics of PSQs can be defined. Cheng et al. proposed a classification scheme for different types of PSQ [4]. In that scheme, a PSQ is classified according to the forms of answers. An *entity-based query* is one that returns a set of objects (e.g., list of objects that satisfy a range query or join conditions), whereas a *value-based query* returns a single numeric value (e.g., value of a particular sensor). Another criterion is based on whether an *aggregate* operator is used to produce results. An aggregate query is one where there is interplay between objects that determines the results (e.g., a nearest-neighbor query). Based on these two criteria, four different types of probabilistic queries are defined. Each query type has its own methods for computing answer probabilities. In [4], the notion of *quality* has also been defined for each query type, which provides a metric for measuring the ambiguity of an answer to the PSQ.

In the rest of this section, two important PSQs, namely the probabilistic range queries and the probabilistic nearest-neighbor queries, will be studied.

Probabilistic Range Queries A well-studied PSQ is the *probabilistic range query* (PRQ). Figure 2a illustrates this query, which shows the shape of the uncertainty regions, as well as the user-specified range, *R*. The task of the range query is to return the each object that can be inside *R*, as well as its probability. The PRQ can be used in location-based services, where queries like: "return the suspect vehicles in a crime scene" can be asked. It is also used in sensor network monitoring, where sensor IDs whose physical values (e.g., temperature, humidity) are returned to the user. Figure 2a shows the probability values of the items (*A*, *B*, and *C*) that are located inside *R*. A PRQ is an *entity-based* query, since it returns a list of objects. It is also a *non-aggregate* query, because the probability of each object is independent of the existence of other objects [4].

To compute an item's probability for satisfying the PRQ, one can first find out the overlapping area of each item's region within *R* (shaded in Fig. 2a), and perform an integration of the item's pdf inside the overlapping area. Unfortunately, this solution may not be very efficient, since expensive numerical integration may need to be performed if the the item's pdf is arbitrary [7]. Even if an R-tree is used to prune items that do not overlap *R*, the probability of each item that are non-zero still needs to computed. A more efficient solution was developed in [7], where the authors proposed a user-defined constraint, called the *probability threshold P*, with $P \in (0,1]$. An item is only returned if its probability of satisfying the PRQ is not less than *P*. In Fig. 2a, if $P = 0.6$, then only *A* and *C* will be returned to the user. Under this new requirement, it is possible to incorporate the uncertainty information of items into a spatial index (such as R-tree). The main idea is to precompute the *p-bounds* of an item. A *p*-bound of an uncertain item is essentially a function of *p*, where $p \in [0,0.5]$. In a 2D space, it is composed of four line segments, as illustrated by the hatched region in Fig. 2b. The requirement of right *p*-bound (illustrated by the thick solid line) is that the probability of the location of the item on the right of the line has to be exactly equal to *p* (the shaded area). Similarly, the probability of the item on the left of the left *p*-bound



Probabilistic Spatial Queries. Figure 2. Probabilistic range queries over uncertain items, showing (a) the probability of each item, and (b) the *p*-bound of an uncertain item.

is exactly equal to p. The remaining line segments (top and bottom p-bounds) are defined analogously. Once these p-bounds are known, it is possible to know immediately whether an item satisfies the PRQ. Figure 2b shows that a range query R overlaps the item's uncertainty region, but does not cut the right p-bound, where p is less than P. Since the integration of the item's pdf inside the overlapping area of R and the uncertainty region cannot be larger than P, the item is pruned without doing the actual probability computation.

By precomputing a finite number of p-bounds, it is possible to store them in a modified version of the R-tree. Called *Probability Threshold Index* (PTI), this index can facilitate the pruning of uncertain items in the index level [7]. Compared with the R-tree which uses the MBR of the object for pruning, the use of p-bounds in the PTI provides more pruning power. In Fig. 2b, for example, although the range R overlaps with the MBR of the object (dashed rectangle), it does not cut the p-bounds, and so it can be pruned by the PTI but not by the R-tree. [7] also examined special cases of pdf (uniform and Gaussian distributions) and proposed an indexing scheme where p-bounds can be computed on-the-fly without being stored in the index. Since storing p-bounds for high-dimensional uncertain items can be expensive, Tao et al. [17,18] proposed a variant of PTI called *U-tree*, which only stores approximate information of p-bounds in the index. With these improvements, it is possible to index uncertain items in the high-dimensional space. The p-bound techniques were also used in [6] to facilitate the processing of join queries over uncertain spatial data.

Another PRQ evaluation technique was recently proposed by Ljosa et al. [7], who used piecewise linear functions to approximate the cdf of an uncertain item in order to avoid expensive integration. They also described an index that stored these piecewise linear functions, so that a PRQ can be evaluated more efficiently. More recently, the problem of evaluating *imprecise location dependent range queries* is studied [18,2]. This is a variant of PRQ, where the range query is defined with reference to the (imprecise) position of the query issuer. For instance, if the query issuer looks for his friends within 2 miles of his current position, and his position is uncertain, then the actual query range (a circle with a 2-mile radius) cannot be known precisely. The authors of [2] proposed several approaches to efficiently evaluate these queries, by (i) using the Minkowski Sum (a computational geometry technique), (ii) switching the role of query issuer and data being queried, and (iii) using p-bounds.

Nearest-Neighbor Queries Another important PSQ for uncertain items is the probabilistic nearest-neighbor queries (PNNQ in short). This query returns the non-zero probability of each object for being the nearest neighbor of a given point q [4]. A PNNQ can be used in a sensor network, where sensors collect the temperature values in a natural habitat. For data analysis and clustering purposes, a PNNQ can find out the district(s) whose temperature values is (are) the closest to a given centroid. Another example is to find the IDs of sensor(s) that yield the minimum or maximum wind-speed from a given set of sensors [9,4]. A minimum (maximum) query is essentially a special case of PNNQ, since it can be characterized as a PNNQ by setting q to a value of $-\infty$ (∞).

Evaluating a PNNQ is not trivial. In particular, since the exact value of a data item is not known, one needs to consider the item's possible values in its uncertainty region. Moreover, since the PNNQ is an entity-based aggregate query [4], an item's probability depends not just on its own value, but also on the relative values of other objects. If the uncertainty regions of the objects overlap, then their pdfs must be considered in order to derive their corresponding probabilities. This is unlike the evaluation of PRQ, where each item's probability can be computed independent of others. To evaluate PNNQ, one method is to derive the pdf and cdf of each item's distance from q. The probability of an item for satisfying the PNNQ is then computed by integrating over a function of distance pdfs and cdfs [9,4,5]. In [5], an R-tree-based solution for PNNQ was presented. The main idea is to prune items with zero probabilities, using the fact that these items' uncertainty regions must not overlap with that of an item whose maximum distance from q is the minimum in the database. The *probabilistic verifiers*, recently proposed in [3], are algorithms for efficiently computing the lower and upper bounds of each object's probability for satisfying a PNNQ. These algorithms, when used together with the probability threshold defined by the user, avoid the exact probability values to be calculated. In this way, a PNNQ can be evaluated more efficiently.

There are two other solutions for PNNQ that base on a different representation of uncertain items. Kriegel et al. [10] used the Monte-Carlo method, where the pdf of each object was sampled as a set of points. The probability was evaluated by considering the portion of points that could be the nearest neighbor. In [11], Ljosa et al. used piecewise linear representation of the cdf for an uncertain item to propose efficient evaluation and indexing techniques.

Another important entity-based aggregate query over uncertain items, namely the probabilistic skyline queries, has been studied in [13]. A skyline query returns a set of items that are not dominated by other items in all dimensions. In that paper, the issues of defining and computing the probability that an uncertain item was in the skyline were addressed. Two bounding-pruning-refining based algorithms were developed: the bottom-up algorithm used selected instances of uncertain items to prune other instances of uncertain items, while the top-down algorithm recursively partitions the instances of uncertain items into subsets. The authors showed that both techniques enable probabilistic skyline queries to be efficiently computed.

Key Applications

A PSQ can be used in applications that require the processing of uncertain spatial data. These applications include location-based services, road traffic monitoring, wireless sensor network applications, and biometric feature matching, where the data collected from the physical environments (e.g., location, temperature, humidity, images) cannot be obtained with a full accuracy. Recent works that propose to inject uncertainty to a user's location for location privacy protection also requires the use of a PSQ [2].

Future Directions

A lot of work remains to be done in the area of uncertain spatial data processing. An important future work will be the definition and evaluation of important spatial queries, such as reverse nearest-neighbor queries. It will also be interesting to study the development of data mining algorithms for spatial uncertainty. Another direction is to study spatio-temporal queries over historical spatial data (e.g., trajectories of moving objects). Other works include revisiting query cost estimation, query plan evaluation, and user interface design that allows users to visualize uncertain data. A long term goal is to consolidate these research ideas and develop a comprehensive spatio-temporal database system with uncertainty management facilities.

Probabilistic Temporal Databases

V. S. Subrahmanian
University of Maryland, College Park, MD, USA

Synonyms

Temporally uncertain databases; Temporally indeterminate databases

Definition

There are many applications where the fact that a given event occurred is known, but where there is uncertainty about exactly when that event occurred. Such events are called temporally indeterminate events. Probabilistic temporal databases attempt to store information about events that are both temporally determinate and temporally indeterminate. For the latter, they specify a set of time points (often an interval) – it is known that the event occurred at some time point in this set. The probability that the event occurred at a specific time point is given by a probability distribution or by one of a set of probability distributions.

Historical Background

There is no shortage of events that are known to have certainly occurred, but where the exact dates are not known with certainty. For instance, the exact date of the extinction of dinosaurs is unknown – nor does the historical record show the precise date when Cyrus the Great of Persia was born. The latter, estimated by scholars to be between 590–576 BC, is an excellent example of a temporally indeterminate event.

Techniques to study such temporally indeterminate events in databases started with information about *partial null values* [9,13]. Meanwhile, in a largely separate community, researchers focused on the problem of incorporating probabilistic information within a relational database. One of the earliest efforts was due to Cavallo and Pittarelli [4] who proposed an extension of the relational data model to include probabilities – they proposed a partial algebra consisting of projection and join operators. Much early work in this field, such as that of [2,7] made important advances under some restrictions Lakshmanan et al.'s ProbView system [11] proposed two representations of probabilistic data: a *probabilistic tuple* has the form $((t_1,V_1),\ldots,(t_n,V_n))$ where each t_i is a set of possible values and V_i is a probability distribution over the set. They then showed that each probabilistic tuple could be "flattened" into an "annotated" representation. Annotated tuples look like ordinary tuples except that a probability is attached to the tuple as a whole (and a special "path" field was introduced to handle tuples with identical data). ProbView introduced the important concept of conjunction and disjunction strategies that allowed users to specify – in their query – their knowledge about the dependencies between events when posing the query. Thus, the barrier of the independence assumption in previous works was overcome. They proposed a query algebra for annotated tuples, developed query rewrite rules, and developed view maintenance algorithms.

Much work has subsequently been done on temporal probabilistic data. Despite a long history of reasoning about time and uncertainty in AI [10], a major advance in temporal probabilistic databases occurred when Dyreson and Snodgrass [8] proposed the notion of an indeterminate instant. This is just like one of the (t_i,V_i) pairs in the annotated representation of [11] with the exception that the t_i component represents a set of time points. They then extended the SQL query language in several ways. First, they added constructs to indicate that a temporal attribute in indeterminate. Second, they added the concept of "correlation credibility" which allows a query to modify indeterminate temporal data (e.g., by choosing a max temporal value or an expected temporal value). Third, they introduced the concept of "ordering plausibility" which specifies an ordering about the plausibility levels of different conditions in the WHERE clause of an SQL query. The next major breakthrough in temporal probabilistic databases came when Dekhtyar et al. [6] proposed a temporal probabilistic relational database model that added “tp-cases” to ordinary relational tuples. A tp-case contained two constraints one of which was used to denote valid time points as solutions of the constraints, and the other was used in conjunction with a distribution function to infer a probability distribution on the solutions of the first constraint. They developed an extension of the relational algebra that directly manipulated tp-tuples and used the conjunction and disjunction strategies of ProbView [11] to avoid making independence assumptions. TP-databases were one of the first temporal probabilistic DBMSs to report real world applications for the US Navy [12]. It was later used to build similar applications for the US Army as well. Later, Biazzo et al. [3] extended this work to the case of object bases containing temporal indeterminacy. The Trio system [1] extends temporal indeterminacy models to include lineage information as well. More recently, SPOT databases [14] allow reasoning in the presence of space, time and uncertainty.

Foundations

Consider a relation $R(A_1,\ldots,A_n)$ which describes events whose temporal validity is not precisely known. In order to identify when the tuples in such a relation are valid, *constraints* can be to describe the period of validity of the tuple. The table below (ignoring the shaded column for now) is a temporally indeterminate database about vehicle locations.

The first row in this table says that the event “Vehicle V1 was at location *a*” occurred at some time during the closed interval [11,20]. This is a form of temporal indeterminacy with no probabilities. Suppose there is a probability distribution over the last column. A common temptation is to add an additional column specifying the “name” of the distribution (e.g., “u” might be the uniform distribution, g_r may be a geometric distribution with a parameter r, and so forth). Such a table might now look like this:

VehicleID	Vehicle Type	Location	Time	PDF
V1	T72	*a*	11 < = t < = 20	U
V1	T72	*b*	18 < = t < = 25	$\gamma_{0.5}$
V1	T72	*c*	24 < = t < = 27	$\gamma_{0.2}$

Now consider the table above with the shaded column included. The first row in the table now says that there is a 10% probability that vehicle V1 will be at location *a* at time 11 (and the same for times 12, 13, and so on till time 20) and that the probability is uniformly distributed (probability distribution function or pdf “u”). In contrast, the second row says something different because the pdf γ treats time intervals differently. It says, implicitly, that the probability that vehicle V1 will be at location *b* at time 18 is 0.15, at time 19 is 0.25, at time 20 is 0.125, and so on.

How should queries over this representation of the database be answered? To see this, consider a temporal query which says “Select all tuples where $20 < Time < 23$.” The only tuple that has any chance of satisfying this constraint is the second one. However, there is no *guarantee* that the second tuple actually is valid during this interval. Fortunately, there is a 9.375% chance that this is the case – so the system could return the probabilistically valid response saying that the second tuple is valid with probability 9.375%. Unfortunately, there is no way of returning this answer to the user *unless the implicit assumption in all relational databases that the output schema for selection queries should match the input schema is sacrificed.* It is clearly inappropriate to just return the table:

VehicleID	Vehicle Type	Location	Time	PDF
V1	T72	*b*	20 <t<23	$\gamma_{0.5}$

The *Time* field here is computed merely by solving the constraint in the second tuple of the input relation in conjunction with the constraint in the query. Unfortunately, the distribution in the *PDF* field is incorrect, and would need to be recomputed. This is further complicated by the fact that the shape of the original geometric distribution does not look the same when restricted to a portion (of interest) of the original distribution.

There have been two attempts to solve the problem of dealing with what happens when a distribution is manipulated. Dyreson and Snodgrass [8] develop a “rod and point” method to store distributions and infer new distributions when selection operations of the kind above are performed. They approximate a probability mass by splitting it into chunks called “rods.” However, each chunk can have a different length. An approximate representation of the original distribution is obtained through this rod mechanism.

Dekhtyar et al. [6] solve this problem by using some extra space. They require that the "base relation" contains *two constraints*, both of which are identical initially. They would represent the original relation as follows:

VehicleID	Vehicle Type	Location	Time	Time 2	PDF
V1	T72	*a*	11 < = t < = 20	11 < = t < = 20	U
V1	T72	*b*	18 < = t < = 25	18 < = t < = 25	$G_{0.5}$
V1	T72	*c*	24 < = t < = 27	24 < = t < = 27	$G_{0.2}$

In base relations, the *Time* and *Time2* fields have exactly the same constraints in them. When queries are executed, the *Time* field ends up denoting valid time and changes based on the query – however, the *Time2* field rarely changes. When the selection query mentioned above is execution, they would return the answer:

VehicleID	Vehicle Type	Location	Time	Time 2	PDF
V1	T72	*B*	20 < t < 23	18 < = t < = 25	$G_{0.5}$

This is very subtle. The *Time* attribute here specifies the valid time (in this case, time points 21 and 22). The *Time2* attribute is a system-maintained attribute that need not be shown to the user which says apply the PDF mentioned in the *PDF* field to the solutions of the *Time2* constraint – but only show the probability values for the solutions of the *Time* constraint). Thus, *Time2* is used to derive the probabilities for each valid time point. In the above case, the valid time points are 21 and 22, and their probabilities are derived – using the distribution in the *PDF* column applied to the constraint in the *Time2* column – to get probabilities of 0.0625 and 0.03125, respectively. Dekhtyar et al. [6] goes on and specifies how to add additional "low" and "high" probability fields to such relations and provides normalization methods.

Cartesian products between two relations are more complex. When concatenating tuple *st1* and *t2* from two different relations, it is important to consider the probability that both tuples will be valid at a given time point. This requires knowing the relationship between the events being denoted by these two tuples: are they independent? Are they correlated somehow? Is there no information about the relationship? Thus, a *conjunction strategy* must be specified in the query when a Cartesian product (and hence a join operation) is being performed. Dekhtyar et al. [6] show how Cartesian products and joins can be computed under any assumption specified in a user query.

Another recent effort is the one on Trio [1] which attempts to deal with time, uncertainty, and lineage. They address the fact that in many applications involving uncertainty (such as crime-fighting applications), any "final" answer needs to be explainable. As a consequence, they introduce "lineage" parameters when answering a query – informally speaking, the lineage parameter associated with a tuple in an answer (similar to the "path" parameter in [11]) associates a "justification" for each tuple. This justification references the set of base tuples that caused the derived tuple to be placed in an answer.

Key Applications

Temporal probabilistic databases have already been used in defense applications. For instance, [12] describes work in which temporal probabilistic databases are used to store the results of predictions about where enemy submarines will be in the future, when they will be there, and with what probability. In fact, this raises a large set of possible applications based on reasoning about moving objects. For defense applications, cell phone applications, logistics applications, and many other application domains, there is interest in knowing where a moving object will be in the future, when it is expected to be there, and with what probability. Cell phone companies can use such data to understand and better handle load on cell towers.

Moreover, as the world is becoming increasing "geo-location aware" through the use of devices like RFID tags and GPS locators, it is clear that reasoning about where vehicles will be in the future and with what probability will be important in a wide range of applications such as traffic light settings to ease road congestion, recommending detours on highway signs, and more effectively directing 911 traffic in congested situations. These would not be possible without a good estimate of when and where and with what probabilities vehicles will be in the future.

Logistics applications are another important class of applications where companies need to plan activities in the presence of uncertainty about when various supply items will arrive. Corporations today use complex prediction models to learn about suppliers' performance.

Financial applications are another major source of temporal uncertainty. Banks need to have a good idea of their incoming funds. For instance, a credit card provider deals with constant uncertainty about when people will pay their credit card bills, how much of the bills they will pay, and how much they will carry forward as debt. Such applications embody a mix of data uncertainty and temporal uncertainty.

Future Directions

Three major areas of expansion include:

1. *Temporal probabilistic aggregates*. To date, there are almost no techniques to manage aggregates efficiently in temporal probabilistic databases. Most methods would compute aggregates by first answering a non-aggregate query and then deriving aggregates from there: however, techniques to scalably answer aggregate queries are required.
2. *Probabilistic spatio-temporal reasoning*. Moving objects clearly have a spatial component – hence, reasoning about them involves a neat fusion of temporal reasoning, spatial reasoning, and probabilistic reasoning. Some work on indexing in such domains has recently been proposed. However, much future work is needed, especially in understanding the correlations that exist between the presence of a vehicle at time *t* and its presence at another location at time *t* + *1*.
3. *Query optimization*. Recent work [5] has made a good start on query optimization in probabilistic databases – however, query optimization in databases involving time and uncertainty has a ways to go. Such methods are critical for scaling applications.

Probability Ranking Principle

Ben He
University of Glasgow, Glasgow, UK

Synonyms

PRP

Definition

The probability ranking principle asserts that relevance has a probabilistic interpretation. According to this principle documents are ranked by a probability $p(Rel|d, q)$, where *Rel* denotes the event of a document *d* being relevant to a query *q*. Robertson called this principle the *probability ranking principle* [1].

Key Points

By assuming independence between query terms, Robertson and Sparck-Jones proposed for the probability $p(Rel|d,q)$ the following model (the RSJ model [2]):

$$\log(p(Rel|d,q)) \propto \sum_{t \in q} \log \frac{p(t|Rel) \cdot p(\overline{t}|\overline{Rel})}{p(t|\overline{Rel}) \cdot p(\overline{t}|Rel)} \qquad (1)$$

where $\overline{Rel}$ indicates the event of non-relevance; t and $\overline{t}$ indicate the events that the term t occurs in document d or does not, respectively. For each query term t, the probability $p(Rel|d,t)$ is given by the sum of two log-odds, $\log \frac{p(t|Rel)}{p(t|\overline{Rel})}$ and $\log \frac{p(\overline{t}|\overline{Rel})}{p(\overline{t}|Rel)}$.

If N is the number of documents in the whole collection, R is the number of relevant documents, r is the number of relevant documents containing t, N_t is the document frequency, i.e., the number of documents containing t, [3] instantiated the RSJ model as follows:

$$w^{(1)} = \log \frac{(r+0.5)(N-N_t-R+r+0.5)}{(R-r+0.5)(N_t-r+0.5)} \qquad (2)$$

where $w^{(1)}$ is the raw weight of a term t in a document d. The number 0.5 is used to avoid assigning negative weights. The formula is called the "point-5" formula.

If relevance information is not available, i.e., $R = r = 0$, the point-5 formula can be written as:

$$w^{(1)} = \log \frac{N - N_t + 0.5}{N_t + 0.5} \qquad (3)$$

As one of the most well-established IR systems, Okapi uses a weighting model that is based on the RSJ model introduced above, and takes also term frequency (tf) and query term frequency (qtf) into consideration.

Probability Smoothing

Djoerd Hiemstra
University of Twente, AE Enschede, The Netherlands

Definition

Probability smoothing is a language modeling technique that assigns some non-zero probability to events that were unseen in the training data. This has the effect that the probability mass is divided over more events, hence the probability distribution becomes more *smooth*.

Key Points

Smoothing overcomes the so-called *sparse data problem*, that is, many events that are plausible in reality are not found in the data used to estimate probabilities. When using maximum likelihood estimates, unseen events are assigned zero probability. In case of information retrieval, most events are unseen in the data, even if simple unigram language models are used documents are relatively short (say on average several hundreds of words), whereas the vocabulary is typically big (maybe millions of words), so the vast majority of words does not occur in the document. A small document about "information retrieval" might not mention the word "search," but that does not mean it is not relevant to the query "text search." The sparse data problem is the reason that it is hard for information retrieval systems to obtain high recall values without degrading values for precision, and smoothing is a means to increase recall (possibly degrading precision in the process). Many approaches to smoothing are proposed in the field of automatic speech recognition [1]. A smoothing method may be as simple so-called Laplace smoothing, which adds an extra count to every possible word. The following equations show respectively (1) the unsmoothed, or maximum likelihood estimate, (2) Laplace smoothing, (3) Linear interpolation smoothing, and (4) Dirichlet smoothing [3]:

$$P_{ML}(T=t|D=d) = tf(t,d) / \sum_{t'} tf(t',d) \qquad (1)$$

$$P_{LP}(T=t|D=d) = (tf(t,d)+1) / \sum_{t'} (tf(t',d)+1) \qquad (2)$$

$$P_{LI}(T=t|D=d) = \lambda P_{ML}(T=t|D=d) + (1-\lambda)P_{ML}(T=t|C) \quad (3)$$

$$P_{Di}(T=t|D=d) = (tf(t,d) + \mu P_{ML}(T=t|C)) / ((\sum_{t'} tf(t',d)) + \mu) \quad (4)$$

Here, $tf(t,d)$ is the frequency of occurrence of the term t in the document d, and $P_{ML}(T|C)$ is the probability of a term occurring in the entire collection C. Both linear interpolation smoothing and Dirichlet smoothing assign a probability proportional to the term occurrence in the collection to unseen terms. Here, λ $(0<\lambda<1)$ and μ $(\mu>0)$ are unknown parameters that should be tuned to optimize retrieval effectiveness. Linear interpolation smoothing has the same effect on all documents, whereas Dirichlet smoothing has a relatively big effect on small documents, but a relatively small effect on bigger documents. Many smoothed estimators used for language models in information retrieval (including Laplace and Dirichlet smoothing) are approximations to the *Bayesian predictive distribution* [2].

Definition

The stages of life from the start to the end of a process instance within the context of workflow management.

Key Points

The Process Life Cycle represents the stages of a process instance as it evolves from instantiation to termination. This life cycle is most closely related to the life cycle of a thread, and is distinct from the life cycle approach to Business Process Management initiatives, involving an iterative or recursive evolution through the five stages of design, modeling, execution, monitoring, and optimization.

The latter notion of Business Process Management Life cycle is associated with the discipline of continuous process improvement, whereby processes are never deemed "complete" and thus no longer subject to change, but rather are continuously improved through multiple instances of execution, examination, and modification. In contrast, the Process Life Cycle as defined herein refers to the "life span" of a process instance and has definitive start and end points. Thus the Process Life Cycle of the individual process instance is more aptly described as linear as opposed to cyclical, although at various steps in the process it may cycle between running and suspended states.

The steps of the Process Life Cycle are "Instantiate" representing the creation of a new instance (making it live but not necessarily running); "activate" representing the activation of the process instance (now live and running); "passivate" which refers to temporarily suspending the instance (live but not running); "terminate" which represents the end of life of the process instances, through either abortion, cancellation, or completion after running through the full process as defined.

Process Mining

W. M. P. van der Aalst

Workflow mining

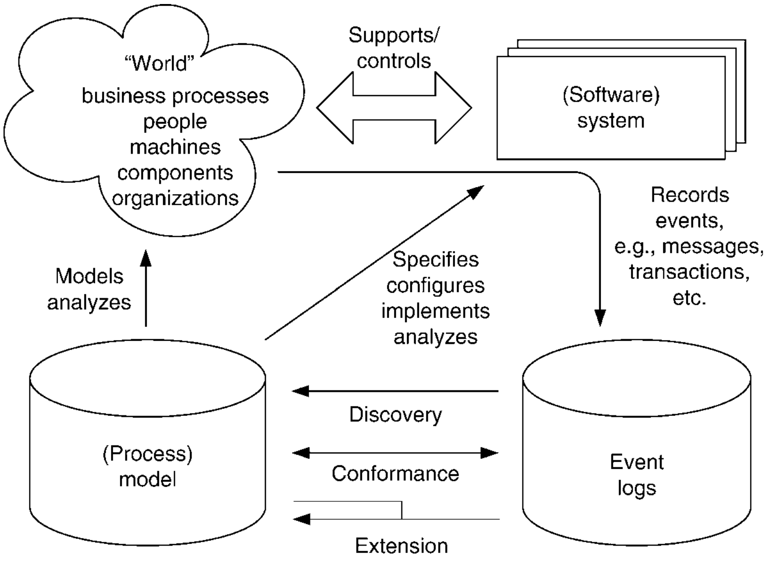
Definition

Process mining techniques allow for the analysis of business processes based on event logs. For example, the audit trails of a workflow management system, the transaction logs of an enterprise resource planning system, and the electronic patient records in a hospital can be used to discover models describing processes, organizations, and products. Moreover, such event logs can also be used to compare event logs with some a priori model to see whether the observed reality conforms to some prescriptive or descriptive model.

The basic idea of *process mining* is to discover, monitor, and improve *real* processes (i.e., not assumed processes) by extracting knowledge from event logs. Today many of the activities occurring in processes are either supported or monitored by information systems. Consider for example ERP, WFM, CRM, SCM, and PDM systems to support a wide variety of business processes while recording well-structured and detailed event logs. However, process mining is not limited to information systems and can also be used to monitor other operational processes or systems. For example, process mining has been applied to complex X-ray machines, high-end copiers, web services, careflows in hospitals, etc. All of these applications have in common that *there is a notion of a process* and that *the occurrences of activities are recorded in so-called event logs*. Assuming that the supporting systems log events, a wide range of *process mining techniques* comes into reach. The basic idea of process mining is to learn from observed executions of a process and can be used to (i) *discover* new models (e.g., constructing a Petri net that is able to reproduce the observed behavior), (ii) check the *conformance* of a model by checking whether the modeled behavior matches the observed behavior, and (iii) *extend* an existing model by projecting information extracted from the logs onto some initial model (e.g., show bottlenecks in a process model by analyzing the event log). All three types of analysis have in common that they assume the existence of some *event log*.

Key Points

The goal of process mining is to discover, monitor, and improve real processes by extracting knowledge from event logs. Clearly, process mining is relevant in a setting where much flexibility is allowed or needed, because the more ways in which people and organizations can deviate, the more variability and the more interesting it is to observe and analyze processes as they are executed. Three basic types of process mining can be identified (Fig. 1):



Process Mining. Figure 1. Three types of process mining: (i) discovery, (ii) conformance, and (ii) extension.

1. *Discovery*. There is no a priori model, i.e., based on an event log some model is constructed. For example, using the α-algorithm [2] a process model can be discovered based on low-level events.
2. *Conformance*. There is an a priori model. This model is used to check if reality conforms to the model. For example, there may be a process model indicating that purchase orders of more than one million Euro require two checks. Another example is the so-called four-eyes principle where two activities need to be executed by different people. Conformance checking may be used to detect deviations, to locate and explain these deviations, and to measure the severity of these deviations.
3. *Extension*. There is an a priori model. This model is extended with a new aspect or perspective, i.e., the goal is not to check conformance but to enrich the model. An example is the extension of a process model with performance data, i.e., some a priori process model dynamically annotated with performance data (e.g., bottlenecks are shown by coloring parts of the process model). Figure 1 shows that a log and a model are used to create a new model.

Traditionally, process mining has been focusing on *discovery*, i.e., deriving information about the original process model, the organizational context, and execution properties from enactment logs. An example of a technique addressing the control flow perspective is the α-algorithm, which constructs a Petri net model describing the behavior observed in the event log. However, process mining is not limited to process models (i.e., control flow) and recent process mining techniques are more and more focusing on other perspectives, e.g., the organizational perspective or the data perspective. For example, there are approaches to extract social networks from event logs and analyze them using social network analysis [1]. This allows organizations to monitor how people and groups are working together.

Conformance checking compares an a priori model with the observed behavior as recorded in the log. In [4] it is shown how a process model (e.g., a Petri net) can be evaluated in the context of a log using metrics such as "fitness" (Is the observed behavior possible according to the model?) and "appropriateness" (Is the model "typical" for the observed behavior?). However, it is also possible to check conformance based on organizational models, predefined business rules, temporal formula's, Quality of Service (QoS) definitions, etc.

There are different ways to *extend* a given process model with additional perspectives based on event logs, e.g., decision mining. Decision mining, also referred to as decision point analysis, aims at the detection of data dependencies that affect the routing of a case. Starting from a process model, one can analyze how data attributes influence the choices made in the process based on past process executions. Classical data mining techniques such as decision trees can be leveraged for this purpose. Similarly, the process model can be extended with timing information (e.g., bottleneck analysis).

Process mining is strongly related to classical data mining approaches. However, the focus is not on data but on process-related information (e.g., the ordering of activities). Process mining is also related to monitoring and business intelligence [3].

Business process optimization; QoS-based web services composition

Definition

With the development of the service oriented architecture (SOA), complex applications can be composed as business processes invoking a variety of available Web services (WSs) with different characteristics. Advanced SOA systems [1,12,15] allow the development of applications by specifying component WSs in a process only through their required functional characteristics, and to select WSs during process execution from the ones included in a registry of available services. Service descriptions are stored and retrieved from enhanced UDDI registries, which also provide information about quality of service (QoS) on the provider side. Usually, a set of functionally equivalent services can be selected, i.e., services which implement the same functionality but differ for the quality parameters.

Process optimization identifies the best set of services available at run time, taking into consideration end-user preferences and constraints on the QoS properties.

Historical Background

Process optimization has its roots in workflow scheduling problems. Scheduling of workflows [13] is the problem of finding a correct execution sequence of workflow tasks such that some temporal constraints or resource constraints (i.e., agents which can support tasks executions) are met. In workflow management systems, agents could be human beings or software applications, in Process optimization the available resources are component WSs. Process optimization is related also to workflow/process planning [3] where the problem of synthesizining a complex behavior from an explicit goal and a set of candidates which contribute to a partial reaching of this goal is investigated. In Process optimization, vice versa, the *process schema*, i.e., the sequence of activities, is given and the optimum mapping of activities to component WSs candidate for their execution is identified.

Process optimization has been applied in context-aware business processes and e-science research fields. The literature has provided *three generations* of solutions. First generation solutions implemented *local* approaches [3,14,15] which select WSs one at the time by associating the running abstract activity to the best candidate service which supports its execution. Local approaches can guarantee only local QoS constraints, i.e., candidate WSs are selected according to a desired characteristic, e.g., the price of *a single WS* is lower than a given threshold.

Second generation solutions proposed *global* approaches [5,8,10,12,15]. The set of services which satisfy the process constraints and user preferences for the whole application are identified before executing the process. In this way, QoS constraints can predicate at a global level, i.e., constraints posing restrictions over the *whole composed service execution* can be introduced. In order to guarantee the fulfilment of global QoS constraints, second generation optimization techniques consider the worst case execution scenario for the composed service. For cyclic processes, loops are unfolded, i.e., unrolled according to their maximum number of iterations [5,15]. This approach could be very conservative and constitutes the main limitation of second generation techniques. Furthermore, global approaches introduce an increased complexity with respect to local solutions. The main issue for the fulfillment of global constraints is WSs performance variability. Indeed, the QoS of a WS may evolve relatively frequently, either because of internal changes or because of workload fluctuations [15]. If a business process has a long duration, the set of services identified by the optimization may change their QoS properties during the process execution or some services can become unavailable or others may emerge. In order to guarantee global constraints, WS selection and execution are interleaved: optimization is performed when the business process is instantiated and its execution is started, and is iterated during the process execution performing *re-optimization* at run time.

To reduce optimization/re-optimization complexity, a number of solution have been proposed which guarantee global constraints only for the critical path [15] (i.e., the path which corresponds to the highest execution time), or reduce loops to a single task [5], satisfying global constraints only statistically, by applying the reduction formula proposed in [7].

Another drawback of second generation solutions is that, if the end-user introduces severe QoS constraints for the composed service execution, i.e., limited resources which set the problem close to un-feasibility conditions (e.g., limited budget or stringent execution time limit), no solutions could be identified and the composed service execution fails [5].

Third generation techniques [3] overcome the limits of the previous approaches and focus on the execution of processes under severe QoS constraints. Severe constraints are very relevant whenever processes have to be performed with stringently limited resources. Third generation solutions are based on loops peeling, which significantly improves the solutions based on loops unfolding. Furthermore, negotiation is exploited if a feasible solution cannot be identified, to bargain QoS parameters with service providers offering services, reducing process invocation failures.

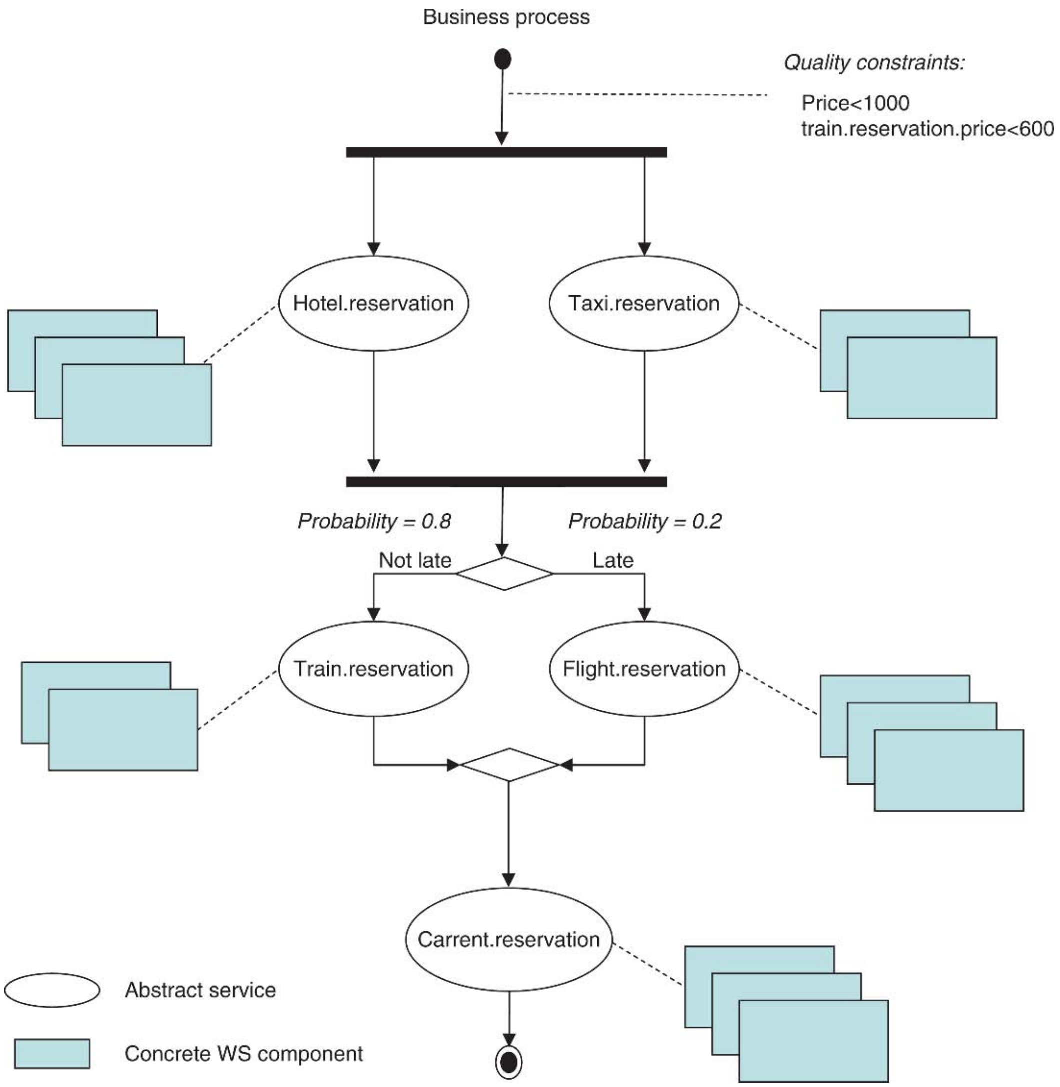
Foundations

Process optimization allows the specification of complex applications as business processes composed by *abstract services* which act as *place holders* of WS components invoked at run time. The best set of services, selected by solving an optimization problem, is invoked at run time by implementing a *dynamic/late binding* mechanism.

Process optimization is usually formalized as a multi-objective optimization problem since several quality criteria can be associated with WS execution. Past approaches [5,12,15] focussed on *execution time* (the expected delay, between the time instant when a request is sent and the time when the result is obtained), *availability* (the probability that the service is accessible), *price* (the fee that a service requester has to pay to the Service Provider for the service invocation), and *reputation* (a measure of the service trustworthiness). Furthermore, the optimization is performed statistically, i.e., by considering the probability of execution of the execution paths of the business process (i.e., any possible sequence of invocations of abstract services). For this reason, some annotations are added to the BPEL specification in order to identify: (i) the maximum [15] or the probability distribution [3] of the number of iterations of loops; (ii) the expected frequency of execution of conditional branches; (iii) global and local constraints on quality dimensions.

Figure 1 shows an example of composed process which implements a virtual travel agency, and the corresponding annotations which specify constraints. The BPEL specification includes invocation to abstract WSs which can be supported at run time by *concrete* WS components.

The probability distribution of the number of iterations of loops and the frequency of execution of conditional branches can be evaluated from past executions by inspecting system logs or can be specified by the composite service designer. If an upper bound for loops execution cannot be determined, then the optimization cannot guarantee that global constraints are satisfied [15]. Prior to perform process optimization, loops are unfolded [15] or peeled [3] (see Fig. 2) and are modeled as directed acyclic graphs (DAGs). Loops peeling is a form of loops unrolling where loop iterations are represented as a sequence of branches and each branch condition evaluates if the loop has to continue with the next *i*th iteration or it has to exit with probability p_i.

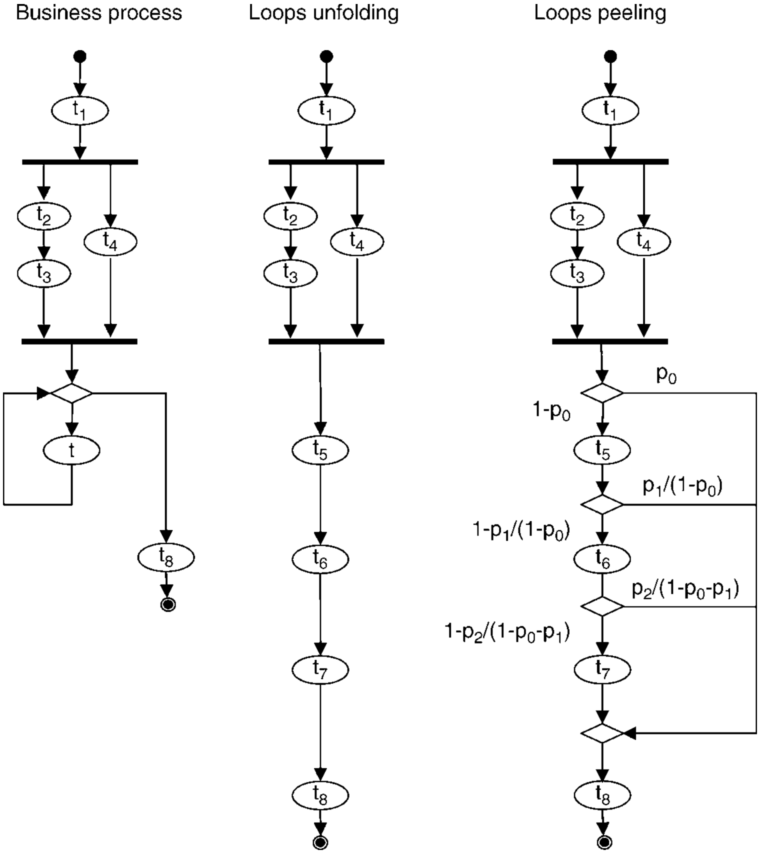


Process Optimization. Figure 1. Virtual travel agency process specification.

The objective function to be optimized is, usually [3,14,15], the aggregated value of QoS for the end user which can be obtained by applying the simple additive weighting (SAW) technique. SAW is one of the most widely used techniques to obtain a *score* from a list of dimensions. Since the quality dimensions have different units of measure, the SAW method first normalizes the raw values for each quality dimension. Each quality dimension is also associated with a weight which expresses the user preferences among multiple quality parameters. The overall value of QoS is calculated as a weighted sum of the normalized values of quality dimension. The SAW method originates a linear objective function, other proposal introduces more general utility functions (i.e., functions which map each possible configuration of the business process to a scalar value) which can be non-linear [5].

First generation solutions considered only *local constraints*. In that case, the process optimization is very simple and the optimum solution can be identified by a greedy algorithm which selects the best candidate service suitable for the execution. An example of first generation technique can be found in [11], where Web agents can migrate to invoke services locally in order to minimize also the network bandwidth.

Second generation solutions support *global constraints* and introuce NP-hard optimization problems. In [4] the complexity of some variants of the global process optimization problem is analyzed, while an overview of heuristic techniques, which hence identify



Process Optimization. Figure 2. Loops unfolding and peeling.

only sub-optimal solutions, can be found in [10]. In [14] global process optimization has been modeled as a multiple choice multiple dimension knapsack problem (MMKP) and as a graph constrained optimum path problem. A MMKP is one kind of knapsack problem where the resources are multidimensional, that is, there are multiple resource constrains for the knapsack (e.g., weight and volume) and items are classied in groups. Each item of the group has a particular value and it requires resources. The objective of the MMKP is to pick exactly one item from each group for maximum total value of the collected items, subject to the resource constraints of the knapsack. Process optimization can be reduced to a MMKP since each abstract service corresponds to a group, each concrete WS is an item in a group and each QoS constraint corresponds dimension of the knapsack. Authors in [14] has implemented ad hoc efficient techniques to identify sub-optimal solutions of the MMKP.

Global approaches have been proposed for the first time in [15], where the Process optimization problem has been formalized as a mixed integer linear programming problem, solved by integer linear programming solvers. The authors separately optimize each execution path and obtain the abstract services to concrete services mapping by composing separate solutions according to the frequency of execution. This approach has some limitations (e.g., availability and response time constraints are guaranteed only for the critical path, and global constraints cannot always be fulfilled) which have been solved by following research proposals [3,14].

Some recent proposals face the Process optimization problem by implementing genetic algorithms [5,8]. In Canfora et al. [5] the reduction formulas presented in [7] are adopted, the re-optimization is considered but abstract services specified in loops are always assigned to the same concrete WS component. Furthermore, by applying reduction formulas the solution guarantees global constraints only statistically. At run time, if low probability paths are taken (see [5]), then the solution could become infeasible and re-optimization must be triggered. In [8], the multi-objective evolutionary approach NSGA-II (non-dominated sorting genetic algorithm) is implemented, which identifies a set of Pareto optimal solutions without introducing a ranking among different quality dimensions. Every identified solution is characterized by the fact that no other plans exist such that a quality dimension is improved without worsening the other ones. Genetic algorithms are more flexible than mixed integer linear approaches, since they allow considering also non-linear composition rules for composed WSs, but are less computationally efficient. In current implementations, some execution time is wasted by generating also non-feasible solutions and, sometimes, no solution can be identified even when the problem is feasible in case the global constraints are stringent.

The work presented in [3] proposes a third generation solution which poses the basis for the execution of processes under severe QoS constraints. The solution is based on loops peeling which significantly improves the solutions based on loops unfolding (up to 40%). Furtheremore, negotiation techniques are exploited to identify a feasible solution of the problem, if one does not exist, reducing process invocation failures. The joint optimization and negotiation approach has been proved to be effective for large processes (including up to 10,000 abstract services), when QoS constraints are severe and reduces also the re-optimization overhead.

Key Applications

Context-Aware Business Process

Dynamic WS selection for composed WSs focused in particular on context aware business processes. Context awareness may be needed both when considering WS personalization, where a generic process is personalized choosing services according to user preferences, and in mobile composed services, to provide ubiquitous services where selection and execution depend on the available services and their QoS [1].

E-Science and Grid Computing

In e-science complex processes, defined as workflows enacted in grid environments, are being developed reaching the dimension of thousands of tasks in "in silico" experiments [9]. Each task is performed selecting and invoking a service. In this case, the Process optimization problem is more challenging, since the concrete resources have to be modeled with a more fine grain and are represented by the physical machines which can support tasks execution instead of abstract WSs. Current solutions propose to create a hierarchy of processes or distributing the workflow over a number of engines, partitioning in this way the optimization problem but leading to sub-optimal solutions.

Future Directions

All of the above approaches consider the optimization of a single process instance and assume a constant QoS profile. Cardellini et al. [6] tackled the problem of optimization of multiple process instances in order to reduce optimization overhead. The work presented in [2] considered variable (periodic) quality of service profiles of component WSs and explicitly addressed long term process execution. The execution of multiple instances, variable QoS profiles, and long term process execution make the optimization problem more cumbersome. Only heuristic approaches have been proposed so far, more efficient solutions, both in term of optimization time and quality of the final solution, are needed.

Experimental Results

For every presented approach, there is an experimental evaluation in the corresponding reference. Zeng et al. [15] discuss local and global approaches. Tao Yu et al. [14] present a comparison among linear integer programming approaches and heuristic solutions. The work presented in [3] analyzes loops peeling and second and third generation solutions.

Definition

Database Management Systems are typically implemented on top of operating systems which allow execution within processes. Different systems have chosen different process structures as they map their computation onto the operating system. This section surveys some of these choices.

Historical Background

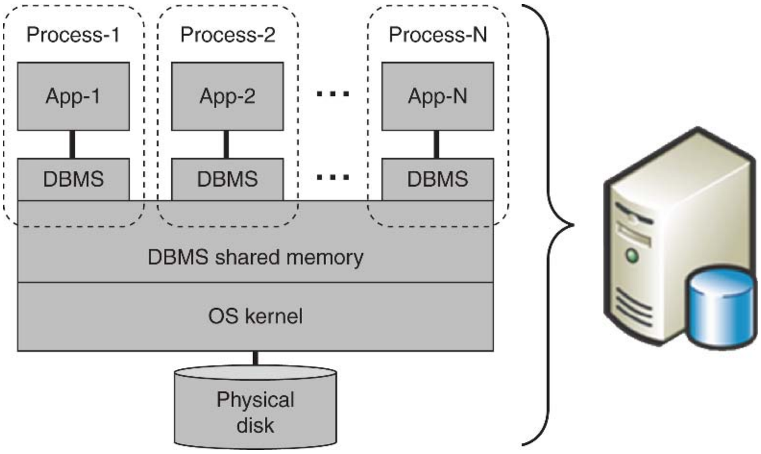
The first database management systems were simple libraries that ran inside the process of the application. While the use of these libraries offered leverage to the applications by providing essential functionality, they did not offer protection for the data in the presence of application errors.

To provide protection, DBMSs were initially moved into higher security rings accessible by hardware protected transitions to memory and code which was more secure than the application but less secure than the operating system kernel. Running the DBMS in shared (but secured) memory allowed access by multiple applications (in separate processes). The shared memory within the DBMS allowed for efficient cross application management of data (See Fig. 1).

Two trends caused gradual retreat from the implementation of the DBMS within a trusted security ring. First, there is the emergence of DBMSs that were designed to be ported across operating systems. Second, the emergence of distributed computing drove the need to run different portions of the computing stack (both application and database) across different machines. Both of these trends grew throughout the 1980s and led to a constellation of process and processor architectures for both applications and database management systems.

The process structure of database management systems has evolved and today can be seen in many forms. As mentioned above, initial implementations of DBMS systems in the 1960s and 1970s were embedded in the same process (but soon with protection for the DBMS within a security ring).

In the 1980s, a number of distributed databases emerged, exemplified by Tandem's NonStop SQL. In these, the application interface remained an in-memory call to portions of the database system but behind the scenes there were cross-process and cross-processor calls to other portions of the DBMS. This was implemented transparently to the application except, of course, with some performance implications which could be both positive and negative.



Process Structure of a DBMS. Figure 1. Early implementations of DBMS systems used shared memory as a technique to allow the DBMS to run in process with the application. This minimized app to DBMS communication costs.

In the 1990s, the client-server computing first arrived with the separation of the client and server-side database in what became known as *two-tier client-server* applications. This necessitated the creation of the *database connection*, exemplified by ODBC (Open Database Connectivity). With a database connection, both DML (Data Manipulation Language) and the resultant data sets were returned across process boundaries, allowing the application process (and processor) to be different than the database process and processor. Subsequently, the application itself began to break across processes and processors resulting in *three-tier client-server* or even later *N-tier client-server systems*. Within each of these architectures, the application program still perceived the notion of a single database even though the work was potentially spread across multiple systems.

Shortly after the year 2000, the industry began to recognize the importance of the relationships of applications and databases running independently and speak about what is today called *SOA (Service Oriented Architecture)*. This is delineated from N-tier client-server by the absence of a common DBMS; SOA services each have the own DBMS whereas a client-server system shares a common DBMS, even if the common DBMS is distributed across processes and/or processors.

Foundations

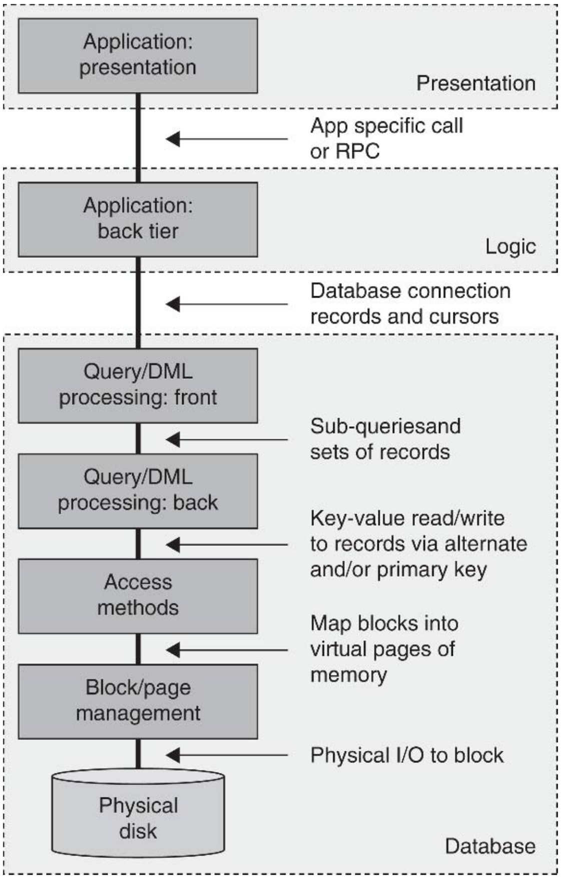
To understand the process and processor architecture of DBMS and applications, the reader first looks at a sketch of their high-level architecture independent of the processes and processors implementing the components of the architecture, followed by some common patterns for breaking this work up.

Layers of the DBMS and Application

Figure 2, depicts a breakdown of both the 3-tier application and the underlying DBMS. The dotted lines show the classic 3-tier architecture. The *presentation tier* is connected to the *logic tier* with an application specific call or RPC. The *logic tier* is connected with the *database tier* using a database connection.

Inside the database, more layers of abstraction are utilized to examine different process and processor architectures. Closest to the application is the front-end to the *Query and DML Processor*: it accepts a database connection from the application and is responsible for the processing DML and queries and returning the results across the connection. The front-end of this function will interact with a back-end which is intimate with the various access methods which hold the database records and/or alternate keys. The back-end of the Query and DML Processor will interact with the *Access Methods* using keys and records. The Access Methods, in turn, use blocks (which are mapped into in-memory pages) by the *Block and Page Manager*, which issues physical I/Os to the disks themselves.

In the simplest DBMS architectures, the *Shared-Everything* design, all DBMS components are resident on the same computer system and they interact through memory. In the *Shared Disk* architecture, the interactions between the *Block and Page Management*



Process Structure of a DBMS. Figure 2. The architecture of a 3-Tier application and its supporting database management system. The notations beside the arrows denote the formats of the requests and data flowing between the layers.

and the *Physical Disk* are spread apart. Finally, the *Shared Nothing* architecture separates the front and back ends of the Query and DML Processor.

Client-Server Computing

When client-server computing first arrived on the scene, its hallmark was the separation of the application from the DBMS itself leaving the database on its own system. Initially, this was done with two tiers, the client and DBMS-server. The client interacted with the server using a database connection such as ODBC (See Fig. 3).

The transition between two-tier client-server systems and three-tier (or even N-tier) client-server systems lies in the architecture of the application itself. It is simply the splitting up of the application tiers that differentiate these (See Fig. 4).

As soon as the 3-tier architecture was introduced, new challenges arose in the management of transactions as they propagated through the system. In 2-tier client-server architectures, the transactional scope was bounded by a time interval on the database connection. Now, in a 3-tier client-server scheme, the work initiated by the Presentation layer may need to be atomic as it propagates through different servers implementing the Logic layer. For the moment, consider this architecture with a single process DBMS at the back-end (See Fig. 5).

New notions in the management of transaction identifiers needed to be created for this to work. The identity of the atomic transaction needed to be propagated with the RPC or other app-specific call from the client to the middle-tier server. Also, the same transaction-id could now arrive at the database from *different* database connections. A window of time using the database-connection could no longer be a surrogate for the transaction. These challenges came as the application that related to the database underwent changes in its process architecture.

Multi-Database Computing

As distributed systems progressed, there were occasions in which a 2-tier client wished to do transactional work across multiple database servers. This was only possible with the arrival of BOTH distributed transactions (implemented with two-phase commit) AND the ability for the client application to create a transaction independent of the database connection and manage the association of the transaction to the connections to the separate databases. This involved both extensions to the client libraries and the creation of DBMS server to DBMS server distributed transaction management.

Most systems did not implement transactional support for multiple databases in 2-tier applications until after this was accomplished for 3-tier applications. The need to have a client call different middle-tier application servers with different databases was the pressure that led to the implementation of two phase commit for distributed transactions across the multiple databases. Only later were the facilities for sharing transactions across database connections directly connected to a single client implemented. See Fig. 6 for a depiction of a 3-tier client-server application where some of the middle-tier servers use different databases all associated with a single common transactional scope.

Service-Oriented Architectures (SOA)

A recently popular application architecture is the service-oriented architecture. It is distinguished from the client-server application architecture in that there are no transactions shared across the service boundaries and, indeed, no direct visibility to the partner's database. All access to the database is indirect and mitigated by the application. Because there are no shared transactions across the service boundaries and there are no database connections or semantics across these boundaries, the database management system does not see the SOA architecture.

SOA implementations often use an internal client-server architecture to build out a single service. Still, from the standpoint of the process architecture of a DBMS, the use of an application combined with its database in a larger SOA system is not of any impact on the DBMS process structure.

Shared-Memory (Single Database) DBMS Architectures

In a shared-memory (or sometimes called shared-everything) system, the DBMS runs in a single process or, at least, in a fashion where the processes are able to share their memory. Figure 1 is an example of a shared-memory system, one where multiple processes have a special mechanism to access special (protected) memory. The architecture depicted in Fig. 1 is not a client-server system.

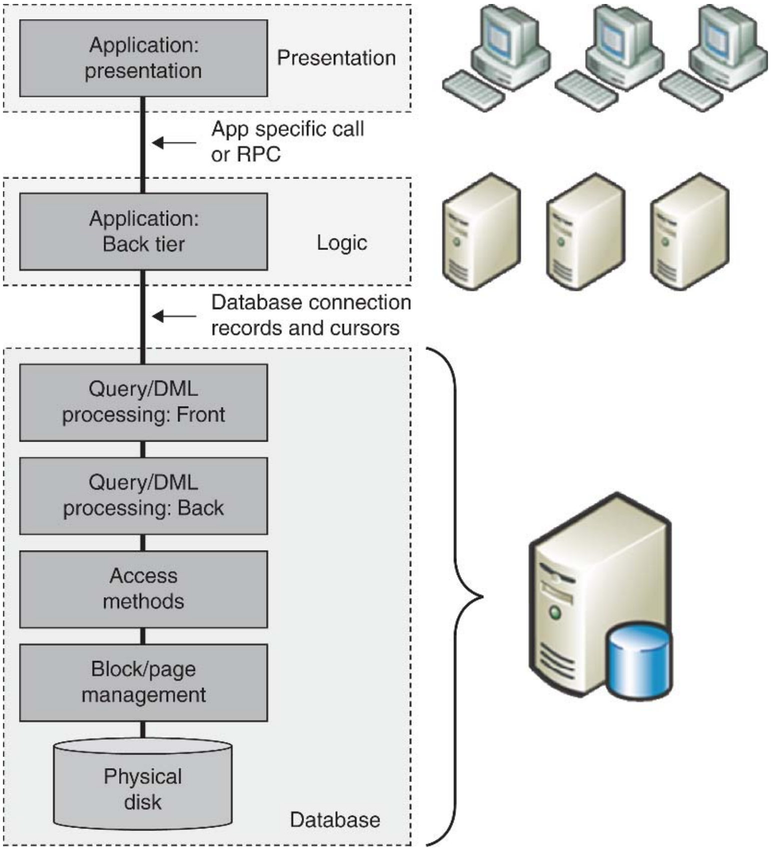
Most shared-nothing systems are a little less exotic and look like Figs. 3–5. There is a single database and it runs on a large process (perhaps with multiple threads within a shared-memory multiprocessor).

Figure 6 is considered to be a shared-everything system *precisely because each database is a separate database*, and there cannot be queries issued across them. There is no way to view the data from these multiple databases except through the assistance of application logic. There cannot exist a single database connection to that pool of databases – they are separate databases.

The presence of distributed transactions spanning multiple databases does not make them a single database.

Shared-Disk (Single Database) DBMS Architectures

Shared-Disk systems comprise a cluster in which multiple independent machines have access to a pool of disks. In addition to some mechanism for sending messages across the machines, each of the computers



Process Structure of a DBMS. Figure 4. 3-tier client-server architecture. The presentation, logic, and database are distributed across different systems.

in the cluster can read and write pages of disk across a collection of many disk spindles. Typically, this is implemented with some form of disk controller managing access by the computers to the disks. Figure 7 shows a sketch of the hardware architecture of a shared-disk cluster.

The distinction between the database process architecture versus the application process architecture is sometimes confusing. The first shared-disk systems used block mode terminals and there was no notion of a smart client at that time. As an example, consider Fig. 8 which is a slight modification of Fig. 7. Figure 8 depicts a system in which the business logic (the middle tier of a three tier system) runs on the same processors (or potentially the same processes in the same spirit as shown in Fig. 1). In this example, the business logic of the application as well as the entire processing of the DBMS can run in the same process (or at least the same processor) while still scaling across a multiprocessor cluster with tremendous efficiency if the load characteristics are appropriate for the architecture.

Shared-Disk DBMS systems have the advantage that, once all of the blocks are brought into memory, the entire query can be processed within a single process. This style of distributed implementation delivers high performance when the workload splits into easily partitioned sets of blocks but works less efficiently when the workload has conflicts over the blocks needed by the different processes.

Shared-Nothing (Single Database) DBMS Architectures

Share-Nothing DBMS architectures are implemented by splitting the query processing engine into a front-end and a back-end. Messaging is used to pass portions of the query or update from the front-end to the back-end. Resulting sets of records are passed from the back-end to the front-end where the completion of the query is performed. The optimizations used in these architectures have been the source of significant research and engineering and can result in fascinating performance gains. Figure 9 shows a Shared-Nothing DBMS in which the application's Business Logic is

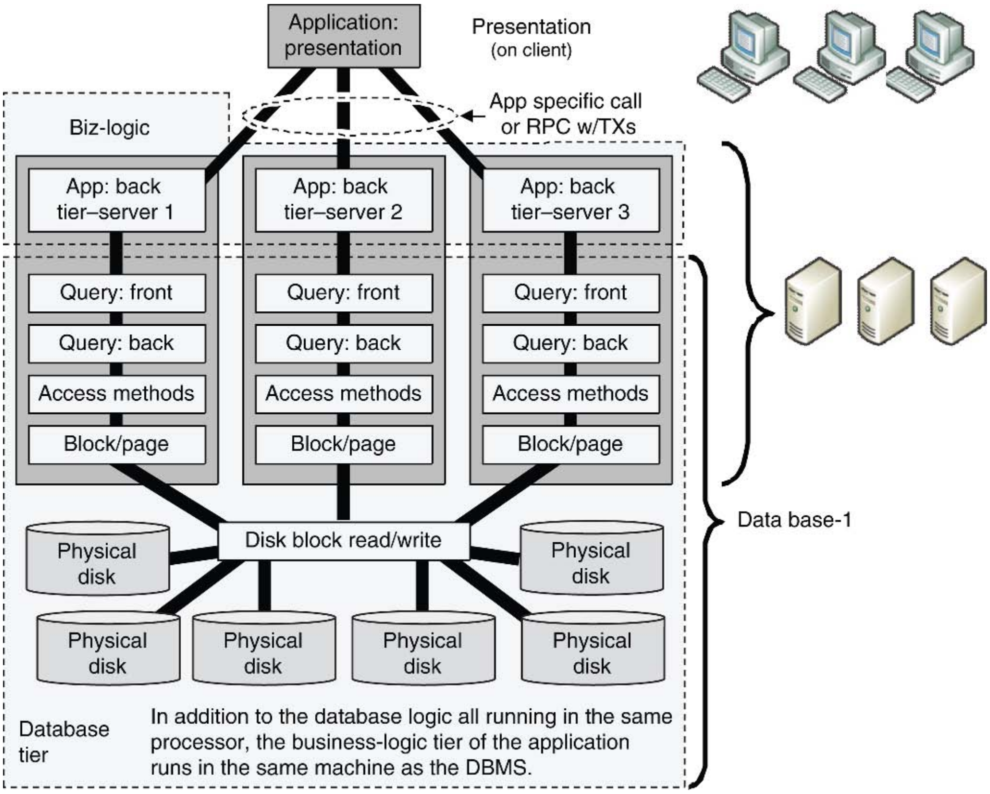
Process Structure of a DBMS. Figure 7. A Shared-Disk Database Management System. For the first time in our figures, the single database SPANS multiple processes and, indeed, multiple processors. The single database (with single database semantics presented to the application) runs on many different computers but sharing the access to the physical disks. Special locking infrastructure on the contents of the blocks of disk must be maintained.

running on the same scale out cluster as the DBMS. Just like the Shared-Disk DBMS, it is important to realize that the application's process/processor architecture may take different forms. Running the Business Logic close to the Front-End of the DBMS is one configuration of Shared-Nothing.

Implications of Shared-Nothing, Shared-Disk, and Shared-Everything Architectures

For a number of years, there have been debates in the industry about the strengths and weaknesses of different process architectures for a DBMS system. Before even engaging in these, it is important to remember the delineation of the DBMS architecture from that of a Service Oriented Architecture and, also, from the application architecture of an N-tier system. The term DBMS is used to refer to a single collection of records across which relational operations may occur. Service Oriented Architectures (SOAs) offer an aggregation of computation connected by business logic without the presence of spanning relational operations or transactions. N-tier application environments frequently offer atomic transactions across different databases but do not offer relational operations across the contents of the databases. So, the taxonomy of DBMS process structures refers only to the portion of the system providing a single relational database semantic.

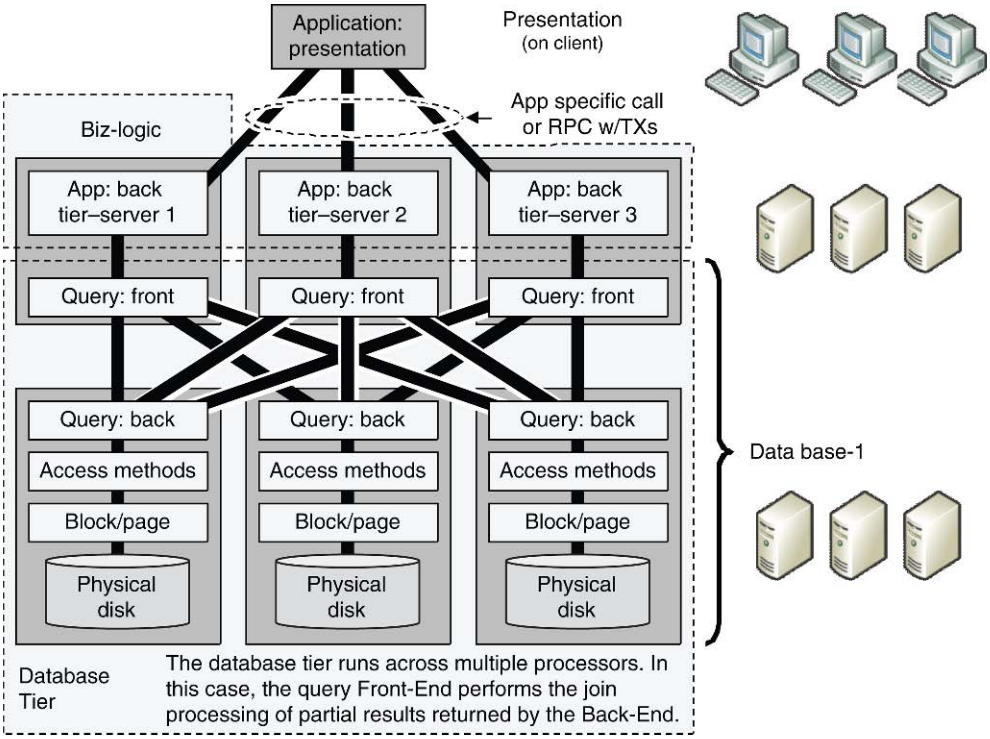


Process Structure of a DBMS. Figure 8. Shared-Disk DBMS within a Two-Tier application architecture.

The *Shared-Everything* DBMS architecture is by far the highest performing architecture in that it offers the most throughput for a single computer (it is not necessarily the most scalable one; scalability is discussed below). Shared-Everything DBMSs do not need to perform any messaging or other cross process communication because they don't cross processes in their implementation of the DBMS. All of the work is done within a single machine. Included in this architecture are various single memory multi-processor implementations. There are few concerns in a Shared-Everything DBMS about the types of queries and usage patterns because everything coexists in a single shared process. Again, Shared-Everything works wonderfully until the DBMS grows too large to fit into one system.

A *Shared-Disk* DBMS architecture allows for additional sharing by letting multiple DBMS processes and processors to access the same physical disks. When the usage pattern of the application has a low probability of conflict in its updates of a shared page, Shared-Disk DBMS systems are very efficient. The pages needed for a query are brought into the processor requesting them and the work of the application's transaction is handled inside one processor of the cluster in what is (hopefully) a very efficient fashion. When the data in question has low update rates, this typically works well. When a single data item is rapidly updated (called a "hot-spot"), this can lead to performance conflicts which cause the block of the database to be pulled back-and-forth across processors. Another challenge occasionally presented by Shared-Disk DBMS systems lies in block (or page) mode locking. Distinct records in the same block may observe lock conflicts causing performance challenges that would not be present in other architectures. Still, Shared-Disk DBMS systems have been wildly successful for many applications and allow many databases to scale beyond what a single shared-memory system could offer.

Shared-Nothing DBMS architectures typically carry a heavier cost to set up a complex transaction but can, in some cases, offer greater throughput over a particular amount of data. It is typical for a Shared-Nothing system to offer record locking. For systems with very high throughput "hot-spots," the data for the



Process Structure of a DBMS. Figure 9. A Shared-Nothing DBMS running with an application configuration which places the business logic tier on the same cluster as the Shared-Nothing DBMS. Also, in this configuration, the Query Front-End of the DBMS runs on the same processors as the Business-Logic.

"hot-spot" does not move around the cluster and it is possible for the system to get more transactions over the same piece of data in a fixed period of time. This is sometimes referred to as "moving the operation to the data" (Shared-Nothing) rather than "moving the data to the operation" (Shared-Disk).

When a database can fit into a single shared-memory multiprocessor, Shared-Everything offers distinct advantages (at least until the application's demands exceed the single machine and you have a problem). For databases that exceed this size and yet want full database semantics, there is a lively debate within the community about which architecture is better and different applications offer different performance characteristics.

Key Applications

Database process structures are an essential part of scaling past a single system. As discussed, the distinction between an application multi-processor architecture and a DBMS multi-processor architecture has many nuances.

Processing Overlaps

Georgina Ramírez

Synonyms

Removing overlap; Controlling overlap

Definition

In semi-structured text retrieval, processing overlap techniques are used to reduce the amount of overlapping (thus redundant) information returned to the user. The existence of redundant information in result lists is caused by the nested structure of semi-structured documents, where the same text fragment may appear in several of the marked up elements (see Fig. 1). In consequence, when retrieval systems perform a focused search on this type of document and use the marked up elements as retrieval objects, very often result lists contain overlapping elements. In retrieval applications where it is assumed that the user does not want to see the same information twice, it may be necessary to reduce or completely remove this overlap and return a ranked list of no overlapping elements. Thus, depending on the underlying user model and retrieval application, different processing overlap techniques are used in order to decide, given a set of relevant but overlapping elements, what are the most appropriate elements to return to the user.

Historical Background

Although the problem of overlap in semi-structured text retrieval is as old as the semi-structured documents themselves, not much work has been published on processing techniques for reducing or removing overlap. Some related work can be found in the area of passage retrieval, where approaches that use a varying window size for passage selection might produce result lists with overlapping passages. However, most of this work is performed on unstructured documents and the approaches taken for processing overlap tend to be simpler.

In the domain of semi-structured documents, there are several areas where different overlap issues are studied. For example, there is quite some work in the area of evaluation of XML systems that addresses the so called overlap problem (e.g., [3]). A different overlap problem is created by the possibility that standards like SGML provide of having multiple annotations (markups) on the same document (a.k.a. multiple hierarchies). In this case the overlap is produced by the structure of the different annotations. Since the multiple hierarchies complicate the use of standard retrieval techniques on this type of documents, work on this area is still focusing on addressing other indexing and retrieval issues. It is only recently that in the domain of XML documents, several approaches have been presented that address the problem of processing overlap from result lists containing overlapping elements. The next section summarizes some of them.

Foundations

One of the advantages of semi-structured documents is that retrieval systems can perform focused search by simply using the marked up divisions of the documents (elements) and retrieving those instead of the whole documents. However, since elements overlap with each other (see Fig. 1), when using traditional ranking techniques to independently rank these elements, result lists often contain many overlapping elements. This is due to the nested structure of semi-structured documents, where the same text fragment is usually contained in several of the marked up elements. Thus, when a specific element is estimated relevant to the query, all the elements containing this element (a.k.a. ancestors) will also be estimated to some degree relevant to the query. Furthermore, this element is probably estimated relevant because it contains several relevant elements (a.k.a. descendants). For example, if a section of a document is estimated highly relevant, it probably contains several highly relevant paragraphs and it is contained in a relevant article. If all of these elements are returned to the user, the amount of redundant information contained in the result list will be considerable. In retrieval scenarios where users do not like to see the same information twice, retrieval systems

Processing Overlaps. Figure 1. Example of a semi-structured document and its tree structure representation. Note that each fragment of the document is contained in three different elements (nodes in the tree).

need to decide which of these relevant but overlapping elements is the most appropriate piece of information to return to the user. The final decision on which elements the system should return depends on the search application and the underlying user model but a common goal is to reduce redundancy in the result lists. Although this can be done at indexing time (e.g., by selecting a subset of non-overlapping elements as potential retrievable objects), commonly this is done by removing overlapping elements from the result set, after retrieval systems have produced an initial ranking of all elements. Processing overlap techniques have recently been widely discussed in the domain of XML retrieval, where different approaches have been presented. The rest of this section presents and discusses some of them.

Using Element Types

A simple way to reduce overlap is to select a subset of element types and consider only these for retrieval. For example, if sections of documents are considered to be the most appropriate pieces of information, retrieval systems might want to use only these as retrievable objects and ignore all the other element types. This can be done at indexing time or by post-filtering the result lists. Depending on the number and element types selected, overlap is reduced at different degrees. Note that it might not always be possible to completely remove overlap; even if a single element type is selected as a unique retrievable object, it is still possible that elements of the same type overlap each other. The main drawback of this approach is that, since it is desirable to select element types that are likely to be relevant and useful to the user, it requires knowledge of the structure of the documents and its common usage.

Using Paths

A common approach for processing overlaps keeps the highest ranked element on each path and removes its ancestors and descendants from the result list, i.e., all the elements in the result list that contain or are contained within it (e.g., [6], [2]). It is important to notice that depending on the order in which the different paths are processed different outputs might be produced.

In [6] the authors present a two steps algorithm to remove the overlap. The first step is used to select the highest scored element from each relevant path. Since their algorithm selects the elements from the different paths simultaneously, the output may still contain overlapping elements. That is why a second step is needed, to completely remove overlap. This is done by selecting again (this time from the output of the first step) the highest scored element from each path:

Algorithm 1

1. Select highest scored element from each relevant path.
2. Select highest scored element from each relevant path in output of step 1.

Another common way to remove overlap using paths [5] is to recursively process the result list by selecting the highest ranked element and removing any element from lower ranks that belongs to the same path (it contains the selected element or it is contained within it):

Algorithm 2

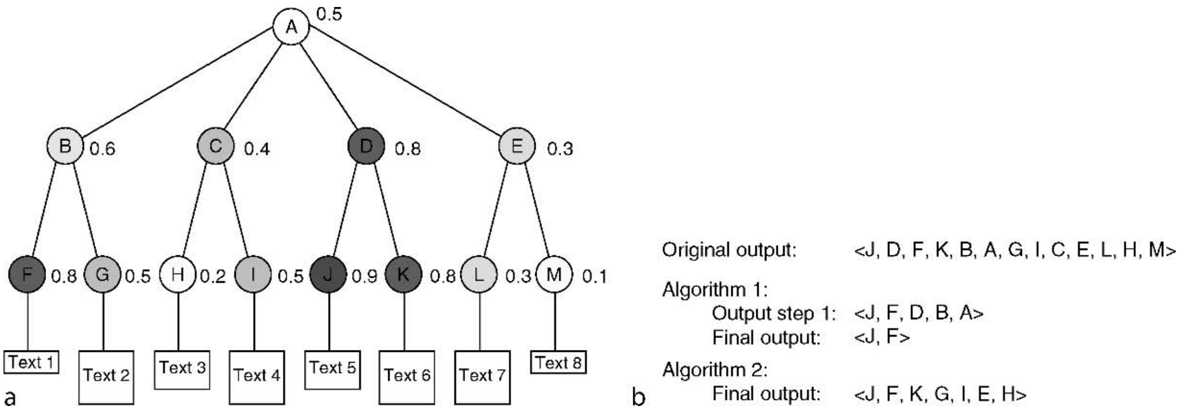
1. Return highest ranked element from result list.
2. Remove from result list all the elements belonging to the same path.
3. Repeat step 1 and 2 until result list is empty.

The underlying assumption of this type of approaches is that the most appropriate piece of information in each path has been assigned a higher score than the rest and therefore, removing overlap is simply a presentation issue. These approaches rely completely on the underlying retrieval models to produce the best ranking. This could indeed be the case if the retrieval model would consider, when ranking, not only the estimated relevance of the element itself but also its *appropriateness* compared to other elements in the same path. However, since many retrieval models rank elements independently, the highest scored element may not be the most appropriate one, i.e., the one the user prefers to see.

To illustrate the different outputs of the previous algorithms, have another look at the example document from Fig. 1. Imagine now that, given a query, the retrieval model estimates the relevance of each element in the document. Figure 2 shows the retrieval scores obtained by each of the elements and the outputs produced when removing overlap with the algorithms described above. Both algorithms produce a result list of non-overlapping elements. However, there are substantial differences. The main drawback of the first algorithm is that it might miss some relevant information. For example, one could argue that element K should also be contained in the output list. To be able to do that, the algorithm should consider structural relationships between elements and re-add element K to the result list when it decides to remove element D in the second step.

Although the second algorithm produces a more complete list, someone could argue that the output produced is not the most desirable. For example, imagine that elements F and G are, respectively, the title and the abstract of the document. In this case, even if the title has been ranked high (it may contain most or all of the query terms), users might prefer to see a result item containing both, title and abstract (i.e., element B) instead of seeing both elements independently. In general, it can be argued that retrieval systems should only return those elements that have enough content information to be useful and can stand alone as independent objects. A similar example can be seen for elements D, J, and K. Even if J is ranked higher, element D contains mostly relevant information and therefore, it might be more desirable (from a user perspective) to read element D, than J, and K independently. Furthermore, for elements E, L, and M it could be argued that it is better to return L than E because the relevance estimated for element E is due to the content of L and no extra benefit is obtained when returning E.

In these, cases a better output might be produced if the algorithms would consider structural relationships between elements when deciding which elements to return to the user.



Original output: <J, D, F, K, B, A, G, I, C, E, L, H, M>
Algorithm 1:
Output step 1: <J, F, D, B, A>
Final output: <J, F>
Algorithm 2:
Final output: <J, F, K, G, I, E, H>

Processing Overlaps. Figure 2. Example of a retrieval run and the resulting outputs when removing overlapping elements with algorithm 1 and 2. The numbers on the tree indicate the initial retrieval scores obtained by each of the elements.

Using Structural Relationships for Re-Ranking

The following approaches present more advanced techniques that exploit the structural relationships within a document to decide which elements should be removed or pushed down the ranked list and which ones should be returned to the user (e.g., [5], [1], [4]). These techniques often modify the initial ranking predicted by the retrieval model.

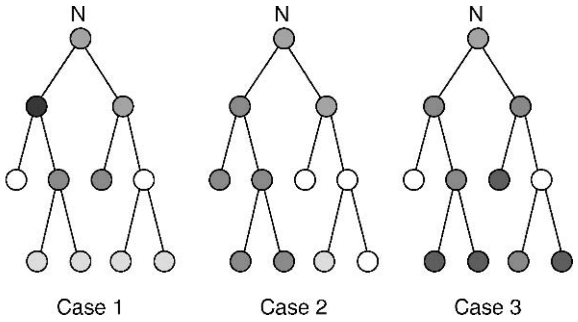
In [1] elements are re-ranked by adjusting the element scores of the lower ranked elements according to their containment relationship with other higher ranked elements. The assumption underlying this approach is that the score of the elements that are contained or contain other elements that have been already shown to the user (i.e., are ranked higher) should be adjusted in order to reflect that the information they contain might be redundant. They do that by reducing the importance of terms occurring in already reported elements. The basic algorithm is similar to algorithm 2 but instead of removing the ancestors and descendants of the reported elements, their scores get adjusted:

Algorithm 3

1. Report the highest ranked element.
2. Adjust the scores of the unreported elements.
3. Repeat steps 1 and 2 until m elements are reported.

The author also presents an extended version of the algorithm where different weighting values are used for ancestors and descendants and where the number of times an element is contained within others is considered. For example, a paragraph contained in an already seen section and in an already seen article is further punished because the user has already seen this information twice. Note that this algorithm is not designed to remove the overlap but to push down the result list those elements that contain redundant information.

In [4] a completely different approach is taken. The authors present a two step re-ranking algorithm for removing overlap. The first step identifies clusters of highly ranked results and picks the most relevant element from each cluster. The second round is used to remove any remaining overlap between the selected elements. The selection criteria for the first step is based on three different cases (illustrated in Fig. 3): (i) if an element N has a descendant that is substantially more relevant, the element N is removed from the result list, (ii) if case 1 does not hold and the element N has a child that contains most of the relevant information (the relevant elements are concentrated under this child), the element N is also removed from the result list, and (iii) if none of the previous cases hold and the results are evenly distributed under the element N, then the element N is kept and all its descendants removed from the result list. In the rest of the cases they do not do anything and leave the final overlap removal for the second phase. In the second step, they remove overlap by comparing the score of each element with the ones of its descendants. If the score of the element is bigger, all the descendants are removed and the element is kept. Otherwise, the element is removed.



Processing Overlaps. Figure 3. Illustration of the three cases considered in the approach presented in [4]. The grayer the node, the higher the relevancy estimated for that node.

In [5] the authors present an approach that makes use of an *utility* function that captures the amount of *useful* information contained in each element. They argue that to model the *usefulness* of a node three important aspects need to be considered: (i) the relevance score estimated by the retrieval model, (ii) the size of the element, and (iii) the amount of irrelevant information the element contains. They present an algorithm that selects elements according to the estimated *usefulness* of each element. If an element has an estimated *usefulness* value higher than the sum of the *usefulness* values of its children, then the element is selected and the children are removed. Otherwise, the children elements whose *usefulness* value exceeds some threshold are selected and the element is removed.

Key Applications

Processing overlap techniques are needed in any retrieval application where users need to be directed to specific parts of documents and there are not predefined retrieval units.

Experimental Results

For every presented approach, there is an accompanying experimental evaluation in the corresponding reference. Commonly, the referred article provides an overview of the performance of the approach and of its variations. However, it is difficult to use the reported evaluations to compare approaches between articles. The main reason is that all approaches make use of different retrieval models for their initial runs, thus it is not clear whether the performance obtained after removing overlap is due to the underlying retrieval model or to the approach used to remove the overlap. Besides, not all the presented approaches experiment on the same dataset or use the same evaluation measures to report their numbers.

In [5] the authors present an experimental comparison between several of the approaches described above. They show that the best performing approach is the one that returns only paragraphs. As a general trend for the first type of approach (the ones that select a specific element type), the longer the element type selected, the worse the performance. The authors also show that their approach of estimating the *usefulness* of an element can help to improve retrieval performance (in terms of precision at low recall levels) when compared to the approach of using paths (algorithm 2).

Data Sets

Since 2005 the *INitiative for the Evaluation of XML Retrieval* (INEX) provides a data-set that can be used to test processing overlap strategies (see http://inex.is.informatik.uni-duisburg.de/).

Processing Structural Constraints

Andrew Trotman
University of Otago, Dunedin, New Zealand

Definition

When searching unstructured plain-text the user is limited in the expressive power of their query – they can only ask for documents that are about something. When structure is present in the document, and with a query language that supports its use, the user is able to write far more precise queries. For example, searching for "smith" in a document is not necessarily equivalent to searching for "smith" as an author of a document. This increase in expressive power should lead to an increase in precision with no loss in recall. By specifying that "smith" should be the author, all those instances where "smith" was the profession will be dropped (increasing precision), while all those in which "smith" is the author will still be found (maintaining recall).

Historical Background

With the proliferation of structured and semi-structured markup languages such as SGML and XML came the possibility of unifying database and information retrieval technologies. The Evaluation of XML Retrieval (INEX) was founded in 2002 to examine the use of semi-structured data for both technologies. It was expected that the use of structure would not only unify the two technologies but would also improve the performance of both.

Foundations

User Querying Behavior

When using an information retrieval search engine the user typically has some information need. This information need is expressed by the user as a keyword query. There are many different queries that could be drawn from the same information need. Some might contain only keywords, others phrases, and others a combination of the two. It is the task of the search engine to satisfy the information need given the query. Because the task is not to satisfy the query, the terms in the query can be considered nothing more than hints by the user on how to identify relevant documents. It is likely that some relevant documents will not contain the user's keywords, while others that do might not be relevant.

If the user does not immediately find an answer they will often change their query, perhaps by adding different keywords, or by removing keywords. If the query syntax permits they might add emphasis markers (plus and minus) to some terms.

With a few exceptions semi-structured search engines remain experimental, so user behavior cannot be studied in a natural environment. Instead the user behavior is expected to mirror that of other search engines, or search engines that include some structural restriction.

The model used at INEX is that a user will give a query containing only search terms, then, if they are dissatisfied with the results, they might add structural constraints to their query. The keyword searches are known as Content Only (CO) and when structure is added as Content Only + Structure (CO + S) or Content And Structure (CAS) queries. Just as the keywords are hints, so too are the structural constraints. For this reason they are commonly referred to as structural hints.

The addition of structure to an otherwise content only search leads to a direct comparison of the performance of a search engine before and after the structural constraint has been added. The two queries are instantiations of the same information need, so the same documents or document components are relevant to each query making a direct comparison meaningful.

The analysis of runs submitted to INEX 2005 (against the IEEE document collection) showed no statistical difference in performance between the top CO and top CO + S runs – having structural hints in the query did not improve performance [12]. Even at low levels of recall (1 and 10%) no significant improvement was seen. About half the systems showed a performance gain, the other half no gain.

There are several reasons why improvements are not seen: first it could be a consequence of the structure present in the IEEE collection; second (and more likely) it could be that users are not proficient at providing structural hints.

The result was backed up by a user study [13] in which users were presented with three ways of querying the document collection: keywords, natural language (including structure), and Bricks [15] (a graphical user interface). Sixteen users each performed six simulated work tasks, two with each interface. The same conclusion is drawn, that is no significant improvement was seen when structure was used in querying.

Structural Constraints

There are two reasons a user might add structural constraints to a query. The first is to constrain the size of the result. When searching a collection of textbooks it is, perhaps, of little practical use to identify a book that satisfies the user need. A better result might be a chapter from the book, or a section from the chapter, or even a single paragraph. One way to identify the best granularity of result is to allow the user to specify this as part of the query. These elements are known as target elements.

The user may also wish to narrow the search to just those parts of a document he or she knows to be appropriate. In this case the user might search for "smith" as an author in order to disambiguate the use from that as any of: an author, a profession, a street, or a food manufacturer. Restricting a query to a given element does not affect the granularity of the result; instead it lends support on where to look so such elements are known as support elements. Both target elements and support elements can appear in the same query.

It is not at all obvious from a query whether or not the user expects the constraint to be interpreted precisely (strictly) or imprecisely (vaguely). In the case of "smith" as an author, it is likely that "smith" as a profession is inappropriate, but "smith" as an editor might be appropriate. If the target element is a paragraph, then a document abstract (about the size of a paragraph) is likely to be appropriate, but a book not so.

The four possible interpretations of a query were examined at INEX 2005 [11]. Runs that perform well with one interpretation of the target elements do so regardless of the interpretation of the support elements. The interpretation of the target element does, however, matter. The consequence is that the search engine needs to know, as part of the query, whether a strict or vague interpretation of the target element is expected by the user.

Processing Structural Constraints

Given a search engine, the strict interpretation of target elements can be satisfied by a simple post-process eliminating all results that do not match. As just discussed above, strictly processing support elements has been shown to be unnecessary.

Several techniques for vaguely satisfying target element constraints have been examined including ignoring them, pre-generating a set of tag-equivalences, boosting the score of elements that match the target element, and propagating scores up the document tree.

Ignoring Structural Constraints

Structural constraints might be removed from the query altogether and a Content Only search engine used to identify the correct granularity of result.

Tag Equivalence

A straightforward method for vaguely processing structural constraints is tag equivalence. A set of informational groups are chosen *a priori* and all tags in the DTD (DTD is the Document Type Definition, specifying the format of the XML documents forming the collection.) are mapped to these groups. If, for example, <p> is used for paragraphs and <ip> is used for initial paragraphs, these would be grouped into a single paragraph group.

Mass and Mandelbrod [5] *a priori* choose appropriate retrieval units (target elements) for the document collection and build a separate index for each. The decision about which units these are is made by a human before indexing. A separate index is built for each unit and the search is run in parallel on each index. Within each index the traditional vector space model in used for ranking. The lexicon of their inverted index contains term and context (path) information making strict evaluation possible. Vague evaluation of paths is done by matching lexicon term contexts against a tag-equivalence list.

Mihajlović et al. [6] build their tag equivalence lists using two methods, both based on prior knowledge of relevance. For INEX 2005 they build the first list by taking the results from INEX 2004 and selecting the most frequent highly and fairly relevant elements and adding the most frequently seen elements from the queries. In the second method they take the relevant elements from previous queries targeting the same element and normalize a weight by the frequency of the element in the previous result set (the training data, in this case INEX 2004). Using this second method they automatically construct many different tag equivalence sets using the different levels of relevance seen in the training data.

In a heterogeneous environment in which many different tags from many different DTDs are semantically but not syntactically identical, techniques from research into schema-matching [1] might be used to automatically identify tag equivalence lists.

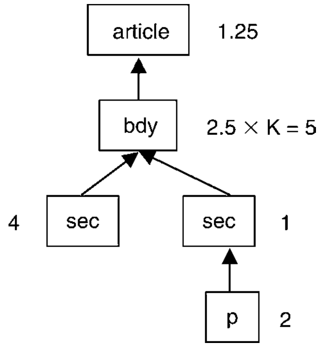
Structure Boosting

Van Zwol [14] generates a set of results ignoring structural constraints then boosts the score of those that do match the constraints by linearly scaling by some tag specific constant. The consequence is to boost the score of elements that match the structural constraints while not removing those that do not. A score penalty is also used for deep and frequent tags in the expectation of lowering the score of highly frequent (and short) tags. A similar technique is used by Theobald et al. [9] who use it with score propagation.

Score Propagation

Scores for elements at the leaves of the document tree (that is, the text) are computed from their content. Scores for nodes internal to the document tree are computed from the leaves by propagating scores up the tree until finally a score for the root is computed. Typically as the score propagates further up the tree, its contribution to the score of an ancestor node is reduced (see the entry on *Propagation* based structured text Retrieval for details).

Figure 1 illustrates score propagation. A search term is found to occur two times in the p element, and four times in the (left) sec element. With a decay factor of 0.5, the score of the bdy element is computed as 4 *0.5 + 2 * 0.5 * 0.5 = 2.5. The score for the article element is computed from that score likewise. If the target element is bdy and the score, for example, is boosted by $K = 5$, then the element with the highest



Processing Structural Constraints. Figure 1. Score Propagation, each time a score is propagated the score is weakened (in the example: halved), but at target nodes it is boosted (in the example: K = 2).

score is that element. The score for K and the propagation value are chosen here for illustrative purposes only and should be computed appropriately for a given document collection.

Hurbert [3] uses score propagation with structure reduction – if a node in the tree does not match a constraint in the query then the score there is reduced by some factor. In this way all nodes in the tree obtain scores but those matching the constraints are over-selected for. Sauvagnat et al. [8] use score propagation in a similar way but in combination with tag equivalence.

Key Applications

Retrieval of document components from structured document collections.

Future Directions

The best performing search engines that interpret structural constraints have not yet significantly outperformed those that ignore them. Several reasons have been forwarded.

There is evidence to suggest specifying a structural constraint is difficult for a user. Studies into the use of structure in INEX queries suggest that even expert users, when asked to give structured queries, give simple queries [12]. This is inline with studies that show virtually no use of advanced search facilities on the web.

Structure aware search engines are not as mature as web search engines and as yet the best way to use structural constraints (when present in a query) is unknown. The annual INEX workshop provides a forum for testing and presenting new methods.

Improvements were not seen when the IEEE document collection was used, but this result may not generalize to all collections. Alternative collections including newspapers, radio broadcast, and television, have been suggested [7,10]. In 2006, INEX switched to using the Wikipedia as the primary test collection for *ad hoc* retrieval, but a comparative study on that collection has not yet been conducted.

Relevance feedback including structural constraints has been examined. Users might provide feedback on both the desired content and the preferred target element, or just one of these. Evidence suggests that including structure in relevance feedback does improve precision.

Experimental Results

Evidence that use of structure increases precision is tentative. In the XML search engine of Kamps et al. [4], no significant difference is seen overall, however significant differences are seen at early recall points (the first few tens of documents). The search engine of Geva [2] recently performed better without structure than with.

At INEX 2005, a comparative analysis of performance with and without structural constraints on the same set of information needs was performed [1]. The best structure run was compared to the best non-structure run and no significant difference was found. Not even a significant difference at early recall points was found. On a system by system basis about half the search engines show a performance increase.

Processor Cache

Peter Boncz
CWI, Amsterdam, The Netherlands

Synonyms

Data cache; Instruction cache; CPU cache; L1 cache; L2 cache; L3 cache; Translation Lookaside Buffer (TLB)

Definition

To hide the high latencies of DRAM access, modern computer architecture now features a memory hierarchy that besides DRAM also includes SRAM cache memories, typically located on the CPU chip. Memory access first check these caches, which takes only a few cycles. Only if the needed data is not found, an expensive memory access is needed.

Key Points

CPU caches are SRAM memories located on the CPU chip, intended to hide the high latency of accessing off-chip DRAM memory. Caches are organized in cache lines (typically 64 bytes). In a fully-associative cache, each memory line can be stored in any location of the cache. To make checking the cache fast, however, CPU caches tend to have limited associativity, such that storage of a particular cache line is possible in only 2 or 4 locations. Thus only 2 or 4 locations need to be checked during lookup (these are called 2-resp. 4-way associative caches). The cache hit ratio is determined by the spatial and temporal locality of the memory accesses generated by the running program(s).

Cache misses can either be compulsory misses (getting the cache lines of all used memory once), capacity misses (caused by the cache being too small to keep all multiply used lines in cache), or conflict misses (due to the limited associativity of the cache).

Most modern CPUs have at least three independent caches: an instruction cache to speed up executable instruction fetch, a data cache to speed up data fetch and store, and a Translation Lookaside Buffer (TLB) used to speed up virtual-to-physical address translation for both executable instructions and data. The TLB is not organized in cache lines, it simply holds pairs of (virtual, logical) page mappings, typically a fairly limited amount (e.g., 64). In practice, this mean that algorithms that repeatedly touch memory in more than 64 pages (whose size is often 4 KB) shortly after each other, run into TLB thrashing. This problem can sometimes be mitigated by setting a large virtual memory page size, or by using special large OS pages (sometimes supported in the CPU with a separate, smaller, TLB for large pages).

Another issue is the tradeoff between latency and hit rate. Larger caches have better hit rates but longer latency. To address this tradeoff, many computers use multiple levels of cache, with small fast caches backed up by larger slower caches. Multi-level caches generally operate by checking the smallest Level 1 (L1) cache first; if it hits, the processor proceeds at high speed. If the smaller cache misses, the next larger cache (L2) is checked, and so on, before external memory is checked. As the latency difference between main memory and the fastest cache has become larger, some processors have begun to utilize as many as three levels of on-chip cache.

For multi-CPU and multi-core systems, the fact that some of the higher levels of cache are not shared, yet provide coherent access to shared memory, causes additional cache-coherency inter-core communication to invalid stale copies of cache lines on other cores when one core modifies it. In multi-core CPUs, an important issue is which cache level is shared among all cores – this cache level is on the one hand a potential hot-spot for cache conflicts, on the other hand provides an opportunity for very fast inter-core data exchange.

In case of sequential data processing, the memory controller or memory chipset in modern computers often detect this access pattern and start requesting the subsequent cache lines in advance. This is called hardware prefetching. Prefetching effectively allows to hide compulsory cache misses. Without prefetching, the effective memory bandwidth would equate cache line size divided my memory latency (e.g., 64/50 ns = 1.2 GB/s). Thanks to hardware prefetching, modern computer architectures reach four times that on sequential access. Modern CPUs also offer explicit prefetching instructions, which a software writer can exploit to perform (non-sequential) memory accesses in advance, hiding their latency. In database systems, such software prefetching has successfully been used in making hash-table lookup faster (e.g., in hash-join and hash-aggregation).

In database systems, a series of cache-conscious data storage layouts (e.g., DSM and PAX) have been proposed to improve cache line usage. Also, a number of cache-conscious query processing algorithms, such as cache-partitioned hash join and hash-join using memory prefetching, have been studied. In the area of data structures and theoretical computer science, there has recently been interest in cache-oblivious algorithms, that regardless the exact parameters of the memory hierarchy (number of levels, cache size, cache line sizes and latencies) perform well.

Projection

Cristina Sirangelo
University of Edinburgh, Edinburgh, UK

Definition

Given a relation instance R over set of attributes U, and given a subset X of U, the projection of R on X – denoted by $\pi_X(R)$ – is defined as a relation over set of attributes X whose tuples are the restriction of tuples of R to attributes X. That is $t \in \pi_X(R)$ if and only if $t = t'(X)$ for some tuple t' of R (here $t'(X)$ denotes the restriction of t' to attributes X).

Key Points

The projection is one of the basic operators of the relational algebra. It operates by "restricting" the input relation to some of its columns.

The arity of the output relation is bounded by the arity of the input relation. Moreover the number of tuples in $\pi_X(R)$ is bounded by the number of tuples in R. In particular, the size of $\pi_X(R)$ can be strictly smaller than the size of R since different tuples of R may have the same values on attributes X.

As an example, consider a relation *Goods* over attributes (*code*, *price*, *quantity*), containing tuples

{(001, 5.00, 10), (002, 5.00, 10), (003, 25.00, 3)}. Then $\pi_{price,quantity}(Goods)$ is a relation over attributes (*price, quantity*) with tuples {(5.00, 10), (25.00, 3)}.

In the case that attribute names are not present in the relation schema, the projection is specified by an expression of the form $\pi_{i_1,...,i_n}(R)$. Here $i_1,...,i_n$ is a sequence of positive integers – where each i_j is bounded by the arity of R – identifying attributes of R. The output is a relation of arity n with tuples $(t(i_1),..., t(i_n))$, for each tuple t in R. In this case the arity n of the output relation can be possibly larger than the arity of R, since integers $i_1,...,i_n$ need not be distinct.

Propagation-based Structured Text Retrieval

Karen Pinel-Sauvagnat
IRIT-SIG, Toulouse Cedex, France

Synonyms

Relevance propagation; Score propagation

Definition

Evaluate the relevance score of text components. Approaches using propagation view the logical structure of a structured document as a tree whose nodes are components of the document and whose edges represent the relationships between the connected nodes. A document component can be either a leaf or an inner node. Leaf nodes are document components that correspond to the last elements of hierarchical relationship chains and that contain raw data (textual information). With propagation, relevance scores are first calculated for leaf components. They are then propagated upwards in the document tree structure to calculate relevance scores for the inner components.

Historical Background

With appropriate query languages, users may want to exploit the structure of structured text documents to perform fine-grained and flexible retrieval. Instead of treating documents as atomic units, structured text retrieval systems aim thus at retrieving document components that answer a given information need in the most *specific* way. Classical information retrieval (IR) models (e.g., the vector space model, the probabilistic model, language models) have been extended in order to take into account the structural dimension of documents. IR research has shown that document term weighting is a crucial concept for effective retrieval, thus classical formalisms were adapted with additional weighting parameters: component type, number of descendant components, frequency of the component type, to name a few. However, most of these adaptations do not use (or make little use of) the tree representation of structured documents to identify the most specific components.

The idea behind relevance propagation method is to follow the way *relevance* changes in a document tree to estimate the relevance of the document components. Indeed *relevance* in structured text documents has been expressed in terms of *specificity* and exhaustivity: the specificity (its coverage of the topic and nothing else) of components in the tree typically decreases as one moves up the tree, and when a component has multiple relevant descendants, its exhaustivity (coverage of the topic) usually increases compared to that of each of the descendant elements.

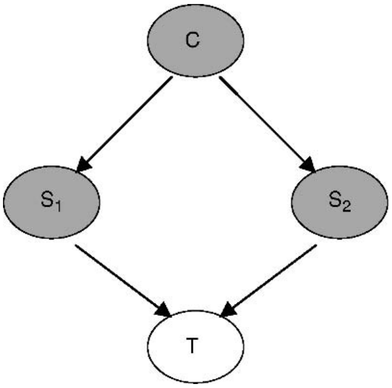
In propagation methods, relevance scores are thus first computed at leaf level, and then propagated up the document tree: to allow the identification of the most specific components, the relevance score of leaf components should be somehow decreased while being propagated upwards in the document tree, and to allow the identification of the most exhaustive components, relevance scores may be aggregated (a parent score should be evaluated using its children scores). A naive solution would be to just sum the relevance scores of each inner component relevant children. However, this would ultimately result in root components being returned at top ranks although they may not be the most specific components for the given information need.

Few relevance propagation approaches were proposed before 2002 (when *INEX*, the evaluation Initiative for XML Retrieval, was set-up). One can however cite the method presented in [5] using inference nets. The retrieval process is applied to SGML documents but can be extended to any type of structured documents. The basic retrieval strategy is to calculate the degree to which a component at any level of the document hierarchy satisfies the query by considering what components are contained in that component. This strategy makes it possible to systematically calculate the expected relevance of a component at any level, taking into account its relationship with other components in the hierarchy. Consider the following net made of two section components S_1 and S_2 that are the parent node of a term node T and the children nodes of the component C (see Fig. 1).

The retrieval process is performed in a bottom-up fashion, because of the way documents are represented in the inference net: no components other than leaf components contain actual text, and the retrieval process must start from leaf components whose text contains a query term.

The degree of belief of T given the network topology is computed with a simplified formula as follows (the simplification comes from considering only positive events):

$$\begin{aligned} B(T|C) &= P(T|S_1) \times P(S_1) + P(T|S_2) \times P(S_2) \\ &= P(T|S_1) \times P(S_1|C) \times P(C) + P(T|S_2) \\ &\quad \times P(S_1|C) \times P(C). \end{aligned} \tag{1}$$



Propagation-based Structured Text Retrieval. Figure 1. A simple network.

Children components S_i and their parent C are represented as $S_i = <s_{i1}, s_{i2},...,s_{in}>$ and $C = <c_1, c_2,...,c_n>$ respectively, where n is the number of index terms and s_{ij} and c_i are calculated using standard term frequency (TF) and inverse document frequency (IDF) statistics. The probability $P(S_i|C)$ of observing S_i given C (or the degree of belief that C supports S_i) is calculated as a similarity between the two vectors:

$$P(S_i|C) = \lambda_i \times (S_i \cdot C), \tag{2}$$

where λ_i is a weight associated to the component type, representing its overall importance relative to other types of components sharing the same parent. This computation incorporates both the content and the type of components.

The probability $P(T|S_i)$ of observing a term T given a component S_i (or the degree of belief that S_i supports T) is estimated with:

$$P(T|S_i) \cong IDF_T \times TF_{i,S_i}. \tag{3}$$

$P(C)$ is the probability of observing C assuming that C is the root node (i.e., document) in the inference net. In the implementation, it is set to 1. This approach was however not evaluated, since no suitable test collection was available.

Other approaches presented in the rest of the entry were developed and evaluated in the context of the *INEX* evaluation campaign, which is concerned with the evaluation of XML retrieval. In this case, document components correspond to XML elements.

Foundations

As all IR approaches, propagation-based approaches can be caracterized in terms of indexing and scoring methods (here both for leaf and inner elements).

Indexing

Approaches using relevance propagation consider *indexing units* as disjoint units: the text of each element is the union of one or more of its disjoint parts. Thus, as textual information is only present in leaf elements, inverted index only concern leaf elements. Propagation accounts then for the fact that the text in a given leaf element is also contained in its ancestors. The document structure is generally stored in a separate index and used to build the document trees.

Relevance Scores Evaluation for Content-Only Queries

In the rest of the entry, the following notations are used. Let q be a query composed of k terms $t_{1,}...t_k$. In the document tree, *le* is a leaf element and e an inner element having n children. *RSV*(q, *le*) is the relevance score of the leaf element *le* with respect to query q and *RSV*(q, e) is the final score of element e with respect to query q.

Scoring Leaf Elements To evaluate leaf element scores (*RSV*(q, *le*)), approaches found in the literature have used the following parameters:

1. Frequency of term t_i in query q or leaf element *le*
2. Frequency of term t_i in the whole collection
3. Number of leaf elements containing t_i
4. Length of leaf element
5. Average length of leaf elements
6. Inverse element frequency *ief*, which is similar to *idf* (inverse document frequency) but that takes into account the collection of leaf elements instead of the collection of documents.

In [1], the weighting scheme used to compute the relevance score of leaf elements also uses the cross-structural importance of t_i relative to *le* and q, which allows to increase or decrease the importance of a term depending on its location in the query (some terms may be more important than others in a content-and-structure query). In [3], the frequency of terms in the leaf elements and in the whole collection are used with a parameter scaling up the score of elements having multiple query terms. The formula penalizes elements with frequently occurring query terms (frequent in the collection), and rewards elements with more unique query terms within a result element. One can also cite the leaf elements weighting scheme presented in [9], where term frequency and inverse element frequency *ief* are applied together with *idf*. This allows to take into account the importance of terms in both the collection of leaf elements and the collection of documents.

Propagating Relevance Scores Once the relevance score of the leaf elements have been calculated, they are used to evaluate the relevance score of the inner elements. The main issue here is how to combine these scores. As already said, a naive solution that simply sums the relevance sores of leaf elements will result in root elements being ranked at the top of the result lists, although they are likely to not constitute the most specific elements to the query.

In [1] the relevance of inner elements is for instance evaluated using the maximum of their leaf element scores. Other approaches use a weighted sum of leaf or children element scores, and make some assumptions related to the document tree structure. They are described below.

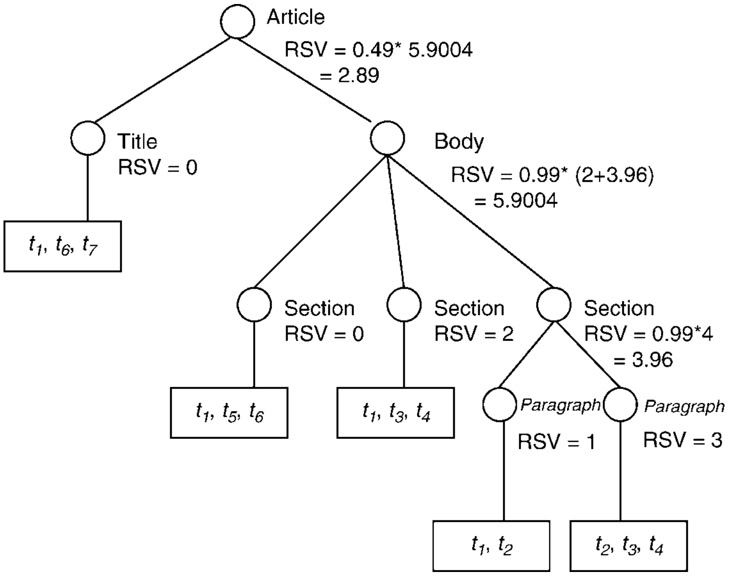
For example, in the GPX approach [3], a heuristically derived formula is proposed to evaluate the scores of inner elements that accounts for specificity and exhaustivity:

$$\mathrm{RSV}(q,e) = D(n)\sum_{l=1}^{n}\mathrm{RSV}(q,l), \tag{4}$$

where n is the number of children elements, $D(n)$ = 0.49 if n = 1, 0.99 otherwise, and *RSV*(q, l) is the relevance score of the lth child element.

The value of the decay factor D depends on the *number of relevant children* that the inner element has. If the element has one relevant child then the decay constant is 0.49. An element with only one relevant child will be ranked lower than its child. If the element has multiple relevant children the decay factor is 0.99. An element with many relevant children will be ranked higher than its descendants. Thus, a section with a single relevant paragraph would be judged less relevant than the paragraph itself, but a section with several relevant paragraphs will be ranked higher than any of the paragraphs.

"t_2 t_3 t_4". The method is illustrated in Fig. 2, with the content-only query "t_2 t_3 t_4". To simplify, the weight of a term in a leaf element is equal to 1 if it is a query term and 0 otherwise. For example the /article[1]/body[1]/section[3]/paragraph[2] element that contains three query terms has thus a score of 3. Its parent (/article[1]/body[1]/section[3]) contains two relevant children with scores 1 and 3. Its score is then calculated with a decay factor equal to 0.99 as follows: 0.99 × (1 + 3). To evaluate the score of the root element (which only contains one relevant child), the decay factor used is 0.49, and the root element has consequently a lower score than its child /article[1]/body[1]. As a result of the propagation, the /article[1]/body[1] element has the highest score and will be ranked first by the GPX system.



Propagation-based Structured Text Retrieval. Figure 2. Relevance propagation according to [3].

The *distance between an element and its descendant leaf elements* has also been used as a weight in the weighted sum that calculates the relevance score of inner elements. Terms that occur close to the root of a given subtree are more significant to the root element that ones at deeper levels of the subtree. It seems therefore that the greater the distance of a element from its ancestor, the less it should contribute to the relevance of its ancestor. This can be modeled with the $d(x, y)$ parameter, which is the distance between elements x and y in the document tree, i.e., the number of arcs joining x and y.

In [4], the relevance score of an inner element takes into account this distance and also the distance separating the root element and leaf elements. The latter is used as a normalization factor. The relevance score of an inner element e is calculated as follows:

$$\mathrm{RSV}(q,e) = \sum_{le_j \in L_e} \left(1 - 2\lambda\lambda \frac{d(e, le_j)}{d(e, le_j) + d(root, le_j)}^{2}\right) \mathrm{RSV}(q, le_j). \tag{5}$$

λ is a constant coefficient ≥ 0, le_j are leaf elements being descendant of e, and L_e is the set of leaf elements being descendant of e. This process tends to consider an element having a relevant descendant element less relevant than the descendant element itself, which is comparable to the approach followed in [3], as above described.

Finally, in [9], the distance between elements and the number of relevant descendant leaf elements are used together with an additional parameter, β, in the weighted sum. The β factor captures the assumption that small elements may be used by authors to highlight important information (*title* elements, *bold* elements, ...). *Small elements can therefore give important indications on the relevance of their ancestors* and their importance should be increased during propagation. The relevance value of an element e is thus computed according to the following formula:

$$\mathrm{RSV}(q,e) = |L_e^r| . \sum_{le_j \in L_e} \alpha^{d(e, le_j) - 1} \times \beta(le_j) \times \mathrm{RSV}(q, le_j), \tag{6}$$

where α is a constant coefficient $\in]0,1]$ used to tune the importance of the distance $d(e, le_j)$ parameter and $|L_e{}^r|$ is the number of leaf elements being descendant of e and having a non-zero relevance value. $\beta(le_j)$ is experimentally fixed and allows to increase the role of elements smaller than the average leaf element size in the propagation function.

Sauvagnat et al. (2005) [9] also propose a backward propagation after the first propagation, in order to account for the whole document relevance (and thus for the element context) in the calculation of the relevance score of inner elements.

Content-and-Structure Queries Processing

In most of the approaches using relevance propagation, results elements are simply filtered to satisfy the structural constraints of *content-and-structure queries* [3,4]. The approach described in [8] however uses relevance propagation to process structural constraints. Queries may have several constraints, and each constraint is composed of both a content and a structure condition, one of them indicating which type of elements should be returned (target elements). For each constraint, propagation starts from leaf nodes answering the content condition and goes until an element that matchs the structure constraint is found. The score of result elements of each constraint is then propagated again to elements belonging to the set of targeted structures.

Key Applications

The access to structured text documents such as SGML or XML documents is the main application of the relevance propagation approach described in this entry. Propagation can also be used to access HTML documents in the context of web retrieval, for example to determine among a set of related web pages, which one corresponds to the best entry in the set. Moreover, propagation can also be applied to distributed IR, as presented in [2].

Future Directions

Propagation methods presented in this entry are relatively independent of the DTDs of collections, since most of them do not use the type of elements to estimate relevance. However, propagation cannot be done in the same way on small document collections and large document collections. Methods should be adapted to process large document collections and efficiency issues that follow.

Relevance propagation may evolve in the future with the use of another source of evidence to calculate inner element relevance score, for example, link information. Indeed, web approaches using relevance propagation have also used links to find relevant web pages (a relevant page may be linked to other relevant pages) [7]. The same approaches could be used for structured text retrieval.

Experimental Results

INEX evaluation campaign. For example, the approach in [3] was ranked in the top 5 for the focused retrieval task (which aims at targeting the appropriate level of granularity of relevant content that should be returned to the user for a given topic) and comparable results were achieved by the approach described in [8] using content-and-structure queries.

Definition

Let t be a data element in the result of a query Q applied to a dataset D. A data element may be a tuple in the relational model, or a subtree in the semi-structured model. The *provenance* of t is the set of all proofs for t according to Q and D. A proof for t according to Q and D is a set D' of data elements in D so that t is in the result of applying Q on D'. In some cases, a proof also details the process by which t is derived from Q and D'.

Most work on provenance in databases focused on finding data elements of D that witness the existence of t in the result, as well as which data elements of D is t copied from. In scientific workflows, the provenance of a result is typically a detailed description of the entire workflow used to arrive at the result.

Key Points

The need to understand and manage the provenance of data arises in almost every application. For example, it is natural to ask for the provenance of data seen on the Web. In scientific experiments, the provenance of results generated by the experiments constitutes to the proof of correctness directly or indirectly, and is typically regarded to be as important as the result itself.

There are generally two types of provenance: data provenance and workflow provenance [1,3].

Data provenance is an account of the derivation of a piece of data in a dataset that is typically the result of a database operation on an input database. There are two approaches for computing data provenance [2]: annotation-based versus non annotation-based approaches. In annotation-based approaches, provenance is captured by propagating annotations (i.e., extra information) from input to output along database transformations. Hence, the provenance of an output data can typically be determined by analyzing the associated annotations. In contrast, non annotation-based approaches do not carry along extra information. Instead, the provenance of an output data is in the determined by analyzing the database transformation, as well as the input and output databases.

Workflow provenance refers to the record of the history of the derivation of some dataset in a scientific workflow. The amount of information recorded for workflow provenance varies, depending on application needs. For example, workflow provenance of a scientific result may include details about the type and model of external devices used, as well as the versions of softwares used for deriving the result.

Definition

Scientific databases contain data which may have been produced as answer to a query posed over other resources, or generated by in-silico experiments (or scientific workflow) involving various softwares, or manually curated by domain experts based on analysis of several other resources. The provenance of a piece of data in scientific databases typically includes information of where this piece of data originates from, as well as details of the scientific process (e.g., parameters used in the experiments, software versions etc.) by which it arrived in the scientific database.

Historical Background

Provenance of scientific databases has been studied in two granularities: *workflow provenance* and *data provenance*.

Workflow provenance (or *coarse-grained provenance*) refers to the record of the history (or workflow) of the derivation of some dataset in a scientific workflow [5,13,14]. The amount of information recorded for workflow provenance varies, depending on application needs. For example, in some cases, a workflow provenance may record the type and model of external devices used, such as sensors, cameras, or other data collecting equipments, as well as the associated versions of software used for processing data; in other cases, these information may be deemed unnecessary.

More recently, workflow systems developed within the scientific community to conduct and manage experiments have started recording information about the processes used to derive intermediate and final data objects from raw data. Survey papers dedicated to workflow provenance approaches have been proposed [5,14] and "provenance challenges" [13] have been held to encourage system designers to learn about the capabilities and expressiveness of each others' systems and work towards interoperable solutions.

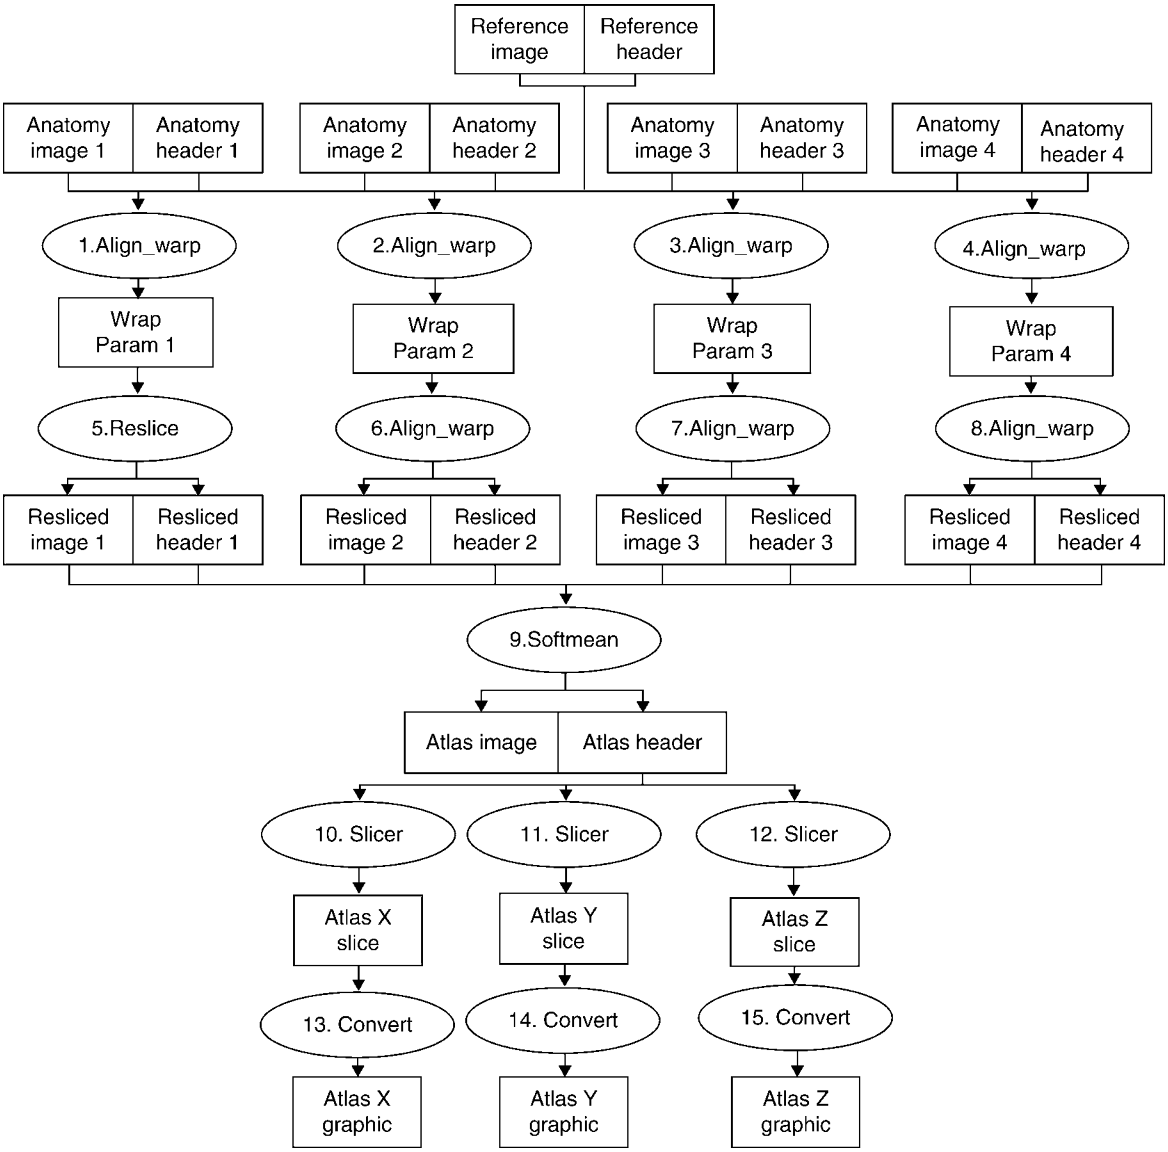
Data provenance (or *fine-grained provenance*) is an account of the derivation of a piece of data in a dataset that is typically the result of executing a database query against a source database [9]. This type of provenance determines the parts of source data that were used to generate a piece of data in the resulting dataset. Typically, data provenance is obtained by carefully reasoning about the algebraic form of the database query and the underlying data model of the source and resulting databases. In contrast, transformations occurring in scientific workflows are often external processes (e.g., perl scripts), and the log files of scientific workflows provide only object identifiers to pieces of data involved in the transformation at best. Often, such external processes and data involved do not possess good properties for detailed analysis. Hence, a fine-grained analysis of an external process is not always possible and the provenance recorded for such transformation is usually more coarse-grained.

Foundations

Workflow Provenance: The notion of workflow provenance is illustrated using the workflow of the first provenance challenge, which aimed to establish an understanding of the capabilities of available provenance-related systems. This simple workflow is inspired from a real experiment in the area of functional Magnetic Resonance Imaging (fMRI) and formed the basis of the challenge. It is represented in Fig. 1 as a graph where oval nodes represent steps and rectangle nodes represent kind of data exchanged between them. Typical provenance queries ask for the history of some data item, e.g., "What caused Atlas X Graphic (one final output) to be as it is?". Depending on whether the complete history of the data is asked or only the previous step and its inputs, queries are qualified as *deep* (or *recursive*) or *immediate*. For example, the immediate provenance of *Atlas X Graphic* is given by the step *13.convert* and its input, *Atlas X slice*, while its deep provenance is given by all the data and steps used to compute the step *9.softmean* and *Atlas Image, Atlas Header, 10.slicer, Atlas X slice*, and *13.convert*. Other provenance queries may include *annotation queries* finding data annotated with some specific metadata, such as "Find all invocations of procedure align_warp using a twelfth order nonlinear 1365 parameter model?" (metadata on the procedure used should be recorded) and "Find the outputs of align_warp where the inputs are annotated with center = UChicago" (metadata on the data used should be recorded).

Various workflow provenance approaches have been designed and applied to very diverse scientific domains (e.g., biology, ecology, astronomy, meteorology). As workflow provenance is by nature associated with actual scientific experiments, most of these approaches have been implemented into prototypes or systems that have typically participated in such challenges [13].

Approaches differ in various aspects. In particular, provenance can be tracked at various degrees of granularity: from OS or instrument level to input/output data and metadata associated to them. The graphs formed by the workflow provenance information are



Provenance in Scientific Databases. Figure 1. Workflow of the first provenance challenge.

also represented using various data models, from relational to tree-based data models (e.g., XML, such as in the Kepler and ES3 projects) or graph-based data models (e.g., Web semantic approaches based on RDF, such as in the myGrid or Wings/Pegasus projects). As a consequence, a plethora of languages have been used to query workflow provenance information including SQL, XQuery, and SPARQL while several dedicated graph query languages have been designed.

More precisely, Foster et al. [13] tackle with the problem of reproducing experiments by providing a *virtual data system* approach offering the ability to not only track the data consumed and produced during computations but also rederive deleted intermediate results of an experiment (virtual data).

Callahan et al. [13] focus on the problem of *workflow evolution*: *VisTrails* provides techniques to compute workflow differences and similarities.

In an orthogonal way, Miles et al. define an *open architecture for provenance* [13] designed to be domain and technology independent. In this architecture, *process documentations* describe what actually occurred at execution time and are created and stored by provenance-aware applications.

Finally, Biton et al. provide abstraction mechanisms to help users face the overwhelming amount of provenance information in workflow environments, offering the possibility of focusing on the most relevant provenance information. The technique pursued in *ZOOM*UserViews* is that of “user views” [3]: Since bioinformatics tasks may themselves be complex sub-workflows, a user view determines what level of sub-workflow the user can see, and thus what data and steps are visible in provenance queries. Algorithms to compute relevant user views have been proposed in [4].

Data Provenance: Here, biological databases are used as example scientific databases for illustrating data provenance. The relations and SQL query are shown below.

```
SELECT swissprot, pir, s.desc
FROM SWISS-PROT s, PIR p, Mapping
      Table m
WHERE s.id = m.swissprot AND p.id = m.
       pir
```

The result of executing the SQL query consists of two tuples (a231, p445, AB) and (w872, p267, CD). Work on data provenance [7,11] has provided explanations for why a tuple, such as (a231, p445, AB), is in the query result. The reason is because the first tuples in SWISS-PROT, PIR and Mapping-Table respectively, joined according to the query to produce the output tuple. This type of provenance is termed *why-provenance* in [7]. In contrast, the *where-provenance* of “AB” in the output tuple (i.e., where “AB” is copied from) is the desc attribute of the first tuple in SWISS-PROT. In particular, no other source tuples are involved in the explanation of where-provenance. Subsequent work by Green et al. [12] is also able to explain *how* a tuple is derived in the result of a query.

Another line of work captures provenance by propagating annotations of source data to the output, based on provenance, along query transformations. Wang and Madnick [15] first articulated the idea of using propagated annotations to analyze source attribution. Subsequently, Buneman et al. [8] studied the *annotation placement problem* using a variation of the propagation scheme of [15]. The propagation scheme of [8,15] is essentially based on where data is copied from. This scheme forms the *default* propagation scheme of DBNotes [2]. A serious drawback of the default scheme is that two equivalent SQL queries (select-project-join-union queries) may not propagate annotations in the same way. In DBNotes, the authors proposed an alternative *default-all* scheme to overcome this limitation. In the default-all propagation scheme, equivalent queries always propagate annotations in the same way. Additionally, DBNotes also support the *custom* propagation scheme, where one is allowed to customize a propagation scheme as desired. So far, all systems [2,8,15] only allow annotations on attribute values. Subsequent research efforts have proposed techniques to relax this restriction.

SWISS-PROT

Most database and workflow techniques provide little help for managing provenance in curated databases. This is because curated databases are, by definition, not constructed from the result of executing a query but rather, created manually by scientists through the analysis of information from several sources. In [6], the authors proposed a copy-and-paste model that captures a scientist’s manual curation efforts as provenance-aware transactions. These transactions are logged and various hierarchical compression techniques were proposed and validated experimentally.

Key Applications

There are many application domains that can benefit from a provenance system in science. Several uses of provenance information are considered here, as described in the literature [5,13,14].

Informational: Interpreting and understanding the result of a scientific experiment necessitates to know the provenance or context in which the data has been produced.

Data Quality: By providing the source data and transformations, provenance may help to estimate data quality and data reliability.

Error Detection: Provenance can be used to detect errors in data generation.

Re-use: Reproducing a local experiment or an experiment described in a research paper may be possible if precise provenance information is provided.

Attribution: The copyright and ownership of data can be determined using provenance information. It enables its citation, and may determine liability in case of erroneous data.

Probabilistic Databases: Provenance has been used to compute the confidences in the result of a probabilistic query correctly, as well as to correctly reason about the set of possible instances in the result of the query [1].

Data Sharing and Data Integration: Provenance has also been used to describe trust policies in the data sharing system Orchestra and to prioritize updates, as well as to understand and debug a data exchange or data integration specification [10].

Pseudonymity

Simone Fischer-Hübner
Karlstad University, Karlstad, Sweden

Synonyms

Nymity

Definition

The term pseudonymous originates from the Greek word "*pseudonymos*" meaning "having a false name."

A pseudonym is an identifier of a subject other than one of the subject's real names, and pseudonymity is the use of pseudonyms as identifiers. Sender pseudonymity is defined as the sender being pseudonymous, recipient pseudonymity as the recipient being pseudonymous [2].

Key Points

Pseudonymity resembles anonymity as both concepts aim at protecting the real identity of a subject. The use of pseudonyms, however, allows one to maintain a reference to the subject's real identity, e.g., for accountability purposes [1]. A trusted third party, adhering to agreed rules, could for instance reveal the real identities of misbehaving pseudonymous users. Pseudonymity also allows a user to link certain actions under one pseudonym. For instance, a user could re-use the same pseudonym for purchasing items at a certain online shop for building up a reputation or for collecting bonus points under this so-called relationship pseudonym.

The degree of anonymity protection provided by pseudonyms depends on the amount of personal data of the pseudonym holder that can be linked to the pseudonym, and on how often the pseudonym is used in various contexts/for various transactions. The best protection can be achieved if for each transaction a new so-called transaction pseudonym is used that is unlinkable to any other transaction pseudonyms and at least initially unlinkable to any other personal data items of its holder (see also [2]).

Publish/Subscribe

Hans-Arno Jacobsen
University of Toronto, Toronto, ON, Canada

Definition

Publish/Subscribe is an interaction pattern that characterizes the exchange of messages between publishing and subscribing clients. Subscribers express interest in receiving messages and publishers simply publish messages without specifying the recipients for a message. The publish/subscribe message exchange is decoupled and anonymous. That is, publishers neither know subscribers' identities nor whether any subscribers with matching interests exist at all. This supports a many-to-many style of communication, where data sources publish and data sinks subscribe. Different classes of publish/subscribe approaches have crystallized. Their main differences lie in the way subscribers express interest in messages, in the structure and format of messages, in the architecture of the system, and in the degrees of decoupling supported. Publish/Subscribe is widely used as middleware abstraction, applied to enterprise application integration, system and network monitoring, and selective information dissemination.

Historical Background

The definition in this entry aims to be general and characterizes publish/subscribe as an *interaction pattern* that governs the interaction between *many* publishing data sources and *many* subscribing data sinks. However, in practice, publish/subscribe is often interpreted to mean many slightly different concepts, such as an asynchronous communication style, a messaging paradigm, a message routing approach, an event filtering (matching) approach, or a design pattern. Moreover, research on publish/subscribe has been conducted in different communities, such as distributed systems, networking, programming languages, software engineering, and databases. The exact origins of publish/subscribe are therefore difficult to pinpoint exactly. Today, publish/subscribe-style abstractions can be found in many messaging standards, messaging products, databases, and even in special purpose hardware solutions.

The interpretation of publish/subscribe as asynchronous communication style emphasizes the data dissemination aspect and the associated qualities of service. The primary concern is the distribution of data from *many* sources to *many* sinks. Sometimes only a single source is considered and publish/subscribe is viewed as a *one-to-many* data dissemination paradigm, analogous to multicast. The channel-based publish/subscribe model best represents this interpretation. The indirect ancestry of publish/subscribe in this context are early reliable broadcast protocols [3] and primitives for process group management in operating systems [4], which inspired work on group communication as abstraction for reliable many-to-many communication, surveyed in [5]. It is this context that resulted in the subject-based publish/subscribe approach (a.k.a. topic-based model), first articulated by Oki et al. [16] and popularized by TIBCO with its TIBCO/RV product.

The interpretation of publish/subscribe as mesaging paradigm emphasizes the asynchronously decoupled nature of publishing data sources and subscribing data sinks. This view of publish/subscribe results from the inclusion of publish/subscribe functionality into standard messaging system specifications and products, such as MQ Series from IBM or the Java Message Service specification [9]. While these abstractions focus more on asynchronous one-to-one communication realized through message queues, they also include publication, subscription and filtering capabilities, often realized as subscriber-side filtering.

The interpretation of publish/subscribe as event filtering and matching approach emphasizes the selective filtering capabilities of the approach. Subscriptions represent filter expressions and publications represent observations about events in the environment that need to be selectively brought to the attention of subscribing entities. The ancestry of this work goes back to the formulation of the *many-to-many pattern matching problem* in the artificial intelligence domain by Forgy [7] who proposed the Rete algorithm for solving this problem. Rete is the basis of many rule-based expert systems. It efficiently evaluates observed facts provided as input against rules compiled into a memory resident graph (network), or an equivalent program [7]. This work was succeeded by approaches for efficient trigger management in database systems [2,6] and research on active databases. In software engineering, similar concepts were applied for integrating software tools resulting in approaches such as YEAST [12]. Around the same time work on specifying events for event correlation and root cause analysis appeared in network management [14].

The interpretation of publish/subscribe as design pattern is based on the *Observer design pattern*, first articulated in the Gang of Four book [8], where the Observer pattern is also synonymously referred to as Publish/Subscribe. This reference is somewhat unfortunate, as the prescribed realization of the Observer pattern in the literature violates a key property of publish/subscribe. The Observer pattern is suggested for use in expressing one-to-many dependency between objects in a system. When the state of one object (the subject) changes state, all dependent objects are notified. This is achieve by having the subject know about its dependents by maintaining a list of them and requiring dependents to register, if they are interested in the subject's state changes. This violates the anonymous communication property of publish/subscribe, which requires that publishers and subscribers do not know each other.

There are a few other approach that have appeared independently in different contexts, such as tuple spaces in the programming languages context to model concurrency in the 1980's blackboard architectures in the context of artificial intelligence to model the interaction of agents, continuous query processing in the data management context, and stream processing, also in the data management context. All these approaches resemble publish/subscribe, but also differ in fundamental ways.

Foundations

A publish/subscribe system comprises *publishers*, *subscribers*, and *publish/subscribe message broker(s)*, also referred to as *message router(s)*.

Publishers and subscribers are roles held by applications built with the publish/subscribe abstraction. That is a client of the system could be publisher as well as subscriber at the same time. Subscribers express interest by registering subscriptions with the publish/subscribe system and publishers report on events by publishing messages to the publish/subscribe system. The system evaluates publications against registered subscriptions and determines which subscriptions match for a given publication. The complexity of matching varies among different publish/subscribe models. In the content-based publish/subscribe model, matching involves the evaluation of publication message content against expressive subscription filters. In the topic-based publish/subscribe model matching involves the evaluation of message topics against path-like subscription language expressions. In the channel-based publish/subscribe model, no explicit matching takes place; subscribers select among a set of channels and listen for messages broadcast on the channel.

Publications are transient and once match are not further stored or processed. Exceptions to this treatment are state-based publish/subscribe systems and the Subject spaces model [10,11] where publications might be maintained as partial matching state and as persistent state per se, respectively.

Matching and notification are performed by the publish/subscribe message brokers. In centralized installations, there is a single broker to which subscribers and publishers connect. In distributed installations, there are multiple brokers to which subscribers and publishers connect.

Publish/Subscribe offers the following decoupling characteristics. Decoupling in space allows clients to be physically distributed. Decoupling in time allows clients to be independently available. Decoupling in location means that clients do not know each others identity. This last characteristics is also referred to as anonymous communication.

A publish/subscribe system is defined by the subscription language model, the publication data model, and the matching semantic. All these elements closely depend on each other and define the subscription, the notification, the advertisement, the publication and specify the matching of the former.

The subscription language model defines the language for expressing subscriptions. It determines the expressiveness of the publish/subscribe model. For example, in the content-based model a subscription is a Boolean function over Boolean predicates. Predicates test conditions, such as equality, binary relations, or string operators over attribute values in publications. Subscriptions are also referred to as *filters*, as they specify which publication to filter out from a flow of publications processed. Some systems distinguish among the *subscriber* and the *consumer*. The subscriber is the entity that specifies subscriptions and the *consumer* is the entity that receives notifications when certain subscriptions match. Subscriber and consumer entities must not be the same.

The publication data model defines the structure, the format, and the content type of publication messages. Publications are the messages emitted by publishers. They represent the *event* of interest about the state of the system or world in the context of the modeled application. An *event* is an asynchronous state transition of interest to subscribers. The publication is the message that conveys the occurrence of the event to any interested subscribers. In practice, the term publication and event are often used synonymously without distinguishing between the actual state transition and the message published about the event. The publication concept can be further refined by introducing *notifications*. A notification is the message sent from the publish/subscribe system to subscribers with matching subscriptions, whereas a publication is the message published by publishers. A notification must not be identical to a publication that triggered it. Systems may define a notification semantic that specified which values of a publication to forward to subscribers. Also, more refined notification semantics that apply transformations to publications before notifying subscribers are imaginable. However, many authors do not distinguish between the publication and notification concept defined above and use both terms synonymously. Some publish/subscribe approaches rely on the concept of an *advertisement*. An *advertisement* is similar to a type in programming languages or schemas in databases and specifies the kind of information a publisher will publish. It is used by publish/subscribe systems to optimize matching and routing of publications. In symmetry to the difference between subscriber and publisher, a similar difference could be made among publisher and producer, where one entity publishes, while the other entity merely advertises. However, this difference does not seem to have been explored in practice so far. Not all publish/subscribe approaches use advertisements.

The matching semantic defines the conditions under which a publication matches a subscription. For example, in content-based publish/subscribe, subscriptions are often conjuncts of Boolean predicates. That is a publication matches a subscription, if each predicate in the subscription evaluates to true given the values specified in the publication. This is a *crisp* matching semantic; it requires that the publication matches the subscription exactly by either evaluating to true or false. In contrast, an approximate matching semantic weakens the matching condition and tolerates that certain predicates do not match or only match to a certain degree. A model based on fuzzy set theory and possibility distribution is model realized in the Approximate Toronto Publish/Subscribe (A-ToPSS) project [13]. Similarly, probabilistic matching semantics that are defined by evaluating the probability that a publication matches a subscription are conceivable. Also, similarity-based semantics that measure the similarity between a publication and subscription based on some similarity measure or metric are conceivable.

Publish/Subscribe. Table 1. Comparison of models

Model	Filtering	Publication	Subscription
Channel-based	No filtering	Messages	Listening to channels
Topic-based	Topics &topic hierarchy	Messages tagged with topics	Expressions with wildcards over topics
Type-based	Type checking	Objects	–
Content-based	Message content	Messages	Content-based filters

Various publish/subscribe models have crystallized over time. These models are the channel-based, topic-based, type-based, content-based, state-based, and subject spaces. Table 1 compares these models with respect to publications, subscriptions, and filtering capabilities they support. More details about each model and additional subject spaces and state-based smodels is provided in a separate definition for each term.

Rule-based systems are intended to process *facts* against *rules* through logical inference, forward chaining or backward chaining algorithms, or by evaluating rules on events. Facts represent the state of the world and rules represent knowledge. Rule-based systems generally require the maintenance of state in the rule engine, as multiple facts processed over time may contribute to the evaluation of rules.

Key Applications

Applications of publish/subscribe include Information dissemination, information filtering, alerting and notification.

Standards that implement the publish/subscribe are the CORBA Event Service [18], the CORBA Notification Service [19], AMQP [1], JMS [9], WS Topics, WS Notifications, WS Brokered Notifications, WS Eventing, OMG's Data Dissemination Service Specification [17], OGF's INFO-D [15].

Data Sets

The publish/subscribe research community has yet to produce benchmarks and collect data sets. Initial efforts are starting to emerge [20].

Publish/Subscribe over Streams

Yanlei Diao[1], Michael J. Franklin[2]
[1]University of Massachusetts Amherst, MA, USA
[2]University of California-Berkeley, Berkeley, CA, USA

Definition

Publish/subscribe (pub/sub) is a many-to-many communication model that directs the flow of messages from senders to receivers based on receivers' data interests. In this model, publishers (i.e., senders) generate messages without knowing their receivers; subscribers (who are potential receivers) express their data interests, and are subsequently notified of the messages from a variety of publishers that match their interests.

Historical Background

Distributed information systems usually adopt a three-layer architecture: a presentation layer at the top, a resource management layer at the bottom, and a *middleware layer* in between that integrates disparate information systems. Traditional middleware infrastructures are tightly coupled. Publish/Subscribe [13] was proposed to overcome many problems of tight coupling:

- With respect to communication, tightly coupled systems use static point-to-point connections (e.g., remote procedure call) between senders and receivers. In particular, a sender needs to know all its receivers before sending a piece of data. Such communication does not scale to large, dynamic systems where senders and receivers join and leave frequently. Pub/sub offers loose coupling of senders and receivers by allowing them to exchange data without knowing the operational status or even the existence of each other.

- With respect to content, tight coupling can occur in remote database access. To access a database, an application needs to have precise knowledge of the database *schema* (i.e., its structure and internal data types) and is at risk of breaking when the remote database schema changes. Extensible Markup Language (XML)-based pub/sub has emerged as a solution for loose coupling at the content level. Since XML is flexible, extensible, and self-describing, it is suitable for encoding data in a generic format that senders and receivers agree upon, hence allowing them to exchange data without knowing the data representation in individual systems.

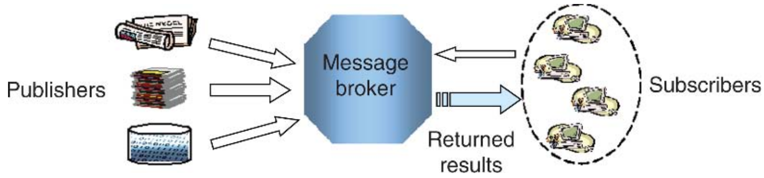
In many pub/sub systems, message brokers serve as central exchange points for data sent between systems. Figure 1 illustrates a basic context in which a broker operates. Publishers provide information by creating streams of messages (Besides "messages," the words "events," "tuples," and "documents" are often used with similar meanings in various contexts in the database literature.) that each contain a header describing application-specific information and a payload capturing the content of the message. Subscribers register their data interests with a message broker in a subscription language that the broker supports. Inside the broker, arriving subscriptions are stored as *continuous queries* that will be applied to all incoming messages. These queries remain effective until they are explicitly deleted. Incoming messages are processed on-the-fly against all stored queries. For each message, the broker determines the set of queries matched by the message. A query result is created for each matched query and delivered to its subscriber in a timely fashion.

Figure 2 shows a design space for publish/subscribe over data streams. In this diagram, pub/sub systems are first classified by the data model and the query language that these systems support. Roughly speaking, there are three main categories.

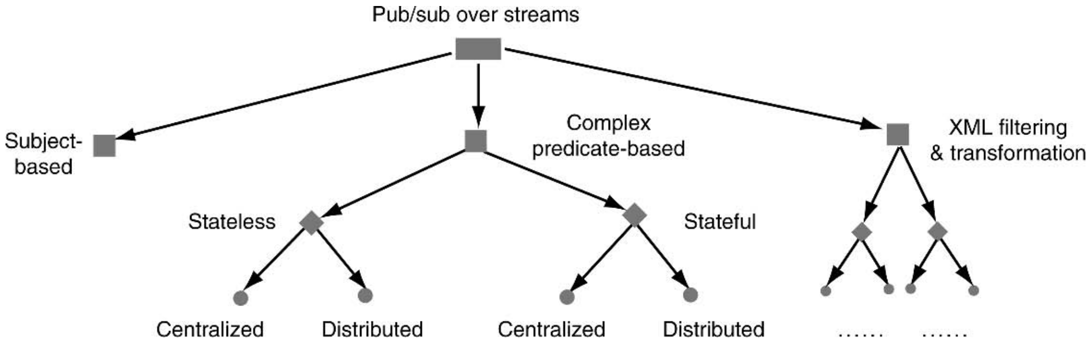
- *Subject-based*: Publishers label each message with a subject from a pre-defined set (e.g., "stock quote") or hierarchy (e.g., "sports/golf"). Users subscribe to the messages in a particular subject. These queries can also contain a filter on the data fields of the message header to refine the set of relevant messages within a particular subject.
- *Complex predicate-based*: Some pub/sub systems model the message content (payload) as a set of attribute-value pairs, and allow user queries to contain predicates connected using "and" and "or" operators to specify constraints over values of the attributes. For example, a predicate-based query applied to the stock quotes can be "Symbol = 'ABC' and (Change > 1 or Volume > 50,000)."
- *XML filtering and transformation*: Recent pub/sub systems have started to exploit the richness of XML-encoded messages, in particular, the hierarchical, flexible XML structure. User queries can be written using an existing XML query language such as XQuery. The rich XML structure and use of an XML query language enable potentially more accurate filtering of messages and further re-structuring of messages for customized result delivery.

Pub/sub systems can be further classified based on the style of query processing. In some systems, queries are applied only to individual messages, e.g., filtering messages, which does not involve any interaction across message boundaries. Such processing is referred to as *stateless*. Stateless processing is in contrast to stream query processing that maintains *state* over a long stream of messages, hence referred to as *stateful* processing. This distinction is illustrated for complex predicate-based systems in Fig. 2.

Finally, pub/sub systems can be distinguished based on the distribution of the architecture, as also shown in Fig. 2. In a coarse-grained fashion, this design space considers centralized and distributed processing. Distributed processing spreads the processing load for



Publish/Subscribe over Streams. Figure 1. Overview of publish/subscribe.



Publish/Subscribe over Streams. Figure 2. Design space for publish/subscribe over streams.

larger-scale pub/sub services; accordingly, it requires a more sophisticated routing functionality.

Foundations

As with stream processing, subscriptions, stored as continuous query inside a broker, need to be evaluated as data continuously arrives from other sources; that is, queries are evaluated every time when a new data item is received. Besides stream processing, pub/sub raises several additional challenges:

- *Scalability.* A key distinguishing requirement of pub/sub is scalability, in particular, in query population that pub/sub systems need to support. Such query populations can range from hundreds to millions in applications such as personalized content delivery. Given such populations, a salient issue is to efficiently search the huge set of queries to find those that can be matched by a message and to construct complete query results for them.
- *Robustness.* A second requirement of message brokers is the ability to perform in highly-dynamic environments where subscribers join and leave and their data interests change over time. Since message brokers see a constantly changing collection of queries, they must react quickly to query changes without adversely affecting the processing of incoming messages.
- *Distribution.* Due to the scale of message volume and query population, large-scale pub/sub may require the use of a network of message brokers to distribute the query population and message processing load. In this case, an additional issue is how to efficiently route a message from its publishing site to the set of brokers hosting relevant queries for complete query processing.

Scope of this entry. The rest of the entry focuses on complex predicate-based pub/sub systems. Pub/sub systems exploring XML filtering and transformation are described in detail in the entry "XML Publish/Subscribe."

Centralized, Stateless Publish/Subscribe

Le Subscribe [9] and *Xlyeme* [12] are predicate-based message filtering systems that use centralized processing. In these systems, a predicate is a comparison between an attribute and a constant using relational operators such as "=", ">", and "<". The main issue they address is how to efficiently match an incoming event, in the form of attribute value pairs, with the predicates of a large number of queries. The key idea is to *index* predicates as well as to *cluster* queries. In particular, *Le Subscribe* uses multi-attribute hash indexes to evaluate several predicates in a query with a single operation. In addition, it groups queries based on the number of contained predicates and the common conjunction of equality predicates, so many queries can be (partly) evaluated using a single operation. It further offers cost-based algorithms to find optimal clustering and to dynamically adjust it.

Centralized, Stateful Publish/Subscribe

NiagaraCQ [6] considers continuous queries with more complex predicates that can compare attributes of an input message to constants or to attributes of another message. To efficiently handle multiple queries, it groups query plans of continuous queries based on common *expression signatures*: an expression signature presents the same syntax structure, but possibly different constant values, in different queries. Consider queries that are interested in stock quotes of different symbols. Traditional query processing involves repeated retrieval of the symbol attribute from input and evaluation of different predicates on this attribute for different queries. The group plan employs a constant table to store the constant values form different queries, and retrieves this attribute from the input once and then performs an equality join of the retrieved value and the constant table to find all matching queries. For robust processing, NiagaraCQ constructs group plans incrementally: Given a new query, it constructs the query plan, and merges the query plan bottom up with a group plan with the same signature, extending the group plan with the mismatched branch(es) if necessary. This process is incremental as the addition of the new query plan does not affect existing queries.

Recently, there has been a significant amount of activity on handling continuous and time-varying tuple streams, resulting in the development of multiple general-purpose stream management systems [1,5,11]. These systems support complex continuous queries that join multiple streams and/or compute aggregate values over a period of time called a *window* (hence, performing stateful processing). While this surge of research explores a broad set of issues such as adaptivity and approximation, shared processing of window-based queries [5,11,10] is of particular relevance to pub/sub.

Several special-purpose pub/sub systems have been recently proposed to handle temporal correlations among events in a stream. SASE [15] supports sequencing operators that integrate parameterized predicates (i.e., predicates that compare different events), negation, and windowing. It explores a new query processing abstraction that uses an automaton-based implementation for fast sequence operations and relational-style post-processing for other tasks such as negation and windowing. It also devises a set of optimizations in this automaton-based framework for efficiency and scalability. Cayuga [7] offers an algebra for expressing event sequences that may address a finite yet unbounded number of events with a similar property, and employs a more sophisticated automaton model to support this algebra. Its implementation focuses on multi-query optimization including merging states of automata for different queries and further indexing query predicates.

Distributed, Stateless Publish/Subscribe

In distributed pub/sub systems, messages are published and subscriptions are registered to different brokers. A key issue is to efficiently route each message from its publishing site to the subset of brokers hosting relevant queries for complete query processing. For complexity reasons, most distributed pub/sub systems restrict themselves to stateless services.

ONYX [8] presents an overview of a pub/sub network exploring *content-based routing*. In this paradigm, brokers are organized as an application-level overlay network with a particular topology. When a new message enters the broker network, the root broker as well as each intermediate broker routes the message to its neighboring brokers based on the correspondence between the content of the message and the subscriptions residing at and reachable from those brokers. Content-based routing is used as a key mechanism to avoid the flooding of messages to all brokers in the network, hence reducing bandwidth usage and broker processing load and rendering better scalability.

ONYX consists of two layers of functionality. The lower layer deals with the overlay network; in particular, for each broker, it constructs a broadcast tree that is rooted at that broker and reaches all other brokers in the network. On top of these broadcast trees, the higher layer performs content-based processing by dealing with subscriptions and messages. Two issues determine the effectiveness of content-based routing. The first is how to partition subscriptions and assign them to host brokers. Results of ONYX show that content-based routing is most effective if the clustering of subscriptions results in mutual exclusiveness in data interest among host brokers. The second issue is how to aggregate subscriptions from their host brokers and place such aggregations as routing specifications in the intermediate brokers for later directing the message flow. Different degrees of generalization are possible depending on the precision-efficiency tradeoff suitable for each pub/sub system.

For content-based routing, Gryphon [2] and Siena [3] both aggregate subscriptions into compact, precise in-network data structures and use efficient algorithms to search these data structures to determine the routing of the messages to other brokers in the network.

XPORT [14] focuses on the construction, maintenance, and optimization of an overlay dissemination tree of the available message brokers in the system. Its tree-oriented optimization framework consists of a generic aggregation model that allows system cost to be expressed through various combinations of aggregation functions and local metrics, and distributed iterative optimization protocols for cost-based optimization of the overlay structure.

Distributed, Stateful Publish/Subscribe

For stateful publish/subscribe, Chandramouli et al. [4] adopt the following model: Users define subscriptions as SQL views over a conceptual (possibly distributed) database and messages are published as updates to the database; if a database update affects a subscription, the pub/sub system sends a notification to the subscriber containing the change to the content of the subscription view. The main idea of this work is to explore appropriate interfacing between the database and the pub/sub network so that existing stateless pub/sub networks can be leveraged for efficient dissemination. To do so, the key is to transform published messages into a semantic description of affected subscriptions (performed at the database side) and subscriptions into a predicate over the semantic description (evaluated in the stateless pub/sub network). Consider a selection-join subscription $\sigma_p(\sigma_{p\text{-}R}\ R \bowtie \sigma_{p\text{-}S}\ S)$. If a new message applies an update ΔR to table R, its effect on the subscription, $\sigma_p(\sigma_{p\text{-}R}\ \Delta R \bowtie \sigma_{p\text{-}S}\ S)$, requires access to table S that is not in the original update message (hence, stateful processing). The proposed solution reformulates each message ΔR into a series of messages containing the tuples in $\Delta R \bowtie S$ at the database side; to utilize a stateless pub/sub network, it transforms the select-join subscription into a simple condition that evaluates $\sigma_{p\ \wedge\ p\text{-}R\ \wedge\ p\text{-}S}$ over reformulated messages.

Key Applications

Personalized content delivery. This class of applications provide personalized filtering and delivery of news feeds, web feeds (RSS), stock tickers, sport tickers, etc. to large numbers of online users.

Online auction and online procurement. Through these applications, users can create their own feeds for their favorite searches, for example, on eBay.

Enterprise information management. Pub/sub has been traditionally used to support application integration, which integrates disparate, independently-developed applications into new services via the loose coupling of senders and receivers based on receivers' data interest.

System and network monitoring. Pub/sub has been recently used in system and network monitoring, where large-scale complex systems generate reports categorizing various aspects of system performance and resource utilization, and system administrators, end users, and visualization applications subscribe to receive updates on particular aspects of those reports.

Data Sets

Many data sources are available online, including RSS feeds (indicated by the orange button labeled with "RSS" or "XML" in many web pages) and financial feeds (e.g., Yahoo! Finance).

Punctuations

David Maier[1], Peter A. Tucker[2]
[1]Portland State University, Portland, OR, USA
[2]Whitworth University, Spokane, WA, USA

Definition

A *punctuation* is an item embedded in a data stream that specifies a subset of the domain of that stream. A data item that belongs to the subset specified by a punctuation is said to *match* that punctuation. A data stream is said to be *grammatical* if, for each punctuation, no data items will follow that match that punctuation. Consider a stream of bids for online auctions. When an auction closes, a punctuation *p* is embedded in the stream that matches all bids for that auction. In a grammatical stream, *p* indicates no more bids will arrive from that stream for that auction.

In the most common format, a punctuation is a tuple of *patterns*, where each pattern corresponds to an attribute of the data items in a stream. Typically, four patterns are used: a *wildcard* (denoted by '$\ast$') is matched by all values, a *literal* is matched by only the given value, a *list* (denoted by { }) is matched by any value in the given list, and a *range* (denoted by [ ]) is matched by any value that falls in the given range. If each value in a data item matches its corresponding pattern in a punctuation, then the data item matches the punctuation. For example, if auction bids have schema <*auction_id*, *bidder_id*,*price*,*timestamp*>, given the punctuation $p = P{<}\{\ 105{,}106\},\ast,[0.00{,}100.00],\ast{>}$, all bids for auctions 105 and 106 with prices between 0 and 100 match *p*. Thus, the data item <105,95,90.00,10495> matches *p*, but the data items <104,95,90.00,10495> and <105,95,105.00,10495> do not.

Key Points

Punctuations have been shown to unblock query operators and reduce the amount of state required by query operators [2] when processing non-terminating data streams. In addition, punctuations have proven useful for dealing with disorder in streams [1] and in specifying window semantics [1,3].

A *punctuation-aware operator* is a stream query operator that can take advantage of grammatical streams. Such an operator implements three different behaviors in the presence of punctuations [2]. A *pass behavior* allows operators to output data items due to punctuations. For example, when a punctuation arrives, an aggregate can output results for a particular group if all possible data items for that group match that punctuation. A *keep behavior* specifies which data items must remain in state when a punctuation arrives. For example, when a punctuation arrives, some data items that are held in state for symmetric hash join may be released. Finally, a *propagation behavior* defines which punctuations can be output when punctuation arrives. For example, union can output any punctuation that has arrived from both inputs.

Most punctuation-aware operators are counterparts of operators on finite relations. However, there can be more than one way to define pass, keep and propagation behavior when extending a relational operator to be punctuation-aware. An important property here is for a stream operator *s* to be *faithful* to its analogous relational operator *r*, which means that on any finite prefix *x* of a stream, the output of *s* on *x* is consistent with the output of *r* on any finite extension of *x*.

Synonyms

Hierarchical spatial indexes; Hierarchical regular-decomposition structures; Quadtree variations

Definition

In general, the term Quadtree refers to a class of representations of geometric entities (such as points, line segments, polygons, regions) in a space of two (or more) dimensions, that recursively decompose the space containing these entities into blocks until the data in each block satisfy some condition (with respect, for example, to the block size, the number of block entities, the characteristics of the block entities, etc.).

In a more restricted sense, the term Quadtree (Octree) refers to a tree data-structure in which each internal node has four (eight) children and is used for the representation of geometric entities in a two (three) dimensional space. The root of the tree represents the whole space/region. Each child of a node represents a subregion of the subregion of its parent. The subregions of the siblings constitute a partition of the parent's regions.

Several variations of quadtrees are possible, according to the dimensionality of the space represented, the criterion guiding the subdivision of space, the type of data represented, the type of memory (internal or external) used for storing the structure, the shape, position and size of the subregions, etc. However, the term Quadtree usually refers to tree structures that divide space in a hierarchical and regular (decomposing to equal parts on each level) fashion. Since final subregions/blocks (that are no further subdivided, i.e., the blocks of the tree leaves) do not overlap, the underlying space is partitioned to a set of regions, in favor of the efficient processing of spatial queries.

Historical Background

As computer science evolved, the need for representing and manipulating spatial data (data expressing geometric properties of entities, conceptually expressed by points, line segments, regions, geometric shapes, etc.) arose in several applications areas, like Computer Graphics, Multimedia, Geographical Information Systems, or VLSI Design. The recursive decomposition of space was naturally identified as a means for organizing spatial data. The term "quadtree" was used by Finkel and Bentley [3] to express an extension of the Binary Search Tree in two dimensions that was able to index points (Point Quadtree). Since then, several Quadtree variations for a multitude of spatial data types that were used for almost all sorts of spatial-data manipulations have appeared in the literature.

The term Quadtree has taken a generic meaning and is used to describe a class of hierarchical data structures whose common property is that they are based on the principle of recursive decomposition of space. The Quadtree, a variable resolution structure, is often confused with the Pyramid [11], a multi-resolution representation consisting of a hierarchy of arrays. Quadtrees and family are space-driven methods (follow the embedding space hierarchy): the division to subregions obeys a predefined way. On the contrary, R-trees and family are data-driven methods (follow the data space hierarchy): the division to subregions depends on the data.

The Region Quadtree is the most famous such structure. As its name implies, is used for representing regions and was initially termed Q-tree by Klinger and Dyer [6]. This is a main memory tree. A secondary memory implementation, the Linear Quadtree, was proposed by Gargantini [4]. The MX and PR Quadtrees are adaptations of the Region Quadtree for representing point data [11]. The MX-CIF Quadtree is a structure able to represent a collection of rectangles [11]. The PM family of Quadtrees are used for representing polygonal maps and collections of line segments. In general, extensions to three or more dimensions of each quadtree-like structure are possible. For example, the extension of the Region Quadtree for three dimensional volume data is called Region Octree. More details about the history of these and other quadtree-like structures can be found at [11,10]. There have also been proposed Quadtree variations for storing a pictorial database, like the DI-Quadtree, for binary images and the Generic Quadtree, for grayscale and color images. These and other quadtree-based methods that have been proposed for representation and querying in image database applications are reviewed in [8]. Quadtree variations have also been proposed for evolving regional data, like Overlapping Quadtrees [15], Overlapping Linear Quadtrees, the Multiversion Linear Quadtree, the Multiversion Access Structure for Evolving Raster Images and the Time-Split Linear Quadtree [13]. The XBR tree [13] is a quadtree-like structure for indexing points, or line segments especially designed for external memory. The Skip Quadtree [2] is based on Region Quadtrees and Skip Lists. It indexes points and can be used for efficiently answering point location, approximate range, and approximate nearest neighbor queries. Quadtrees have also been used in commercial Database Management Systems [7]. Demos of several Quadtree structures can be found at [1].

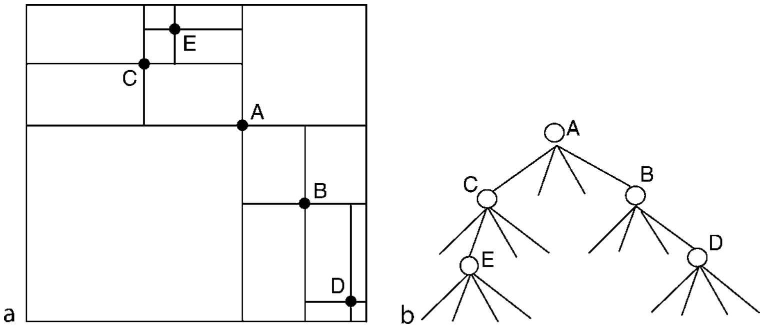
Foundations

This section briefly presents some key Quadtree structures among the numerous structures that have appeared in the literature.

Point Quadtree

The Point Quadtree [11] is an indexing mechanism for points. Each tree node corresponds to a point that subdivides the region of the node in four parts defined by two lines (parallel to the coordinate axes) on which this point lies. Thus, the shape, and position of subregions depend on the coordinates of the point (data-driven subdivision). However, each region is always subdivided in four parts. A region is considered closed in relation to its lower and left border. If multiple points with the same coordinates are allowed, each node contains a list of the points it stores. In Fig. 1, a collection of points and the resulting partitioning of space (a) and the corresponding Point Quadtree (b) are depicted. By convention, in this and other Quadtree variations, the children of a node correspond in order to the North-West, North-East, South-West and South-East subregions of the node. Note that the partitioning of space and the tree shape depend on the order of insertion of the points. Balanced versions of this tree have been proposed in the literature [11].

A Point Quadtree is not only suitable for point indexing (e.g., discovering if there is and which is the



Quadtrees (and Family). Figure 1. A collection of points (a) and the corresponding point quadtree (b).

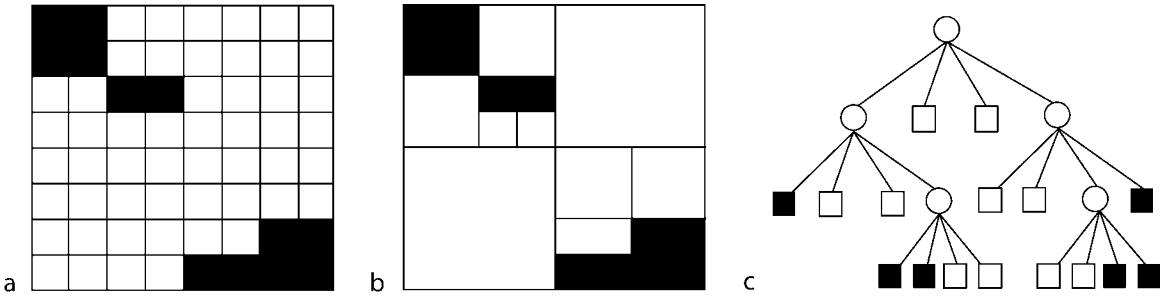
gas station that lies at a given pair of coordinates), but for answering range queries, as well (e.g., finding all the cities that reside within a specified distance from a given pair of coordinates). The efficiency of the Point Quadtree during this operation comes from pruning the search space only to nodes that may contain part of the answer.

Region Quadtree

The Region Quadtree [11] (or Q-tree [6]) is a popular hierarchical data structure for the representation of binary images, or regional data. Such an image can be represented as a $2^n \times 2^n$ binary array, for some natural number n, where an entry equal to 0 stands for a white pixel and an entry equal to 1 stands for a black pixel. The Region Quadtree for this array is made up either of a single white (black) node if every pixel of the image is white (black), or of a gray root, which points to four subquadtrees, one for every quadrant of the original image. Each region is always subdivided in four equal parts (space-driven subdivision). An example of an 8 × 8 binary image, its Region Quadtree and the unicolor blocks to which it is partitioned by the Quadtree external nodes are shown in Figs. 2a, 2b and 2c, respectively.

The Region Quadtree, depending on the distribution of data, may result in considerable space savings. However, it can be used for several operations on regional data. One of the them is the determination of the color of a specific pixel, or the determination of the block where this pixel resides (a specialized point-location query). Set theoretic operations are also well adapted to Region Quadtrees (recoloring, or dithering of a single image, or overlaying, union, intersection of sets of images). Connected component labeling (that is grouping pixels according to their color) is performed by utilizing Region Quadtrees. Other operations that are well adapted to Region Quadtrees include window clipping and certain transformations (like scaling by a power of two, or rotating by 90°). For more operations and details, see [9].

The pointer-based implementation of Region Quadtrees is a main memory implementation with one node type that consists of pointer fields and one color field. This node type is used for internal and external nodes according to the value of the color field. Although such an implementation is memory consuming it simplifies several operations. A secondary memory implementation of a Region Quadtree, called a Linear Quadtree [4], consists of a list of values where there is one value for each black node of the pointer-based Quadtree. The value of a node is an address describing the position and size of the corresponding block in the image. These addresses can be stored in an efficient structure for secondary memory (such as a B-tree or one of its variations). Evidently, this representation is very space efficient, although it is not suited to many useful algorithms that are designed for pointer-based Quadtrees. The most popular linear implementations are the FL (Fixed Length) and the FD (Fixed length – Depth) linear implementations. In the former implementation, the address of a black Quadtree node is a code-word that consists of n base 5 digits. Codes 0, 1, 2 and 3 denote directions NW, NE, SW and SE, respectively, while code 4 denotes a do-not-care direction. If the black node resides on level i, where $n >= i >= 0$, then the first n-i digits express the directions that constitute the path from the root to this node and the last i digits are all equal to 4. In the latter implementation, the address of a black Quadtree node has two parts: the first part is a code-word that consists of n base 4 digits. Codes 0, 1, 2 and 3 denote directions NW, NE, SW and SE, respectively. This code-word is formed in a similar way to the code-word of the FL-linear implementation with the



Quadtrees (and Family). Figure 2. A binary image (a), its partition to blocks (b) and its region quadtree (c).

difference that the last i digits are all equal to 0. The second part of the address has $[\log_2(n + 1)]$ bits and denotes the depth of the black node, or in other words, the number of digits of the first part that express the path to this node. Another interesting secondary memory implementation of the Region Quadtree is the Paged-pointer Quadtree [12] that partitions the tree nodes into pages and manages these pages using B-tree techniques.

PR Quadtree

The PR Quadtree [11] (P comes from point and R from region) is an indexing technique for points (with similar functionality to Point Quadtrees) that is based on the Region Quadtree. Points are associated with quadrants that are formed according to the Region Quadtree rules. A leaf node may be white (without any points residing in its region), or black (with one point residing in its region). In Fig. 3, the collection of points of Fig. 1 and the resulting partitioning of space (a) and the corresponding PR Quadtree (b) are depicted.

The final shape of the PR Quadtree is independent to the order of insertion of the points. A problem with this structure is that the maximum depth of recursive decomposition depends on the minimum distance between two points (if there are two points very close to each other, the decomposition can be very deep). This effect is reduced by allowing leaf nodes to hold up to C points. When this capacity is exceeded, the node is split in four. By storing leaf nodes on secondary memory and setting C according to the disk-page size, a structure that partially resides on disk is created.

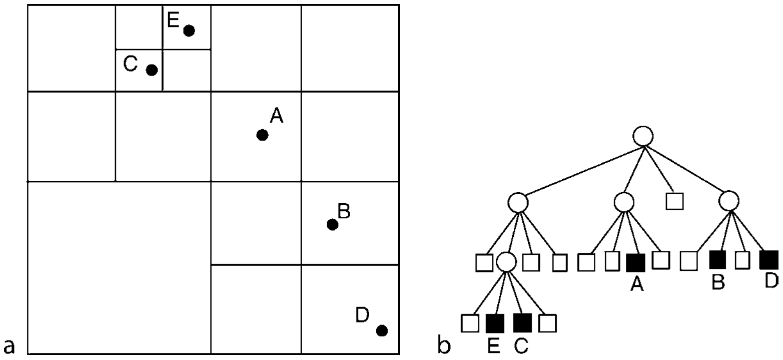
PMR Quadtree

The PMR Quadtree [11] is capable of indexing line segments and answering window queries (e.g., find the line segments that intersect a given window/area in the plane). The internal part of the tree consists of an ordinary Region Quadtree. The leaf nodes of this Quadtree are bucket nodes that hold the actual line segments. Each line segment is stored in every bucket whose quadrant (region) it crosses. A line segment can cross the region of a bucket either fully or partially. Each bucket has a maximum capacity. When this capacity is exceeded due to an insertion of a line segment, the bucket is split in four equal quadrants. However, it is possible that one (or more) of these quadrants holds a number of line segments that still exceeds the bucket capacity. Since this is not occurring very often in practical applications (e.g., when line segments represent a road network) a bucket is split only once in four and overflow buckets are created when needed. The PMR quadtree can be implemented with bucket nodes residing on disk.

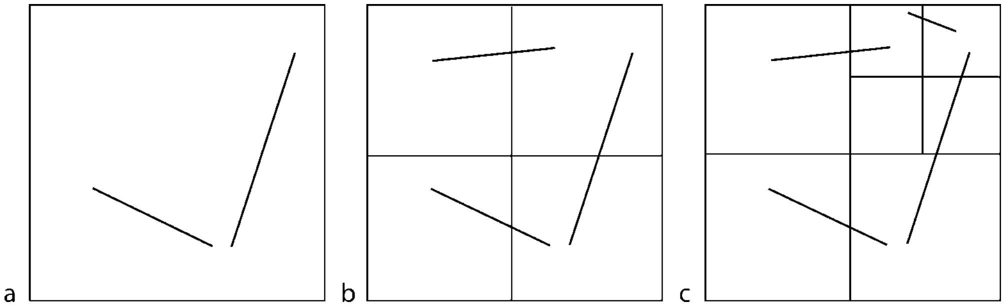
In Fig. 4, an example of the splitting of regions during the creation of a PMR Quadtree by the successive insertion of line segments is depicted. The bucket capacity is two (just for demonstration purposes). Figures 4a, 4b and 4c show the subdivision of space and the buckets created as line segments are inserted. Overflow buckets do not result from the insertions of Fig. 4. Note that the shape of the PMR Quadtree depends on the order of insertion of the line segments.

XBR Tree

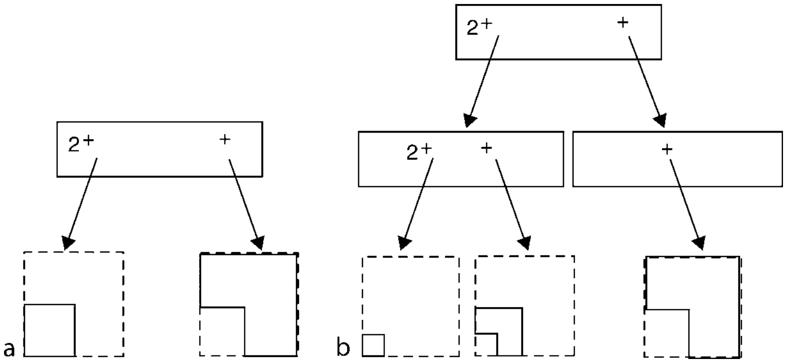
The XBR tree (XBR stands for eXternal Balanced Regular) is an indexing method suitable for indexing points (like a bucket PR Quadtree), or line segments (like a PMR Quadtree). It totally resides in secondary memory. Its hierarchical decomposition of space is the same as the one in Region Quadtrees. There are two types of nodes in an XBR-tree. The first are the internal nodes



Quadtrees (and Family). Figure 3. A collection of points (a) and the corresponding PR quadtree (b).



Quadtrees (and Family). Figure 4. Splitting of PMR-quadtree regions by the successive insertion of line segments.



Quadtrees (and Family). Figure 5. XBR trees with one level (a) and two levels (b) of internal nodes.

that constitute the index. The second are the leaves containing the data items. Both the leaves and the internal nodes correspond to disk pages.

In an internal node, a number of pairs of the form <address, pointer> are contained. The number of these pairs is non-predefined because the addresses being used are of variable size. An address expresses a child node region and is paired with the pointer to this child node. Both the size of an address and the total space occupied by all pairs within a node must not exceed the node size. The addresses in these pairs are used to represent certain subquadrants that result from the repetitive subdivision of the initial space. This is done by assigning the numbers 0, 1, 2 and 3 to NW, NE, SW and SE quadrants respectively. For example, the address 1 is used to represent the NE quadrant of the initial space, while the address 10 to represent the NW subquadrant of the NE quadrant of the initial space.

In the XBR-tree, the region of a child is the subquadrant specified by the address in its pair, minus the subquadrants corresponding to all the previous pairs of the internal node to which it belongs. Figure 5 presents XBR-trees of one (a) and two (b) levels of internal nodes. The $^{+}$, is used to denote the end of each variable size address. The address 2^{+} in the root denotes the SW quadrant of the initial space. On the other hand, the address $^{+}$ in the root specifies the initial space minus the SW quadrant.

Each leaf node in the XBR tree may contain a number of data items, which is limited by a predefined capacity C. When an insertion causes the number of data items of a leaf to exceed C, the leaf is split following a hierarchical decomposition analogous to the quadtree decomposition. In case line segments are stored, (like PMR Quadtrees) a leaf is split only once in four and overflow buckets are created when needed.

Due to the incremental (level-by-level) formation of absolute addresses and the variable length coding of them, XBR trees are very compact structures. Thus, I/O during query processing is reduced, favoring processing efficiency.

Quadtree and Time-Evolving Regional Data

In Tzouramanis et al. [13] and previous papers by the same authors, four temporal extensions of the Linear Region Quadtree are presented: the Time-Split Linear

Quadtree, the Multiversion Linear Quadtree, the Multiversion Access Structure for Evolving Raster Images and Overlapping Linear Quadtrees. These methods comprise a collection of specialized quadtree-based access methods that can efficiently store and manipulate consecutive raster images. Through these methods, efficient support for spatio-temporal queries referring to the past is provided. An extensive experimental space and time performance comparison of all the above-mentioned access methods, presented in Tzouramanis et al. [13], has shown that the Overlapping Linear Quadtrees is the best performing method. For more details, see [13] and its references.

Key Applications

Quadtree-based access methods speed up access and queries in database systems that support spatial data. Some common uses of Quadtrees include representation and indexing of images, spatial indexing for several spatial types (points, regions, line segments, polygonal maps), several set operations, point location, range, and nearest neighbor queries and temporal queries on series of evolving images. Quadtrees have been employed in numerous application areas that require efficient retrieval of complex objects, such as Computer Graphics and Animation, Computer Vision, Robotics, Geographical Information Systems (GIS), Image Processing, Image and Multimedia Databases, Content-Based Image Retrieval, Medical Imaging, Urban Planning, Computer-Aided Design (CAD), or even in recent novel database applications such as P2P Networks. Furthermore, together with the R-tree family, Quadtrees serve as an important bridge for extending spatial databases to applications of several scientific areas, such as Agriculture, Oceanography, Atmospheric Physics, Geology, Astronomy, Molecular Biology, etc. Commercial database vendors like IBM and Oracle [7] have recently implemented the Quadtree and the Linear Quadtree to cater for the large and diverse above application markets.

Future Directions

Since Quadtrees were mainly introduced as main memory structures, the development of further external memory versions of several Quadtree variations and the study of their performance for several queries remain a target. Recent papers, like [5], show that the comparative performance study for several query types between space-driven and data-driven indexing techniques can lead to interesting conclusions. Algorithms for queries based on the joining of data (e.g., image data) traditionally stored in Quadtree structures and other types of spatial data stored in data-driven structures (e.g., point data stored in R-tree family structures) are worth developing and studying, especially when the evolution of the data is considered (spatio-temporal data).

Qualitative Temporal Constraints between Time Intervals

► Allen's Relations

Qualitative Temporal Reasoning

Paolo Terenziani
University of Turin, Turin, Italy

Synonyms

Non-metric temporal reasoning; Reasoning with qualitative temporal constraints

Definition

Qualitative temporal constraints are non-metric *temporal constraints* stating the *relative* temporal position of facts that happen in time (e.g., fact F_1 is *before* or *during* fact F_2). Different types of qualitative constraints can be defined, depending on whether facts are instantaneous, durative, and/or repeated. *Qualitative temporal reasoning* is the process of reasoning with such temporal constraints. Given a set of qualitative temporal constraints, qualitative temporal reasoning can be used for different purposes, including checking their *consistency*, determining the *strictest constraints* between pairs of facts (e.g., for query answering purposes), pointing out a *consistent scenario* (i.e., a possible instantiation of all the facts on the timeline in such a way that all temporal constraints are satisfied).

Historical Background

In several domains and\or application areas, *temporal indeterminacy* has to be coped with. In such domains, the *absolute time* when facts hold (i.e., the exact temporal location of facts) is generally unknown. On the other hand, in many of such domains, *qualitative* temporal constraints about the *relative* temporal location of facts are available, and reasoning about such constraints is an important task. As a consequence, there is a long tradition for qualitative temporal reasoning within *philosophical logic* (consider, e.g., Walker [15], who first formulated a kind of logical calculus about durative periods, and Prior's seminal branching time logics [11].

In particular, qualitative temporal reasoning is important in several artificial intelligence areas, including planning, scheduling, and natural language understanding. Therefore, starting from the beginning of the 1980s, several *specialized* approaches (as opposed to *logical* approaches, which are usually general-purpose) to the *representation* of *qualitative* temporal constraints and to temporal *reasoning* about them have been developed, especially within the artificial intelligence area.

The first milestone in the specialized approaches to qualitative temporal reasoning dates back to Allen's Interval Algebra [1], coping with qualitative temporal constraints between intervals (called *periods* by the database community, and henceforth in this entry), to cope with durative facts. Further on, several other algebrae of qualitative temporal constraints have been developed, to cope with instantaneous [14] or repeated/periodic [9,12] facts, and several temporal reasoning systems have been implemented and used in practical applications (see e.g., some comparisons in Delgrande et al. [4]).

Significant effort in the area has been devoted to the analysis of the *trade-off* between the *expressiveness* of the representation formalisms and the *complexity* of *correct* and *complete* temporal reasoning algorithms operating on them (see e.g., the survey by Van Beek [13]). Since consistency checking in Allen's algebra is NP-complete, several approaches, starting from Nebel and Burkert [10], have focused on the identification of *tractable fragments* of it. The *integration* of qualitative and metric constraints has also been analyzed (see e.g., Jonsson and Backstrom [7]). Recent developments also include *incremental* [6] and *fuzzy* [2] qualitative temporal reasoning. Moreover, starting in the 1990s, some approaches also started to investigate the adoption of qualitative temporal constraints and temporal reasoning within the temporal database context [8,3].

Foundations

Qualitative temporal constraints concern the relative temporal location of facts on the timeline. A significant and milestone example is Allen's Interval Algebra (IA). Allen pointed out the 13 primitive qualitative relations between time periods: before, after, meets, met-by, overlaps, overlapped-by, starts, started-by, during, contains, ends, ended-by, equal. These relations are *exhaustive* and *mutually exclusive*, and can be combined in order to represent disjunctive relations. For example, the constraints in (Ex.1) and (Ex.2) state that F_1 is before or during F_2, which, in turn, is before F_3.

(Ex.1) F_1 (BEFORE,DURING) F_2
(Ex.2) F_2 (BEFORE) F_3

In Allen's approach, qualitative temporal reasoning is based on two algebraic operations over relations on time periods: intersection and composition. Given two possibly disjunctive relations R_1 and R_2 between two facts F_1 and F_2, temporal intersection (henceforth $\cap$) determines the most constraining relation R between F_1 and F_2. For example, the temporal intersection between (Ex.2) and (Ex.3) is (Ex.4). On the other hand, given a relation R_1 between F_1 and F_2 and a relation R_2 between F_2 and F_3, composition (@) gives the resulting relation between F_1 and F_3. For example, (Ex.5) is the composition of (Ex.1) and (Ex.2) above.

(Ex.3) F_2 (BEFORE,MEETS,OVERLAPS) F_3
(Ex.4) F_2 (BEFORE) F_3
(Ex.5) F_1 (BEFORE) F_3

In Allen's approach, temporal reasoning is performed by a *path consistency* algorithm that basically computes the *transitive closure* of the constraints by repeatedly applying intersection and composition. Abstracting from many optimizations, such an algorithm can be schematized as follows:

```
Repeat
For all triples of facts<$F_i$,$F_k$,$F_j$>
    Let $R_{ij}$ denote the (possibly ambiguous) relation
between $F_i$ and $F_j$
    $R_{ij} \leftarrow R_{ij} \cap (R_{ik} @ R_{kj})$
    Until quiescence
```

Allen's algorithm operates in a time *cubic* in the number of periods. However, such an algorithm is *not complete* for the Interval Algebra (in fact, checking the consistency of a set of temporal constraints in the Interval Algebra is NP-hard [14]).

While in many approaches researchers chose to adopt Allen's algorithm, in other approaches they tried to design less expressive but *tractable* formalisms. For example, the Point Algebra is defined in the same way as the Interval Algebra, but the temporal elements are time points. Thus, there are only three primitive relations between time points (i.e., <,=, and>), and four disjunctive relations (i.e., (<,=), (>,=), (<,>), and (<,=,>). In the Point Algebra, sound and complete constraint propagation algorithms operate in polynomial time (namely, in $O(n^4)$, where n is the number of points [13]). Obviously, the price to be paid for tractability is expressive power: not all (disjunctive) relations between periods can be mapped onto relations between their endpoints. For instance *F_1 (BEFORE,AFTER) F_2* cannot be mapped into a set of (possibly disjunctive) pairwise relations between time points; indeed an explicit disjunction between two different pairs of time points is needed (i.e., *(end(F_1)<start(F_2)) or (end(F_2)<start(F_1))*. The Continuous Point Algebra restricts the Point Algebra excluding inequality (i.e., (<,>)). Allen's path consistency algorithm is both sound and complete for such an algebra, and operates in $O(n^3)$ time, where n is the number of time points (for more details, see e.g., the survey by Van Beek [13]).

A different simplification of Allen's Algebra has been provided by Freksa [5]. Freska has identified coarser qualitative temporal relations than Allen's ones, based on the notion of *semi-intervals* (i.e., beginnings and ending points of durative events). As an example of relation on semi-intervals, Freksa has introduced the "older" relation (*F_1* is *older* than *F_2* if *F_1*'s starting point is before *F_2*'s starting point, with no constraint on the ending points). Notice that Freska's *older* relation corresponds to a disjunction of five Allen's relations (i.e., *before*, *meets*, *overlaps*, *finished-by*, *contains*). Freska has also shown that relations between semi-intervals result in a possible more compact notation and more efficient reasoning mechanisms, in particular if the initial knowledge is, at least in part, coarse knowledge.

Another mainstream of research about qualitative temporal reasoning focused on the identification of *tractable fragments* of Allen's algebra. The milestone work by Nebel and Burkert [10] first pointed out the "*ORD-Horn subclass*," showing that reasoning in such a class is a polynomial time problem and that it constitutes a maximal tractable subclass of Allen's algebra.

Starting in the early 1990s, some *integrated* temporal reasoning approaches were devised in order to deal with both qualitative and quantitative (i.e., metric) temporal constraints. For instance, Jonsson and Backstrom [7] proposed a framework, based on *linear programming*, that deals with both qualitative and metric constraints, and that also allows one to express constraints on the relative duration of events (see e.g., (Ex.6)).

(Ex.6) John's drive to work is at least 30 minutes more than Fred's.

Many other important issues must be taken into account when considering qualitative temporal reasoning. For example, starting from Ladkin's seminal work [9], qualitative constraints between *repeated* facts have been considered. In the same mainstream, Terenziani has proposed an extension of Allen's algebra to consider qualitative relations between periodic facts [12]. Terenziani's approach deals with constraints such as (Ex.7):

(Ex.7) Between January 1, 1999 and December 31, 1999 on the first Monday of each month, Andrea went to the post office *before* going to work.

In Terenziani's approach, temporal reasoning over such constraints is performed by a path consistency algorithm which extends Allen's one. Such an algorithm is sound but not complete and operates in cubic time with respect to the number of periodic facts.

As concerns more strictly the area of (temporal) databases, starting in the mid 1990s, some researchers started to investigate the treatment of qualitative temporal constraints within temporal (relational) databases (see e.g., [8,3]). In such approaches, the *valid time* of facts (tuples) is represented by symbols denoting time periods, and *qualitative* and *quantitative temporal constraints* are used in order to express constraints on their relative location in time, on their duration, and so on.

Koubarakis [8] first extended the constraint database model to include indefinite (or uncertain) temporal information (including qualitative temporal constraints). Koubarakis proposed an explicit representation of temporal constraints on data; moreover, the local temporal constraints on tuples are stored into a dedicated attribute. He also defined the algebraic operators, and theoretically analyzed their complexity. On the other hand, the work by Brusoni et al., [3] mainly focused on defining an integrated approach in which "standard" artificial intelligence temporal reasoning capabilities (such as the ones sketched above in this entry) are suitably extended and paired with an (extended) relational temporal model. First, the data model is extended in such a way that each temporal tuple can be associated with a set of identifiers, each one referring to a time period. A separate relation is used in order to store the qualitative (and quantitative) temporal constraints of such periods. The algebraic operations of intersection, union and difference are defined over such sets of periods, and *indeterminacy* (e.g., about the existence of the intersection between two periods) is coped with through the adoption of *conditional intervals*. Algebraic relational operators are defined on such a data model, and their complexity analyzed. Finally, an integrated and modular architecture combining a temporal reasoner with an extended temporal database is described, as well as a practical application to the management of temporal constraints in clinical protocols and guidelines.

Key Applications

Qualitative temporal constraints are pervasive in many application domains, in which the absolute and exact time when facts occur is generally unknown, while there are constraints on their relative order (or temporal location). Such domains include the "classical" domains of planning and scheduling, but also more recent ones such as managing multimedia presentations or clinical guidelines.

As a consequence, temporal reasoning is already a well-consolidated area of research, especially within the artificial intelligence community, in which a large deal of works aimed at building *application-independent* and *domain-independent* managers of temporal constraints. Such managers are intended to be *specialized knowledge servers* that represent and reason with temporal constraints, and that *co-operate* with other software modules in order to solve problems in different applications. For instance, in planning problems, a temporal manager could co-operate with a planner, in order to check incrementally the temporal consistency of the plan being built. In general, the adoption of a specialized temporal manager is advantageous from the computational point of view (e.g., with respect to general logical approaches based on theorem proving), and it allows programmers to focus on their domain-specific and application-specific problems and to design modular architectures for their systems.

On the other hand, the impact and potentiality of extensively exploiting qualitative temporal reasoning in temporal databases have only been minimally explored by the database community, possibly due to the computational complexity that it necessarily involves. However, (temporal) databases will be increasingly applied to new applications domains, in which the structure and the inter-dependencies of facts (including the temporal dependencies) play a major role, while the assumption that the absolute temporal location of facts is known does no longer hold. Significant application areas include database applications to store workflows, protocols, guidelines (see, e.g., the example in [3]), and so on. To cope with such applications, "hybrid" approaches in which qualitative (and/or quantitative) temporal reasoning mechanisms are paired with classical temporal database frameworks (e.g., along the lines suggested in [3]) are likely to play a significant role in a near future. The role of qualitative temporal constraints (and temporal reasoning) may be even more relevant at the *conceptual* level. Several temporal extensions to conceptual formalisms (such as the Entity-Relationship) have been proposed in recent years, and there is an increasing awareness that, in many domains, qualitative (and/or quantitative) temporal constraints between conceptual objects are an intrinsic part of the conceptual model. As a consequence, qualitative temporal reasoning techniques such as the ones discussed above, may in the near future, play a relevant role at the conceptual modeling level.

Future Directions

One of several possible future research directions of qualitative temporal reasoning, which may be particularly interesting for the database community, is its application to "Active Conceptual Modeling." In his keynote talk at ER'2007, Prof. P. Chen, the creator of the Entity-Relationship model, has stressed the importance of extending traditional conceptual modeling to "Active Conceptual Modeling." Roughly speaking, the term "active" denotes the need for coping with evolving models having learning and prediction capabilities. Such an extension is needed in order to adequately cope with a new range of phenomena, including disaster prevention and management. Chen has stressed that "Active Conceptual Modeling" requires, besides the others, an explicit treatment of time. The extension and integration of qualitative temporal reasoning techniques into the "Active Conceptual Modeling" context is likely to give a major contribution to the achievement of predictive and learning capabilities, and to become a potentially fruitful line of research.

Quality and Trust of Information Content and Credentialing

Chintan Patel, Chunhua Weng
Columbia University, New York, NY, USA

Definition

The quality and reliability of biomedical information is critical for practitioners (clinicians and biomedical scientists) to make important decisions about patient conditions and to draw key scientific conclusions towards developing new drugs, therapies and procedures. Evaluating the quality and trustworthiness of biomedical information [1] requires answering questions such as, *where did the data come from*, *under what conditions was the data generated, how accurate and complete is the data,* and so on.

Key Points

The quality and reliability of biomedical information is dependent on the task or the context of the application. There is a basic set of domain-independent features that can be used to characterize the quality and trustworthiness of the information:

Accuracy: The correctness of the information. Inherent noisiness in the underlying data generating clinical processes or biological experiments often leads to various errors in the resulting data. It is critical to quantify the frequency and source of such errors using the measure of accuracy to enable the clinicians and researchers for making informed decisions using the data.

Completeness: In biomedical settings, it is often necessary to have all the pertinent (complete) information at hand while making important clinical decisions or performing complex biological experiments. There are various constraints due to limited technology and the nature of clinical practice that leads to incomplete biomedical data:

1. In healthcare settings, only partial data gets recorded in electronic form and vast amount of data is still only available on paper [4]. For example, various clinical notes such as admit, progress and discharges notes containing valuable clinical information are generally written on paper charts and not entered electronically.
2. In several instances, despite the availability of electronic data, the information is not usable or accessible due to differences in underlying data standards, information models, terminology, etc. Consider for example, two biological databases using different ontologies for protein annotation, which will not be able to support data reuse or sharing across.

Transparency: An important aspect for determining the trustworthiness of information is the understanding or knowledge of the underlying processes or devices generating the data. Various tools or resources that provide transparency to data sources are more likely to be trusted by clinicians or biologists [2].

Credentialing: The trustworthiness of information in turn depends on the level of trust in data originators. Hence, it is important to attribute the information to its source in order to allow consumers of information to make appropriate decisions. Consider for example that a biological annotation reviewed by human curators will be trusted more than an annotation automatically extracted from literature using text-mining [3].

As the biomedical domain becomes more and more information driven, the methods and techniques to characterize the quality and trustworthiness of information will gain more prominence.

Quality of Data Warehouses

Rafael Romero[1], Jose-Norberto Mazón[1], Juan Trujillo[1], Manuel Serrano[2], Mario Piattini[2]
[1]University of Alicante, Alicante, Spain
[2]University of Castilla – La Mancha, Spain

Definition

Quality is an abstract and subjective aspect for which there is no universal definition. It is usually said that there is a quality definition for each person. Perhaps the most abstract definition for this topic is that the data warehouse quality means the data is suitable for the intended application by all users. In this way, it is very complex to measure or assess the quality of a data warehouse system. Normally, the *data warehouse* quality is determined by: (i) the quality of the data presentation, and (ii) the quality of the *data warehouse* itself. The latter is determined by the quality of the Database Management System (DBMS), the data quality and the quality of the underlying data models used to design it. A good design may (or may not) lead to a good data warehouse, but a bad design will surely render a bad data warehouse of low quality. In order to measure the quality of a data warehouse, a key issue is defining and validating a set of measures to help to assess the quality of a data warehouse in an objective way, thus guaranteeing the success of designing a good data warehouse.

Historical Background

Few works have been presented in the area of objective indicators or measures for data warehouses. Instead, most of the current proposals for data warehouses still delegate the quality of the models to the experience of the designer.

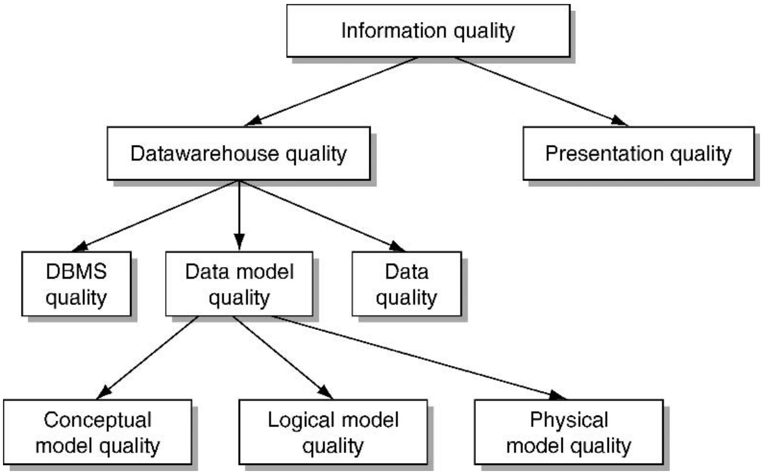
Only the model proposed by Jarke et al. [5], which is described in more depth in Vassiladis' Ph.D. thesis [14], explicitly considers the quality of conceptual models for data warehouses. Nevertheless, these approaches only consider quality as intuitive notions. In this way, it is difficult to guarantee the quality of data warehouse conceptual models, a problem which has initially been addressed by Jeusfeld et al. [6] in the context of the DWQ (Data Warehouse Quality) project. This line of research addresses the definition of measures that allows designers to replace the intuitive notions of quality of conceptual models of the data warehouse with formal and quantitative measures. Sample research in this direction includes normal forms for data warehouse design as originally proposed in [8] and generalized in [7]. These normal forms represent a first step towards objective quality metrics for conceptual schemata.

Following the idea of assessing the quality of data warehouses in an objective way, several measures for evaluating the quality of data warehouse logical models have been proposed in recent years and validated both formally and empirically [11,12].

Lately, Si-Saïd and Prat [13] have proposed some measures for multidimensional schemas analyzability and simplicity. Nevertheless, none of the measures proposed so far has been empirically validated, and therefore, their practical utility has not been proven.

Foundations

The information quality of a data warehouse is determined by: (i) the quality of the system itself, and (ii) the quality of the data presentation (see Fig. 1). In fact, it is important that the data of the data warehouse not only correctly reflects the real world, but also that the data are correctly interpreted. Regarding data warehouse quality, three aspects must be considered: the quality of the DBMS (Database Management System) that supports it, the quality of the data models



Quality of Data Warehouses. Figure 1. Quality of the information and the data warehouse.

used in their design (conceptual, logical and physical), and the quality of the data contained in the data warehouse. The presentation quality of data warehouses is more related to the data presentation according to front-end tools such as OLAP (On-Line Analytical Processing), data reporting or data mining. For this reason, the following issues pertaining to data warehouse quality are described next: (i) DBMS quality, (ii) data model quality, and (iii) data quality.

Quality of DBMS

The quality of the DBMS in which the data warehouse is implemented is important, since the database engine is the core of the data warehouse system and has a deep impact on the performance of the whole system. A good DBMS could improve the performance of the system and the quality of the data by implementing constraints and integrity rules. In order to assess the quality of a DBMS, several international standards can be used, such as ISO/IEC 9126 [3] and ISO/IEC 9075 [4] or even information from database benchmarks [9].

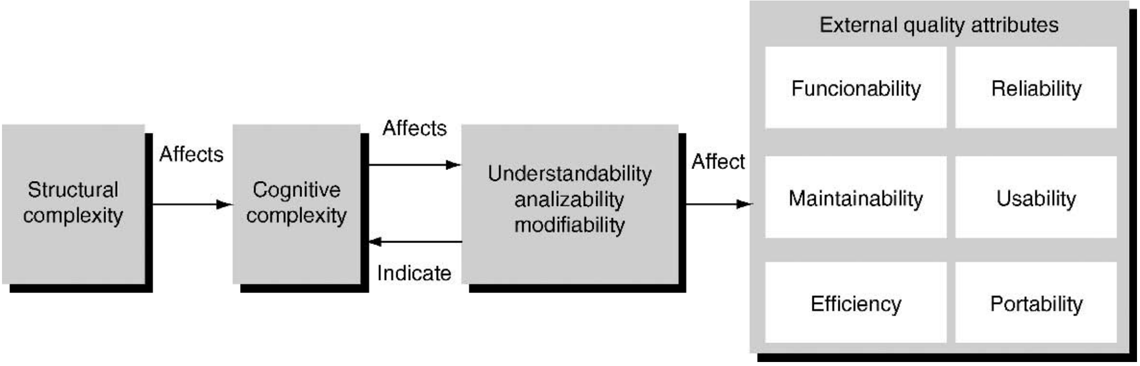
Quality of Data Warehouse Data Models

The quality of the data models used in the design of data warehouses relies on the quality of the conceptual, logical, and physical models used for its design. A first step towards obtaining high quality data models is the definition of development methodologies. However, a methodology, though necessary, may not be sufficient to guarantee the quality of a data warehouse. Indeed, a good methodology may (or may not) lead to a good product, but a bad methodology will surely render a bad product of low quality. Furthermore, many other factors could influence the quality of the products, such as human decisions. Therefore, it is necessary to complete specific methodologies with measures and techniques for product quality assessment.

Structural properties (such as structural complexity) of a software artifact have an impact on its cognitive complexity as shown in Fig. 2. Cognitive complexity means the mental burden on those who have to deal with the artifact (e.g., developers, testers, maintainers). High cognitive complexity of an artifact reduces its understandability and leads to undesirable external quality attributes as defined in the standard ISO/IEC 9126 [3]. The model presented in Fig. 2 is an adaptation of the general model for software artifacts proposed in Briand et al. [2].

Indeed, as data warehouse models are software artifacts, it is reasonable to consider that they follow the same pattern. It is thus important to investigate the potential relationships that can exist between the structural properties of these schemas and their quality factors.

In order to get a valid set of data warehouse measures, the definition of measures should be based on clear measurement goals and the measures should be defined following the organization's needs related to external quality attributes. In defining measures, it is also advisable to take into account the expert's



Quality of Data Warehouses. Figure 2. Relationship between Structural Properties, Cognitive Complexity, Understandability and External Quality Attributes – based on the work described in Briand et al. [12].

knowledge. Figure 3 presents a method (based on the method followed in [11,12]) for obtaining valid and useful measures. In this figure, continuous lines show measure flow and dotted lines show information flow.

This method has five main phases starting at the identification of goals and hypotheses and leading to the measure application, accreditation, and retirement:

1. *Identification*: Goals of the measures are defined and hypotheses are formulated. All of the subsequent phases will be based upon these goals and hypotheses.

2. *Creation*: This is the main phase, in which measures are defined and validated. This phase is divided into three sub phases:

a) *Measures definition*. Measure definition is made by taking into account the specific characteristics of the system to be measured, the experience of the designers of these systems and the work hypotheses. A goal-oriented approach as GQM (Goal-Question-Metric [1]) can also be very useful in this step.

b) *Theoretical validation*. The formal (or theoretical) validation helps identify when and how to apply the metrics. There are two main tendencies in measuring formal validation: the frameworks based on axiomatic approaches [7] and the ones based on measurement theory [10]. The goal of the former is merely definitional, as in this type of formal framework, a set of formal properties is defined for given software attributes and it is possible to use this set of properties for classifying the proposed measures. On the other hand, in the frameworks based on measurement theory, the information obtained is the scale to which a measure pertains and, based on this information, statistics and transformations, which can be applied to the measure, can be known.

c) *Empirical validation*. The goal of this step is to prove the practical utility of the proposed measure. Empirical validation is crucial for the success of any software measurement project as it helps to confirm and understand the implications of the measurement of products. Although there are various ways perform to this step, the empirical validation can be divided into experiments, case studies, and surveys.

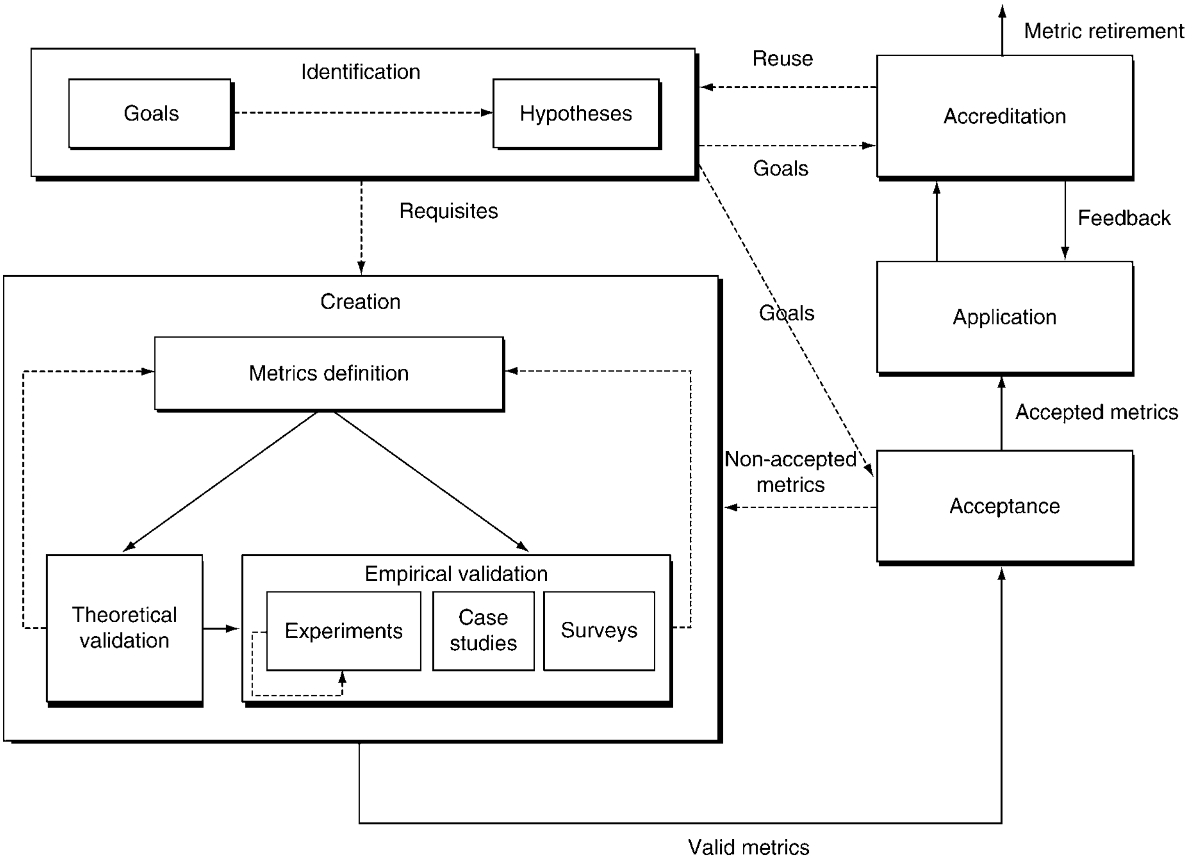
This process is evolutionary and iterative and as a result of the feedback, the measure could be redefined or discarded, depending on their formal and empirical validation. As a result of this phase a valid metric is obtained.

3. *Acceptance*: The goal of this phase is the systematic experimentation of the measure. This is applied in a context suitable to reproduce the characteristics of the application environment, with real business cases and real users, to verify its performance against the initial goals and stated requirements.

4. *Application*: The accepted measure is used in real cases.

5. *Accreditation*: This is the final phase of the process. It is a dynamic phase that proceeds simultaneously with the application phase. The goal of this phase is the maintenance of the measure, so it can be adapted to the changing environment of the application. As a result of this phase, the measure can be retired or reused for a new measure definition process.

The most important data models for measuring quality are conceptual and logical models as the quality of physical models has to do with performance issues and the physical distribution of data. Following the above method, a set of measures can be defined and validated for data warehouse conceptual models



Quality of Data Warehouses. Figure 3. Metrics creation process.

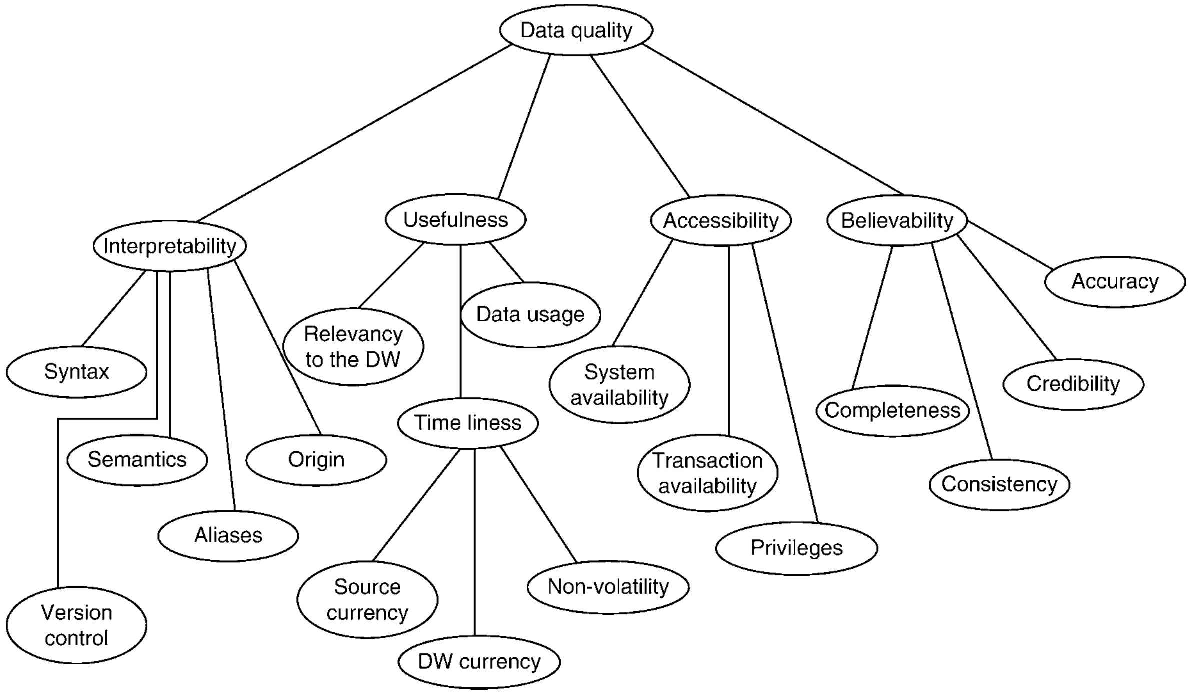
quality [12]. Some examples of the measures defined in [12] are: number of dimensions of the multidimensional conceptual model, number of hierarchy levels of the multidimensional conceptual model, ratio of hierarchy levels (i.e., number of hierarchy levels per dimension of the multidimensional conceptual model), and the maximum depth of the hierarchy relationships of the multidimensional conceptual model.

Taking into account these characteristics, a set of measures for data warehouses logical models have also been defined and validated in [11]. Specifically, these measures are defined for a relational implementation (tables, columns, foreign keys, etc.). Some examples of the measures defined in [11] are: number of fact tables of the schema, number of shared dimension tables (i.e., number of dimension tables shared for more than one star (fact) of the schema), number of foreign keys in all the fact tables of the schema, and ratio of schema attributes (i.e., number of attributes in dimension tables per attributes in fact tables).

Data Quality

Finally, data quality is a multidimensional concept that is made up of several aspects, all of which depend on the needs of the data consumers or system designers. The most accurate definition for data quality is fitness for use, i.e., how suitable the data is for a concrete task. This concept can be defined in terms of particular criteria, related either to the data life-cycle or to the way data are meant to be used. Usually, the way of determining the data quality of an application is to define a framework that specifies the data quality dimensions in a concrete domain. The reader is referred to the DWQ project [6]. Figure 4 shows the quality factors as stated in the DWQ project.

As stated in the DWQ project, data warehouse data quality is related to several characteristics or quality dimensions, such as interpretability, usefulness, accessibility and believability. These quality dimensions should be interpreted as the ability to understand, use, access and trust the data that is stored in



Quality of Data Warehouses. Figure 4. Data warehouse quality factors.

the data warehouse. Each dimension tackles a different aspect of data quality and is broken up into several sub-categories, such as timeliness, availability, clarity, and accuracy.

When dealing with interpretability, the data must be easy to understand, and special attention should be placed on the format and structure of the data. In this sense, the syntax of the data should be inspected, since aliases and abbreviations may be eluded and the origin and the different versions of the data must be controlled.

Data relevancy and timeliness are the main problems to be tackled in data usefulness. Data relevancy can be analyzed in ETL processes, while timeliness is more related to the currency of the data. It is universally known that data warehouses are typically not updated everyday, but irrelevant data cannot be allowed in the system. A good schedule of data warehouse refresh process can avoid this problem.

Accessibility is related to system availability and access privileges. Data warehouse systems should be in stable and well-dimensioned systems and privileges should be studied in great detail. It is also necessary to test and maintain the system periodically.

Believability is a very important aspect of data warehouse data quality, as it deals with completeness, consistency, credibility and accuracy of the data. Probably this quality dimension is the most studied by data quality experts, but it is usually the most difficult to assess. This quality dimension is not only related to source data quality and ETL processes' quality, it is also related to the data warehouse update processes that can pollute the data warehouse data. In this way, data cleaning algorithms could be very useful.

In order to detect data quality problems, it is advisable to have indicators that can help identify the different quality threats for each of the data warehouse data quality dimensions. There are several quality indicator proposals, but they are not oriented to the data warehouse field and are only usually oriented to a specific quality dimension such as accuracy, completeness and timeliness. Further research has to be done in this field in order to obtain a complete set of data warehouse data quality indicators.

Key Applications

The main application of Data Warehouse Quality is oriented to the work of data warehouse designers. Introducing quality aspects from early phases of data warehouse design is a good way to improve the quality and success of a data warehouse. In this way, quality models and quality driven design methods are good approaches to design successful data warehouse systems. These design methods should be based on the metrics and techniques that have been discussed in the previous sections.

Future Directions

Some open research lines within data warehouse quality are: (i) to provide a complete set of quality measures that allows to measure and assess data warehouse quality models in different dimensions such as the complexity, understandability, usability and so on (Fig. 2), (ii) the traceability of the measures throughout all the design steps (conceptual, logical and physical), and (iii) the measure's thresholds, which should be the last step in defining measures, i.e., being able to provide a number for each measure under which one can completely assure the quality of a model. The latter is definitely the most difficult issue that has not yet been covered.

Experimental Results

Generally speaking, before doing an experiment with data quality measures, the settings must first be defined (including the main goal of the experiment, the subjects that will participate in the experiment, the main hypothesis under which the experiment will be run, the independent and dependent variables to be used in the model, the experimental design, the experiment running, material used and the subjects that performed the experiment). After that, the collected data validation must be discussed. Finally, the results are analyzed and interpreted to find out if they follow the formulated hypothesis. Only after a complete set of experiments, and following the method presented in Fig. 3, a measure can be accepted or rejected.

The reader is referred to the work of the Software Engineering Lab [15] for expanding the concepts about experimental process. A complete set of experimental works can be found in [11,12]. In those works several data warehouse quality measures are empirically validated as data warehouse quality indicators.

Quantiles on Streams

Chiranjeeb Buragohain[1], Subhash Suri[2]
[1]Amazon.com, Seattle, WA, USA
[2]University of California-Santa Barbara, Santa Barbara, CA, USA

Synonyms

Median; Histogram; Selection; Order statistics

Definition

Quantiles are order statistics of data: the ϕ-quantile $(0 \leq \phi \leq 1)$ of a set S is an element x such that $\phi|S|$ elements of S are less than or equal to x and the remaining $(1 - \phi)|S|$ are greater than x. This entry describes data stream (single-pass) algorithms for computing an approximation of such quantiles.

Historical Background

Since the earliest days of data processing, there has been a need to summarize data. Large volumes of raw, unstructured data easily overwhelm the human ability to comprehend or digest. Tools that help identify the major underlying trends or patterns in data have enormous value. Quantiles characterize distributions of real world data sets in ways that are less sensitive to outliers than simpler alternatives such as the mean and the variance. Consequently, quantiles are of interest to both database implementers and users: for instance, they are a fundamental tool for query optimization, splitting of data in parallel database systems, and statistical data analysis.

Quantiles are closely related to the familiar concepts of frequency distributions and histograms. The cumulative frequency distribution $F()$ is commonly used to summarize the distribution of a (totally ordered) set S. Specifically, for any value x,

$$F(x) = \text{Number of values less than } x. \qquad (1)$$

The quantile $Q(\phi)$, or the ϕ-th quantile is simply the inverse of $F(x)$. Specifically, if the set S has n elements, then the element x has the property that

$$Q(F(x)/n) = x. \qquad (2)$$

Thus, the 1⁄2-quantile is just the familiar median of a set, while 0- and 1-quantiles are the minimum and the maximum elements of the set. Histograms are another popular method for summarizing data into a smaller number of "buckets": the buckets only retain the information how many elements fall between two consecutive bucket boundaries, but not their precise values. It is easy to see that a sequence of quantiles resembles a *histogram* of the underlying set, and provides a natural and complete summary of the entire *distribution* of the data values.

In computer science, sorting and selection (another name for quantile computation) are two of the most basic problems, with long and intellectually rich history of research. Indeed, the computational complexity of selection, namely, determining the element of a given rank, is one of the earliest celebrated problems, and the elegant, linear-time algorithm of Blum et al. [2] is a classical result, taught regularly in the undergraduate algorithms and data structures course. For more recent theoretical results on the complexity of selection in the classical comparison-complexity model, please refer to the survey by Paterson [16].

Foundations

The problem with quantile computation, while well-solved in the classical model of computation, assumes a new and challenging character within the constraints of single-pass computation (the streaming model). Indeed, when the algorithm's memory is limited and significantly smaller than the size of the data set S, it is not possible to compute the quantile precisely, and the best possible solution is an approximation. This was formalized in a 1980 paper by Munro and Paterson [15], who proved that any algorithm that determines the median of a set by making at most p sequential scans of the input requires at least $\Omega(n^{1/p})$ working memory. Thus, computing the true median will require memory linear in the size of the set.

Against this backdrop, the main focus of recent research has been on achieving provable-quality approximation of the quantiles. In particular, an ε-approximate quantile summary of a sequence of n elements is a data structure that can answer quantile queries about the sequence to within a precision of εn. In other words, when queried for a ϕ-quantile, for $0 \leq \phi \leq 1$, the structure returns an element x that is guaranteed to be in the $[\phi - \varepsilon, \phi + \varepsilon]$ quantile range. The key evaluation metric for the performance of these approximation schemes is the size (memory footprint) of their summary data structures, although other factors such as simplicity of implementation are also desirable.

The discussion in this entry will focus on algorithms that operate in the *data stream* model: the algorithm is endowed with a finite memory, which is significantly smaller in size than the size of the input. The input is presented to the algorithm in an arbitrary (perhaps adversarial) order, and any data not explicitly stored by the algorithm is irretrievably lost. Thus, the algorithm is restricted to a single scan of the data in the input order, and after this scan it must output an approximation of the quantiles of the input values.

Before discussing the state of the art for this problem, it may help to consider a real-world scenario for the use of quantiles in data streams, both to illustrate a motivating application and to appreciate the scale of the problem. A web site, such as a search engine, consists of several web server hosts. The users' queries (requests) are collectively handled by these servers (using some scheduling protocol); and the overall performance of the web site is characterized by the latency (delay) encountered by the users. The distribution of the latency values is typically very skewed, and a common practice is to track some particular quantiles, for instance, the 95th percentile latency. In this context, one can ask several questions.

- What is the 95th percentile latency of a single web server?
- What is the 95th percentile latency of the entire web site (over all the servers)?
- What is the 95th percentile latency of the website during the last 1 h?

The Yahoo website, for instance, handles more than 3.4 billion hits per day, which translates to 40,000 requests per second. The Wikipedia website handles 30,000 requests per second at peak, with 350 web servers.

While all three questions relate to computing of quantiles, they have different technical nuances, and often require different algorithmic approaches. In particular, the first question is the most basic version, asking for a determination of quantiles for a stream of data; the second extends the setting to *distributed input*, and thus demands an algorithm in the distributed computing model. The third problem is an instance of the *sliding window* model, where the computation must occur over a subset (time window) of the stream, and this subset is continuously changing. This entry is primarily focused on the stream setting (problem 1), also known as the cash register model, but will also discuss, when appropriate, extensions to these other models.

Randomized Algorithms

One can estimate the quantiles of a stream by the quantiles of a random sample of the input. The key idea is to maintain a random sample of appropriate size and when asked for a quantile of the input set, simply report the corresponding quantile of the random sample. If the size of the input stream, N is known, then the following simple algorithm can compute a random sample of size k in one-pass: choose each element independently with probability k/N to include in the sample. If the size of the full data stream is not known in advance, or if the ability to answer queries during reading the stream is required as well, then the reservoir sampling algorithm of Vitter [19] can be used instead. To maintain a sample of size k, the reservoir sampling algorithms begins by including the first k stream elements in the sample; from then on, the ith element from the stream is chosen with probability i/n. If the ith element is chosen, one of the elements from the current sample is evicted uniformly at random to keep the size of the sample constant at k. While straightforward to implement, random sampling has the disadvantage of needing a rather large sample to achieve expected approximation accuracy. Specifically, in order to estimate the quantiles with precision εn, with probability at least $1 - \delta$, a sample of size $\Theta(\frac{1}{\epsilon^2}\ \log\ \frac{1}{\delta})$ is required, where $0 < \delta < 1$.

In [3], Cormode and Muthukrishnan proposed a more space-efficient data structure, called Count-Min sketch, which is inspired by Bloom filters. Count-Min sketch allows ε-approximation of quantiles using $O(\frac{1}{\epsilon}\log^2 n \log(\frac{\log n}{\phi\delta}))$ memory. Although the space needed by Count-Min is worse than the two deterministic schemes discussed below, it has the advantage of allowing general updates to the streams: past elements can be deleted as well as their values updated.

Deterministic Algorithms

The first deterministic streaming algorithm for quantiles was proposed by Manku et al. [13,14], building on the prior work by Munro and Paterson [2]. This algorithm has space complexity $O(\frac{1}{\epsilon}\log^2 \epsilon n)$, meaning that using memory that grows poly-logarithmically in the stream size and inversely with the accuracy parameter ε, the quantiles can be estimated with precision εn. This result has since been improved by two groups: in [10], Greenwald and Khanna propose a $O(\frac{1}{\epsilon}\, log\ \epsilon n)$ memory scheme, and in [18], Shrivastava et al. propose a $O(\frac{1}{\epsilon}\log U)$ memory scheme, where U is the size of domain from which the input is drawn.

The Greenwald-Khanna (GK) algorithm is based on the idea that if a sorted subset $\{v_1, v_2, \ldots\}$ of the input stream S (of current size n) can be maintained such that the ranks of v_i and v_{i+1} are within 2ε of each other, then an arbitrary quantile query can be answered with precision εn. Their main contribution is to show how to maintain such a subset of values using a data structure of size $O(\frac{1}{\epsilon}\log \epsilon n)$. The Q-Digest scheme of Shrivastava et al. [18] approaches the quantile problem as a histogram problem over a universe of size U; thus $\log U$ is the number of bits needed to represent each element. Q-Digest maintains a set of buckets dynamically, merging those that are light (containing few items of the stream) and splitting those that are heavy, with an aim to keep the relative sizes of all the buckets nearly equal. Specifically, using a $O(\frac{1}{\epsilon}\log U)$ size data structure, Q-Digest ensures that the input stream is divided into $O(1/\epsilon)$ buckets, with each bucket containing $O(\epsilon n)$ items. Thus, the rank of any item can be determined with precision εn by locating its bucket.

In theoretical terms, the GK scheme has better performance when the input is drawn from a large universe, but the stream itself has only modest size. The Q-Digest, on the other hand, is superior when the stream size is huge but elements are drawn from a smaller universe. The GK algorithm is very clever, but requires a sophisticated analysis. The Q-Digest is simpler to understand, analyze, and implement, and it lends itself to easy extensions to distributed settings.

Practical Considerations

A detailed study of the empirical performance of quantile algorithms was carried out by Cormode et al. [5] on IP stream datasets. They concluded that with careful implementation, a commodity hardware machine (dual Pentium 2.8 GHz CPU and 4 GB RAM) can keep up with a 2 Gbit/s stream (310,000 packets per second). Performance numbers can depend also on the input distribution. For example, the deterministic algorithms presented above can have different memory usage and accuracy depending on the order in which the input values are presented, but sketching techniques such as the Count-Min sketch are not affected by the order of the input. The input value distribution can also impact perceived accuracy of the approximate quantiles. For example, for skewed distributions, the *numeric value* of the exact ϕ-th quantile can be arbitrarily far from the numeric values of the $(\phi \pm \epsilon)$-th quantile.

Extensions

Given the fundamental nature of quantiles and their widespread applications in data processing, it is no surprise that there are multiple extensions of the basic setting that have been considered so far. There are many interesting and practically-motivated applications, such as the latency of the web site mentioned earlier, where quantiles must be computed over distributed data, or over a sliding window portion of the stream etc. In the following, the current state of algorithms for these variants are briefly discussed.

Quantiles in Distributed Streams In many settings, data of interest are naturally distributed across multiple sources, such as servers in a web application and measurement devices in a sensor network. In these applications, it is necessary to compute the quantile summary of the entire data, but *without* creating a centralized repository of data, which could be undesirable because of the additional latency, communication overhead, or energy constraints of untethered sensors. The efficiency of an algorithm in this distributed setting is measured by the amount of information each node in the system must transmit during the computation.

One natural approach for distributed approximation of quantiles is for each node (server, sensor, etc.) to compute a local summary of its data, and arrange the nodes in a virtual hierarchy that guides them to merge these summaries into a final structure computed at the root of the hierarchy. The tree-based Q-digest [18] algorithm extends rather easily to the distributed setting, as the histogram boundaries of the Q-Digest are aligned to binary partition of the original value space U. The space complexity of the distributed version remains the same as the stream version, namely, $O(\frac{1}{\epsilon}\log U)$. The GK algorithm is little more complicated to extend to distributed streams, but Greenwald and Khanna themselves developed such an extension in [9]. However, the space complexity of their distributed data structure grows to $O(\frac{1}{\epsilon}\log^3 n)$ [9]. The Bloom filter based Count-Min sketch [3] also extends easily to the distributed setting also without any increase in the space complexity.

Quantiles in Sliding Windows In many applications, the user is primarily interested in the most recent portion of the data stream. This poses the *sliding window* extension of the quantiles problem, in which the desired quantile summary for the most recent N data elements – the window slides with the arrival of each new element, as the oldest element of the window is discarded and the new arrival added. In [12], Lin et al. presented such a sliding window scheme for quantile summaries, however, the space requirement for their algorithm is $O(\frac{1}{\epsilon^2} + \frac{1}{\epsilon}\log \epsilon^2 N)$. This was soon improved by Arasu and Manku [1] to $O(\frac{1}{\epsilon}\log\frac{1}{\epsilon}\log N)$.

Biased Estimate of Quantiles The absolute measure of approximation precision is quite reasonable as long as the error εn is quite small compared to the rank of the quantile sought, namely, ϕn. This holds as long as the quantiles of interest are in the middle of the distribution. But if ϕ is either close to 0 or 1, one may prefer a *relative* error, so that the estimated quantile is in the range $[(1-\varepsilon)\phi, (1+\varepsilon)\phi]$. This variant was solved by Gupta and Zane [13] using random sampling techniques with a $O(\frac{1}{\epsilon^3}\log n \log\frac{1}{\delta})$ size data structure. The space bound has since been improved by Cormode et al. [4] to $O(\frac{1}{\epsilon}\log U \log(\epsilon n))$ using a deterministic algorithm.

Duplicate Insensitive Quantiles In some distributed settings, a single event can be observed multiple times. For example in the Internet, a single packet is observed at multiple routers. In wireless sensor networks, due to the broadcast nature of the medium, and to add fault-tolerance, data can be routed along multiple paths. Summaries such as quantiles or the number of distinct items are clearly not robust against duplication of data; on the other hand, simpler statistics such as minimum and maximum are not affected by duplication. Flajolet and Martin's distinct counting algorithm [8] is the seminal work in this direction. Cormode et al. have introduced algorithms based on sampling to compute various duplicate insensitive aggregates [6]. Their Count-Min sketch can be also easily adapted to compute duplicate insensitive quantiles.

Key Applications

Internet-scale network monitoring and database query optimization are two important applications that originally motivated the need for quantiles summaries over data streams. Gigascope [7] is a streaming database system that employs statistical summaries such as quantiles for monitoring network applications and systems. Quantile estimates are also widely used in query optimizers to estimate the size of intermediate results, and use those estimates to choose the best execution plan [5]. Distributed quantiles have been used to succinctly summarize the distribution of values occurring over a sensor network [8]. In a similar context, distributed quantiles are also used to summarize performance of websites and distributed applications [17].

Future Directions

The field of computing approximate quantiles over streams have led to a fertile research program and is expected to bring up new challenges in both theory and implementation. Although there is an obvious lower bound of $\Omega(\frac{1}{\epsilon})$ memory required to compute ε-approximate quantiles, there is no known non-trivial lower bound on memory. Since the current best algorithms requires $O(\frac{1}{\epsilon}\log(\epsilon n))$ or $O(\frac{1}{\epsilon}\log(U))$ memory, it will be useful to either lower the memory usage or prove a better lower bound.

Another direction in which improvements are highly desirable is running time. The current deterministic algorithms require amortized running time of $O(\log\frac{1}{\epsilon} + \log\log(\epsilon n))$ or $O(\log\frac{1}{\epsilon} + \log\log(U))$ per item. In high data-rate streams, even such low processing times are not fast enough: what is desired is a $O(1)$ insert time, or even a sublinear time quantile algorithm. As of now, there is no memory efficient sub-linear time quantile algorithm known except for random sampling.

Quantitative Association Rules

Xingquan Zhu
Florida Atlantic University, Boca Ration, FL, USA

Synonyms

Numeric association rules

Definition

Quantitative association rules refer to a special type of association rules in the form of $X \rightarrow Y$, with X and Y consisting of a set of numerical and/or categorical attributes. Different from general association rules where both the left-hand and the right-hand sides of the rule should be categorical (nominal or discrete) attributes, at least one attribute of the quantitative association rule (left or right) must involve a numerical attribute. Examples of this type of association rule can be categorized into the following two classes, depending on whether the rules are measured by the frequency of the supporting data records or by some distributional features of some numerical attributes.

1. *Frequent Rules:* Out of all applicants whose age is between 30 and 39 and marriage status is "yes," (→) 95% of them have two cars, and 10% applicants in the database satisfy this rule.
2. *Distributional Rules:* If the patient is non-smoker and wine-drinker then (→) his/her average life expectancy is 85 (whereas the average life expectancy in the overall population is 80).

In the above first example, "applicant age" is a numerical attribute, and "marriage status" and "# of cars" are categorical attributes. The support and confidence measures indicate that out of all the data records matching the left-hand of the rule, 95% of them satisfy the whole rule (*Confidence*) and there are 10% of the data records which hold this rule (Support). The key to discovering this type of rules is to discretize numerical attributes into discrete regions, so the frequency of the data records satisfying the rule can be measured and the general Apriori-based association rule mining approaches [1] can apply.

Distributional rules denote a set of quantitative association rules with instances covered by the rules rendering themselves statistically different from the overall population (with respect to some statistical measures, such as mean and standard deviation values). Because the calculation of the statistical values over numerical attributes is straightforward, attribute discretization is unnecessary, which consequently avoids possible information loss from the data discretization. The key to discovering this type of rules is to find a small group of instances (with respect to the left-hand side of the rules) statistically and significantly different from the overall population, if the right-hand of the rules is considered.

Historical Background

The problem of discovering quantitative association rule was first introduced by Srikant and Agrawal [4], and the main focus then was to discover frequent rules. The solution proposed in the paper [4] adopts a data discretization for mining association rules. Their approach first partitions the values of the numerical attributes into fine intervals and then combines adjacent intervals if necessary. A partial completeness measure was introduced to quantify the information loss due to the partitioning, so the algorithm can properly determine the number of partitions. Traditionally, numerical attribute discretization can be achieved through the following two approaches, with the latter preferred in practice:

- *Equal-width discretization* divides the range of a numerical attribute into N intervals of equal width. For example, ages from 20 to 60 can be divided into four intervals of 10-year width. This method can be easily implemented, but subject to a clear drawback that there may be too few instances in some intervals and too many in other intervals, and both cases hinder mining high quality association rules.
- *Equal-depth discretization* divides the range of numerical attribute into N intervals such that each interval equally contains $1/N$ of the total instances. This method avoids the possible imbalance inherent in the equal-width discretization method, but it may separate similar attribute values into different intervals and group dissimilar attributes into the same interval.

Noticing the adoption of the information discretization can lead to unavoidable information loss or misleading association rules, Aumann and Lindell [2] suggested distributional quantitative association rules, where the general structure of the rules take the form of:

$$\text{population} - \text{subset} \rightarrow \text{interesting} - \text{behavior}$$

More specifically, the left-hand of the rule confines a population subset, whereas the right-hand of the rule provides the statistical measures of the confined subset. The objective is to discover subsets significantly different from the whole population (with respect to the underlying measures, e.g., mean or standard deviation values). Following this principle, Webb [5] extended the framework to include other measures such as the minimum and the count measures.

Foundations

Frequent Rules

To demonstrate the procedures of the frequent quantitative association rule discovery, take the toy database in Fig. 1(a) as an example [4], where attribute "Age" is numerical, and "Married" and "NumCars" are categorical attributes. Assuming the user specified *Support* and *Confidence* values are 40% and 50% respectively, it means that a prospective rule (the left-hand and the right-hand together) should cover at least two records (5 × 40%). For all data records satisfying the left-hand of the rule, 50% of them should also contains the right-hand sides of the rule ($X \rightarrow Y$). The major steps of discovering frequent quantitative association rules can then be summarized as follows [4]:

1. Determining the partition numbers and the region of partitioning for each numerical attribute. E.g., Fig. 1(a) lists four partitions for "Age" (denoted by [20,24], [25,29], [30,34], and [35,39]), with each region mapping to one integer value {1,2,3,4}.
2. Applying each mapping table to all records of the corresponding numerical attribute, with numerical values replaced by the matching integer values. The example of the mapped database is shown in Fig. 1(c).
3. Generating frequent itemsets based on the mapped database and the user specified *Support* value (the existing Apriori like association rule mining methods can be applied directly).
4. Using discovered frequent itemsets to generate quantitative association rules, with each frequent itemset decomposed into two (left- and right-hand) components. For example, if itemset "ABCD" is found frequent, a possible quantitative association rule can be made by decomposing "ABCD" as "AB" → "CD." As long as the validate check asserts that confidence value of this rule ("AB" → "CD") is greater than the user specified value (*Confidence*), the rule is taken as a valid rule.
5. Collect all quantitative association rules generated from the above process and prune redundant rules. *E.g.*, if "AB" → "CD" and "AB" → "CDE" are both valid rules, "AB" → "CD" can be pruned as it can be generalized (inferred) from "AB" → "CDE".

⟨Age: 30..39⟩ and ⟨Married: Yes⟩ ⇒ ⟨Numcars: 2⟩	40%	100%
⟨Age: 20..29⟩ ⇒ ⟨Numcars: 0.1⟩	60%	66.6%

Quantitative Association Rules. Figure 1. Example of problem decomposition for quantitative association rule mining (revised from [2]).

Distributional Rules

Different from the frequent quantitative association rules, where the main challenge is to determine the "optimum" number of partitions and the region of partitioning, the distributional rules represent a set of quantitative association rules, where the statistical features of the samples covered by the rule are different from the whole population. Similar to general association rules, the distributional rules also contain the left- and the right-hand. The left-hand side of the rule is a description of a subset of the database, while the right-hand side provides a description of outstanding behaviors of this subset. A rule is only interesting if the mean for the subset (specified by the left-hand side) is significantly different from the rest and is therefore unexpected. Consider the following distributional rule, the left-hand side consists of two categorical attributes (Non-smoker: {Yes or No}, and Wine-drinker: {Yes or No}), and the right-hand side is a numerical attribute (life expectancy). The rule is considered informative and meaningful as it indicates that individuals characterized by the left-hand side of the rule (Non-smoker and wine-drinker) have a longer average life expectancy (85) than the whole population (80).

$$\begin{aligned}&\text{Non} - \text{smoker and wine} - \text{drinker}\\&\quad \rightarrow \text{life expectancy} = 85\ (\text{overall} = 80)\end{aligned}$$

Following this definition, one can easily extend the framework to allow one or multiple numerical attributes to appear on the left- or right-hand sides of the rule (or both), or employ other statistical measures rather than the mean values to assess the rules.

In order to discover distributional rules, Aumann and Lindell [3] proposed two methods to discover the following two types of rules:

- $X \rightarrow Mean_J\ (T_X)$, where X and J denote a single numerical attribute, T_X denotes transactions confined by attribute X and $\text{Mean}_J(T_X)$ represents the mean value of attribute J (for all samples in T_X).
- $X \rightarrow M_J\ (T_X)$, where X denotes one or multiple categorical attributes, J consists of one or multiple quantitative attributes, and M means one particular statistical measure (there is no restriction on the number of attributes in X and J).

The solution to the first type of distributional rules is straightforward, since the rules only involve two numerical attributes (one on each side), an algorithm can afford to go through each pair of numerical attributes to discover meaningful rules. More specifically, for any two numerical attributes *i* and *j*, one can first sort all records in the database based on the attribute *i*, then any above or below average continuous region of values in *j* can form a prospective quantitative rule. For example, given the toy database in Fig. 2(a) which records the age and the size of the striped bass, the sorted database with respect to attribute *i* (age) is given in Fig. 2(a). The average of attribute *j* for the top three records (001, 003, and 002) is 0.77, which is significantly lower than the mean of the whole population (1.83). Therefore, the below average region (001, 003, and 002) forms a meaningful quantitative association rule denoted by:

$$\text{Age} \leq 2 \rightarrow \text{Mean weight } 0.77 \text{ lbs (Overall } 1.83)$$

Because any above or below average continuous region of values in *j* can form a prospective quantitative rule, one can continuously span the region with respect to the attribute *j*, and discover the maximum region satisfying the user specified requirements (e.g., α times less/larger than the average).

In order to discover the second type of distributional quantitative association rules, one can employ a two-stage approach, which applies general association rule to the whole database by considering categorical attributes only, followed by a refining process to check each rule by considering the numerical attribute values [5].

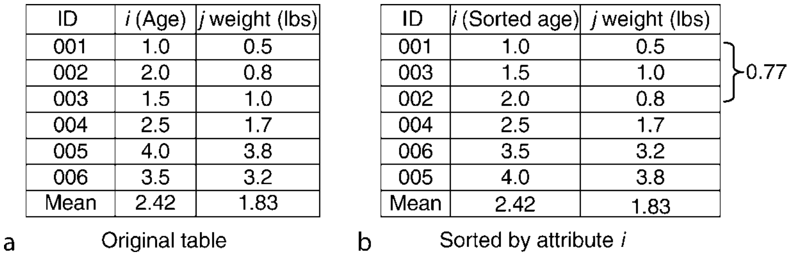
1. *Discovering frequent itemsets:* Finding all frequent itemsets by considering categorical attributes of the database only (this can be easily achieved through existing Apriori-like algorithms [1].
2. *Calculating statistical distribution values:* For each numerical attribute, calculate the value of the distribution measures (mean/variance) over samples confined by each frequent itemset. For example, if "Non-smoker and Wine-drinker" are found frequent (i.e.,, a frequent itemset), all samples matching this itemset form a sample set *P*, from which the statistical distribution value of a numerical attribute can be calculated.
3. *Refining quantitative association rules:* For every frequent itemset (denoted by *X*) and one numerical attribute *e*, the algorithm continuously check if $X \rightarrow Mean_e\ (T_X)$ and $X \rightarrow Variance_e\ (T_X)$ are meaningful rule (comparing to the whole population). In addition, for any two rules $X \rightarrow Mean_e\ (T_X)$ and $Y \rightarrow Mean_e\ (T_Y)$, the algorithm will check whether the former is a sub-rule of the latter, or vice versa, such that the algorithm can output compact rules with minimum redundancy.

Key Applications

Business intelligence, market basket analysis, fraud detection (fraud medical insurance claims).

Future Directions

All of the above techniques intend to discover quantitative association rules in the forms of the conjunction of individual attributes. One interesting problem is to find quantitative association rules with (linearly or nonlinearly) combined attributes. For example, finding rules like "Age $\leq \alpha \rightarrow$ Length/Weight $\leq \beta$." Here the right-hand of the rule is a non-linear combination of the numerical attributes (Length and Height), and α and β are some discovered values. In [3], *Ruckert* et al. proposed a quantitative association rule mining approach which is able to discover similar rules with linearly weighted attributes like "Age $\leq \alpha \rightarrow \alpha_1$·Length + α_2·Weight $\leq \beta$." Future research may emphasize the generalized quantitative association



ID	*i* (Age)	*j* weight (lbs)

Quantitative Association Rules. Figure 2. Example of distributional association rule mining (age and weight of the striped bass).

rule discovery, where rules consist of non-linearly combined attributes.

Another interesting problem concerning quantitative association rules is to discover relational patterns of the quantitative association rules across multiple databases. *E.g.*, Finding patterns that are frequent with a support level of α in database A, but significantly infrequent with a support level of β in databases B or/and C. In [6], Zhu and Wu proposed a hybrid frequent pattern tree based solution to address this problem with a focus on the general association rules. Extending the problem of relational frequent pattern discovery to quantitative association rules is another interesting topic for future research.

QUEL

Tore Risch
Uppsala University, Uppsala, Sweden

Definition

QUEL was the query language used in the original Ingres system from Berkeley University.

Key Points

QUEL was one of the first relational database query languages. It can be seen as a syntactically sugared tuple relational calculus language. The Postgres extension of Ingres originally used an extention of QUEL called PostQUEL, but was later replaced with SQL.

Synonyms

Music retrieval; Time series database querying

Definition

With the appearance of large scale audio and video databases in various application areas, novel information retrieval methods adapted to the specific characteristics of these data types are required. A natural way of searching in a musical audio database is by humming the tune of a song as a query, which is so-called "query by humming". In this entry, state-of-the-art techniques for effective and efficient querying by humming are described.

Historical Background

In 1995, Asif Ghias et al. [1] proposed the basic architecture for a system supporting query by humming. Three main components are introduced in the system: a pitch-tracking module, a melody database, and a query engine. Queries are hummed into a microphone, digitized, and fed into a pitch-tracking module. Then, a symbol sequence representation upon the relative pitch transitions of the hummed melody is sent to the query engine, which produces a ranked list of matching melodies.

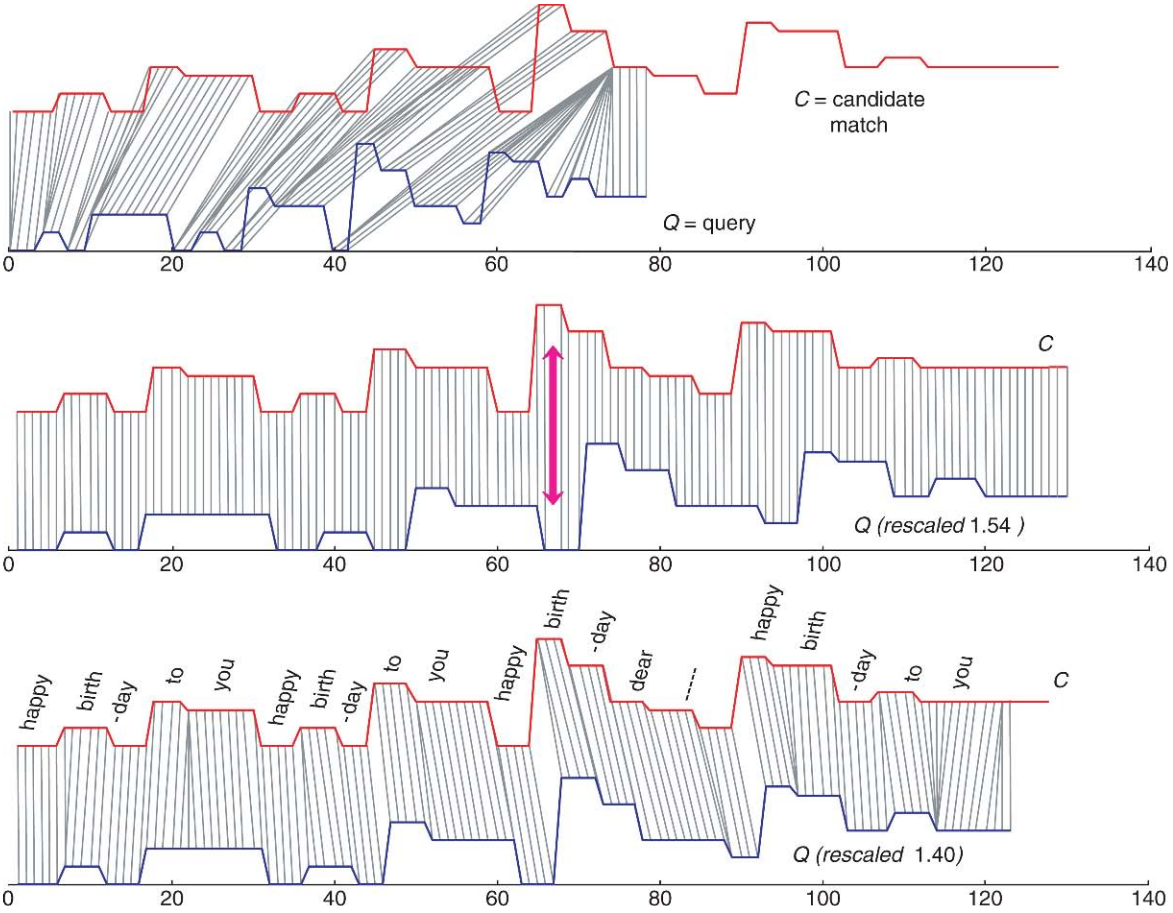
Foundations

In recent researches, musical data are modeled as time series which are real valued sequences rather than symbol sequences. In speech comparisons, small fluctuation of the tempo of the speaker could be allowed in order to identify similar contents. There have been some works that match a melody more effectively by considering warping and scaling in humming queries. This generally gives better query results because it is free from the error-prone note segmentation. However, those works rely on distance measures such as universal scaling (US), dynamic time warping (DTW) [2,4] and scaling and time warping (SWM) [5], the efficiency might be rather poor. Fortunately, tight lower bounds for DTW and SWM could greatly improve the efficiency by pruning large portions of non-candidate data at an early stage.

Comparisons of Distance Measures on Examples

Figure 1 demonstrates the effects of different distance measures with a typical piece of music, *Happy Birthday to You*, from top to bottom:

1. Since the query sequence is performed at a much faster tempo, direct application of DTW fails to produce an intuitive alignment;



Query by Humming. Figure 1. Motivating example.

2. Rescaling the shorter performance by a scaling factor of 1.54 seems to improve the alignment, but the higher pitched note produced on the third "*birth...*" of the candidate is forced to align with the lower note of the third "*happy...*" in the query;
3. Only the application of *both* uniform scaling and DTW produces the appropriate alignment.

Dynamic Time Warping (DTW)

Intuitively, *dynamic time warping* is a distance measure that allows time series to be *locally* stretched or shrunk before the base distance measure is applied. Given two sequences $C = C_1, C_2,...,C_n$ and $Q = Q_1, Q_2,...,Q_m$, the time warping distance DTW is defined recursively as follows:

$$\begin{aligned}
\text{DTW}(\phi,\phi) &= 0\\
\text{DTW}(C,\phi) = \text{DTW}(\phi,Q) &= \infty\\
\text{DTW}(C,Q) &= D_{base}(\text{First}(C),\text{First}(Q))+\\
&\min\begin{cases}\text{DTW}(C,\ \text{Rest}(Q))\\ \text{DTW}\ (\text{Rest}(C),\ Q)\\ \text{DTW}\ (\text{Rest}(C),\text{Rest}(Q))\end{cases}
\end{aligned}$$

where Φ is the empty sequence, $\text{First}(C) = C_1$, $\text{Rest}(C) = C_2, C_3,...,C_n$, and D_{base} denotes the distance between two entries. Several L_p measures were used as the D_{base} distance in previous literature, such as Manhattan Distance (L_1), squared Euclidean Distance (L_2) and maximum difference (L_∞). Typically *Squared Euclidean Distance* is used as the D_{base} measure. That is,

$$D_{base}(C_i, Q_j) = (C_i - Q_j)^2.$$

Thus in the following parts, without loss of generality, it is assumed that D_{base} is the squared Euclidean Distance and D is also used to denote it. However, the time complexity of DTW distance calculation is *O(mn)*, and intensive computations are employed for the corresponding dynamic programming. Thus, lower bounds on the distance are adopted to effectively prune the search space and support efficient search.

Constraints and Lower Bounds on Dynamic Time Warping

Keogh et al. [2] viewed a global constraint as a constraint on the warping path entry $w_k = (i, j)_k$ and gave a general form of global constraints in terms of inequalities on the indices to the elements in the warping matrix,

$$j - r \le i \le j + r$$

where r is a constant for the Sakoe–Chiba Band and r is a function of i for the Itakura Parallelogram. Incorporating the global constraint into the definition of dynamic time warping distance, DTW can be modified as follows.

Given two sequences $C = C_1,C_2,...,C_n$ and $Q = Q_1, Q_2,...,Q_m$, and the time warping constraint r, the constrained time warping distance cDTW is defined recursively as follows:

$$\begin{aligned}
Dist_r\,(C_i, Q_j) &= \begin{cases}D_{base}\,(C_i, Q_j) & if|\ i\ -\ j\ |\ \le r\\ \infty & otherwise\end{cases}\\
{}_{C}\text{DTW}(\phi,\phi,r) &= 0\\
{}_{C}\text{DTW}(C,\phi,r) &= {}_{C}\text{DTW}(\phi,\ Q,\ r) = \infty\\
{}_{C}\text{DTW}(C,Q,r) &= Dist_r(\text{First}(C),\ \text{First}(Q))+\\
&\min\begin{cases}{}_{C}\text{DTW}((C,\ \text{Rest}(Q),r)\\ {}_{C}\text{DTW}(\ (\text{Rest}(C),\ Q,\ r)\\ {}_{C}\text{DTW}((\text{Rest}(C),\ \text{Rest}(Q),r)\end{cases}
\end{aligned}$$

where Φ is the empty sequence, $\text{First}(C) = C_1$, $\text{Rest}(C) = C_2, C_3,...,C_n$. The *upper bounding sequence UW* and the *lower bounding sequence LW* of a sequence C are defined using the time warping constraint r as follows.

Let $UW = UW_1, UW_2,...,UW_n$ and $LW = LW_1, LW_2,...,LW_n$,

$$\begin{aligned}
UW_i &= \max(C_{i-r},...,C_{i+r}) \text{ and}\\
LW_i &= \max(C_{i-r},...,C_{i+r})
\end{aligned}$$

Considering the boundary cases, the above can be rewritten as

$$\begin{aligned}
UW_i &= \max(C_{\max(1,i-r)},...,C_{\min(i+r,n)}) \text{ and}\\
LW_i &= \min(C_{\min(1,i-r)},...,C_{\min(i+r,n)})
\end{aligned}$$

$E(C) = < UW, LW >$ is called the envelope sequences of Keogh et al. [2] propose the lower bound distance LB_Keogh based on envelope sequences. The time warping distance between two sequences Q and C is lower bounded by the squared Euclidean distance between Q and the envelope sequences of C. Equation (1) below formally defines the lower bounding distance.

$$\begin{aligned}
\text{LB\_Keogh}(Q,\ C) &= D\,(Q,\ E(C))\\
&= \sum_{i=1}^{m}\begin{cases}(Q_i - UW_i)^2\ if & Q_i > UW_i\\ (Qi - LW_i)^2\ if & Q_i < LW_i\\ 0 & \text{otherwise}\end{cases}
\end{aligned} \qquad (1)$$

Zhu et al. [3] further improve on LB_Keogh. If a transformation T is a linear transform and lower-bounding, and $Env_r(C_i)$ is the envelope of C_i by global constraint r then

$$D(T(Q),\ T(Env_r(C_i))) \leq \mathrm{cDTW}(\mathrm{Q},\ \mathrm{C_i}\ ,\ \mathrm{r}) \quad (2)$$

Therefore transforms such as PAA, DWT, SVD and DFT on the envelope sequence of a candidate sequence could still lower bound DTW distance, since those transforms are both linear and lower bounding.

Uniform Scaling (US)

Given two sequences $Q = Q_1,\ldots,Q_m$ and $C = C_1,\ldots,C_n$ and a scaling factor bound $l, l \geq 1$. Let $C(q)$ be the prefix of C of length q, where $\lceil m/l \rceil \leq q \leq lm$ and $C(m,q)$ be a rescaled version of $C(q)$ of length m,

$$C(m,\ q)_i\ =\ C(q)_{\ \lceil i.q/m \rceil} \text{ where } 1\ \leq\ \mathrm{i}\ \leq\ \mathrm{m}$$

$$\mathrm{US}(C, Q, l) = \min_{\mathrm{q}=\lceil m/l \rceil}^{min(lm,n)} D(C(m,q), Q)$$

where D(X, Y) denotes the Euclidean distance between two sequences X and Y.

Lower Bounding Uniform Scaling

The two sequences $UC = UC_1,\ldots,UC_m$ and $LC = LC_1,\ldots, LC_m$, such that

$$UC_i = \max(C_{\lceil i/l \rceil},\ldots,C_{\lceil il \rceil})$$
$$LC_i = \min(C_{\lceil i/l \rceil}),\ldots,C_{\lceil il \rceil})$$

bound the points of the time series C that can be matched with Q. The lower bounding function, which lower bounds the distance between Q and C for any scaling ρ, $1 \leq \rho \leq l$, can now be defined as:

$$LB_s(Q, C) = \sum_{i=1}^{m} \begin{cases} (Q_i - UC_i)^2 & \text{if } Q_i > UC_i \\ (Q_i - LC_i)^2 & \text{if } Q_i < UC_i \\ 0 & \text{otherwise} \end{cases} \quad (3)$$

Scaling and Time Warping (SWM)

Having reviewed time warping, uniform scaling, and lower bounding, this part introduces *scaling and time warping* (SWM) distance. Given two sequences $Q = Q_1,\ldots,Q_m$ and $C = C_1,\ldots,C_n$, a bound on the scaling factor $l, l \geq 1$ and the Sakoe–Chiba Band time warping constraint r which applies to sequence length m. Let $C(q)$ be the prefix of C of length q, where $\lceil m/l \rceil \leq q \leq \min(lm, n)$ and $C(m, q)$ be a rescaled version of $C(q)$ of length m,

$$\mathrm{C}(m, q)i = C(q)_{\lceil i.q/m \rceil} \text{ where } 1 \leq i \leq m$$

$$\mathrm{SWM(C, Q, l, r)} = \min_{\mathrm{q=\lceil m/l \rceil}}^{\mathrm{min(lm,n)}} \mathrm{cDTW(C(m, q), Q, r)}$$

If time warping is applied on top of scaling, i.e., the sequence is first scaled, and then measure the time warping distance of the scaled sequence with the query. Typically, time warping with Sakoe–Chiba Band constrains the warping path by a fraction of the data length, which is translated into a constant r. Hence, if the fraction is 10%, then $r = 0.1|C|$. If the length of C is changed according to the scaling fraction ρ, that is, C is changed to ρC, then the Sakoe–Chiba Band time warping constraint is $r = 0.1|\rho C|$. Hence, $r = r'\rho$, where r' is the Sakoe–Chiba Band time warping constraint on the unscaled sequence, and ρ is the scaling factor.

Lower Bounding SWM

The lower envelope L_i and upper envelope U_i on C can be deduced as follows: recall that the upper and lower bounds for uniform scaling between $1/l$ and l is given by the following:

$$UC_i = \max(C_{\lceil i/l \rceil},\ldots,C_{\lceil il \rceil})$$
$$LC_i = \min(C_{\lceil i/l \rceil},\ldots,C_{\lceil il \rceil})$$

and the upper and lower bounds for a Sakoe –Chiba Band time warping constraint factor of r for a point C_i is given by:

$$UW_i = \max(C_{\max(1,i-r)},\ldots,C_{\min(i+r,n)})$$
$$LW_i = \min(C_{\max(1,i-r)},\ldots,C_{\min(i+r,n)})$$

Therefore, when time warping is applied on top of scaling the upper and lower bounds will be:

$$\begin{aligned} U_i &= \max(\mathrm{UW}_{\lceil i/l \rceil},\ldots,UW_{\lceil il \rceil}) \\ &= \max(C_{\max(1,\lceil i/l \rceil - r')},\ldots,C_{\min(\lceil i/l \rceil + r',n)},\ldots, \\ &\qquad C_{\max(1,\lceil il \rceil - r')},\ldots,C_{\min(\lceil il \rceil + r',n)}) \\ &= \max(C_{\max(1,\lceil i/l \rceil - r')},\ldots,C_{\min(\lceil il \rceil + r',n)}) \end{aligned} \quad (4)$$

$$\begin{aligned} L_i &= \min(\mathrm{LW}_{\lceil i/l \rceil},\ldots,LM_{\lceil il \rceil}) \\ &= \min(C_{\max(1,\lceil i/l \rceil - r')},\ldots,C_{\min(\lceil i/l \rceil + r',n)},\ldots, \\ &\qquad C_{\max(1,\lceil il \rceil - r')},\ldots,C_{\min(\lceil il \rceil + r',n)}) \\ &= \min(C_{\max(1,\lceil i/l \rceil - r')},\ldots,C_{\min(\lceil il \rceil + r',n)}) \end{aligned} \quad (5)$$

In [4], the lower bound function which lower bounds the distance between Q and C for any scaling in the range of {1/*l*,*l*} and time warping with the Sakoe–Chiba Band constraint factor of r' on C is given by:

$$LB(Q,C) = \sum_{i-1}^{m} \begin{cases} (Q_i - U_i)^2 & \text{if } Q_i > U_i \\ (Q_i - L_i)^2 & \text{if } Q_i < L_i \\ 0 & \text{otherwise} \end{cases} \qquad (6)$$

Efficient Pruning Algorithm by Lower Bounds

Algorithm 1 gives the pseudocode for the search algorithm, which utilizes the computational efficient lower bounds on computational intensive distance measures to prune candidate sequences at an early stage. “real_distance” could be DTW, US, or SWM distance, while “lower_bound_distance” denotes the corresponding lower bound.

```
Algorithm 1: Lower_Bounding_Sequential_Scan(Q)
best_so_far = infinity;
for each sequence with index i in database do
    LB_dist = lower_bound_distance($C_i$, $Q$);
    if LB_dist < best_so_far then
        true_dist = real_distance($C_i$, $Q$);
        if true dist < best_so_far then
            best_so_far = true_dist;
            index_of_best_match = $i$;
        end
    end
end
```

Key Applications

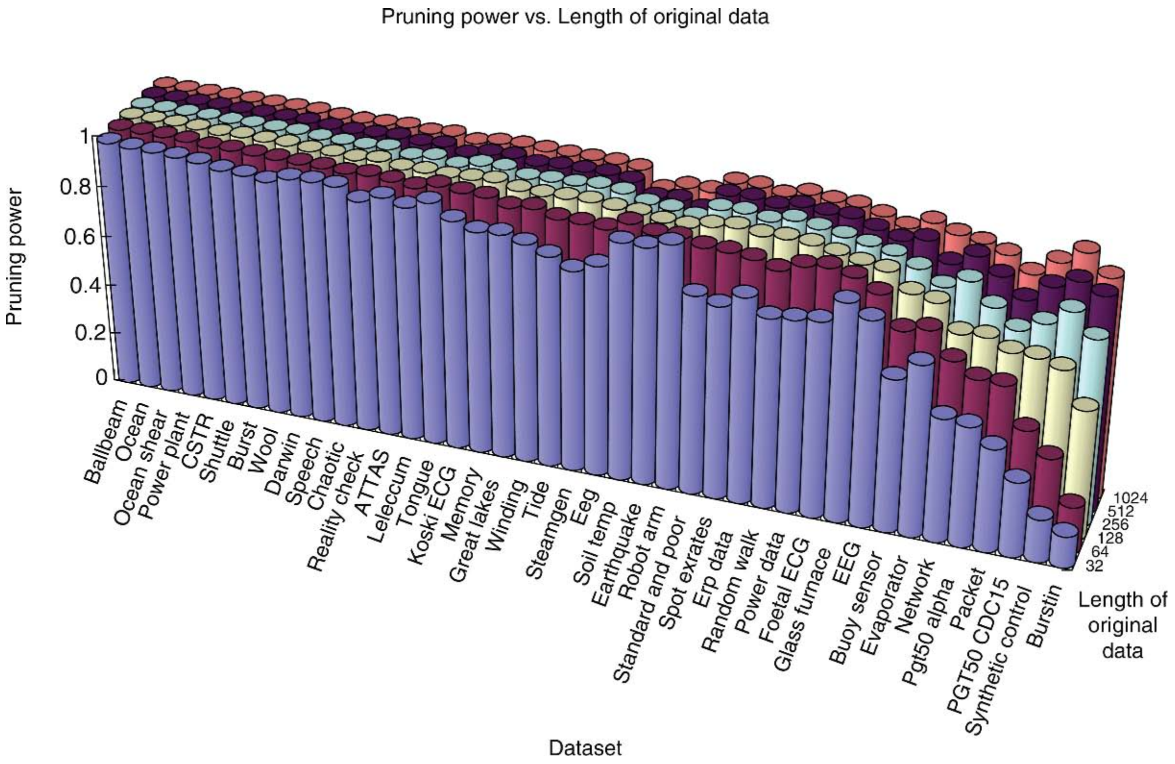
Query by humming is essential for audio information retrieval in terms of both effectiveness and efficiency.

Future Directions

In [3], a unified framework is proposed to explain the existing lower-bound functions for dynamic time warping distance. A new lower-bound function that is shown by experiments to be superior is also proposed. For future studies, this function can be investigated for the effectiveness in query by humming.

Experimental Results

This section describes the experiments carried out to verify the effectiveness of the proposed lower bounding



Query by Humming. Figure 2. Pruning power vs. length of original data.

distance for the most effective distance measure: SWM. The *Pruning Power P* is defined in [2] as follows:

$$p = \frac{\text{Number of objects that do not require full SWM}}{\text{Number of objects in database}}$$

The pruning power is an objective measure because it is free of implementation bias and choice of the underlying spatial index. This measure has become a common metric for evaluating the efficiency of lower bounding distances, therefore, it was adopted in evaluating the proposed lower bounding distance.

Figure 2 shows how the pruning power of the lower bounding measure varies as the length of data changes for different datasets. More than 78% (32 out of 41) of the datasets achieved a pruning power above 90%.

Query Containment

Rada Chirkova
North Carolina State University, Raleigh, NC, USA

Definition

One query is contained in another if, independent of the values of the "stored data" (that is, database), the set of answers to the first query on the database is a subset of the set of answers to the second query on the same database. A formal definition of containment is as follows: denote with $Q(D)$ the result of computing query Q over database D. A query Q_1 is said to be contained in a query Q_2, denoted by $Q_1 \sqsubseteq Q_2$, if for all databases D, the set of tuples $Q_1(D)$ is a subset of the set of tuples $Q_2(D)$ – that is, $Q_1(D) \subseteq Q_2(D)$. This definition of containment, as well as the related definition of query equivalence, can be used to specify query containment and equivalence on databases conforming to both relational and nonrelational data models, including XML and object-oriented databases.

Historical Background

Testing for query containment on finite databases is, in general, co-recursively enumerable: The procedure is going through all possible databases and simultaneously checking for noncontainment via bottom-up evaluation. See [6] for the details and for a discussion of the relationship between regular and unrestricted (that is, on not necessarily finite databases) containment and equivalence of relational expressions.

Chandra and Merlin [3] have shown that the problems of containment, equivalence, and minimization of conjunctive queries are NP complete. (Conjunctive queries are a subset of Datalog that is equivalent in expressive power to SQL select-project-join queries with only equality comparisons permitted.) It is also shown [3] that there is a simple test for containment, and thus for equivalence. While the question of whether one conjunctive query is contained in another is NP complete, all the complexity is caused by "repeated predicates," that is, predicates appearing three or more times in the body. In the very common case that no predicate appears more than twice in any query, containment can be tested in linear time [11]. Moreover, conjunctive queries tend to be short, so in practice containment testing is not likely to be too inefficient.

Klug [8] has shown that containment for conjunctive queries with arithmetic – that is, inequality or disequality – comparisons (CQAC) is in $\Pi_2{}^P$, while being in NP for some proper subclasses. In addition to reporting some new results on the complexity of CQAC query containment, Afrati and colleagues [2] provide a survey, comprehensive as of 2006, on the complexity of query containment, for query classes including conjunctive queries, CQAC and its subclasses, as well as recursive and nonrecursive Datalog. More original work and further references on query containment in relational and nonrelational databases can be found in [1,5,7,9,10,12–15].

Foundations

This overview of key ideas concerning conjunctive queries, Datalog programs, and their containment is based on [9] as well as on [15], which includes the details and references to the original sources of the results discussed here. The first item on the agenda is a review of containment of conjunctive queries. A conjunctive query is a single Datalog rule with subgoals that are assumed to have predicates referring to stored relations. (The standard Datalog notation is reviewed in, e.g., Sect. 6.1 of [4].) A conjunctive query is applied to the stored relations in a given database by considering all possible substitutions of values for the variables in the body. If a substitution makes all the subgoals true, then the same substitution, applied to the head of the rule, is an element of the set of answers to the head's predicate on the given database.

For example, rule

$$p(X,Z) \ :- \ a(X,Y), \ a(Y,Z)$$

talks about predicate a, for stored relation that contains information about arcs in a directed graph: $a(X, Y)$ means that there is an arc from node X to node Y in the graph. The rule also talks about predicate p whose relation is constructed by the rule. The rule says "$p(X, Z)$ is true if there is an arc from node X to some node Y and also an arc from Y to Z." That is, conjunctive query p represents paths of length 2, in the sense that $p(X, Z)$ will be inferred exactly when there is a path of length 2 from X to Z in the graph represented by stored relation a.

It was proved in [3] that $Q_1 \sqsubseteq Q_2$ if and only if there is a homomorphism $h : Q_2{}^D \rightarrow Q_1{}^D$, where Q^D is the canonical database associated with conjunctive query Q. The canonical database Q^D for query Q is defined as the result of "freezing" the body of Q, which turns each subgoal of Q into a fact in the database. That is, the "freezing" procedure replaces each variable in the body of Q by a distinct constant, and the resulting subgoals are the only tuples in the canonical database Q^D.

Consider now an example of checking conjunctive-query containment using canonical databases. Rule

$$r(W,W) \ :- \ a(W,U), \ a(U,W)$$

defines conjunctive query r, whose answer represents circular paths of length 2 in a graph specified by arcs stored in relation a. As each circular path of length 2 is also an (arbitrary) path of length 2, the containment $r \sqsubseteq p$ is expected to hold. Indeed, the canonical database r^D, for the query defining predicate r, is a set of tuples $\{a(w, u), a(u, w)\}$, while the canonical database p^D, for the query defining predicate p, is a set of tuples $\{a(x, y), a(y, z)\}$. There exists a homomorphism from p^D to r^D that maps x into w, y into u, and z into w (or, alternatively, maps $a(x, y)$ into $a(w, u)$ and $a(y, z)$ into $a(u, w)$). Thus, by [3], the set of tuples in the answer to r on every database D is a subset of the set of tuples in the answer to p on D.

As no homomorphism exists from r^D to p^D, the conclusion is that p is not contained in r, which is to be expected from an intuitive interpretation of the two queries. However, if conjunctive query t defined by the rule

$$t(L,N) \ :- \ a(L,M), \ a(M,N), \ a(M,S)$$

is also considered, it is possible to ascertain both $p \sqsubseteq t$ and $t \sqsubseteq p$, by constructing a homomorphism from p^D to t^D (for the query defining predicate t) and another homomorphism from t^D to p^D. Thus, conjunctive queries p and t are *equivalent.* Indeed, each of p and t represents arbitrary paths of length 2 in a graph. However, p is more efficient to evaluate than t, because computing the set of answers to p requires only one join on the stored relation a, while evaluating t requires two joins. As described in [3], one can *minimize* conjunctive queries for more efficient evaluation; in fact, query p in this example can be obtained as a result of minimizing query t.

Another test for containment of conjunctive query Q_1 in conjunctive query Q_2 consists in computing the set of answers to Q_2 on the canonical database $Q_1{}^D$ for Q_1. The test succeeds if the frozen head of Q_1 is an element of $Q_2({Q_1}^D)$; otherwise the database ${Q_1}^D$ is a counterexample to the containment.

An important extension of the theory of containment of conjunctive queries is the inclusion of arithmetic comparisons as subgoals, with so-called built-in, or interpreted, predicates (e.g., subgoal $X \leq Y$ with built-in predicate $\leq$). When testing two conjunctive queries with arithmetic comparisons (CQACs) for containment $Q_1 \sqsubseteq Q_2$ using canonical databases, one must consider the set of values in the database as belonging to a totally ordered set, e.g., the integers or reals.

The containment test using canonical databases is conducted as follows. Each basic canonical database is constructed from only those subgoals of Q_1 that have uninterpreted predicates. Each basic canonical database is the canonical database (Q^D for query Q) defined above, together with a partition of the variables of the query into a list of blocks, such that each block is associated with a distinct integer value for all its variables, in increasing order of the integer values on the list of the blocks. The containment test succeeds if the frozen head of Q_1 is an element of $Q_2(Q_1^{D_i})$ on *all* basic canonical databases $Q_1^{D_i}$ for Q_1; otherwise any $Q_1^{D_i}$ on which the test fails is a counterexample to containment. Another more general containment test for conjunctive queries with interpreted (not necessarily arithmetic-comparison) predicates uses homomorphisms on the uninterpreted predicates and logical implication on the built-in predicates; see [15] for the details.

The problem of testing CQACs for containment is complete for ${\Pi_2}^{\mathrm{P}}$, at least in the case of a dense domain such as real numbers. (In fact, the problem is ${\Pi_2}^{\mathrm{P}}$ complete even for conjunctive queries with disequalities $\neq$ as the only comparison predicate.) A containment test for conjunctive queries with negation is outlined in [15]. The test in this case is also complete for ${\Pi_2}^{\mathrm{P}}$, as it also involves exploring an exponential number of canonical databases. The query-containment problem is also ${\mathit{\Pi}_2}^P$ complete for unions of conjunctive queries [1].

Containment questions involving Datalog programs are often harder than for conjunctive queries. It is known that containment of Datalog programs is undecidable, while containment of a Datalog program in a conjunctive query is doubly exponential. However, the important case for purposes of information integration is the containment of a conjunctive query in a Datalog program, and this question turns out to be no more complex than containment of conjunctive queries. To test whether a conjunctive query Q is contained in a Datalog program P, one would "freeze" the body of Q to make a canonical database D. Then a check is done to see if $P(D)$ contains the frozen head of Q. The only significant difference between containment in a conjunctive query and containment in a Datalog program is that in the latter case one must keep applying the rules until either the head of Q is derived or no more facts can be inferred in evaluating $P(D)$.

Key Applications

Query containment was recognized fairly early as a fundamental problem in database query evaluation and optimization. The reason is, for conjunctive queries – a broad class of frequently used queries, whose expressive power is equivalent to that of select-project-join queries in relational algebra – query containment can be used as a tool in query optimization, since the problem of conjunctive-query equivalence is equivalent to the problem of conjunctive-query containment. Specifically, to find a more efficient *and* answer-preserving formulation of a given conjunctive query, it is enough to "try all ways" of arriving at a "shorter" query formulation, by removing a query subgoal, in a process called query minimization [3]. In this process, a subgoal-removal step succeeds only if a containment test ensures equivalence (via containment) of the "original" and "shorter" query formulations.

Note that the problems of query containment and query equivalence are equivalent for conjunctive queries under the common setting of *set semantics for query evaluation,* where both stored relations and query answers are interpreted as sets of tuples. Interestingly, the relationship between the problems of containment and equivalence is very different under *bag semantics for query evaluation,* where both stored relations and query answers are allowed to have duplicates. See Jayram and colleagues [5] for a discussion and references on containment and equivalence under bag semantics, for conjunctive queries as well as for more expressive classes of queries, including CQACs and queries with grouping and aggregation. Jayram and colleagues [5] also present original undecidability results for containment of conjunctive queries with inequalities under bag and bag-set semantics for query evaluation.

In recent years, there has been renewed interest in the study of query containment, because of its close relationship to the problem of answering queries using views [4]. Intuitively, the problem of answering queries using views is as follows: Given a query on a database schema and a set of views (i.e., named queries) over the same schema, can the query be answered (efficiently) using only the views? Alternatively, what is the maximum set of tuples in the answer to the query that can be obtained from the views? As another alternative, in case it is possible to access both the views and the database relations, what is the cheapest query-execution plan for answering the query?

The problem of answering queries using views has emerged as a central problem in integrating information from heterogeneous sources, an area that has been the focus of concentrated research efforts for a number of years [4,15]. An information-integration system can be described logically by views that specify what queries the various information sources can answer. These views might be conjunctive queries or Datalog programs, for example. The "database" of predicates over which these views are defined is not a concrete database but rather a collection of "global" predicates whose actual values are determined by the sources, via the views. Information-integration systems provide a uniform query interface to a multitude of autonomous data sources, which may reside within an enterprise or on the World-Wide Web. Data-integration systems free the user from having to locate sources relevant to a query, interact with each one in isolation, and manually combine data from multiple sources.

Given a user query Q, typically a conjunctive query, on the global predicates, an information-integration system determines whether it is possible to answer Q by using the various views in some combination. In addressing the problem of answering queries using views in the information-integration setting, query containment appears to be more fundamental than query equivalence. In fact, answering a query using only the answers to the views is considered "good enough" even in cases where equivalence does not hold (or cannot be demonstrated), provided that the view-based query rewriting can be shown to be contained in the query and is a maximal (i.e., returning the maximal set of answers) rewriting of the query using the available views and a given rewriting language. (For the details and references on maximally contained rewritings see, e.g., [2].)

Besides its applications in information integration, the problem of answering queries using views is of special significance in other data-management applications. (Please see [4] for the details and references.) For instance, in query optimization finding a rewriting of a query using a set of materialized views (i.e., the answers to the queries defining the views) can yield a more efficient query-execution plan, because part of the computation necessary to answer the query may have already been done while computing the materialized views. Such savings are especially significant in decision-support applications when the views and queries contain grouping and aggregation.

In the context of database design, view definitions provide a mechanism for supporting the independence of the logical and physical views of data. This independence enables the developers to modify the storage schema of the data (i.e., the physical view) without changing its logical schema, and to model more complex types of indices. Provided the storage schema is described as a set of views over the logical schema, the problem of computing a query-execution plan involves figuring out how to use the view answers (i.e., the physical storage) to answer the query posed on the logical schema.

In the area of data-warehouse design the desideratum is to choose a set of views (and indexes on the views) to materialize in the warehouse. Similarly, in web-site design, the performance of a web site can be significantly improved by choosing a set of views to materialize. In both problems, the first step in determining the utility of a choice of views is to ensure that the views are sufficient for answering the queries expected to be posed over the data warehouse or the web site. The problem, again, translates into the view-rewriting problem.

The problem of query containment is also of special significance in artificial intelligence, where conjunctive queries, or similar formalisms such as description logic, are used in a number of applications. The design theory for such logics is reducible to containment and equivalence of conjunctive queries. Original results and a detailed discussion concerning an intimate connection between conjunctive-query containment in database theory and constraint satisfaction in artificial intelligence can be found in [9].

Query Evaluation Techniques for Multidimensional Data

Amarnath Gupta
University of California-San Diego, La Jolla, CA, USA

Synonyms

Spatial data

Definition

There are two senses of the term "multidimensional data." The first relates to the data warehousing and online analytical processing (OLAP). The second sense of the term, used mostly in the context of scientific data, refers to variants of array-representable data where the dimensionality refers to the dimensions of the array. Query processing for this class of data uses array algebras [3] and array-specific storage [1] indexing techniques [4].

Key Points

In many scientific applications, data can be represented as multidimensional arrays. For example, the current flow in oceans is a time-varying vector field and can be roughly viewed as 4-dimensional data. In many applications the array may not be uniform, but it can be nested, and even irregular. Query evaluation on this kind of data is greatly dependent on applications. Some applications need to perform operations like value-based clustering on the data, while other applications need fast computation of aggregates such as temporal trends in regions that are selected by user queries. It has been established that storing the multidimensional data as relational tables and developing special routines to handle such relational data is feasible but not optimal, especially when the data is large. ESRI, the GIS provider, has assembled a number of operations collectively called the MapAlgebra for the case where the arrays are two dimensional and the applications are spatial. Recently [2] developed a generic algebra called the gridfield algebra for manipulating arbitrary gridded datasets (i.e., arrays), and present algebraic optimization techniques in these applications. This system is implemented in a system called CORIE (http://www.ccalmr.ogi.edu/CORIE/) for an environmental observation and forecasting system.

Query Expansion for Information Retrieval

Olga Vechtomova
University of Waterloo, Waterloo, ON, Canada

Synonyms

QE, Query enhancement; Term expansion

Definition

Query expansion (QE) is a process in Information Retrieval which consists of selecting and adding terms to the user's query with the goal of minimizing query-document mismatch and thereby improving retrieval performance.

Historical Background

The work on query expansion following relevance feedback dates back to 1965, when Rocchio [9] formalized relevance feedback in the vector-space model. Early work on using collection-based term co-occurrence statistics to select query expansion terms was done by Spärck Jones [10] and van Rijsbergen [12].

Foundations

The central task of information retrieval (IR) is to find documents that satisfy the user's information need. This is usually taken to mean finding documents or some parts of them, such as passages, which contain information that would help resolving the user's information need. Therefore, at least in a more traditional sense, IR does not involve providing the user directly with the information needed. The user usually expresses his/her information need in free-text using natural language words and phrases (terms). Sometimes, prior to retrieving the documents, the user's free-text query is translated into controlled vocabulary which is a subset of the words that comprise a natural language. A document is similarly indexed either by the natural language terms that constitute its content, or by a set of controlled index terms that map its contents to the concepts in a given domain. Both directly matching free-text query terms to free-text index terms and translating natural language words to controlled vocabularies are inherently imprecise. In the first case, the main problem is that the user and the author of a document may express the same idea by means of different terms. In the second case, the shades of meanings that natural language terms carry may be lost in the translation process. In addition to these problems, the user's query may be incomplete or inaccurate, i.e., the user may not specify his/her information need exactly or express it accurately.

The goal of query expansion is to enrich the user's query by finding additional search terms, either automatically, or semiautomatically that represent the user's information need more accurately and completely, thus avoiding, at least to an extent, the aforementioned problems, and increasing the chances of matching the user's query to the representations of relevant ideas in documents. Query expansion techniques may be categorized by the following criteria:

- Source of query expansion terms;
- Techniques used for weighting query expansion terms;
- Role and involvement of the user in the query expansion process.

Query expansion can be performed automatically or interactively. In automatic query expansion (AQE), the system selects and adds terms to the user's query, whereas in interactive query expansion (IQE), the system selects candidate terms for query expansion, shows them to the user, and asks the user to select (or deselect) terms that they want to include into (or exclude from) the query.

There are three main sources of QE terms: (i) hand-built knowledge resources such as dictionaries, thesauri, and ontologies; (ii) the documents used in the retrieval process; (iii) external text collections and resources (e.g., the WWW, Wikipedia).

Hand-built knowledge resources have three main limitations: they are usually domain-specific, have to be kept up-to-date, and typically do not contain proper nouns. Experiments with QE using knowledge resources did not show consistent performance improvements. For example, in [13] QE with words manually selected from WordNet, a large domain-independent lexical resource with lexical-semantic relations between words, did not improve well-formulated queries, but significantly improved performance of poorly-constructed queries.

The most common source of QE terms is the text collection used in the retrieval process or its subset (e.g., retrieved documents). These QE techniques showed overall better performance than techniques using hand-built knowledge resources. They can be subdivided into the following categories:

- QE following relevance feedback. QE terms are extracted from the documents retrieved in response to the user's query and judged relevant by the user.
- QE following blind (pseudo-relevance) feedback. QE terms are extracted from the top-ranked documents retrieved in response to the user's query.
- QE using automatically built association thesauri and collection-wide word co-occurrences.

Query Expansion Following Relevance and Pseudo-Relevance Feedback

Relevance feedback (RF) is a process by which the system, having retrieved some documents in response to the user's query, asks the user to assess their relevance to his/her information need. Documents are typically shown to the user in some surrogate form, for example, as document titles, abstracts, snippets of text, query-biased, or general summaries, keywords and key-phrases. The user may also have an option to see the whole document before making the relevance judgement. After the user has selected some documents as relevant, query expansion terms are extracted from them, weighted and the top-weighted terms are either added to the query automatically, or shown to the user for further selection.

Query expansion following relevance feedback has consistently yielded substantial gains in performance in experimental settings. Many term selection methods have been proposed for query expansion following RF. The general idea behind all such methods is to select terms that will be useful in retrieving previously unseen relevant documents. Below is a brief description of a query expansion method [11] which showed consistently high performance results on Text REtrieval Conference (TREC) test collections. The first step is to retrieve documents in response to the user's initial query, which is done by calculating document matching score (Eq. 1) using the Robertson/Spärck-Jones probabilistic model.

$$MS = \sum_{i \in Q} \frac{(k_1 + 1) \times tf_i}{k_1 \times NF + tf_i} \times w_i \tag{1}$$

Where i is a term in the query Q, tf_i is the frequency of i in the document, k_1 is term frequency normalization factor, NF is document length normalization factor and is calculated as $NF = (1\text{-}b) + b \times DL/AVDL$, where DL is document length, $AVDL$ is average document length, b is a tuning constant, w_i is term collection weight, calculated as $w_i = log(N/n_i)$, where N is the number of documents in the collection, n_i is the number of documents containing i.

After the user looks through the top-retrieved documents, and judges some of them as relevant, the system extracts all terms from these documents, ranks them according to the Offer Weight (OW) in Eq. 2, and either adds a fixed number of terms to the query (automatic query expansion), or asks the user to perform the term selection.

$$OW = r \times RW \tag{2}$$

Where r is the number of relevant documents containing the candidate query expansion term and RW is Relevance Weight calculated as shown in Eq. 3:

$$RW = \log\left(\frac{(r+0.5)(N-n-R+r+0.5)}{(R-r+0.5)(n-r+0.5)}\right) \tag{3}$$

Where R is the number of documents judged relevant; r is the same as above; N is the number of documents in the collection; n is the number of documents containing the term.

The subsequent document retrieval with the expanded query is performed using Eq. 1 for document ranking with RW used instead of w.

A related approach to RF is pseudo-relevance or blind feedback (BF), which uses a number of top-ranked documents in the initially retrieved set for query expansion without asking the user to assess their relevance. The query expansion method described above can be used in BF with R being the number of top documents *assumed* to be relevant. Many other QE methods following blind feedback have been proposed. Two of the methods that showed good performance on large test collections are briefly introduced below.

Local Context Analysis (LCA) [14] technique consists of extracting terms (nouns and noun phrases) from n top ranked passages retrieved in response to the user's query. The extracted terms are ranked by their similarity to the entire user's query, and top m terms are added to the query. Carpineto et al. [3] proposed a term ranking method for QE based on Kullback-Leibler divergence (KLD) measure. The method ranks candidate QE terms based on the difference between their distribution in pseudo-relevant documents and in the entire collection.

In general, blind feedback has been demonstrated to be less robust in performance than relevance feedback. The QE performance following BF depends greatly on the performance of the user's initial query: if many of the top-ranked documents retrieved in response to the initial query are relevant, then it is likely that QE terms from these documents will be useful in retrieving other relevant documents. However, if the initial query is poorly formulated or ambiguous, and many top-ranked documents are nonrelevant, then QE terms extracted from such documents may deteriorate performance. Billerbeck and Zobel [2] report that blind feedback in their experiments improves performance of less than a third of queries. They also conclude that the best values for such BF parameters as the number of documents and terms used for QE vary widely across topics.

Query Expansion Using Association Thesauri and Term Co-Occurrence Measures

Unlike QE following relevance or pseudo-relevance feedback, where terms are selected from documents at search time, QE techniques in this category rely on lexical resources automatically constructed prior to the search process. Typically, statistical measures of term similarity are applied to identify terms in a large document collection that co-occur in the same contexts, and which, therefore, are likely to be conceptually related.

For example, Qiu and Frei [7] developed a query expansion method where query expansion terms are selected from an automatically constructed co-occurrence based term-term similarity thesaurus on the basis of the degree of their similarity to all terms in the query. Jing and Croft [4] developed a technique for automatic construction of a co-occurrence thesaurus. Each indexing unit, defined through a set of phrase rules, is recorded in the thesaurus with its most strongly associated terms. An evaluation of different similarity measures (Dice, Jaccard, Cosine, Average Conditional Probability, and Normalized Mutual Information) for selecting query expansion terms from a document collection is reported in [5]. The Dice, Jaccard, and Cosine led to better QE results than Average Conditional Probability and Normalized Mutual Information.

Interactive Query Expansion

In interactive query expansion the task of selecting and adding terms to the user's query is split between the user and the system in such a way that the system selects the candidate query expansion terms, but it is the user who makes the final decision which terms to include into the query. Similarly to automatic query expansion, the most common source of terms used in IQE is a set of documents resulting from either relevance, or pseudo-relevance feedback. Terms are extracted by the system, ranked, and the top-ranked terms are shown to the user for selection. The process of IQE is iterative, and may be triggered either by the system, or the user.

Several studies comparing the effectiveness of AQE and IQE have been conducted. Intuitively, since the user is the one who decides which document is relevant to his/her information need, the user should be able to make better decisions than the system with respect to which terms to add to the query. However, experiments do not offer conclusive results that IQE is more effective than AQE. For instance, Beaulieu [1] showed that AQE is more effective than IQE in operational settings. On the other hand, Koenemann and Belkin [6] reported higher subjective user satisfaction with an IQE system, as well as better performance. This suggests that the effectiveness of IQE is highly variable, depending on the specific interactive system, the users, and the task. Ruthven [8] did a simulation study of a potential benefit of IQE. He concludes that while IQE has potential to achieve higher performance than AQE, this potential may not be easy to realize, because it is difficult for the users to make decisions about which terms are better in differentiating between relevant and nonrelevant documents.

Key Applications

Query expansion is used in some web search engines and enterprise search systems. Although QE following relevance feedback has been experimentally shown as one of the most successful IR techniques, its use in Web search has been limited.

Term expansion models

Definition

In information retrieval, the query expansion models are the techniques, algorithms or methodologies that reformulate the original query by adding new terms into the query, in order to achieve a better retrieval effectiveness.

Historical Background

The idea of expanding a query to achieve better retrieval performance emerged around the early 1970's. A classical query expansion algorithm is Rocchio's relevance feedback technique proposed in 1971 [10] for the Smart retrieval system. Since then, many different query expansion techniques and algorithms have been proposed.

Foundations

Query expansion models can be classed into three categories: manual, automatic, and interactive. Manual query expansion relies on searcher's knowledge and experience in selecting appropriate terms to add to the query. Automatic query expansion weights candidate terms for expansion by processing the documents returned from the first-pass retrieval, and expands the original query accordingly. Interactive query expansion automates the term weighting process, but it is the user who decides which are the expanded query terms.

Manual query expansion inspires and motivates the user to refine the initial query through heuristics, for instance, by providing a list of candidate terms mined from query log, and allowing user the to choose appropriate terms to add.

Automatic query expansion, different from manual query expansion, expands search queries without any form of human interaction. According to [15], the reason for not involving human interaction could be that the searcher does not want to make an effort perhaps he/she simply does not understand and does not bother adding more terms to the query. Efthimiadis [4] categorized the automatic query expansion methods into three subgroups on which the expansion process is based: search results, collection dependent data structures (e.g., term co-occurrence, term frequency distribution etc.), and collection independent data structures (e.g., lexicon relation between terms, synonyms etc.).

The first category (automatic query expansion based on search results) uses the returned documents from the first-pass retrieval with or without relevance information, as feedback for query expansion. In [10], Rocchio proposed a classical query expansion algorithm based on the Vector Space model. His algorithm has the following steps:

1. The first-pass retrieval consists of ranking the documents for the given query.
2. A term weight w(t, d) is assigned to each term occurring in one of the top-ranked document set D_{psd}. Such a document set is usually called a *pseudo relevance set*. A term weight is first assigned to each term document pair, that is the same weight assigned in the first-pass retrieval. The weighting model used is tf·idf (see TF IDF model).
3. Add the most weighted terms in the pseudo relevance set to the query, and modify the query term weights by taking into account both the original-query term weight (qtw) used in the first-pass retrieval, and the weight assigned by the term weighting model. The query used in the first-pass-retrieval is called the *original query*. Moreover, the query with the modified query term weights is called the *reweighed query*. The reweighed query-with the added query terms is called the *expanded query*. Using Rocchio's method, the new query term weight $qtw_m$is given by Rocchio's query expansion formula as follows.

$$qtw_m = \alpha \cdot qtw + \beta \cdot \sum_{d \in D_{psd}} \frac{w(t,d)}{|D_{psd}|} \qquad (1)$$

If an expanded query term is not in the original query, *qtw* is zero. α and β are free parameters. The new query term weight is given by an interpolation of the original query term weight and the average term weight in the pseudo relevance set with $\alpha + \beta = 1$.

Another popular and successful automatic query expansion algorithm was proposed by Robertson [7,8] in the development of the Okapi system. Okapi's query expansion algorithm is similar to Rocchio's, while using a different term weighting function. It takes the top R documents returned from the first-pass retrieval as the pseudo relevance set. Unique terms in this set are ranked in descending order of the Robertson Selection Value (RSV) weights [7]. A number of top-ranked terms, including a fixed number of non-original query terms, are then added to the query. A major difference between Rocchio's and Robertson's methods is that the former explicitly uses relevant documents for feedback, while the latter assumes a pseudo relevance set. Okapi's query expansion method has been shown to be very effective for ad-hoc information retrieval. For example, in TREC-3 ad-hoc retrieval task, a 15.43% improvement over the Okapi BM25 baseline brought by Okapi's query expansion was reported [9].

Recently, Amati proposed a query expansion algorithm in his Divergence from Randomness (DFR) framework [1,2], which similarly follows the steps in Rocchio's algorithm. However, in Amati's method, term weights are assigned by a DFR term weighting model. Two DFR term weighting models have been proposed, namely Bo1 based on Bose-Einstein statistics, and KL based on Kullback-Leibler divergence. For example, using the Bo1 model, the weight of a term *t* in the pseudo relevance document set D(Rel) is given as:

$$w(t) = tf_x \cdot \log_2 \frac{1+\lambda}{\lambda} + \log_2(1+\lambda) \qquad (2)$$

where λ is the mean of the assumed Poisson distribution of the term in the pseudo relevant document set D(Rel). It is given by $\frac{tf_{rel}}{N_{rel}}$. tf_{rel} is the frequency of the term in the pseudo relevant documents, and N_{rel} is the number of pseudo relevant documents. tf_x is the frequency of the query term in the pseudo relevance document set.

Once the first-pass retrieval is finished, using a document weighting model, a weight is assigned to each term in the top-ranked documents returned from the first-pass retrieval. This corresponds to the first and second steps of the relevance feedback process as introduced above.

In the next step, the original query terms are reweighed. The modified query term weight qtw_m is given by the following parameter-free formula [1]:

$$qtw_m = qtw + \frac{w(t)}{M} \qquad (3)$$

where *qtw* is the original query term weight. *w*(*t*) is the weight of the query term that is given by Bo1. *M* is the upper bound of the weight of a term in the top-ranked documents. For Bo1, it is computed by:

$$\begin{aligned} \mathrm{M} &= \lim_{tf_c \to tf_{c,max}} w(t) \\ &= tf_{c,max} \log_2 \frac{1+P_{max}}{P_{max}} + \log_2(1+P_{max}) \end{aligned} \qquad (4)$$

where tf_c is the frequency of the query term in the whole collection, and $tf_{c,max}$ is the frequency of the query term with the highest *w*(*t*) weight in the top-ranked documents. P_{max} is given by $tf_{c,max}/N$. *N* is the number of documents in the collection. An obvious advantage of Amati's approach is that the query term reweighting formula is parameter free. The parameter α in Rocchio's formula (see Equation (1)) is omitted.

In addition to automatic query expansion based on search results, various query expansion methods have been proposed based on collection dependent data structures (e.g., [6,11,12]), or collection independent data structures (e.g., [3,5,13]).

In interactive query expansion, on one hand, the search system offers the user a list of terms for expansion. On the other hand, it relies on the user to choose the appropriate expanded query terms. Similarly to automatic query expansion, interactive query expansion methods can also be categorized into three subgroups by on which the expansion process is based [4]: search results, collection dependent data structures, and collection independent data structures.

Key Applications

Query expansion models are employed in many information search systems such as library search systems and Web search engines for boosting their retrieval effectiveness.

Experimental Results

Query expansion models are usually helpful in improving retrieval effectiveness for general search tasks such as ad-hoc retrieval [14]. For example, a 15.43% improvement over the BM25 baseline was reported in the TREC-3 adhoc task using Okapi's query expansion method [9].

Table 1 demonstrates the effectiveness of query expansion for ad-hoc retrieval on the TREC (http://trec.nist.gov/) test data. The weighting model used for retrieval is DFRee proposed by G. Amati and implemented in the Terrier Platform (http://ir.dcs.gla.ac.uk/terrier/). Terrier's default query expansion setting is applied, which expands the original query with the 10 most informative terms from the top-3 returned documents. Table 1 shows markable improvement in the retrieval performance, measured by mean average precision, over the baseline. In all cases, the improvement is statistically significant according to the Wilcoxon matched-pairs signed-ranks test.

However, the effectiveness of query expansion becomes unreliable when there are only very few relevant documents, or when the information needed is very specific, in which cases expanding the query does

Query Expansion Models. Table 1. The mean average precision (MAP) obtained with and without query expansion

Task	MAP, No QE	MAP QE	Difference (%)	p-value
TREC-1 ad-hoc	0.2148	0.2478	15.36	4.665e-06

TREC-2005 Genomics	0.2172	0.2500	15.10	0.001759

not bring up more relevant documents. There are also other factors that may affect the effectiveness of query expansion, such as the quality of the top-ranked documents, how much noise the document collection contains etc. For example, query expansion does not improve retrieval performance on the Blog06 test collection (http://ir.dcs.gla.ac.uk/test_collections/blog 06info.html), possibly due to the large amount of spam.

Query Language

TORE RISCH
Uppsala University, Uppsala, Sweden

Synonyms

Data manipulation language

Definition

A query language is a specialized programming language for searching and changing the contents of a database. Even though the term originally refers to a sublanguage for only searching (querying) the contents of a database, modern query languages such as SQL are general languages for interacting with the DBMS, including statements for defining and changing the database schema, populating the contents of the database, searching the contents of the database, updating the contents of the database, defining integrity constraints over the database, defining stored procedures, defining authorization rules, defining triggers, etc. The data definition statements of a query language provide primitives for defining and changing the database schema, while data manipulation statements allow populating, querying, as well as updating the database. Queries are usually expressed declaratively without side effects using logical conditions. However, modern query languages also provide general programming language capabilities through the definition of stored procedures. Most query languages are textual, meaning that the queries are expressed as text string processed by the DBMS. There are also graphical query languages, such as Query-By-Example (QBE), where the queries are expressed graphically and then translated into textual queries interpreted by the DBMS.

Key Points

Since data is represented in terms of the data model used by the DBMS, the syntax and semantics of a query language depends on the data model of the DBMS. For example, the relational data model is based on representing data as tables which allows expressing queries over the tables using expressions expressed in variant of predicate logic called relational calculus. Such queries are non-procedural since the user need not specify the details how a query is executed, but rather only how to select and match data from the tables. It is up to the query optimizer to translate the non-procedural logical queries into an efficient program for searching the database. Queries can also be expressed as relational algebra expressions. A query language is said to be relationally complete if its power is equivalent to the power of the relational algebra or the relational calculus. The most widespread query language is SQL the standard language used for interacting with relational DBMSs. Queries in SQL are mainly expressed as syntactically sugared relational calculus expressions. However SQL also has query constructs based on the relation algebra and other paradigms. The logical query language Datalog, as well as SQL's predecessor QUEL, is purely based on predicate calculus. Other data models use other query languages. For example, OQL is used for searching object-oriented databases and Daplex for functional databases.

Querying DNA sequences; Querying protein sequences

Definition

A common type of data that is used in life science applications is biological sequence data. Data such as DNA sequence and protein sequence data are growing at a very fast rate. For example, the data at GenBank [GB07] has been growing exponentially, doubling roughly every 18 months. These sequence datasets are often queried in complex ways and the methods required to query these sequences go far beyond the simple string matching methods that have been used in more traditional string applications. In order to enable users to easily pose sophisticated queries on these biological sequences, different languages have been designed to support a rich library of functions. In addition, some database systems have been extended to support a rich set of operators on the sequence data type. Compared to the stand-alone approach, the database method brings the power of algebraic query optimization and the use of indexes making it possible to find efficient execution plans for sophisticated queries. Furthermore, biological sequence processing can be integrated with traditional database processing, such as selecting a subset of data for analysis, or combining data from multiple sources, to produce a powerful sequence analysis and mining system.

Historical Background

Several research efforts have tackled the problem of enabling complex and efficient querying on biological data. Early efforts such as [4] investigated the idea of a Genomics Algebra, which would abstract several biological processes and enable users to construct complex expressions, thereby providing a sophisticated platform for processing biological sequences. As part of another effort, the Periscope project, an algebra for biological sequences called PiQA (Protein Query Algebra) was proposed in [12]. PiQA can be used to construct complex expressions that allow sophisticated manipulation of both genetic and protein sequence data. The Periscope/SQ [13] system and the PQL query language are based on this algebra.

One of the primary operations in biological sequence processing is local alignment. A dynamic programming algorithm was proposed in [9] for this problem. The popular BLAST algorithm [1] is a heuristic version proposed in 1990 to support local alignment search on massive datasets.

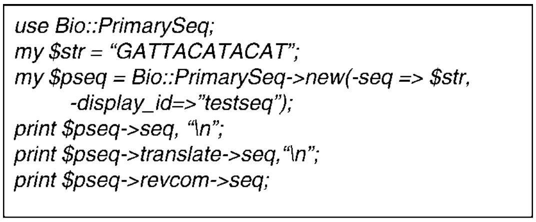
Foundations

The amount of biological sequence data available to scientists for analysis has grown rapidly. While small sequences can be analyzed and queried fairly quickly on computers, large datasets require careful design of algorithms and data structures. Database systems have dealt with the problem of managing and processing large datasets for several years, and the area of query processing for biological sequences aims to bring the benefits of this research to the domain of biological sequences.

One of the most common computations in the context of sequence data is that of finding "similar" sequences. This is often the first step biologists perform to begin investigation of a particular biological sequence they have discovered. For instance, finding a known protein with a sequence similar to the one under investigation may yield some clues to the function of the protein. Sequence similarity is defined in many ways and the type of similarity used may depend on the sequence and the application for which the similarity is being computed. Some distance measures are based on the evolutionary distance between the sequences, while in some cases they simply count the number of mismatches between an alignment of two sequences of the same length. Examples of evolutionary distance matrices include the PAM [3] and BLOSUM [5] matrices for comparing protein sequences. Simple models for mismatches include simply finding sequences that have up to a specified number of mismatches, or models in which mismatches are only tolerated in specific positions (such at the middle portion of the sequence).

The problem of finding a local alignment for two sequences requires finding a region of maximum similarity in a longer sequence that will match with a shorter query sequence. This version of sequence similarity is extremely popular, especially for large DNA sequence repositories. While the Smith-Waterman algorithm [9] is an elegant dynamic programming technique to compute an optimal alignment with $O(n^2)$ cost, for large sequence databases this cost can be prohibitive. In practice, methods that approximate Smith-Waterman but are much faster are used. Popular methods in this category include BLAST [1] and FASTA [8]. While these methods allow the fast evaluation of simple sequence queries, for sophisticated queries, they do not address sophisticated queris, such as a complex string pattern query. Additional methods are required that include a language to express such quires and algorithms to efficiently evaluate the operations in these queries.

Query languages provide a convenient way to express common computational tasks. The class of query languages can be divided into two categories: (i) procedural and (ii) declarative. Several procedural query languages are often general purpose programming languages or scripting languages with a library of functions that support operations on biological sequences. BioPerl and BioPython are two such examples. Figure 1 shows an example of a BioPerl code snippet that uses library function to translate the DNA sequence into the corresponding protein sequence, and another function to compute the reverse complement. These libraries also provide functions to read and translate between several popular sequence file formats. Although such languages make it somewhat easier to develop biological sequence processing applications, they suffer



```
use Bio::PrimarySeq;
my $str = "GATTACATACAT";
my $pseq = Bio::PrimarySeq->new(-seq => $str,
        -display_id=>"testseq");
print $pseq->seq, "\n";
print $pseq->translate->seq,"\n";
print $pseq->revcom->seq;
```

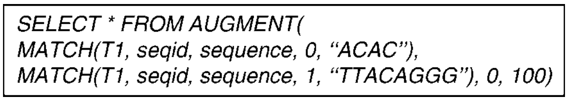
Query Languages and Evaluation Techniques for Biological Sequence Data. Figure 1. Sample BioPerl code.

from two major drawbacks: (i) inability to rapidly express sophisticated queries (ii) lack of an indexing and optimization infrastructure to choose efficient query plans. Applications written in procedural languages often need to solve several database problems in order to scale to larger data sets. As a result, researchers have recently focused on declarative query processing for biological data.

In addition to an algebra, a declarative query infrastructure needs efficient physical operators corresponding to the operators in the algebra in order to produce query evaluation plans. The research prototype system Periscope [14] uses the PiQA algebra and the PiQL query language. Figure 2 shows an example PQL query that finds all instances of the sequence "ACAC" followed by "TTACAGGG" within 100 symbols in the given sequence database. The Periscope system is built as an extension to an object-relational system, which allows the user to mix sequence queries with traditional relation data manipulation queries such as selections and joins. Relational database systems are now commonly used to manage large biological datasets (for example the GMOD project). Arguably, the declarative query processing with the relational frameworks provides a better framework (compared to the procedural framework) for complex biological data analysis.

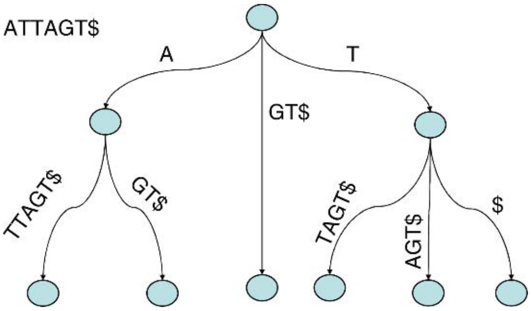
Index Structures

To speed up the evaluation of complex biological sequence operations, a number of index-based methods have been designed. Exploiting these indexes is crucial in having efficient query execution plans, especially to cope with the increasing data volumes and query complexity. The suffix tree is one of the useful data structures in the world of string processing [15]. A Suffix tree is a tree that is built using an input string such that every path from the root of the tree to a leaf node corresponds to a suffix in the string. The edges are labeled with substrings from the string. A suffix tree can be used to evaluate exact substring queries in time proportional to the length of the query. Figure 3 shows an example suffix tree on the string ATTAGT$. In order to check if the string TAG is a substring of the database string (on which the suffix tree is built), one simply follows the labeled edges from the root of the tree while trying to consume the symbols (T,A,G) from the query string.



```
SELECT * FROM AUGMENT(
MATCH(T1, seqid, sequence, 0, "ACAC"),
MATCH(T1, seqid, sequence, 1, "TTACAGGG"), 0, 100)
```

Query Languages and Evaluation Techniques for Biological Sequence Data. Figure 2. Sample PiQL query.



Query Languages and Evaluation Techniques for Biological Sequence Data. Figure 3. Sample suffix tree built on the string "ATTAGT."

Suffix trees can be constructed in time proportional to the length of the input string, i.e., in time O(n). Several algorithms have been designed to accomodate very large input datasets and construct disk based suffix trees. Suffix trees can also be used to efficiently answer approximate matching queries and even compute the local alignment of a query string with the database string.

Another interesting approach to indexing sequence data in the context of similarity search is the use of metric space indexing [7]. While extremely efficient for distance measures that are metrics, such indexing techniques tend to be less flexible than suffix trees.

Given the popularity of BLAST for sequence query processing, a number of approaches have added support for invoking BLAST from a database engine [2,6,11], and regular expression engines in SQL engines have also been adapted for more sophisticated biological pattern matching [10]. Their support for scanning sequences with complex patterns (including arbitrary position-specific weight matrices containing probabilistic models for matching a nucleic or protein sequence) is limited. However, such extensions have recently been made for the declarative framework using suffix trees [12].

Key Applications

Any application that requires complex sequence matching, which include combinity sequence homology matching, and TFBS prediction.

Query Languages for the Life Sciences

Zoé Lacroix
Arizona State University, Tempe, AZ, USA

Synonyms

Biological query Languages; Scientific query Languages; Biological data retrieval, integration, and transformation.

Definition

A *scientific query language* is a query language that expresses the data retrieval, analysis, and transformation tasks involved in the dataflow pertaining to a scientific protocol (or equivalently workflow, dataflow, pipeline). Scientific query languages typically extend traditional database query languages and offer a variety of operators expressing scientific tasks such as ranking, clustering, and comparing in addition to operators specific to a category of scientific objects (e.g., biological sequences).

Historical Background

A scientific query may involve data retrieval tasks from multiple heterogeneous resources and perform a variety of analysis, transformation, and publication tasks. Existing approaches used by scientists include hard coded scripts, data warehouses, link-based federations, database mediation systems, and workflow systems. Hard coded scripts written in Perl and Python are widely used in the biological community. Unlike an approach based on a query language, scripts are very limited in terms of scalability and flexibility. Extending or altering a protocol over time requires writing new scripts. Further, scripts are limited in the degree to which they capture biological expertise so they can be re-used for future related queries. Finally, unless explicitly written to do so, scripts do not assist the user in filtering retrieved data, resolving inconsistencies and sorting and ranking the results, or optimizing the overall execution. Data warehousing consists in collecting data from many possible data sources, curating the data, and creating a new database. Data warehouses typically are relational databases designed to provide users an integrated platform to answer a pre-defined set of scientific tasks.

A federation, e.g., NCBI Entrez and the Sequence Retrieval System (SRS) [4], links semi-autonomous distributed databases with powerful full text indexing and keyword based search techniques for cross database retrieval. The approach expresses navigational queries over linked entries retrieved from multiple databases. In addition, useful tools such as BLAST are often made available. However, the approach is limited in that a federation relies on a materialized index that is difficult to keep up-to-date. Moreover, it focuses on data retrieval and does not support complex queries. Most existing data integration approaches rely on an internal query language that captures data management operations and a user query interface that aims at expressing queries meaningful to the scientists. Existing mediation approaches rely on traditional database query languages such as SQL adapted to handle biological data. K2 follows the Object Data Management Group (ODMG 1999) and its internal query language, called K2 Mediator Definition Language (K2MDL), is a combination of the Object Query Language (OQL) and the Object Definition Language (ODL) both specified by the ODMG. Kleisli (also known as Discovery Hub) provides the collection programming language (CPL) [2], a nested version of SQL, and Java and Perl access programming interfaces (API). Users may express their queries in SQL or through a graphical interface that limits access to query capabilities. The system that supports the Object Protocol Model (OPM) [3] provides a query language similar to OQL (ODMG 1999) and also exploits SQL when integrated data sources are retrofitted from a relational data model. Additional query capabilities may be integrated through CORBA classes. Tools such as BLAST are wrapped through an Application Specific Data Type (ASDT). Users may express their queries in a simplified version of OQL and generate query forms that do not offer access to all query capabilities. Discovery Link (also known as Information Integrator) offers a rich subset of SQL3 (SQL 1993) including user-defined functions, stored procedures, recursion, row types, object views, etc. P/FDM provides support to access specific capabilities of sources. P/FDM uses Daplex that offers a richer syntax than SQL [10] and Prolog. In particular it allows uses of function calls within queries. In addition to these query languages, P/FDM offers users a visual interface that enables users to build their queries by browsing and clicking through the database schema. The P/FDM Web interface uses HTML forms and access the mediator through CGI programs. Both interfaces restrict the query capabilities of the mediator. TAMBIS, which uses CPL internally, is primarily concerned with overcoming semantic heterogeneity through the use of ontologies. It provides users an ontology-driven browsing interface. Thus it too restricts the extent to which sources can be exploited for scientific discovery. To summarize, these systems have made many inroads into the task of data integration from diverse data sources. However they all rely on significant programming effort to adjust to specific scientific tasks, are difficult to maintain and provide user's query language that require programming ability such as SQL, OQL, Daplex, etc. or user's friendly interfaces that significantly limit the query capabilities. A comparative study of these systems and the many causes of failure of traditional database approaches to support the process of scientific discovery are detailed in [6].

Workflows are used in business applications to assess, analyze, model, define, and implement business processes. A workflow automates the business procedures where documents, information or tasks are passed between participants according to a defined set of rules to support an overall goal. In the context of scientific applications, a workflow approach may address the collaboration among scientists, as well as the integration of scientific data and tools. The procedural support of a workflow resembles the query-driven design of scientific problems and facilitates the expression of scientific pipelines (as opposed to a database query). However, because workflows are designed to orchestrate various applications (e.g., Web services) into a combined dataflow they do not provide a query language and do not express the specific queries against biological datasets. Peer-to-Peer (e.g., Chinook) and grid approaches (e.g., myGRID) may offer the support for resource and data sharing without providing a query language.

Foundations

Systems that focus on specific datasets such as sequences, protein structure, phylogenetic trees, metabolic pathways, rely on query languages designed to handle the characteristics of the biological datasets. Life sciences data are exceptionnaly diverse. Biological data include string data (e.g., sequences over various alphabets), 3D geometric data (e.g., protein structure), tree data (e.g., phylogenetic tree), and graph data (e.g., pathways). When their description and annotations are mostly textual and deeply nested in one or several documents, the intrinsic structure of the datasets are often poorly represented by traditional data models, thus poorly accessed and transformed by the corresponding query languages [7]. Each of these specific biological datasets has motivated the design of suitable query languages. For example PiQA, an algebra designed to query sequences, offers a match operator that expresses sequence alignment.

Query languages that express search queries (using regular expressions, wildcards, and Boolean operators) are often developed for life scientific applications. This is because scientific data are mostly textual (annotation on scientific instances) and scientists seem to mimic the manual query process they follow when exploring data sources on the Web. Querying systems that are compatible with scripting languages such as Perl are also favored because most scientific protocols are implemented with scripts. Additional features expected by scientists include the ability to compare and rank results. The ability to express cross-database queries and to integrate scientific analysis tools such as BLAST has a significant value to the scientist.

Scientific queries may exploit metadata as well as data. Querying scientific data through their meaning expressed in a terminology or an ontology is scientist-friendly because it hides the complex structure of data as they are organized and stored in the various repositories. A domain ontology may also provide a global schema for multiple integrated scientific resources. It facilitates scientific tasks such as *profiling* which aims at combining all information known about a scientific object. TAMBIS is an example of a system that provides a ontology-driven query interface.

The challenge for the design of a biological query language is to express the data management tasks involved in the scientific dataflow while offering meaningful and scientist-friendly query functionality. A scientific query language typically handles complex datatypes including text, string, tree, graph, list, variant, etc. for data and metadata. Scientific queries may invoke an increadibly diverse range of functions including extracting information in a textual document, identifying a feature common to two biological sequences, exploring a biological pathway, profiling a gene, etc.

Key Applications

The Acedb Query Language (AQL) is the language developed for the AceDB genome database. It is inspired by the Object Query Language (OQL), and Lorel the query language developed for semi-structured and XML data (also based on OQL). AQL expressions use the Select, From, Where syntax. Queries in AQL express traditional database retrieval and transformation against a data warehouse mostly populated with annotated scientific data (textual). It provides AcePerl and object-oriented Perl module access local or remote AceDB databases transparently. Many biological resources use the AceDB system that is still updated and maintained by the Sanger institute. The former version of AQL consisting of search statements of the form ”find Gene TP*” is currently used to query WormBase.

SRS has its own query language that express retrieval queries using string comparison, wildcards, regular expresions, numeric comparison, Boolean operations, and the *link* operator specific to SRS that allows the navigation through resources exploiting the interal cross-references (hyperlinks, indices, and composite structures) made available by the providers. SRS uses Icarus as its internal interpreted object-oriented programming language. SRS queries return sets of entries or lists of entry identifiers that can be sorted with respect to various criteria. Because SRS integrates scientific analysis tools (e.g., BLAST) as tool-specific databanks, SRS queries may exploit the expressive power of the scientific analysis tools integrated in the federation. However, the SRS query language mostly expresses retrieval queries over cross databases. For a detailed description of the system and its query language see Chapter 5 in [6]. SRS is currently updated and mainted by Biowisdom Ltd.

The Life Sciences community has developed unique approaches to handle complex retrieval and integration tasks. They express the query “retrieve everything known about [a specific scientific instance].” Unlike a query language, the resources where the data are to be retrieved and the criteria for retrieval cannot be selected by the user. These approaches include sequence profiling tools that express complex data retrieval and integration queries over multiple heterogeneous resources to generate summaries of all information related to a particular biological sequence. For example, the Karlsruhe Bioinformatik Harvester (KIT) crawls and crosslinks 25 biological resources. Data integration is limited as queries against KIT are species-specific boolean expressions of keywords and the result is a list of summaries (each summary corresponds to a biological sequences), where each summary is the concatenation of relevant retrieved pages. Other approaches focus on the textual material contained in the biological data sources and use biological language processing to achieve information retrieval, extraction, classification, and integration [5]. These approaches retrieve documents from various resources and generate a document summary as input. Textpresso uses the Gene Ontology (GO) to markup documents related to a particular organism retrieved from PubMed. It provides a query language that expresses Boolean expressions on keyword, category, and attribute. Because the approach is document-driven, the query language expresses advanced search queries. Patent databases are other documented sources of biological information. In addition to the traditional features of querying documented data, Patent Lens offers the useful feature of querying the biological sequences contained in the patent documents with BLAST [9].

The use of a domain ontology as an interface (or view) for biological data is usually well received by the scientists. Such approches typically support exploration, navigation, and search queries. TAMBIS uses an ontology to provide an homogeneous layer over the integrated resources (data sources and applications) that acts as a global schema, to hide the heterogeneities of the integrated resources, and to be used as a query interface. WormBase is a warehouse derived from ACeDB and BioMart databases and uses biomaRt, a bioconductor package that provides a platform for data mining. BioMart databases are annotated with the Gene Ontology (GO) and the eVOC ontologies. These annotations provide support for querying data. EnsMart organizes data with respect to *foci*, that are central scientific objects (e.g., gene). All data are linked to the instances of those central objects. Queries consist of the selection of the species and focus of interest and the specification of filters and outputs. AmiGO provides a query interface to GO, genes, and gene products.

The Pathway Tools developed and maintained at SRI International to support pathway databases produces a query form for basic or advanced search against BioCyc databases. Each form consists of the selection of the BioCyc database (queries are limited to the scope of a single resource), the field(s) to be searched or the ontology term(s), and the format of the output. Most of the databases developed with BioCyc allow the use of BLAST. The BioVelo query language is designed to retrieve data from BioCyc databases. It is based on the object-oriented BioCyc data model composed of object classes that are identified to ontology classes and express set comprehension statements used in functoinal programming languages such as Python.

Future Directions

The design of query languages for the Life Sciences is a challenging problem. The desired expressive power and features of the languages are not well understood. The expectations of the users (life scientists) and the developers (computer scientists) are often dissimilar. Life scientists expect support for all their scientific questions which often go beyond the scope of traditional database query languages handling data retrieval and transformation. Scientific questions are often complex protocols that invoke not only data retrieval and transformation tasks but ranking, comparison, clustering and classification as well as sophisticated analysis tasks. The implementation of such a "query" would require accessing multiple resources and coordinating the dataflow as currently achieved by scientific workflow systems such as Taverna. However, workflow systems lack the elegance of a query language and its benefits such as query planning and optimization. Because many of the scientific tasks invoked in a scientific protocol could be expressed by operators of a query language, the design of a generic query language to handle data retrieval, transformation, comparison, clustering, and integration operations would be valuable to scientific data management.

Query Load Balancing in Parallel Database Systems

Luc Bouganim
INRIA, Rocquencourt, Lechesnay Cedex, France

Synonyms

Resource scheduling

Definition

The goal of parallel query execution is minimizing query response time using inter- and intra-operator parallelism. Inter-operator parallelism assigns different operators of a query execution plan to distinct (sets of) processors while intra-operator parallelism uses several processors for the execution of a single operator thanks to data partitioning. Conceptually, parallelizing a query amounts to divide the query work in small pieces or tasks assigned to different processors. The response time of a set of parallel tasks being that of the longest one, the main difficulty is to produce and execute these tasks such that the query load is evenly balanced within the processors. This is made more complex by the existence of dependencies between tasks (e.g., pipeline parallelism) and synchronizations points. Query load balancing relates to static and/or dynamic techniques and algorithms to balance the query load within the processors so that the response time is minimized.

Historical Background

Parallel database processing appeared very early in the context of database machines in the 1970s. Parallel algorithms (e.g., hash joins) were later proposed in the early 1980s, where tuples are uniformly distributed at every stage of the query execution. However several works (e.g., [8]) gave considerable evidence that data skew, i.e., non-uniform distribution of tuples, exists and its negative impact on query execution was shown in e.g., [7]. This motivated numerous studies [10] on intra- and inter-operator load balancing in the 1990s.

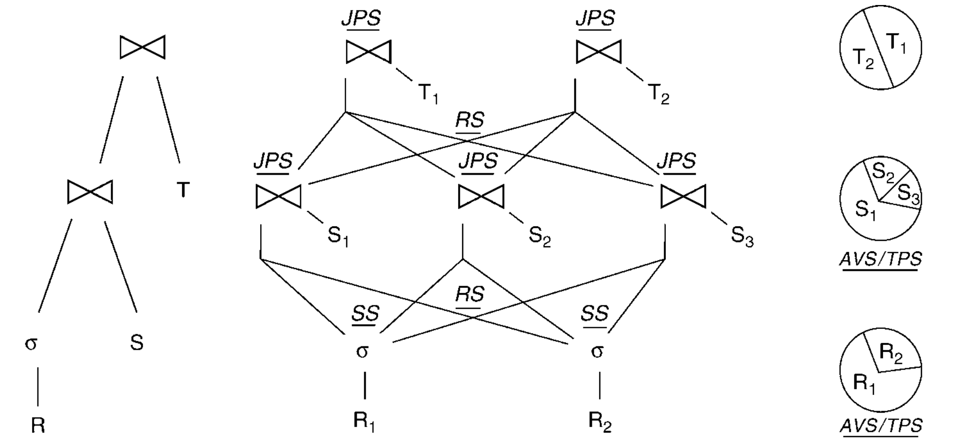
Foundations

Load balancing problems can appear with intra-operator parallelism (variation in partition size, namely *data skew*) and inter-operator parallelism (variation in the complexity of operators, synchronization problems). Intra- and inter-operator load balancing problems are first detailed on a simplified query execution plan example considering a static allocation of processors to the query operators. The main load balancing techniques proposed to address these problems are described next:

Load balancing problems

Figure 1(a) shows a simplified query execution plan for the following query: "Select T.b from R, S, T where R. Rid = S.Rid and S.Sid = T.Sid and R.a = value" (the Scan and Project operators were omitted to simplify the drawing). The following assumptions are made: (i) the degree of parallelism (i.e., number of processors allocated) for the selection on R (called σR), the join with S (called ⋈S) and the join with T (called ⋈T) has been statically fixed, using a cost model, to respectively 2, 3, and 2; and (ii) these operators are processed in pipeline, thus leading to a total degree of parallelism of 7.

Intra-operator load balancing issues are first illustrated using the classification proposed in [13]. As shown in Fig. 1(c), R and S are poorly partitioned because of *Attribute Value Skew (AVS)* inherent in the dataset and/or *Tuple Placement Skew (TPS)*. The processing time of the two instances σR1 and σR2 are thus not equal. The case of ⋈S is likely to be worse (see Fig. 1b). First, the number of tuples received can be different from one instance to another because of poor redistribution of the partitions of R (*Redistribution Skew, RS*) or variable selectivity according to the partition of R processed (*Selectivity Skew, SS*). Finally, the uneven size of S partitions (*AVS/TPS*) yields different processing times for tuples sent by the σR operator and the result size is different from one partition to the other due to join selectivity (*Join Product Skew, JPS*). The skew effects are therefore propagated toward the query tree and even with a perfect partitioning of T, the processing time of ⋈T1 and ⋈T2 can be highly different (uneven size of their left input resulting from ⋈S). Intra-operator load balancing is thus difficult to achieve statically, given the combined effects of different types of data skew.



a Query plan

b Parallel query plan

c Data partitioning

Query Load Balancing in Parallel Database Systems. Figure 1. Intra- and inter-operator load balancing problems on a simple example.

In order to obtain good load balancing at the inter-operator level, it is necessary to choose how many and which processors to assign to the execution of each operator. This should be done while taking into account pipeline parallelism, which requires inter-operator communication and introduces precedence constraints between operators (i.e., an operator must be terminated before the next one begins). In [15], three main problems are described: (i) the degree of parallelism and the allocation of processors to operators, when decided in the parallel optimization phase, are based on a possibly inaccurate cost model. Indeed, it is difficult, if not impossible, to take into account highly dynamic parameters like interference between processors, memory contentions, and obviously, the impacts of data skew; (ii) the choice of the degree of parallelism is subject to errors because both processors and operators are discrete entities. For instance, considering Fig. 1(b), the number of processors for σR, ⋈S and ⋈T may have been computed by the cost model as respectively 1.5, 3.8 and 2.4 and have been rounded to 2, 3 and 2 processors. But the good distribution, taking into account data skew on S partitions should have been 1, 4 and 2; (iii) the processors associated with the latest operators in a pipeline chain may remain idle a significant time. This is called the pipeline delay problem. For instance, while tuples do not match the selection on R or the join with S, processors assigned to ⋈T remain idles.

In a shared-nothing architecture, the inter-operator load balancing problem is even more complex, since the degree of parallelism and the set of processors assigned for some operators is constrained by the physical placement of the manipulated data. For instance, if R is partitioned on two nodes, σR must be executed on these nodes.

This simple example thus shows that static allocation of processors to operators is usually far from optimal, thus advocating for more dynamic strategies. In the following section, existing proposals at the intra- and inter-operator level are detailed.

Intra-Operator Load Balancing

Good intra-operator load balancing depends on the degree of parallelism and on the allocation of processors for the operator. For some algorithms, e.g., the parallel hash join algorithm, these parameters are not constrained by the placement of the data. Thus, the home of the operator (the set of processor where it is executed) must be carefully decided. The skew problem makes it hard for a parallel query optimizer to make this decision statically (at compile-time) as it would require a very accurate and detailed cost model. Therefore, the main solutions rely on adaptive techniques or specialized algorithms which can be incorporated in the query optimizer/processor. These techniques are described below in the context of parallel joins, which has received much attention. For simplicity, each operator is given a home either statically or just before execution, as decided by the query optimizer/processor.

Adaptive techniques: The main idea is to statically decide on an initial allocation of the processors to the operator (using a cost model) and, at execution time, adapt this decision to skew using load reallocation. A simple approach to load reallocation is detecting the oversized partitions and partition them again onto several processors (among those already allocated to the operator) to increase parallelism [6]. This approach is generalized in [2] to allow for more dynamic adjustment of the degree of parallelism. It uses specific *control operators* in the execution plan to detect whether the static estimates for intermediate result sizes differ from the run-time values. During execution, if the difference between estimate and real value is high enough, the control operator performs data redistribution in order to prevent join product skew and redistribution skew. Adaptive techniques are useful to improve intra-operator load balancing in all kinds of parallel architectures. However, most of the work has been done in the context of shared-nothing where the effects of load unbalance are more severe on performance.

Specialized algorithms: Parallel join algorithms can be specialized to deal with skew. The approach proposed in [3] is to use multiple join algorithms, each specialized for a different degree of skew, and to determine the best at execution time. It relies on two main techniques: range partitioning and sampling. Range partitioning is used instead of hash partitioning (in the parallel hash join algorithm) to minimize redistribution skew of the building relation. Thus, processors can get partitions of equal number of tuples, corresponding to different ranges of join attribute values. To determine the values that delineate the range values, sampling of the building relation is used to produce a histogram of the join attribute values, i.e., the numbers of tuples for each attribute value.

Sampling is also useful in determining which algorithm to use and which relation to use for building or probing. The parallel hash join algorithm can then be adapted to deal with skew as follows: (i) Sample the building relation to determine the partitioning ranges. (ii) Redistribute the building relation to the processors using the ranges. Each processor builds a hash table containing the incoming tuples. (iii) Redistribute the probing relation using the same ranges to the processors. For each tuple received, each processor probes the hash table to perform the join. This algorithm can be further improved to deal with high skew using additional techniques and different processor allocation strategies [3]. A similar approach is to modify the join algorithms by inserting a scheduling step which is in charge of redistributing the load at runtime [14].

Inter-Operator Load Balancing

The inter-operator load balancing problem was extensively addressed during the 1990s. Since then many processor allocation algorithms have been proposed for different target parallel architectures and considering CPU, I/Os or other resources, such as available memory.

The main approach in shared-nothing is to determine dynamically (just before the execution) the degree of parallelism and the localization of the processors for each operator. For instance, the Rate Match algorithm [9] uses a cost model in order to define the degree of parallelism of operators having a producer-consumer dependency such that the producing rate matches the consuming rate. It is the basis for choosing the set of processors which will be used for query execution (based on available memory, CPU, and disk utilization). Many other algorithms are possible for the choice of the number and localization of processors, for instance, by a dynamic monitoring and adjustment of the use of several resources (e.g., CPU, memory and disks) [11].

Shared-disk and shared-memory architectures provide more flexibility since all processors have equal access to the disks. Hence there is no need for physical relation partitioning and any processor can be allocated to any operator [12].

Considering the shared-disk architecture, Hsiao et al. [5] propose to assign processors recursively from the root up to the leaves of a so-called *allocation tree*. This tree is derived from the query tree, each pipeline chain (i.e., set of operators having pipeline dependencies) being represented as a node. The edges of the allocation tree represent precedence constraints. All available processors are assigned to the root node of the allocation tree (the last pipeline chain to be executed). Then, a cost model is used to divide the CPU power between each child of the root in order to ensure that all the data necessary for the execution of the root pipeline chain will be produced synchronously.

The approach proposed in [4] for shared-memory allows the parallel execution of independent pipeline chains called tasks. The main idea is combining IO-bound and CPU-bound tasks to increase system resource utilization. Before execution, a task is classified as IO-bound or CPU-bound using cost model information. CPU-bound and IO-bound tasks can then be run in parallel at their optimal IO-CPU balance, by dynamically adjusting the degree of intra-operator parallelism of the tasks.

Intra-Query Load Balancing

Intra-query load balancing combines intra- and inter-operator parallelism. To some extent, given a parallel architecture, the load balancing techniques presented above can be extended or combined. For instance, the control operators used a-priori for intra-operator load balancing can modify the degree of parallelism of an operator, thus impacting inter-operator load balancing [2].

A general load balancing solution in the context of hierarchical parallel architectures (a shared-nothing system whose nodes are shared-memory multiprocessors) is the execution model called Dynamic Processing (DP) [1]. In such systems, the load balancing problem is exacerbated because it must be addressed both locally (among the processors of each shared-memory node) and globally (among all nodes). The basic idea of DP is decomposing the query into self-contained units of sequential processing, each of which can be carried out by any processor. Intuitively, a processor can migrate horizontally (intra-operator parallelism) and vertically (inter-operator parallelism) along the query operators. This minimizes the communication overhead of inter-node load balancing by maximizing intra and inter-operator load balancing within shared-memory nodes.

Key Applications

Load balancing techniques are essential in applications dealing with very large databases and complex queries, e.g., data warehousing, data mining, business intelligence and more generally all OLAP (On Line Analytical Processing) applications.

Data Sets

DBGen, a synthetic data generator can be used to generate biased data distribution, for studying intra-operator load-balancing issues. It allows generating data with non-uniform distribution (Zipfian, Poisson, Gaussian, etc). See http://research.microsoft.com/∼Gray/DBGen/

Query compilation

Definition

A query optimizer translates a query into a sequence of physical operators that can be directly carried out by the query execution engine. The output of the optimizer is called a *query execution plan*. The execution plan may be thought of as a dataflow datagram that pipes data through a graph of query operators. The goal of query optimization is to derive an efficient execution plan in terms of relevant performance measures, such as memory usage and query response time. To achieve this, the optimizer needs to provide: (i) a space of execution plans (search space), (ii) cost estimation techniques to assign a relevant cost to each plan in the search space, and (iii) an enumeration algorithm to search through the space of plans.

Key Points

The query optimizer takes as input a parsed query and produces as output an efficient execution plan for the query. The task of the optimizer is nontrivial, since given a query (i) there are many logically equivalent algebraic expressions (for instance, resulting from the commutativity property among the logical operators), and (ii) for each expression, there are many physical operators supported by the query execution engine for implementing each logical operator (for example, there are several join algorithms, e.g., nested-loop and sort-merge join, for implementing join). The task of finding an equivalent algebraic expression is often called *query rewriting*.

The optimizer needs to enumerate all possible execution plans, estimate their cost and select the one with the smallest cost. The cost assigned to each plan is based on a *cost model* that provides an estimation of the resources needed for its execution, where the resources include CPU time, I/O cost, memory, and communication bandwidth. The cost model relies on statistics maintained on relations and indexes, and uses cost formulas for estimating the selectivity of the various operators and their expected recourse usage. Often, dynamic programming techniques are used to enumerate different plans. These techniques, exploit the fact that to obtain an optimal plan for an expression, it suffices to consider only the optimal plans for its sub-expressions [1,2,3].

Query compilation

Definition

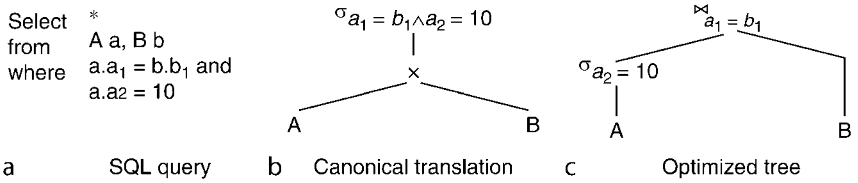
Database queries are given in declarative languages, typically SQL. The goal of query optimization is to choose the best execution strategy for a given query under the given resource constraints. While the query specifies the user intent (i.e., the desired output), it does not specify how the output should be produced. This allows for optimization decisions, and for many queries there is a wide range of possible execution strategies, which can differ greatly in their resulting performance. This renders query optimization an important step during query processing.

Historical Background

One of the first papers to discuss query optimization in relational database systems was the seminal System R paper [2]. It introduced a dynamic programming algorithm for optimizing the join order, and coined the concept of interesting orders for exploiting available orderings. Later approaches increased the set of optimized operators, and included a rule based description of optimization techniques (whereas the optimizations in System R were hard wired). One prominent example is the Starburst [3] optimizer. It introduced a different internal representation (query graph model), that could express complex queries suitably for optimization, and proposed using grammar-like rules to combine low level physical operators (LOLEPOPs) in execution plans. Besides being rule-based, the optimization itself used a bottom-up approach similar to System R. Another family of optimizers was introduced by Volcano [4] (which itself evolved from Exodus) and Cascades [5]. Instead of bottom-up constructive optimization they used transformative top-down optimization with memorization. Besides these more fundamental approaches, a rich literature of optimization techniques exist, ranging from support for specific operators like outer joins or expensive predicates to fundamental data reduction like magic sets.

Foundations

The key idea behind query optimization is the observation that the same query can be formulated in different ways. When a user gives a query in SQL, the query is first parsed and analyzed, and then brought into an internal representation, for example in relational algebra. This translation first creates a canonical representation, as shown in Fig. 1. As a first translation



Query Optimization (in Relational Databases). Figure 1. Translating a SQL query.

step, the *select-from-where* queries in a) can be answered by combining all relations in the *from* clause with a cross product and then checking the *where* condition on each resulting tuple (shown in b)). But cross products are expensive operations, therefore it is preferable to move a part of the *where* condition into the cross product to form a join. The remaining part of the condition can be checked before the join, which further reduces the effort for the join (shown in c)). Both operator's trees produce the same tuples when executed, and thus are different representations of the same query. But executing the tree in (i) is most likely cheaper than executing the tree in (ii), which means that (iii) is preferable. The query optimizer therefore starts by translating the query into a canonical representation, which is easy to construct but inefficient to execute, and therefore finds better representations of the same query.

The base for finding better alternatives is the concept of *algebraic equivalences*. Two algebra expressions are equivalent if they produce the same result when executed. As this is difficult to decide in general, query optimizers instead rely on known equivalences. For example the join operator is commutative and associative:

$$A \bowtie B \equiv B \bowtie A$$
$$A \bowtie (B \bowtie C) \equiv (A \bowtie B) \bowtie C$$

Many equivalences are known from the literature [7]. The equivalences form the search space that is explored by the query optimizer: When two (sub-)expressions are equivalent, the optimizer is free to choose any of the two. Optimizers that are directly based upon this principle are called *transformative* optimizers, as they transform algebra expressions into other algebra expressions by applying algebraic equivalences. Transformative optimizers are relatively easy to build and can potentially make use of arbitrary equivalences, but an efficient exploration of the search space is very difficult. Most transformative optimizers are therefore only heuristical. The family of *constructive* optimizers does not apply the equivalences directly, but builds expressions bottom-up from smaller expressions such that the resulting expression is still equivalent to the original expression. This allows for a much more efficient exploration of the search space, but is difficult to organize for more complex equivalences. Therefore most constructive optimizers are at least partially transformative, applying transformative rewrite heuristics for complex equivalences before (and after) the constructive optimization step.

The goal of query optimization is improving query processing, which means that the query optimizer needs to take into account the runtime effect of different alternatives. This is done by estimating the *costs* of executing an alternative. A primitive way to estimate the costs is to estimate the number of tuples processed. The intuition here is that a larger number of processed tuples implies more effort spent on executing the query. This estimation requires statistical information, in particular the cardinalities of the relations and the selectivities of the operators involved, but given these it can be computed directly from the algebra expression. Unfortunately this is much too inaccurate for practical purposes. A proper cost function should model the expected execution time (as this is the most common optimization goal), which implies taking into account access patterns on disk, costs for evaluating expensive predicates, etc. The cost function is therefore usually a linear combination of expected I/O costs and expected CPU costs. But this information cannot be derived from the algebra expression, as it is not detailed enough.

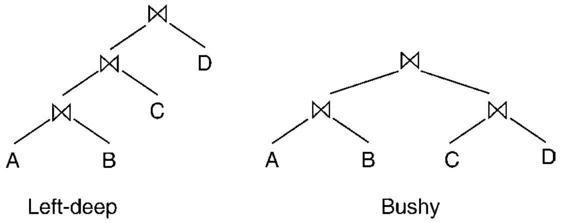
Optimizers therefore distinguish between *logical algebra* and *physical algebra*. The logical algebra consists of all operator concepts known to the optimizer, while the physical algebra consists of the operator implementations supported by the execution engine. For example the logical algebra contains one inner join operator ⋈, while the physical algebra contains one join operator for each supported implementation, like nested loop join $\bowtie^{NL}$ or sort-merge join $\bowtie^{SM}$. While the initial query is represented in logical algebra (or an equivalent calculus), the final result must be in physical algebra, e.g., the optimizer must decide which operator implementations should be used. As these physical algebra expressions (including some annotations) could be executed by the runtime system, they are often called *query execution plans*. The logical algebra is more abstract, which can be useful for optimization, but ultimately the optimizer must construct physical algebra expressions. In particular, cost-based optimization requires physical algebra, as then only costs can be estimated.

Optimizing Simple Queries

The Select-Project-Join queries (SPJ) are relatively simple yet commonly used. They correspond to SQL queries of the form SELECT ... FROM ... WHERE ... without any nested queries. They can be answered by using only selections (σ), joins/cross-products ($\bowtie/\times$), and projections (Π). Nevertheless, it has been shown that finding the optimal execution plan is NP hard in general, even for these simple queries. Several simplification are commonly used to reduce the optimization time. As a first step, the optimization concentrates on the join operators. The projections can be added as needed, i.e., whenever an operator materializes its input (and thus breaks the processing pipeline), all attributes that are no longer needed are projected away. Selections are added greedily, i.e., a selection is applied as early as possible. The rationale is that most selection predicates are cheap to evaluate and the selections reduce the work required by the following operators. Thus the optimizer only has to order the join/cross-product operators, and the other operators are added greedily. Unfortunately the problem remains NP hard even with this simplification.

The problem of finding the optimal join order can be seen as finding the optimal binary tree whose leaves correspond to the relations in the *from* clause. The inner nodes are joins or cross products, depending on available predicates suitable for a join, and are determined implicitly by the relations involved in their subtrees. Therefore, only the structure of the binary tree and the labeling of the leaf nodes has to be specified by the query optimizer. However the number of binary trees with n leaf nodes is $\mathcal{C}(n-1)$, where $\mathcal{C}(n)$ are the Catalan Numbers, which grow in the order of $\Theta(4^n/n^{\frac{3}{2}})$. As this grows very fast, some approaches reduce the search space by considering only a limited set of binary trees. A popular restriction is the limitation to *left-deep* join trees (or more general to *linear* join trees). A linear join tree is a join tree where only one of the two subtrees of a join operator may contain other join operators. If only the left subtree may contain other join operators, the trees are called left-deep. Figure 2 shows an example. General join trees without restrictions are called *bushy* join trees. Left-deep join trees are attractive (e.g., System R used them), as they are potentially easier to execute and the number of left-deep join trees is much smaller than the number of bushy join trees. As there are $n!$ ways to label the leaf nodes of the join tree for n relations, there are $n!\mathcal{C}(n-1)$ bushy trees, but "only" $n!$ left-deep trees. Unfortunately the optimal join tree can be a bushy tree, and these cases are not uncommon, which means that generating only left-deep trees can hurt query execution performance. Most modern query optimizers therefore construct bushy join trees.

The huge factor of $n!$ is caused by the fact that all combinations of relations are considered valid. The search space can be significantly reduced by avoiding the creation of cross products. When combining two relations, the optimizer can either use a cross-product, or use a join if there is a suitable join predicate in the *where* condition. Joins are much more efficient than cross-products, and although it is sometimes beneficial to use cross-products between separate relations, these cases are rare. When allowing cross-products, any relations can be combined, otherwise combinations are only possible if a suitable join predicate exists. The join possibilities implied by the query are captured in the query graph, as shown in Fig. 3. The relations from the *from* clause form the nodes, while the potential join conditions form the edges. Now the optimizer only has to consider sub-problems, i.e., sets of relations, that are connected in the query graph (this assumes that the



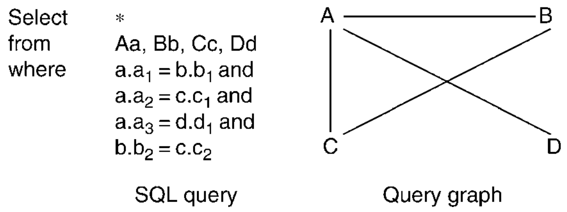
Query Optimization (in Relational Databases). Figure 2. Left-deep Versus bushy join trees.

query graph itself is connected, which can be guaranteed by adding additional edges). For example the relations A,B,C can be joined and thus could be part of a join tree, while no join tree will consist only of B,C,D, as this would require a cross-product. The structure of the query graph greatly affects the size of the search space. If the query graph forms a chain, the join ordering problem is no longer NP hard and can be solved in $O(n^3)$. If the query graph forms a clique, the problem is still NP hard (and just as difficult as when including cross products). Most queries are between those two extremes, and more like a chain than like a clique, and can thus be optimized much more efficiently by avoiding cross products.

Putting these observations together, SPJ queries can be optimized by the following strategy:

1. The only optimization decision is the join order, selections and projections are added greedily
2. The relations in a join tree must be connected in the query graph
3. When constructing left-deep trees, the right hand side of a join must contain only one relation.

The seminal System R paper on query optimization [9] introduced a dynamic programming (DP) strategy to optimize the join order. A slightly generalized version that generates bushy trees is shown in Fig. 4. It computes the optimal join order of the relations $R_1,\ldots,R_n$ (ignoring selections and projections for a moment). The basic strategy is to construct solutions for larger (sub-)problems (i.e., problems involving more relations) from optimal solutions of smaller problems. For example, consider the top-most join in a join tree with four relations. It will either combine two join trees with two relations each or a single relation with a join tree with three relations. The problem of joining four relations can thus be expressed as combining smaller problems with one to three relations each. Accordingly, the DP table is first organized by the size (i.e., number of relations) of a problem. For a given size, the table stores the optimal execution plan for a given set of relations. In lines 1–2 the algorithm initializes the DP table by adding table scans as the optimal solution for problems involving a single relation. The loop starting in line 3 now creates solutions of size s by combining smaller solutions. Lines 4–5 find all pairs of problems already solved (S_1, S_2) that have a combined size of s. If S_1 and S_2 overlap (i.e., they have relations in common) the pair is ignored, as no valid join tree can be constructed (line 6). Similarly (S_1, S_2) is ignored if S_1 and S_2 are not connected in the query graph to avoid the creation of cross-products (line 7). Otherwise it is possible to construct a new execution plan p that joins the known solutions for S_1 and S_2 (line 8). If no solution for $S_1 \cup S_2$ is known, (or the estimated costs of the new plan are less than for the currently known solution), p is added as a solution of size s for $S_1 \cup S_2$ in the DP table (lines 9–10). At the end of the algorithm the DP table entry for size n contains the optimal solution (line 11).



```
Select  *
from    Aa, Bb, Cc, Dd
where   a.a1 = b.b1 and
        a.a2 = c.c1 and
        a.a3 = d.d1 and
        b.b2 = c.c2
```

Query Optimization (in Relational Databases). Figure 3. A query and its query graph.

```
DPsize($R = \{R_1,\ldots,R_n\}$)
for each $R_i \in R$
    dpTable[1][$\{R_i\}$] = $R_i$
for each $1 < s \le n$ ascending // size of plan
    for each $1 \le s_1 < s$ // size of left subplan
        for each $S_1 \in$dpTable[$s_1$], $S_2 \in$dpTable[$s - s_1$]
            if $S_1 \cap S_2 \neq \emptyset$ continue
            if $\neg(S_1$ connected to $S_2)$ continue
            $p$ = dpTable[$s_1$][$S_1$]$\bowtie$dpTable[$s - s_1$][$S_2$]
            if dpTable[$s$][$S_1 \cup S_2$]=$\emptyset$ V cost($p$)<cost(dpTable[$s$][$S_1 \cup S_2$])
                dpTable[$s$][$S_1 \cup S_2$] = p
return dpTable[$n$][$\{R_1,\ldots,R_n\}$]
```

Query Optimization (in Relational Databases). Figure 4. Dynamic programming strategy for SPJ queries.

The algorithm in Fig. 4 is simplified, as it ignores selections and projections. They can be added greedily in lines 2 and 8 and do not affect the algorithm otherwise. A more complex part that is missing is the selection of the physical join operator. Line 8 simply states ⋈, but in a real system, there are multiple join operators available, typically at least nested-loop join, hash join, and sort-merge join. Lines 8–10 should therefore loop over the different join implementations and try all of them. What complicates this choice is that the different implementations behave differently, in particular the sort-merge join. When the input has to be sorted, the sort-merge join is relatively expensive, but when it is already sorted it is very cheap. And the output of a sort-merge join is itself sorted, which can render a following sort-merge join cheap if the order can be reused. Tuple orders that could be used by other operators are called *interesting orderings*, and the set of interesting orderings for the current query is computed before starting the *plan generation* (i.e., the DP algorithm, which constructs execution plans). During plan generation, plans that are more expensive than others have to be preserved, but provide an interesting order the others do not. This can be generalized by the concept of *physical properties*. A physical property is a characteristic of a plan that affects its runtime behavior (i.e., the costs of subsequent operators), but not its logical equivalence. The physical properties define a partial order between plans, describing which plans satisfy "more" properties. For example a plan with sorted output dominates another plan with unsorted output (concerning the physical property "ordered"), while two plans with differently sorted output are not directly comparable. During plan generation, a plan only dominates another plan if both the physical properties are dominating and the estimated costs are lower. As a consequence, the DP table entries no longer consist of single optimal plans, but of sets of plans, in which no plan dominates the other. Note that physical properties are an example for re-establishing the principle of optimality required for dynamic programming, which is also required in other contexts.

More Complex Queries

While Selection-Projection-Join queries are a important class of queries, queries can be much more complex. When only optimizing (inner) joins, the joins are freely reorderable, which means that any join order is valid as long as syntax constraints are satisfied (i.e., the relations required for the join predicates are available). This is no longer the case for other operators like outer joins and aggregations. A simple approach to handle these is to split the query into blocks that are freely reorderable (e.g., above and below an outer join) and to optimize the blocks individually. But this is too restrictive, and outer joins still allow for some reorderings, which have been described as algebraic equivalences. The challenge is to incorporate these equivalences into a cost-based (and potentially constructive) query optimizer. For outer joins, it has been shown how the possible reorderings can be expressed as dependencies on input relations [8]. The algorithm analyzes the original query and computes the set of relations that have to be part of a join tree before a specific outer join is applicable. Using this information the outer joins can be integrated easily, the plan generator just has to check the additional requirements before inserting an outer join. The main difficulty is computing this dependency information, but once it is available, the optimization is relatively simple. Other operators like aggregations are more difficult to integrate. Aggregations can be moved down a join if the join itself does not affect the aggregation results (e.g., a 1:1 join involving the grouping attribute where the join behaves like a selection). Pushing the aggregation down can reduce the effort for the join itself and might thus be beneficial. But in cases where the aggregation can simply be moved are relatively limited. Here, a more general movement of aggregations is possible by allowing for compensation actions. These are computations added to the plan that compensate the fact that the aggregation is performed at a different position. Adding these kinds of optimizations into a cost-based, constructive query optimizer is very challenging, which is why they are usually implemented as heuristical rewrite operations.

Another important aspect of optimizing complex queries is unnesting nested queries and the related problem of view resolution. The SQL query language allows for nesting queries inside other queries, either explicitly by including a nested *select* block, or implicitly by accessing a view. The nested query could be optimized independently from the outer query, and then during the optimization of the outer query treated like a base relation with specific costs. But this will often lead to inferior plans, for example if selection predicates from the outer query could be pushed down into a view. Instead, the optimizer tries to merge the nested query with the outer query into one flat query, which is then optimized in one step. Perhaps even more important than the unified optimization is a decoupling between the nested query and the outer query. The evaluation of the nested query can depend on the attributes of the outer query, which implies a very expensive nested-loop evaluation. In many cases it is possible to unnest these queries such that the nested (and apparently dependent) part can be evaluated independently, and then joined appropriately with the outer part of the query [9]. These optimizations greatly improve the evaluation of nested queries.

Key Applications

Query optimization techniques can improve the query execution time by orders of magnitude. All modern relational database systems therefore implement at least some optimization techniques.

In-network query processing

Definition

Query optimization is the process of producing a query evaluation plan (QEP) for a query that minimizes or maximizes certain objective functions. A query in a sensor network has additional clauses that specify the life time of a query, the frequency in which the sensor data should be monitored, and even the rate in which query answers should be returned. As such, the query plan must reflect these. In addition, a typical query plan comprises two main components: a communication component that sets up the communication structure for data delivery, and a computation component that performs the operation in the sensor network and/or the root node. Because sensor nodes are low-powered, besides minimizing computation cost, optimization criterion include minimizing energy consumption (e.g., by minimizing transmission cost) or maximizing the lifespan of the entire sensor network. As such, the cost model must consider these various factors.

Historical Background

Query optimization has always been an important area of research in database query processing. This is because a poorly chosen query execution plan can result in significant waste of resources, and more importantly, user dissatisfaction. In sensor network, the problem is more critical because of the resource constrains of the sensor nodes which are limited in computation power, bandwidth, memory, and energy.

Most of the existing works focused on in-network aggregation [2,3,5,6,10]. While work in [3,10] aim at precise answers, work in [2,6] assume errors (approximations) can be tolerated. In particular, the work in [6] exploits the tradeoff between data quality and energy consumption to extend the lifetime of the sensor network. Both the Cougar project [10] and the TinyDB project [3], in their prototype design of a sensor network management system, offer broader insights into query processing and optimization issues.

Foundations

To support applications in sensor networks, the database community has viewed the sensor network as a database [3,10]. This provides a good logical abstraction for sensor data management. Users can issue declarative queries without having to worry about how the data are generated, processed, and transferred within the network, and how sensor nodes are (re)programmed. As such, query optimization techniques can also be applied to optimize the network operations.

Queries

Queries are typically expressed using an extended SQL that include additional clauses that specify the duration and sampling rates. As an example, the following query counts the number occupied nests in each loud region of a certain island [3,10]:

```
SELECT region, CNT(occupied), AVG
(sound)
FROM sensors
GROUP BY region
HAVING AVG(sound) > 200
SAMPLE PERIOD 10 FOR 3,600
```

Here, the clause "SAMPLE PERIOD ... FOR" indicates that the sensors will sample the environment every 10 seconds for a duration of 3,600 seconds.

Query Plan

To evaluate a query, a query plan has to be generated for the sensors. A query plan specifies the role of each sensor (the computation to be performed, the rate at which it should sample the data), and the communication structure between sensors. For the sample query above, three alternative plans can be considered: (i) Each sensor samples its data every 10 seconds, and then transmits the data back to the base station; at the base station, it will perform the grouping and aggregate computation as in a centralized system. (ii) A sensor within a region is selected as a cluster head (CH); all sensors within the region send their sampled data to the corresponding CH; the CH performs the aggregate and sends it back to the base station if it satisfies the HAVING clause (i.e., >200). (iii) This is similar to Plan 2, except that sensors within a region can be further hierarchically partitioned so that each partition has a leader that performs partial aggregation of the sampled data from its child nodes.

For Plan 1, each sensor node takes on at most two roles: (i) sample the data and transmit the sampled value back to the base station, and (ii) relay the data it receives from its child nodes if it is an internal node along the path to the base station. For Plan 2, the CH has the additional computation task of performing the aggregate and determining whether it should be routed back to the base station. For Plan 3, leaders have the responsibility to perform partial aggregates.

All the plans may also specify the sensor nodes in which one should be transmitting data to and/or receiving data from, i.e., the communication structure.

Clearly, there are many other possible plans that can be generated, and it is the optimizer's task to pick the one that best suits the objectives.

Metadata

The optimizer makes its decision based on certain metadata. For example, the metadata for each sensor include the static information about its location (region), the sensor types, the amount of memory, the energy consumption per operation type, the energy consumption per sampling per sensor type, and so on. It may also be necessary to maintain dynamic statistics on a sensor's estimated (remaining) battery life, and the selectivity of query predicates. These metadata are periodically collected (via the routing tree) by the optimizer, and used in several ways. For example, for sensor nodes with short battery life, the sampling rate may be adjusted so that they can operate in a doze mode longer in order to extend the lifespan of the entire network. As another example, nodes with long battery life may be selected as the cluster heads or leaders, nodes with moderate amount of energy can relay messages, and nodes with low battery power will simply transmit their sampled data. As such, it is possible to balance the energy across all nodes. As another example, knowing the energy consumption per sampling per sensor type may allow the optimizer to reorder predicates on different sensor types.

Cost Model

For each query plan, the optimizer estimates the cost of the plan. The cost model depends on the objective function. In a sensor network environment, there are two key metrics: energy consumption and transmission cost (as communication consumes most energy).

As an example, consider an arbitrary sensor node along the path of the routing tree. Let N be the number of sensor types and k be the number of predicates. Let E_i is the cost to sample sensor type i, E_{trans} and E_{recv} be the energy to transmit and receive a message respectively, E^i_{pred} be the energy consumed to evaluate predicate i, and E_{agg} be the energy to compute a (partial) aggregate, and C be the number of child nodes routing through this node. The energy at a node s to collect a sample, and transmit its partial aggregate, including the costs to forward data, can be estimated as follows:

$$e_s = \sum_{i=0}^{N} E_i + \sum_{i=0}^{N} E^i_{pred} + E_{recv} \times C + E_{agg} + E_{trans}$$

The energy consumed by the node is the cost to read all the sensors at the node (first component), plus the cost to evaluate the predicates (second component), plus the cost to receive partial aggregates from its child nodes (third component), plus the cost to compute a partial aggregate (fourth component), plus the cost to transmit the partial aggregate (fifth component).

Suppose sensor s has a remaining battery capacity of B_s Joules. Then, s has enough power to last B_s/e_s sample collections. To extend the lifespan of the system, a plan that maximizes this value has to be determined. Let there be P plans, then a plan that maximizes the minimim number of sample collections is the one that should be selected (to maximize the lifespan of the system), i.e.,

$$max^P_{i=1}(min^N_{j=1} B_j/e_j)$$

Depending on different objectives and model, similar cost models can be derived.

Centralized Optimization

Most of the existing work on optimizing sensor network queries are based on a centralized optimizer, i.e., the optimizer at the base station determines the query plan [3,10]. There are two dimensions in which query processing can be optimized. The first dimension deals with the grouping of the sensor nodes to support in-network computation (e.g., aggregates). Essentially, the optimizer enumerates the possible alternative plans based on different ways in which nodes are grouped. Some heuristics are:

1. On one extreme, all nodes belong to a single group;
2. On another extreme, each node forms a single group;
3. Between the two extremes, different group-based heuristics can be adopted: proximity-based schemes cluster nodes that are close-by together, semantic-based schemes cluster nodes that are semantically related, e.g., same set of sensor types, same resources, same metadata, etc.

The second dimension covers heuristics that are used to reorder the operations of a query. Some of these are:

1. When a sensor node is required to sample multiple attributes (temperature, humidity, light) and the query involves a number of predicates, different orderings of the samping and predicate evaluations may result in different energy consumption. This is the case because sampling consumes more power than evaluating a predicate. As such, to conserve energy, it makes sense to order selective predicates first before the non-selective predicates; in addition, data should be sampled only when necessary. Intuitively, once a sampled value is discarded (because it does not satisfy a predicate), there is no need to expend energy to sample other attributes. Thus, the optimizer enumerates different sequences of sampling and predicate evaluations to find the one that is most energy efficient. As an example, consider a query that finds sensor nodes whose accerlerometer and magnetometer readings exceed thresholds a1 and m1 respectively. As the magnetometer consumes 50 times more energy than the accerlerometer to sample a reading, if the selectivity of the predicate on the accerlerometer reading is low, then it makes sense to sample the accerlerometer first. Moreover, the magnetometer should only be sampled when the accerlerometer reading is larger than a1.
2. For certain event monitoring queries, they can be rewritten into a window join queries that can be more efficiently processed in the network.

Distributed Optimization

As centralized optimization schemes require certain metadata that must be periodically obtained from the sensor nodes, it may be costly (in terms of power) to collect this information. An alternative approach is to perform distributed optimization [4]. Here, the basic idea is to identify clusters of nodes with its associated cluster head (CH) so that these CHs optimize the queries for processing within the cluster. Thus, the base stations disseminate the query to the CHs, each of which optimizes the query based on the local metadata and controls the processing within the cluster.

With distributed optimization, the metadata is collected at the CH, rather than the base station. This means that the transmission overhead for metadata is reduced. Moreover, "local" metadata are more accurate as some globally collected metadata may be too coarse (e.g., distribution of data). However, the CHs incur the overhead of optimizing the query.

Here, the challenge is to determine the clusters (either spatially or semantically). In spatial-based clustering scheme, the number of groups are based on the radius of a group, which is the number of hops between a non-CH node and its CH. In the semantic-based clustering scheme, nodes with similar netadata are formed into groups.

Key Applications

Sensor databases can be applied in many applications, e.g., environmental monitoring, military surveillance. To process queries in these applications, it is necessary to optimize the queries in order to ensure that resources are well utilized, and the system lifespan can be sufficiently large to minimize any need to replace the batteries regularly.

Future Directions

Most of the existing work in the literature focused on optimizing aggregate queries one at a time. Recently, join queries have been studied. In [1], static join queries are considered, and in [9], continuous join queries are examined. In both cases, join processing is pushed into the sensor network. In the former, sensor nodes are grouped so that a static table can be partitioned across them; new sampled records are broadcast within a group, and only answers need to be sent back to the base stations. In the latter, the focus is on minimizing the number of subqueries that need to be injected into the sensor network. As sensor nodes become more powerful, there is much opportunity for optimizing complex queries that have not been previously studied. Another promising direction that has recently received attention is the multi-query optimization problem [7,8]. Here, multiple queries submitted by users are optimized collectively to exploit commonality among them so that any redundant data accesses from the sensors can be eliminated. Current focus is on non-join queries. Extending these schemes to handle more complex queries is an interesting direction to explore. Yet another direction is to consider a large scale sensor network deployment that involves multiple base stations. Here, the challenge is to optimize the network lifespan as well as the load across the base stations.

Query Plan

Evaggelia Pitoura
University of Ioannina, Ioannina, Greece

Synonyms

Query plan; Query execution plan; Query evaluation plan; Query tree; Operator tree

Definition

A query or execution plan for a query specifies precisely how the query is to be executed. Most often, the plan for a query is represented as a tree whose internal nodes are operators and its leaves correspond to the input relations of the query. The edges of the tree indicate the data flow among the operators. The query plan is executed by the query execution engine.

Key Points

During query processing, an input query is transformed into an internal representation, most often, into a relational algebra expression. To specify how to evaluate a query precisely, each relational operator is then mapped to one or more physical operators, which provide several alternative implementations of relational operators.

A query plan for each query specifies the physical operators to be used for its execution and the order of their invocation. Most commonly, a query plan is represented as a tree. The leaf nodes of the query tree correspond to the input (or base) database relations of the query and its internal nodes to physical operators. The edges of the tree specify the data flow among the operators. Each operator receives input from its child nodes in the tree and, in turn, its output is used as input to its parent node.

The query optimizer enumerates alternative query plans for each query and selects the most efficient among them using a cost estimation model. The selected query plan is then passed for execution to the query execution engine that results in generating answers to the query.

Query plans can be divided into prototypical shapes and query execution engines can be divided into groups based on which shapes of plans they can evaluate. Such shapes include left-deep, right-deep and bushy plans. Deep plans are plans in which each join involves at least one base relation, whereas bushy plans are more general in that a join could involve one or two base relations or the results of one or two other join operations. Finally, for queries with common subexpressions, the query evaluation plan may be an acyclic directed graph (DAG) instead of a tree.

Query Point Movement Techniques for Content-Based Image Retrieval

Kien A. Hua, Danzhou Liu
University of Central Florida, Orlando, FL, USA

Definition

Target search in content-based image retrieval (CBIR) systems refers to finding a specific (target) image such as a particular registered logo or a specific historical photograph. To search for such an image, query point movement techniques iteratively move the query point closer to the target image for each round of the user's relevance feedback until the target image is found. The goals of query point movement techniques include avoiding local maximum traps, achieving fast convergence, reducing computation overhead, and guaranteeing to find the target.

Historical Background

Images in a database are characterized by their visual features, and represented as points in a multidimensional feature space. A *query point* is one of these image points, selected to find similar images represented by image points nearest to the query point in the feature space. This cluster of nearby or relevant image points has a shape (see Figs. 1 and 2) referred to as the *query shape*.

For each iteration, a query point movement technique attempts to move the query point closer to the target image by refining the query based on user's relevance feedback. Existing query point movement techniques can be divided into two categories: single-point and multiple-point movement techniques. A technique is classified as a single-point movement technique if the refined query Q_r at each iteration consists of only one query point; otherwise, it is a multiple-point movement technique. In the latter category, the query result is the set of images nearest to the set of query points. Typical query shapes of single-point movement and multiple-point movement techniques are illustrated in Figs. 1 and 2, respectively, where the contours represent equi-similarity surfaces. Single-point movement techniques, such as MARS [9] and MindReader [5], construct a single query point close to relevant images and away from irrelevant ones. MARS uses a weighted distance (producing shapes as shown in Fig. 1b), where each dimension weight is inversely proportional to the standard deviation of the relevant images' feature values in that dimension. The rationale is that a small variation among the values is more likely to express restrictions on the feature, and thereby should carry a higher weight. On the other hand, a large variation indicates that this dimension is not significant in the query, and should thus assume a lower weight. MindReader achieves better results by using a generalized weighted distance, see Fig. 1c for its shape.

In multiple-point movement techniques such as Query Expansion [1], Qcluster [6], and Query Decomposition [4], multiple query points are used to define the ideal space that is most likely to contain relevant results. Query Expansion groups query points into clusters and choose their centroids as the representatives of the query Q_r (see Fig. 2a). The distance of a point to Q_r is defined as a weighted sum of individual distances to those representatives. The weights are proportional to the number of relevant objects in the clusters. Thus, Query Expansion treats local clusters differently, compared to the equal treatment in single-point movement techniques. In some queries, clusters

Query Point Movement Techniques for Content-Based Image Retrieval. Figure 2. Multiple-point movement query shapes.

are too far apart for a unified, all-encompassing contour to be effective; separate contours can yield more selective retrieval. This observation motivated Qcluster to employ an adaptive classification and cluster-merging method to determine optimal contour shapes for complex queries. Qcluster supports disjunctive queries, where similarity to any of the query points is considered relevant (see Fig. 2b). To bridge the semantic gap more effectively, A Query Decomposition technique was presented in [4]. Based on user's relevance feedback, this scheme automatically decomposes a given query into localized subqueries, which more accurately capture images with similar semantics but with very different appearance (see Fig. 2c).

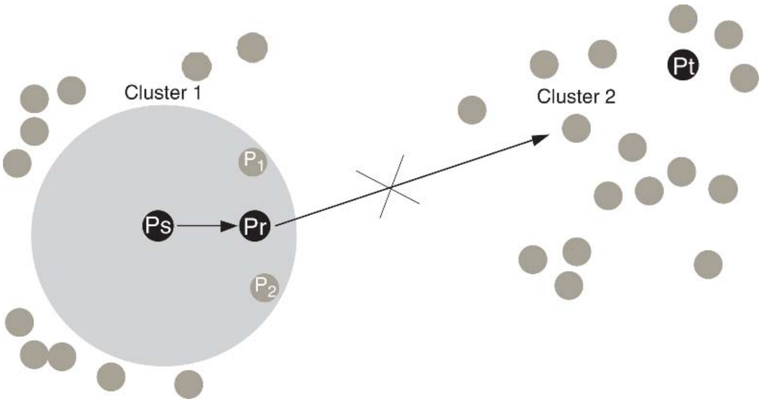
Standard query point movement techniques, explained above, allow re-retrieval of previously determined relevant images when they fall in the search range again. This leads to two major disadvantages:

1. *Local maximum traps*. Since query points in relevance feedback systems have to move through many regions before reaching a target, it is possible that they get trapped in one of these regions. Figure 3 illustrates a possible scenario where p_s and p_t denote the starting query point and the target point, respectively. As a result of a 3-NN search at p_s, the system returns points p_1 and p_2, in addition to query point p_s. Since both p_1 and p_2 are relevant, the refined query point p_r is their centroid and the anchor of the next 3-NN search. In this situation, the system will retrieve exactly the same set; from which, points p_1 and p_2 are again selected. In other words, the system can never get out of the subspace because the retrieval set is saturated with the k selected images. Although the system can escape with a larger k, it is difficult to guess a proper threshold. Consequently, the user might not even know a local maximum trap is occurring, and there is no guarantee to find the target image.
2. *Slow convergence*. The centroid of the relevant points is typically selected as the anchor of refined queries. This, coupling with possible retrieval of already visited images, prevents aggressive movement of the search process (see Fig. 4, where $k = 3$). Slow convergence incurs longer search time, and significant computation and disk access overhead.

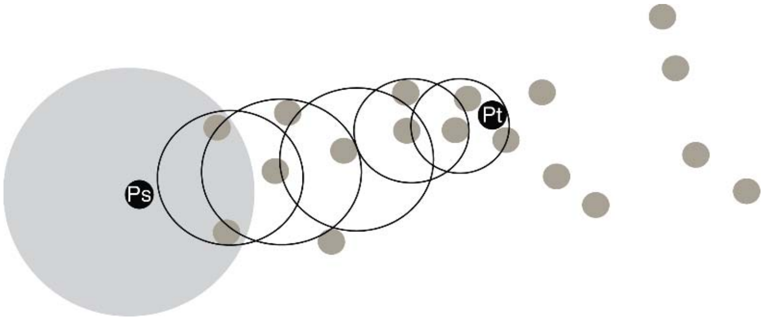
Foundations

To address the limitations of standard query point movement techniques, four target search methods have been proposed [8]: Naïve Random Scan (NRS), Local Neighboring Movement (LNM), Neighboring Divide and Conquer (NDC), and Global Divide and Conquer (GDC) methods. All these methods are designed around a common strategy: they do not retrieve previously selected images (i.e., shrink the search space). Furthermore, NDC and GDC exploit Voronoi diagrams to aggressively prune the search space and move towards the target image faster.

More formally, a query in target search is defined as $Q = \langle n_Q, P_Q, W_Q, D_Q, \mathbb{S}, k \rangle$, where n_Q denotes the number of query points in Q, P_Q the set of n_Q query points in the search space $\mathbb{S}$, W_Q the set of weights associated with P_Q, D_Q the distance function, and k the number of points to be retrieved in each iteration. Using these notations, the four target search techniques can be described as follows:



Query Point Movement Techniques for Content-Based Image Retrieval. Figure 3. Local maximum trap.



Query Point Movement Techniques for Content-Based Image Retrieval. Figure 4. Slow convergence.

Naïve Random Scan Method (NRS)

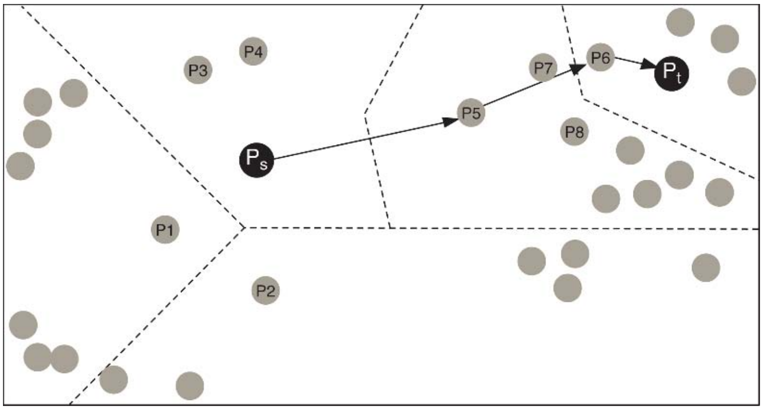
This method randomly retrieves k different images at a time until the user finds the target image or the remaining set is exhausted. Specifically, at each iteration, a set of k not previously selected images are randomly retrieved from the candidate set $\mathbb{S}'$ for relevance feedback, and $\mathbb{S}'$ is then reduced by k for the next iteration. Clearly, this strategy does not suffer local maximum traps and is able to locate the target image after some finite number of iterations. In the best case, NRS takes one iteration, while the worst case requires $\left\lceil \frac{|\mathbb{S}|}{k} \right\rceil$. On average, NRS can find the target in $\left\lceil \sum_{i=1}^{\left\lceil \frac{|\mathbb{S}|}{k} \right\rceil} i / \left\lceil \frac{|\mathbb{S}|}{k} \right\rceil \right\rceil = \left\lceil (\left\lceil \frac{|\mathbb{S}|}{k} \right\rceil + 1)/2 \right\rceil$ iterations. In other words, NRS takes $\mathcal{O}(|\mathbb{S}|)$ to reach the target point. Therefore, NRS is only suitable for a small database set.

Local Neighboring Movement Method (LNM)

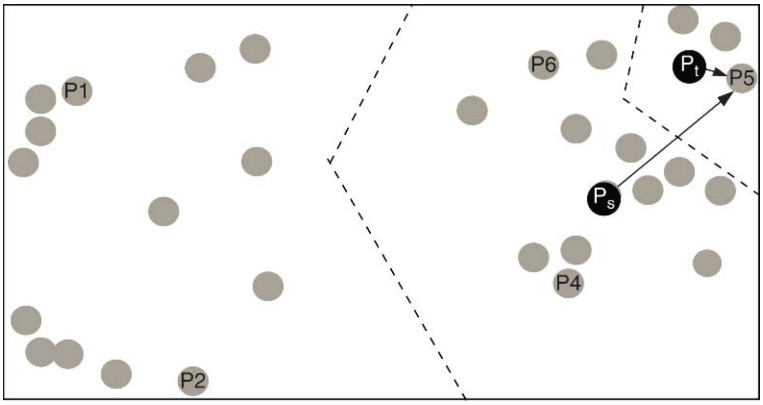
This method applies the non-re-retrieval strategy to MindReader [5]. Specifically, Q_r is constructed so that it moves towards neighboring relevant points and away from irrelevant ones, and k-NN query is now evaluated against $\mathbb{S}'$ instead of $\mathbb{S}$. When LNM detects a local maximum trap, it requests that the user selects the most relevant image. This way, LNM can overcome local maximum traps, although it could take many iterations to do so. Again, one iteration is required in the best case. If data is uniformly distributed in the n-dimensional hypercube, the worst and average cases are $\left\lceil \sqrt{n}\sqrt[n]{|\mathbb{S}|}/\lceil \log_{2^n} k \rceil \right\rceil$ and $\left\lceil (\frac{\sqrt{n}\sqrt[n]{|\mathbb{S}|}}{\lceil \log_{2^n} k \rceil} + 1)/2 \right\rceil$, respectively. If the data are arbitrarily distributed, then the worst case could be as high as that of NRS, i.e., $\left\lceil \frac{|\mathbb{S}|}{k} \right\rceil$ iterations (e.g., when all points are on a line). In summary, in the worst case LNM could take anywhere from $\mathcal{O}(\sqrt[n]{|\mathbb{S}|})$ to $\mathcal{O}(|\mathbb{S}|)$.

Neighboring Divide and Conquer Method (NDC)

Although LNM can overcome local maximum traps, it does so inefficiently, taking many iterations and in the process returning numerous false hits. To speed up convergence, Voronoi diagrams are used in NDC to reduce the search space after each round of relevance feedback. That is, the k-NN search in each iteration is performed only within the Voronoi cell containing the query point. It can be proved that the target image must reside in this Voronoi cell [8]. Since this strategy aggressively prunes the search space and moves rapidly towards the target image, it can overcome local maximum traps and achieve fast convergence. Figure 5 illustrates how NDC approaches the target after pruning the search space three times. In the first iteration, points p_1, p_2, and p_s are randomly chosen by the system, assuming $k = 3$; and they are used to construct a Voronoi diagram partitioning the search space into three regions. The user identifies p_s as the most relevant point (i.e., most similar to the target image). Since the target image must reside in the Voronoi cell containing p_s, the computation of the k-NN query anchored at p_s can be confined to this cell while the other two Voronoi regions can be safely ignored. This step retrieves three new nearest neighbors p_3, p_4, and p_5. Their Voronoi diagram further partitions the current search space into three regions. The user again correctly selects p_5 as the most relevant point, and therefore the query point for the third iteration. This refined query results in another set of relevant points p_6, p_7, and p_8; and another Vonronoi diagram is constructed. This time, the user selects p_6 as the most relevant image. Using it



Query Point Movement Techniques for Content-Based Image Retrieval. Figure 5. Example of NDC.

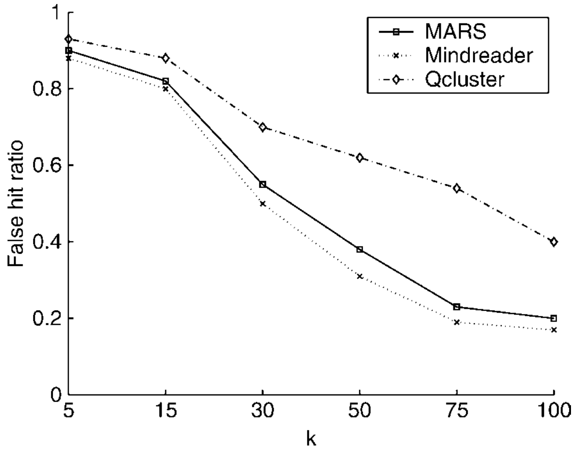


Query Point Movement Techniques for Content-Based Image Retrieval. Figure 6. Example of GDC.

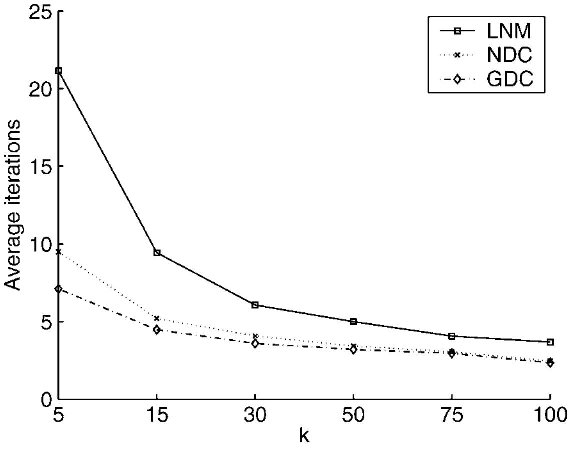
as the query point for the fourth iteration, the system returns three relevant points and the user identifies p_t as the target image. If the data points are uniformly distributed, NDC reaches the target point in no more than $\mathcal{O}(\log_k|\mathbb{S}|)$ iterations. When $\mathbb{S}$ is arbitrarily distributed, the worst case could take up to $\lceil\frac{\mathbb{S}}{k}\rceil$ iterations (e.g., all points are on a line), the same as that of NRS. In other words, NDC could still require $\mathcal{O}(|\mathbb{S}|)$ iterations to reach the target point in the worst case.

Global Divide and Conquer Method (GDC)

To reduce the number of iterations in NDC under the worst case scenario, GDC constructs the Voronoi diagram based on points randomly selected from the current search space, instead of using points from the query result. An example is given in Fig. 6. In the first iteration, a Voronoi diagram is constructed based on three randomly sampled points p_1, p_2, and p_s, assuming $k = 3$. The user selects p_3 as the most relevant point, and this results in p_4, p_5, and p_6 as the query result as computed in NDC. The user now selects p_5 as most relevant in the second iteration. The system randomly selects three points in the Voronoi cell associated with p_5, and uses them to further partition this cell into three smaller Voronoi cells. The computation of the k-NN query anchored at p_5 over the smaller Voronoi cell containing p_5 returns three new points, and the user identifies p_t as the target image in the third round. As proved in [8], the worst case for GDC is bounded by $\mathcal{O}(\log_k|\mathbb{S}|)$. This implies that for arbitrarily distributed datasets, GDC converges faster than NDC in general, although NDC might be as fast as GDC for certain queries, e.g., the starting query point is close to the target point. In the previous example (Fig. 5), NDC could also take three iterations, instead of four, to reach the target point if the initial k points were the same as in Fig. 6, as opposed to Fig. 5.



Query Point Movement Techniques for Content-Based Image Retrieval. Figure 7. False hit ratio.



Query Point Movement Techniques for Content-Based Image Retrieval. Figure 8. Average iterations.

Key Applications

Multimedia Search Engine, Crime Prevention, Graphic Design.

Future Directions

1. Incorporate information from the log file on user relevance feedback to determine the query results in each feedback iteration, instead of performing the traditional *k*-NN computation. This strategy can minimize the effect of the semantic gap between the low-level visual features and the high-level concepts in the images.
2. Multiple query points, as in standard query point movement techniques such as Query Expansion [1] and Qcluster [6], can be used in each iteration to better convey user's relevance feedback.
3. With the growing interest in Internet-scale image search applications, it is desirable to extend the target search techniques because it will enable concurrent users to share computation [7].

Experimental Results

Figure 7 shows that standard techniques MARS [9], MindReader [5], and Qcluster [6] have poor false hit ratio when *k* is small. This is due to the effect of local maximum traps. Even for fairly large *k*, their false hit ratios remain very high. As a result, users of these techniques have to examine a large number of returned images, but might still not find their intended targets. Figure 8 shows that NDC and GDC perform more efficiently when *k* is small, with GDC being slightly better than NDC. Specifically, when $k = 5$, the average numbers of iterations for LNM, NDC, and GDC are roughly 21, 10, and 7, respectively. Experimental studies based on a prototype [8] showed that only seven iterations on average were needed to locate a given target image. Additional performance results can be found in [8].

Data Sets

The data set consists of more than 68,040 images from the COREL library. Thirty-seven visual image features divided into three main groups were used: colors (9 features), texture (10 features), and edge structure (18 features).

Query Processing

EVAGGELIA PITOURA
University of Ioannina, Ioannina, Greece

Synonyms

Query evaluation

Definition

A query processor receives a query, validates it, optimizes it into a procedural dataflow execution plan and executes it to obtain the results of the query.

Key Points

Query processing consists of several phases. In the first phase, the *query parser* checks whether the query is correctly specified, resolves any names and references, verifies consistency, and performs authorization tests. If the query passes validation, it is converted into an internal representation that can be easily processed by the subsequent phases. Then, the *query rewrite module*, or *rewriter*, simplifies the query and transforms it into an equivalent form by carrying out a number of optimizations that do not depend on the physical state of the system, such as view expansion and logical rewriting of predicates. These initial phases rely only on data and metadata in the system catalog.

Next, the *query optimizer* transforms the internal query representation into an efficient query plan. It decides which indices to use, which methods to use for executing the query operators and in which order. A *query plan* may be thought of as a dataflow diagram that pipes data through a graph of query operators. The optimizer enumerates alternative plans and chooses the best plan using a cost estimation model that relies on various selectivity estimation techniques and available statistics regarding the physical state of the system. The *code generation component* transforms the plan produced by the optimizer into an executable plan. Finally, the *query execution engine* operates on the fully-specified query plan. It provides generic implementations for every operator. Most execution engines are based on the *iterator model*. In such a model, operators are implemented as iterators, with all iterators having the same interface [1,2,3].

Query compilation and execution

Definition

Query processing denotes the compilation and execution of a query specification usually expressed in a declarative database query language such as the structured query language (SQL). Query processing consists of a compile-time phase and a runtime phase. At compile-time, the query compiler translates the query specification into an executable program. This translation process (often called *query compilation*) is comprised of lexical, syntactical, and semantical analysis of the query specification as well as a query optimization and code generation phase. The code generated usually consists of physical operators for a database machine. These operators implement data access, joins, selections, projections, grouping, and aggregation. At runtime, the database engine interprets and executes the program implementing the query specification to produce the query result.

Historical Background

In the 1960s and 1970s, navigational database management systems emerged. The hierarchical database management system, IMS from IBM is a prominent example that is still widely used. The Database Task Group developed the CODASYL approach to data management during the standardization of COBOL. The CODASYL approach focuses on following pointers that link a network of data records. CODASYL lacks a declarative query language. Query processing for CODASYL databases is mainly about efficient access to data, where queries are implemented as procedural programs by software developers. There was no query optimization in the CODASYL model.

In 1970, Edgar Codd invented a relational algebra over tables. This relational data model was much more flexible than navigational data models. Relational algebra allowed the specification of arbitrary queries over relations. A combination of five primitive operations (selection, projection, union, filter, Cartesian product) over tables define a query in the relational algebra. Initially, the relational model was considered to be impractical, as it required data to be normalized into relations, and queries were very expensive operations. Queries often have to use the join operation (a combination of a Cartesian product with a selection) in order to reconstruct normalized relations. However, over the years, many inventions (database indexes, join methods like nested-loop join, merge join or hash-join, and techniques for query optimization) have together made relational database management systems feasible.

The prime example of a relational query language is SQL, which is based on a logical calculus called *tuple calculus*. An SQL query specifies *what* data to access and process in order to compute a query result, but not *how* to access and process the data. An SQL query over a relational database can be implemented in many different ways. For complex queries on databases with many indexes and tables, there may be millions of different ways to implement an SQL query. Each implementation may use different orders for combining the normalized tables, or use different join methods like hash join or nested-loop join, or use different types of indexes like B-Trees or bitmap indexes, or using indexes on different columns to efficiently process a selection over a table. Choosing the right method for processing a query over a large database can produce a query result in seconds (or faster), whereas choosing of the wrong method can result in queries running for hours, or even days.

Query optimization aims at selecting the most efficient access path (often called *query execution plan*, or *plan*) for any given query. The task of a query optimizer is to find the most efficient overall implementation of the query. Query optimization has been an active area of research since the 1970s, with advances still being made today. Some standard optimizations are based on simple heuristics. A typical objective may be to avoid large intermediate results during query processing by applying selections as early as possible. However, determining the most efficient access method for each table as well as the best join methods and join orders to combine tables cannot be carried out by simple heuristics alone. In order to find the best plan, the query processor actually needs to know some characteristics of the data that the query will process. For example, a nested-loop join method works best if one of the two tables to be joined is relatively small. A hash join has higher overhead for small tables, but will produce the query result much faster if both tables are large. Similarly, it is good to use an index if a selection results in very few rows of a table. If many rows qualify, a table scan will be much faster, as it can use sequential I/O, avoiding the consecutive repositioning of the read/write head of a hard disk as required when processing an index.

In 1979, Pat Selinger proposed a cost-based query optimizer for System R which determines the optimal query plan based on a mathematical model of the execution cost of each operator in a query execution plan. The System R optimizer, which has become the basis for many commercial database systems (e.g., IBM's DB2 and Oracle), enumerates all possible physical query execution plans for a query in a stratified bottom-up fashion. This is done by first determining the cheapest table accesses, then processing all two-table joins, three-table joins, and so on, and uses dynamic programming to prune the search space. In 1994, volcano introduced an alternative approach of a top-down optimizer based on goal-directed search and branch-and-bound pruning, which has found its way into commercial DBMS like Microsoft's SQL Server.

During the 2000s, advanced techniques for query processing have been proposed and implemented into commercial systems. One of these developments relies on feedback loops to improve query execution. Feedback obtained by monitoring some parameters of the mathematical cost model during query execution is used to either alter the query execution plan while the query is running, or to adjust the mathematical model to increase its accuracy for subsequent queries. In addition, integration of semi-structured data (XML) and the Xquery language are active areas of research, with new requirements imposed on a query processor due to the navigational operators like XPath needed for processing hierarchical data.

Foundations

The figure below gives an architectural overview of a query processor. The query compiler of a relational database translates a declarative SQL query into a procedural program. Initially, a parser carries out tokenization and creates a parse tree of the query based on the grammar of the query language. Semantical analysis then tests semantical correctness of the query. Those tests usually validate if the table names or column names in the query exist and have the right types. These parsing steps are similar to the steps a programming language parser would carry out, except that the query compiler has to generate a program for a data flow engine, not for a microprocessor. The query is therefore usually represented as a data flow graph (also called *query graph*) in a query compiler. A query graph is a graph whose edges represent the data flow and whose nodes represent operations on the data. Typical data flow operations are table access and join, group, and filter. Many query optimizers, like the optimizer of IBM's DB2 or Oracle's rule based optimizer, utilize a rule-based query rewrite phase before carrying out cost-based optimization. Query rewrite translates the query graph into a semantically equivalent query graph, which is preferable to execute. Rewrite rules include, among others, translations from subqueries into joins, or rules to generate transitive predicates to involve indexes in query processing, which would otherwise not be applicable.

The System R approach to cost-based query optimization enumerates all possible physical query execution plans for a the query graph model, associates a cost with them, and selects the cheapest plan to be executed. The cost of a query plan is expressed as a linear combination of intermediate result sizes (cardinalities) weighed by factors for CPU cost, I/O cost. Cost models for distributed systems also factor in a the communication cost for transferring data between the processing components. The optimizer uses dynamic programming and prunes the search space as early as possible by only retaining the plan with the lowest cost whenever possible. The search space can be pruned whenever some (intermediate) plans are comparable. Plans are comparable, when they are semantically equivalent, i.e., when their execution produces the same intermediate result. However, in practice, there are cases where semantically equivalent plans are not yet comparable. For example, a semantically equivalent plan may not be comparable to an intermediate plan that has an interesting property, like a particular sort order for a an intermediate result, which could be exploited at a later stage during query processing to lower the overall cost.

Plans are enumerated bottom-up in a stratified way. This stratification starts with enumerating table access plans for each table then enumerates all (intermediate) plans for combining two of these table access plans, then all (intermediate) plans for three tables, and so on, until the all plans have been enumerated that produce the overall query result. As soon as several semantically equivalent (intermediate) plans have been computed, the optimizer retains only the plan with the lowest cost for further consideration. Dynamic programming has a complexity, which is exponential in the number of tables joined in a query. If the exponential memory requirement of dynamic programming is too high due to too many joins in a query, the optimizer uses a greedy algorithm as a fallback. While dynamic programming is guaranteed to determine the optimal plan with respect to the cost model, greedy algorithms usually do not return the optimal plan. Moreover, greedy algorithms tend to have a bias towards bushy plans (i.e., balanced join trees as opposed to left-deep join trees), which usually has negative impact on pipelining and transactional queries with small intermediate results. Many commercial database systems like DB2 and Oracle use a System R style bottom-up optimizer.

Volcano's alternative approach refines the query graph model by replacing logical operators like join with physical implementations like hash-join or merge-join and uses branch and bound to limit recursion. For instance, the top-down approach is used by the query optimizer of Microsoft's SQL Server.

Both bottom-up and top-down optimizers achieve the goal of determining the optimal plan with respect to a cost model. The quality of the plan does not depend on which of these search methods is used, but rather on the repertoire of rules available for generating or expanding plans. Top-down optimizers have an advantage, though, in that they always maintain a feasible execution plan, so it is possible to stop optimization at any time and execute the currently cheapest plan. Bottom-up optimizers have the risk of running out of memory without having produced a feasible plan, thus the necessary fallback to greedy or other heuristics.

Both bottom-up and top-down optimizers need a good model for the cost of producing the intermediate results that occur during query processing. This execution cost is largely dependent upon the number of rows – often called *cardinality* – that will be processed by each operator in the plan. Typically, an estimate for the cardinality of some intermediate result relies on statistics of database characteristics. Many database systems use simple statistics to approximate the size of an intermediate result, like the number of rows for each table and as well as the number of distinct values for each column. For a simple selections with an equality predicate "$C = value$" on column C of a table with n rows and c distinct values in column C, many cost models use the simple formula $1/c * n$ to estimate the cardinality of the selection predicate. This simple formula assumes a uniform distribution of all values in column C. The cardinality estimate may be vastly incorrect if some values in column C occur more frequently than others.

Estimating the number of rows (after one or more predicates have been applied) has been the subject of much research since the 1980s. The percentage of the number of rows in a table or intermediate result satisfying a predicate P is often called *selectivity* of P. The selectivity of P effectively represents the probability that any row in the database will satisfy P. Database statistics are expensive to compute and cannot always easily be maintained incrementally, when the database changes. In general, there is a trade-off between accuracy of statistics and their storage and maintenance cost. The goal of database statistics is to be good enough to enable the optimizer to produce a robust and efficient plan. The cost model of a database systems therefore uses simplifying assumptions to compute selectivities and cardinalities from the available database statistics. Examples of these assumptions include:

1. *Currency of information*: The statistics are assumed to reflect the current state of the database, i.e., that the database characteristics are relatively stable. This may not be true, if a table is changing rapidly. In this case, statistics need to be collected frequently, using the database statistics collection tool. Outdated statistics are a major source for performance problems in database queries. Many modern database management systems have an infrastructure that tries to automatically detect when statistics are outdated by monitoring update, insert, and delete operations on a table. Those systems can be configured to (re-)collect statistics automatically when a certain amount of changes have occurred.

2. *Uniformity*: As describe above, without detailed statistics on a column, the data values within a column are assumed to be uniformly distributed. If that is not the case, the database administrator can create histograms for particular columns to deal with skew in values. This will improve the accuracy of selectivity estimation for selection predicates on a single table. Only recently have researchers begun to explore ways to improve the estimation of selectivities for join predicates which combine multiple tables.

3. *Independence of predicates*: Without any knowledge about interactions of predicates, selectivities for each predicate are calculated individually and multiplied together, even though the underlying columns may be related, e.g., by a functional dependency. This independence assumption usually results in severe underestimation of the selectivity of predicates on correlated columns. For a table containing cars with two columns, *make* and *model*, the independence assumption will result in severe estimation errors for a selection predicate like "make='VW' and model = 'Jetta'." If 10% of the cars in the table are VW, and 1% of the cars are Jetta, the independence assumption would result in a selectivity:

$$^{s}{}_{\text{VW Jetta}} = {}^{s}{}_{\text{VW}} \times {}^{s}{}_{\text{Jetta}} = 10\% \times 1\% = 0.1\% = 0.001$$

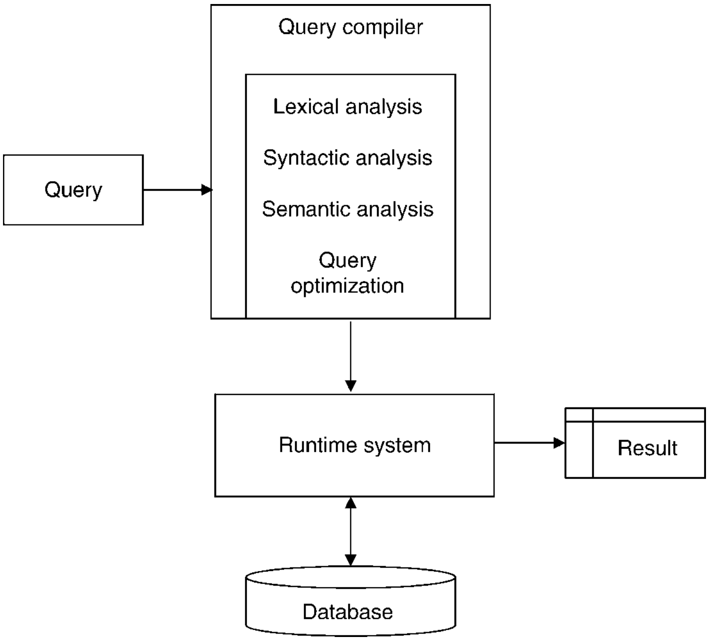
Since only VW makes Jettas, the real number is 1%, with an order of magnitude error in the estimation. This means that the intermediate result size for that part of a query will be ten times larger than what the optimizer assumes. This can result in not allocating enough memory for processing the query, or choice of a suboptimal plan. Overall, this estimation error progressively worsens, as more predicates are present in a query.

Collecting multivariate statistics across multiple columns can overcome the independence assumption when data is correlated. A simple correlation parameter is the number of distinct values over a set of attributes. This statistic is employed for instance by IBM's DB2 to correct the independence assumption for correlated local predicates, or to better estimate the selectivity of a join predicate with correlation between the two tables. While the number of distinct values over a set of columns addresses the correlation between these columns, it assumes all combinations of values in these columns to be uniformly distributed. Correlations inflate errors more than the uniformity assumption. Thus distinct values have proved worthwhile in practice as correlation statistics. In case of non-uniform correlations, multidimensional histograms have been proposed. These histograms store and maintain multivariate distribution statistics. However, multidimensional histograms do not work well for equality predicates or for maintaining correlations over a large set of columns. For that reason, they have not been widely adopted in commercial databases.

4. Principle of inclusion: The selectivity for a join predicate X.a = Y.b is typically defined to be 1/max{|a|, |b|}, where |b| denotes the number of distinct values of column b. This implicitly assumes the "principle of inclusion," i.e., that each value of the smaller domain has a match in the larger domain (which is frequently true for joins between foreign keys and primary keys). Again, correlation statistics can help overcome this assumption. Products like IBM's DB2 or Microsoft's SQL Server offer statistics on views, which can address incorrect assumptions about correlations of columns between tables or within tables.

Applications commonly used today have hundreds of columns in each table and thousands of tables, making it very hard for a database administrator to know on which columns to collect and maintain multivariate statistics or statistics on views. Tooling, either based on query feedback or proactive sampling, is addressing that problem by determining the most important correlated columns that joint statistics need to be collected on, employing statistics methods like χ^2-testing for correlation detection. Methods such as entropy maximization have been proposed to generalize the independence assumption and allow for dealing with arbitrary correlation between columns, either within or across tables.

Once the best overall query plan according to the optimizer's model has been determined, it is handed to the runtime system for execution. In some architectures,



Query Processing (in Relational Databases). Figure 1. An overview of query processing.

e.g., Informix, the query plan is directly interpreted by the runtime system. Other architectures follow the System R design and employ a code generator to produce code for a database machine, which is then executed by the runtime system. This additional code generation step allows for optimizations typically found in programming languages, to reduce path length and copying of data between CPU and memory (Fig. 1).

Key Applications

All major database systems (DB2, SQL Server, Oracle, Sybase, Informix, MySQL, PostGres) implement a query processor that largely follows the previously described architecture and concepts. DB2 and Oracle follow the System R style optimizer as described above, Microsoft SQL server uses a top-down optimizer.

Query Processing and Optimization in Object Relational Databases

Johann-Christoph Freytag
Humboldt University of Berlin, Germany

Synonyms

Query evaluation; Query planning and execution

Definition

In an (object) relational database management system (DBMS) query processing comprises all steps of processing a user submitted query including its execution to compute the requested result. Usually, a user query – for example a SQL query – declaratively describes *what* should be computed. Then, it is the responsibility of the DBMS to determine *how* to compute the result by generating a (procedural) query execution plan (QEP) that is semantically equivalent to the original query. Query processing also includes the execution of this generated QEP.

While generating a QEP for a user submitted query the DBMS explores a large number of potential execution alternatives. To choose the best ones among those alternatives requires one or more (query) optimization phases.

Historical Background

In the late 1960s and early 1970s it became clear that existing DBMSs were too complex and cumbersome to use. The programmer was forced to know the physical layout of the data on disc for efficient access. The answer to those problems was the Relational Model developed by E.F. Codd in the early 1970s.

With the design and implementation of relational DBMSs in the mid-1970s it became clear very quickly that query processing and optimization are the key for implementing DMBSs with acceptable performance for the end user. In 1979, the first relational DBMS, IBM's System-R laid the foundation for today's query processing and optimization approaches: In System-R, query processing consists of three major phases:

1. Syntactic and semantic checking
2. (physical) query optimization
3. Query execution

The INGRES DBMS (Stonebreaker, UC Berkeley) took a similar approach to implement query processing.

Over the last 25 years this phase-based model has been extended by

1. adding more query processing phases such as logical query optimization or query rewrite
2. considering more alternatives during query optimization to generate better QEPs

Furthermore, the complexity of query processing has increased due to more complex query languages (such as SQL-2 or SQL-3), more complex query execution environments such as parallel processors, distributed data collections, and more complex data types, richer data structuring capabilities including object orientation.

As a response to the development of object oriented database management systems (OODBMS) the Relational Model was extended with object oriented concepts and features to embrace the major concepts of those languages. The extension of the language forced the database vendors to extend query optimization and query extension to handle those new concepts correctly efficiently such as objects, classes, path expressions, inheritance, methods, and polymorphism [10]. Most of those language features are reflected in the SQL-3 Standard.

Foundations

The Four Phases of Query Processing

Today's DBMSs usually implement query processing (including query optimization) in three different phases before executing the query to generate the requested result [2,8].

During the first phase, the query is checked for syntactic and semantic correctness. Then, during the second phase the query is rewritten into a semantically equivalent one using additional (logical/conceptual) information, such as schema information (candidate keys/Primary key, uniqueness of values, foreign keys) or integrity constraints. Rewriting might also strive for a normalized form of the query to simplify the processing during the following phases [7].

Example 1:

The SQL query

```
SELECT *
FROM CUSTOMER
WHERE EXIST (
 SELECT *
 FROM ORDER
 WHERE CUSTOMER.ID = ORDER.CUSTOMER_ID
 AND ORDER.VALUE > 10.000)
```

could be rewritten into the query

```
SELECT *
FROM CUSTOMER, ORDER
WHERE CUSTOMER.ID = ORDER.CUSTOMER_ID
AND ORDER.VALUE > 10.000
```

if the inner query block returns zero or one tuple.

The third phase – commonly known as the (physical) query optimization – translates a user query into a query execution plan (QEP). While the initial query declaratively expresses which properties the result should have, the QEP determines the execution steps to evaluate the query generating the requested result.

In general, there are many different ways (QEPs) to evaluate a user submitted query based on the physical properties of the tables accessed, such as available indexes, available materialized views, sorting order, or clustering. Thus, the query optimizers must consider and evaluate many different alternatives to execute a query using different access paths and different operators.

During the QEP generation the optimizer determines

- The best (optimal) way to access each individual relation referenced in the query using indexes (including how and in which order to evaluate local predicates)
- The best (optimal) order to join two or more tables
- The best algorithm to perform the join between two tables

Example 2:

The rewritten query of Example 1

```
SELECT *
FROM CUSTOMER, ORDER
WHERE CUSTOMER.ID = ORDER.CUSTOMER_ID
AND ORDER.VALUE > 10.000
```

might be translated into the following QEP. For the sake of clarity the QEP uses a LISP-like notation to represent the relational algebra-like expression [4].

```
(OUTPUT
  (PROJECT
  (ID CUSTOMER_NAME ADDRESS)
  (NESTED_LOOP_JOIN
    (CUSTOMER.ID = ORDER.CUSTOMER_ID)
    (SCAN CUSTOMER)
    (FILTER
      (ORDER.VALUE > 10.000)
      (SCAN ORDER)))))□
```

Finally, during the last phase the DBMS executes the generated QEP to compute the requested result, i.e., the set of tuples that match the submitted query.

The Fundamentals of a (Physical) Query Optimizer

To generate the best (optimal) QEP any query optimizer embodies the following three aspects [4]:

1. A search strategy
2. (A set of) Cost functions
3. A QEP generation strategy

The search strategy determines which alternative (partial) QEPs should be generated while looking for the best (optimal) QEP among possibilities. Strategies such as exhaustive search strategies (together with dynamic programming) or heuristics (Greedy heuristic) are approaches used in current DBMSs. However it seems that exhaustive strategies – with some restrictions – are still the preferred approach to generate the best QEP despite a large search space whose size is determined by various parameters, such as the number of tables in the query, the available indexes, or the available join methods (algorithms).

While generating different alternatives for query execution, the optimizer must determine which of these alternatives is better. Therefore, cost functions assign cost values to (partially generated) QEPs by determining the resource consumption for that plan. The resources used might be CPU time, space (amount of memory), communication time (distributed query processing), and – most importantly – the number of disk IOs since disk IOs are the dominating cost in almost all QEPs. Cost functions therefore estimate ("foresee") the amount of resources that a plan will consume when being executed.

To feed the cost functions with input, most DBMSs maintain so-called *histograms* which record value distributions for various (sets of) attributes in different tables [5]. Those value distributions allow the optimizer to make informed decisions regarding the different operators of a QEP with respect to their efficiency and effectiveness.

Once the optimizer settled for one alternative during partial QEP generation it must determine how to advance the QEP generation in its search for the best (complete) QEP. This progress might be implemented by extending the current partial QEP with new operators possibly on additional tables not yet considered, or by generating alternatives for the existing QEP by transforming it into a syntactically different QEP. The latter might include considering alternative access paths (using different indexes) or replacing an existing join algorithm with a different one.

The query optimization phase terminates once the optimizers found the best QEP based on the given (searched) alternatives and based on the given cost functions. However, since the search might take time, the optimizer might also terminate after having reached a pre-determined tie limit or after having evaluated a certain number of alternatives.

Formalisms and Approaches for Query Processing and Query Optimization

The (research) literature reports on many different approaches to query processing and query optimization. However, there does not seem to be one formalism to describe those different approaches. Some of them use a relational algebra like notation (with extensions) to show operational approaches. Others use logic based notation such domain/tuple relational calculus or the tableaux notation. Some presentations use proprietary notations based on innovative data structures to present sophisticated algorithms.

Of course, the approach to query processing and query optimization is heavily influenced by the data model and the expressiveness of the query language. The continuous extension of SQL to SQL-2 or SQL-3 has lead to an extended portfolio of query processing and query optimization techniques. The same is true object oriented and object relational DBMSs where introduced. Similarly, the extension of SQL to express Data Warehouse queries leads to new techniques (algorithms and "tricks") for query processing and query optimization.

Implementing Query Optimizers

The first optimizers were implemented for the database prototypes IBM System-R [8] and Berkley's INGRES. The former system laid the foundation conceptually and architecture wise for many optimizers to come including those that are used in today's DBMS products.

In many cases, DBMS products only provide access to the architecture, the optimization strategies, or the cost functions used. Most of the dominant products allow the user to view the QEP as generated by the optimizer together with cost values and cardinality estimates.

However, for several DBMS products, there exist well known prototypes that provide hints how some of the optimizers in existing products might work. The newly researched ideas and novelties in those prototypes are often described in research papers published at well-know conferences like the ACM Sigmod conference, the VLB conference, the IEEE ICDE conference, or the European EDBT conference.

Key Applications

The query optimizer is an integral part of any DBMS (product). The degree and extent of optimization is determined by the vendors or implementers. The repertoire of the optimization step is continuously extended, depending on the requirements coming from OLTP queries, data warehousing/OLAP queries (star schema, aggregate queries), data mining queries, or queries coming from systems such as geographical information systems booking systems, and others.

Future Directions

Over the last several decades, query processing and optimization has adapted to the changes in computing hardware. In the 1990s, parallel hardware became readily available at a reasonable cost, DBMSs and query processing had to be extended and adapted to parallel QEP execution.

In addition, many database experts doubt that the general two-phase query processing approach (optimize the query, then execute) is the right one for future DBMs that should run on the next generation of hardware. Especially when the underlying system continuously changes query optimization and query execution must be closely intertwined to react to those changes in (almost) real time. Furthermore, when executing queries on large tables, it might be desirable to change execution strategies "on the fly." Currently, once the query processing phase is done (determining the best plan) the QEP is fixed. Recent research in the area of query processing has developed approaches to change QEPs either "on the fly" when necessary.

Now, multi-core CPUs seem to be the new development direction for hardware. At the same time, new storage technology comes to life (flash disks) with different operating characteristics that will change the architecture and therefore the processing models and processing capabilities of existing DBMSs. In addition, large CPU farms, large storage farms, and increasing main memory sizes already have a dramatic impact on existing approaches and techniques in query processing and query optimization. Understanding the Web as one large database could completely change today's DBMS architecture standards and assumptions on how to build future DBMSs.

Experimental Results

Unfortunately, there are no benchmarks that consider the database query optimizer as a separate component for benchmarking. However, there are efforts to ensure the stability of the optimizers despite estimation errors during query optimization and despite changes in the expected resources available during query execution.

Query Processing in Data Warehouses

WOLFGANG LEHNER
Dresden University of Technology, Dresden, Germany

Synonyms

Data warehouse query processing; Query answering in analytical domains; Query optimization for multidimensional systems; Query execution in star/snowflake schemas

Definition

Data warehouses usually store a tremendous amount of data, which is advantageous and yet challenging at the same time, since the particular querying/updating/modeling characteristics make query processing rather difficult due to the high number of degrees of freedom.

Typical data warehouse queries are usually generated by *on-line analytical processing* (OLAP) or *data mining* software components. They show an extremely complex structure and usually address a large number of rows of the underlying database. For example, consider the following query: 'Compute the monthly variation in the behavior of seasonal sales for all European countries but restrict the calculations to stores with > 1 million turnover in the same period of the last year and incorporate only 10% of all products with more than 8% market share. 'In a first step, this query has to identify certain stores based on the previous year's sales statistics and it needs to define the top-selling products on a monthly basis. In a second step, the system is able to compute the different behavior based on individual countries.

The structural complexity as well as the huge data volume addressed by data warehouse queries makes it a true challenge to optimize and execute these queries. Therefore, query processing in data warehouse systems encompasses the definition, the logical and physical optimization, as well as the efficient execution of analytical queries. The specific techniques range from classic rewrite rules to rules considering the special structure of a query. For example, data warehouse queries usually target *star schema*s. Such star queries with references to a fact table and foreign-key joins to multiple dimension tables can be beneficially exploited during query optimization and query processing. Moreover, the embedding of specialized operators (like *CUBE* or ROLLUP) or approximate query processing methods using samples or general-purpose synopses has to be addressed in the context of query processing in data warehouse environments. Finally, query processing in data warehouse systems has to address the support of non-*SQL* query languages (e.g., specialized analytical query languages like MDX [13]), alternative storage structures (e.g., column-wise organization), or alternative processing models based purely on main-memory structures.

Historical Background

Query processing has a long history with research and commercial products. The generation of efficient plans for the smooth execution of database queries thus represents one of the most challenging research directions in database history. With the advent of descriptive query languages, this has turned into a crucial problem, since systems must now figure out the optimal way to execute queries.

Traditional *transactional*-style (on-line transaction processing = OLTP) interaction patterns between an application and the database system consist of short read and write queries with correlated sub-queries, which typically compete with a large number of concurrently running transactions. DWH-style query patterns follow a significantly different style. Since the update/load of data warehouse databases is under the control of data warehouse monitors, user queries are typically read queries that touch a large number of rows with star joins and group-by operations as their functional core. Around 1995, the concept of data warehousing emerged and showed that OLTP-style query processing and optimization techniques were insufficient in dealing with this specific class of requirements. This deficit triggered a tremendous amount of research activities to push the envelope in multiple directions. After more than 10 years of research and development, a fairly large number of extensions/modifications have turned it into a commercially available system. However, due to the increasing need for analytical tasks performed within (and not on top of) database systems, the improvement of query processing techniques for analytical applications still represents an active research area with significant potential for innovation.

Foundations

Query processing in data warehouse systems does not address individual methods or techniques. In contrast, query processing in the analytical domain is characterized by a broad range of individual techniques ([3,7]; see 3.13). The challenge in this context is to orchestrate the different and individually deployed methods. The following introduction to important query processing aspects, including a brief discussion of the requirements and specifics of query processing in data warehouse systems and possible solutions, provides a comprehensive overview of the topic.

Requirements and Specifics of the Analytical Context

While the specific character of data warehouse systems poses challenges for query processing from multiple perspectives, it also has constraints, which can be exploited and therefore reduce the number of space limitations. Although the processing and optimization of *SQL* queries attracts the most attention, query processing in data warehouse environments addresses other query languages like MDX [13], DMX [5], or SQL/XML [12] with analytical functionality specified within the *XPath/XQuery* fragments. The complexity of handling domain-specific query languages and of mapping these expressions either to highly specialized storage structures or to SQL is further increased by the need for support of domain-specific operators. In this context, the integration of data mining algorithms for cluster searches or for the computation of association rules into database systems can be seen as a prominent example.

To counterbalance these requirements, query processing in data warehouse systems shows a number of limitations or specializations that facilitate adequate solutions. For example, a high ratio of analytical queries is issued to compute standardized reports (e.g., legal reporting in the financial sector, cockpit solutions, etc.). These canned queries show huge potential to pre-compile the execution plans, to apply multiple-query optimization or to pre-compute partial results using materialized views. Furthermore, the explicitly controlled update transactions in data warehouse systems typically show append-only characteristics, which enable the system to apply specifically tailored optimization strategies. For example, adding incoming rows to a single partition and periodically attaching it to the analytical database in an atomic way affects the concurrently running analytical queries only to a minimal extent. Finally, although analytical queries usually apply aggregation techniques over a large number of rows, the analytical queries may exhibit quite selective predicates. For example, consider the following query: ‘Return the weighted sales distribution of all Californian stores selling Mac and Linux machines with more than 4GB RAM in 2007 and divide it by month.’ It shows a highly selective predicate but may still incorporate a huge number of rows within the computation of the measure. Query processing may tackle this phenomenon by introducing special index structures to support selective predicates of multiple columns from different tables or by applying specialized processing techniques such as online aggregation or approximate query answering in general.

Potential and Solutions for Efficient Data Warehouse Query Processing

The specific characteristics as well as the specific circumstances create a wide range of options to perform query processing in data warehouse scenarios in an efficient way. The following list provides the most prominent classes of methods with an outline of their specific role in this context:

Part I: Query Planning and Execution

Optimizing the Optimization Process

- Since analytical queries usually show a complex structure, the optimization of a query may require a considerable fraction of the overall query execution cost. Therefore, modern techniques propose a variety of solutions ranging from the a-priori limitation of the search space (usually by applying certain heuristics – e.g., the optimization pattern of star queries) to the pruning of alternative plans as early as possible [15].

Optimization Goal

- In contrast to OLTP-style query optimization, the general goal of OLAP-style query optimization is to generate only a good (i.e., not an optimal) but robust plan. Due to the complex structure of a query, potential errors in the cost estimation usually have their origin at the leaf nodes of an operator tree and – after having been propagated along an operator path – they may result in extremely vague estimates. A robust plan is required to expose well-performing behavior even if the data show different characteristics than those used in the planning phase. The notion of robust plans and the design of more adequate statistics (e.g., sample or wavelet synopses) are currently the subject of intense discussions in the research community.

Specific Rewrite Rules

- As already mentioned, data warehouse environments imply a specific characteristic of queries – usually following the notion of star queries, which consist of a join of the fact table and multiple dimension tables followed by a complex selection predicate and a grouping condition with aggregation. Query processing has to detect such situations and apply specific optimization patterns. For example, group-by operations can be pushed down in certain cases to reduce the number of rows for join operations [18]. Another example addresses star joins: the star join technique may decide to compute the Cartesian product of the selected parts of all dimension tables in a first step and then join the (large) fact table in a last step.

Multi-Query Optimization

- A final class of techniques – which have not been considered in OLTP-style query processing due to restrictions of *ACID properties* – address the issue of optimizing a set of queries simultaneously, thus resulting in shared use of different resources. Key applications for these techniques can be found on the application level (in the computation of multiple similarly structured statistical reports) or within a system (in the propagation of changes of a base table to multiple dependent materialized views to share update efforts).

Part II: Considering Logical Access Paths

Partition Management

- Partitions reflect a concept that is useful for the administration of a database system as well as for the optimized execution of partition-aware queries. Within a data warehouse environment, incoming data items are typically stored within staging tables. After transformation and cleaning steps, tables are converted into partitions and attached to the global data warehouse database. Whenever data items in a partition are obsolete, a partition can be detached and moved (as a table) to the archive. From a query optimization perspective, partition pruning represents a powerful mechanism to potentially reduce the number of rows accessed within a query. Whenever a selection predicate refers to a partitioning criterion, the system may restrict the query execution to only those partitions that are actually referenced by the query. The main partitioning criterion usually addresses the time dimension, e.g., by month, but may also be used to partition other dimensions, e.g., by product category or geographical entities.

Materialized Views

- A second component of the logical access path consideration is the transparent use and the implicit maintenance of materialized views. Similar to classic index structures, a query is matched against a view description and internally rewritten to exploit an existing materialized view by producing the same result as the original query. Especially in the context of aggregation queries, the concept of materialized views represents an extremely powerful mechanism to speed up analytical queries. For example, a materialized view may hold summary data grouped on the family level within a product dimension, with an additional grouping based on city and month. Every query with a compatible aggregation function and a grouping condition that is “coarser” than the grouping combination of the materialized view, e.g., sum per quarter, product category, and state, may benefit from the pre-aggregated data stored within a materialized view. In addition (and similar to physical index structures), materialized views are transparently maintained in the case of changing base tables to provide a consistent view of the data.

Part III: Considering Physical Access Paths

Data Organization

- While classic relational database engines favor the concept of row-based storage, a variety of specialized systems exist that follow the concept of column-based storage layout. Query processing in column-based systems benefits from reading only those columns that are actually required to answer an incoming query. This feature is extremely beneficial in the presence of wide dimension tables and queries referring to just a few attributes.

Compression and Main-Memory Techniques (see *main memory DBMS*)

- Although (persistent) storage costs have been decreasing significantly, a compressed version of data may speed up the query processing because of the reduced number of I/O operations. While block- and table-based compression schemes have been well understood, the static characteristics of data warehouse data have provided the motivation to push compression techniques into commercial systems. For column-based systems with the primary goal to be main-memory-centric, compression is a must; a large variety of techniques (e.g., Huffman coding schemes) is applied in different systems.

Additional Index Structures

- The history of database research has shown that different application areas can be supported with specialized index structures. Particularly aimed at the support of queries within the analytical domain, *bitmap index* structures have experienced a rejuvenation and are now part of the prominent commercially available systems [2,16]. Another approach to take advantage of the static characteristic of a data warehouse database can be seen in the concept of *star index*es (also called join indexes or foreign-table indexes), which follow the basic idea to index the result of a join operation. Join indexes are particularly well-suited to exploit the relationship of dimension tables with the corresponding fact table.

Multidimensional Clustering Schemes

- *Clustering* in general tries to preserve the topological relationship of entries in a database. Since data warehouse datasets are typically multidimensional in nature (e.g., sales by shop, date, and product), multidimensional clustering schemes represent a valuable solution to store logically related facts within the same block with the overall goal to reduce the number of I/O operations.

Part IV: Alternative Query Answering Models

Online Aggregation

- Analytical queries typically show a response time in the range of multiple seconds, minutes, and sometimes hours. Online aggregation [9] is a promising technique to return intermediate results of the queries while the query is still running; the intermediate results are refined step by step until the final result is computed or until the application is satisfied with the precision of the answer.

Approximate Query Answering/Approximate Query Processing

- Many application areas that perform statistical analyses prefer to yield an approximate but quick answer instead of delaying an exact answer. The concept of approximate query answering addresses this idea and proposes techniques for the online or offline design of database synopses, which are then used to answer incoming queries. The design of synopses ranges from simple uniform samples over specifically tailored (stratified) samples to wavelet synopses. The main challenge of approximate query answering consists of the creation and exploitation of synopses on the fly (i.e., within the context of the execution of a single query) and of the provision of error bounds to derive a quality measure to be returned to the user.

This list of methods and techniques outlines the most influential factors for query processing in data warehouse environments. Behind every perspective touched in this description, there are huge numbers of specific research issues – solved and unsolved ones.

Key Applications

Over the last 10 years, database systems have become the foundation of every larger analytical infrastructure (usually embedded within a data warehouse system). Therefore, all analytically-flavored applications heavily exploit specialized database support. This obviously large spectrum of applications ranges from mass reporting for the computation of thousands of parameterized reports to the support of interactive data cube exploration (OLAP). As data mining methods are becoming more and more standardized techniques, the computation of association rules, classification trees, and (hierarchical) clusters represent key applications.

Future Directions

In the future, query processing in analytical domains will be driven by two factors. On the one hand, data volumes will continue to grow significantly, mainly because of advances in data integration efforts (to ease the pain of manual integration of additional data sources) and the growing presence of sensors to track individual items. More data will go hand in hand with the presence of increased main-memory capacity and the integration of solid-state disks (SSD) into the memory hierarchy. Physical database design and the corresponding exploitation of specialized structures will be major challenges.

On the other hand, the topic of query processing will be faced with more sophisticated statistical methods, which have to be natively supported by the database engine to yield reasonable query performance. While for many analytical application infrastructures, the "bring the data to the statistical package" method still holds, this approach will be inverted at some point. Statistical packages will work more closely with database systems, implying that computational components are brought closer to the data (as an integral part of a database engine) to be integrated within the overall optimization process. Also, the scope of analytical applications will widen and incorporate comprehensive *data visualization* techniques.

Both future developments on the application level will have significant consequences for the design of query processing techniques ranging from low-level data organization up to the support of a specialized query interface.

Query Processing in Deductive Databases

LETIZIA TANCA
Politecnico di Milano University, Milan, Italy

Synonyms

Datalog query processing and optimization; Recursive query evaluation; Logical query processing and optimization

Definition

Most of the research work on deductive databases has concerned the *Datalog language*, a query language based on the logic programming paradigm which was designed and intensively studied for about a decade. Its origins date back to the beginning of logic programming, but it became prominent as a separate area around 1978, when Hervé Gallaire and Jack Minker organized a workshop on logic and databases. In this entry, the definition of the typical computation styles of Datalog will be given, the most important optimization types will be summarized, and some developments will be outlined.

Historical Background

The research on deductive databases was concentrated mostly between the mid-1980's and the mid-1990's. In those years, substantial efforts were made to merge Artificial Intelligence technologies with those of the Database area, with the aim of building *large and persistent Knowledge Bases*. An important contribution towards this goal came from database theory, which concentrated on the formalization of Datalog – specifically designed for the logic-based interaction with large knowledge bases – and on the definition of computation and optimization methods for Datalog rules [2,5,7,14]. In parallel, various experimental projects showed the feasibility of Datalog as a data-oriented logic programming environment [4,13].

The reaction of the database community to Datalog has often been marked by skepticism. In particular, the immediate practical use of research on sophisticated rule-based interaction has often been questioned. However, the research experience on Datalog, properly filtered, has taught important lessons to Database researchers, setting the basis for the theoretical systematization of several related issues [1].

Foundations

Datalog is in many respects a simplification of the more general *Logic Programming* paradigm [11], where a program is a finite set of *facts* and *rules*. Facts are assertions about the reality of interest, like *John is a child of Harry*, while rules are sentences which allow deducing of facts from other facts. For instance, a rule might say *If X is a child of Y, and Y is a child of Z, then X is a grandchild of Z*. Facts and rules may contain variables; facts that only contain constants are called *ground facts*.

In the formalism of Datalog, both facts and rules are represented as *Horn clauses*:

$$L_0 : -L_1, \ldots, L_n$$

where each L_i is a *literal* of the form $p(t_1 \ldots t_n)$, such that p is a *predicate symbol* and the t_i are *terms*. A term is either a constant or a variable, while functional symbols are not allowed, at least in the basic syntax of Datalog. The left hand side (LHS) of a Datalog clause is also called its *head*, while the right hand side (RHS) is its *body*. Clauses with an empty body are the facts: indeed, the body contains the clause premises, thus if there are no premises this means that the head is an assertion. Clauses with a non-empty body are the rules. A set of ground facts can easily be thought of as a relational database, since each fact *parent (John, Harry)* (between John and Harry there is a child-parent relationship) can be written as a tuple ⟨*John, Harry*⟩ stored into a relation PARENT. Both facts and rules are a form of *knowledge*; indeed, the knowledge stored in the database (alternatively represented as the set of ground facts) is enriched by the knowledge which can be deduced from the rules.

In the context of general Logic Programming, it is usually assumed that all application-relevant knowledge (facts and rules) are contained within a single logic program. On the other hand, Datalog has been developed for applications which use large, relational databases; therefore two sets of clauses will be considered: the set of ground facts, called *Extensional DataBase (EDB)*, and the set of rules, i.e., the Datalog program, called the *Intensional DataBase (IDB)*. The *Herbrand Base* is the set of all ground facts that can be expressed in the language of Datalog, by using all the constants present in the database and all the predicates of *EDB* ∪ *IDB*.

A *Datalog program* is a set of ground facts (possibly stored into a relational database) and rules, satisfying the safety condition that *all the variables contained in the rule head must also be present in its body*.

Note that a Datalog program can be considered as the specification of a *query against the EDB*, producing as answer the (set of) relation(s) of the IDB. It often happens that a user is interested in a subset of the (large) relation(s) that can be defined from a Datalog program: a *goal* is a single literal, preceded by a question mark and a dash, used to express constraints on the relations specified by the Datalog program. For example, ? − *parent*(*John*,*X*). specifies all the *X* such that *John* is a child of *X*.

Consider, as an example, the EDB constituted by a unary relation PERSON and a binary relation PARENT (containing all the pairs ⟨*child*,*parent*⟩) and the following program:

$$r_1 : \ sgc(X, X) : \ -person(X).$$

$$r_2 : \ sgc(X, Y) : \ -parent(X, X1), sgc(X1, Y1), \\ parent(Y, Y1).$$

Rule r_1 simply states that a person is a cousin at the same generation of him/herself, while rule r_2 says that two persons are same generation cousins if they have parents who, in turn, are same generation cousins. Note that r_2 is *recursive*, and that rule r_1 constitutes the recursion base. A typical goal against the set $\{r_1, \ r_2\}$ is ? − *sgc*(*John*, *Y*)., asking for all the same generation cousins of John.

Evaluation of Datalog Programs

Consider a Datalog rule $R = L_0 : -L_1,...,L_n$, and a set of ground facts $F = \{F_1,...F_n\}$. If a substitution θ exists, such that $\forall 1 \leq i \leq n, L_i\theta = F_i$, then, from the rule *R* and from the facts *F*, the fact $L_0\theta$ can be inferred in one step. This fact might be new, or already known.

The just described inference rule – which is actually a meta-rule – is called *EPP (Elementary Production Principle)*. Consider now a whole Datalog program *S*. New knowledge can be obtained from the Datalog program by applying it to the set of all ground facts of the database, to obtain new ground facts. Informally, it can be said that a ground fact *F* is *inferred* from *S* ($S \vdash F$) iff, either *a)* $F \in S$ or *b)* *F* can be obtained by applying the EPP *a finite number of times*. More precisely:

- $S \vdash F$ if $F \in S$.
- $S \vdash F$ if a rule *R* and ground facts $F_1,...,F_n$ exist such that $\forall 1 \leq i \leq n$, $S \vdash F_i$, and F_i can be inferred in one step by the application of *EPP* to *R* and $F_1,...,F_n$.

The sequence of applications of *EPP* which is used to infer a ground fact *F* from *S* is called a *proof* of *F* from *S*. The *proof-theoretical framework* thus established allows to infer new ground facts from an original set of Datalog clauses; on the other hand, there is a model-theoretic approach, which provides a definition of *logical consequence* (⊨). It is possible to prove that:

Theorem 1. (Soundness and completeness of Datalog) Let *S* be a set of Datalog clauses, and let *F* be a ground fact. Then $S \vdash F$ if and only if $S \vDash F$.

A proof of this theorem can be found, for example, in [5].

In order to check whether EPP applies to a rule $R : L_0 : -L_1,...,L_n$ and to an ordered list of ground facts $F_1,...,F_n$, an appropriate substitution θ for the variables of *R* must be found, such that $\forall 1 \leq i \leq n$, $L_i\theta = F_i$.

Given a finite set *S* of Datalog clauses, i.e., a Datalog program, according to the soundness and completeness theorem, the set of all facts which are *derivable* from *S* is the set *cons(S)* of the *logical consequences* of *S*, which can be computed by the following algorithm:

```
FUNCTION INFER(S)
INPUT: a finite set S of Datalog clauses
OUTPUT: cons(S)
begin
W:= S
while EPP produces a new ground fact F ∉ W
do W := W ∪ F
return (facts(W))
end
```

The *INFER* algorithm always terminates and produces as output a *finite* set of ground facts, *cons(S)*, since the number of constants and predicates symbols, as well as the number of arguments of these predicates, is finite. The order in which *INFER* generates new facts corresponds to the *bottom-up* order of a proof tree, thus the principle underlying *INFER* is called *bottom-up evaluation*, or, as in Artificial Intelligence, *forward chaining* (forward in the sense of the logical implication contained in the Datalog rules).

The set *cons(S)* can also be characterized as *the least fixpoint* of the transformation T_S, a mapping from 2^{HB} to itself defined as follows:

$$\forall W \in HB, T_S(W) = W \cup FACTS(S) \\ \cup INFER1(RULES(S) \cup W)$$

where *INFER1(S)* denotes the set of *all* ground facts that can be inferred in one step from S via *EPP*.

Accordingly, *cons(S)* can be computed by fixpoint iteration, i.e., by computing, in order, $T_S(\emptyset)$,$T_S(T_S(\emptyset)$, $T_S(T_S(T_S(\emptyset)))$,...,until a term which is equal to its predecessor is reached. This final term is *cons(S)*.

The *top-down* evaluation of a Datalog program is based on a radically different approach, where proof trees are built from the top to the bottom, by applying *EPP* "backwards," which is much more appropriate when a goal is specified together with *S*. The general principle of *backward chaining* corresponds, in Prolog, to the *SLD resolution (SL resolution with Definite clauses)* inference rule, introduced by Robert Kowalski [9]. Its name is derived from SL resolution, which is both sound and refutation complete for the unrestricted clausal form of logic.

The logic programming formalism is now related to a database query language, in order to show how easy the integration between the two realms is. Each clause of a Datalog program can be translated into an inclusion relationship of Relational Algebra; then, the set of relationships which refer to the same predicate are interpreted as Relational Algebra *equations*, whose constants are the EDB relations and whose variables are the IDB predicates, defining virtual relations. Determining a solution of the thus composed system corresponds to determining the values of the variable relations, i.e., to finding the ground facts in the IDB predicates. Consider a Datalog clause:

$$C : p(\alpha_1 \ldots \alpha_n) : -q_1\left(\beta_{k_1} \ldots \beta_{k_h}\right), \ldots q_m\left(\beta_{k_j} \ldots \beta_{k_m}\right)$$

the translation associates to *C* an inclusion relationship $Expr(Q_1,\ldots,Q_m) \subseteq P$ among the relations $Q_1,\ldots,Q_m,P$ that correspond to the predicates $q_1,\ldots,q_m,p$, adopting the convention that relation attributes are named according to the number of the corresponding argument of the related predicate. For example, the Datalog rules of the *same generation cousins* program are translated into the inclusion relationships:

$$\pi_{1,1} PERSON \subseteq SGC$$

$$\pi_{1,5}\left((PARENT \bowtie_{2=1} SGC) \bowtie_{4=2} PARENT\right) \subseteq SGC$$

The rationale behind this translation is that literals with common variables correspond to equi-joins over those variables, while the variables exported to the rule head correspond to projections. The new (virtual) relation SGC (actually, a *view*) is defined as the extension of the predicate *sgc*. For each IDB predicate, all the related inclusion relationships are collected, generating an algebraic equation that obtains the predicate by performing the union:

$$\begin{aligned} SGC = {} & \pi_{1,1} PERSON \\ & \cup \pi_{1,5}((PARENT \bowtie_{2=1} SGC) \bowtie_{4=2} PARENT) \end{aligned}$$

Logical goals are also translated into algebraic queries, over the EDB or over the just defined views: ? $-$ *sgc* (*John*,*Y*). corresponds to $\sigma_{1=\text{``}John\text{''}} SGC$.

Note that this translation is based on the use of all classical algebraic operators, except *the difference*. In fact, it can be shown that Datalog without recursion is equivalent to Relational Algebra deprived of the difference operator.

Optimization of Datalog Programs

The evaluation of Datalog programs according to various forms of fixpoint computation, similar to the INFER algorithm, is called *naive*, as opposed to better, more performant techniques whose mutual relationship is not always obvious. Optimization methods can be observed with regard to different orthogonal dimensions: the *formalism* (logical vs. algebraic), the *search strategy* (bottom-up vs. top-down), the *technique* (rewriting programs into more efficient ones vs. directly applying an efficient evaluation method), and the *type of information exploited by the optimization process* (semantic vs. syntactic).

Since Datalog programs can equivalently be written as sets of algebraic equations, a Datalog program can actually be evaluated in the same way as any algebraic query, provided that a way to process recursion is available. Actually, algebraic evaluation methods that mimick the naive method have been introduced, and the classical results of algebraic query optimization, like common subexpression analysis and equivalence transformations, have been profitably transformed to be applied to recursive queries [5].

As far as the search strategy is concerned, observe that bottom-up methods actually consider rules as *productions*, generating all possible consequences of *EDB* ∪ *IDB* until no new facts can be deduced; thus, these methods are applied in a set-oriented fashion, which is a desirable feature in the database context, where large amounts of data are stored in mass memory and must be retrieved in the buffer in a "set-at-a-time" way. On the other hand, also observe that bottom-up methods do not take in immediate advantage the selectivity due to the existence of bound arguments in the goal predicate.

By contrast, top-down methods [5,9] use rules as *subproblem generators*, since each goal is considered as a problem to be solved. The initial goal ? $-$ $p(\alpha_1 \ldots \alpha_n)$. is matched against some rule $C : p(\alpha_1 \ldots \alpha_n) : -q_1\left(\beta_{k_1} \ldots \beta_{k_h}\right), \ldots q_m\left(\beta_{k_j} \ldots \beta_{k_m}\right)$, and generates *subgoals* ? $-$ $q_i(\beta_1 \ldots \beta_i)$ that represent new subproblems to be solved. In this case, if the goal contains some bound (i.e., constant) argument, then only facts that are related to the goal constants are involved in the computation. Suppose, for instance, that the goal ? – $sgc(John, Y)$. be given. Then, when applying top-down rule r_2, the subgoal $parent(X, X1)$ is only further analyzed with regard to the parents of John, that is, *only the subrelation* $\sigma_{1\,=\,\text{“John”}}PARENT$ is involved in the computation of the first literal. However, although the algorithms based on this evaluation method already produce some optimization, they may be inappropriate for the database context, because many of them work "one-tuple-at-a-time."

Another analysis dimension for optimization methods is whether they directly interpret the program or first rewrite it into an equivalent, more efficient form and then evaluate it in a naive way. To this category belong, for instance, the *Magic Sets* and *Counting* methods [2], where the authors "simulate" the binding propagation achieved by top-down evaluation by applying a simple program transformation to a certain class of programs, in a similar way as algebraic database optimization techniques (e.g., push of the selections) are applied. A similar approach, directly introduced by means of the algebraic formalism, is taken in the *Reduction of Variables* and *reduction of Constants* methods [5].

Finally, also *semantic information* can be used to optimize programs: for instance, [6] base the optimization on the additional semantic knowledge provided by *database constraints*. For example, a constraint might state that *all sailing vessels in Ischia are sheltered in the main harbour*, thus the query asking for *the harbour in Ischia where the sailing boat "Roxanne" is located* can be answered without even accessing the DB.

Negation in Datalog

In pure Datalog, the negation sign ¬ is not allowed; however, negative facts can be inferred from Datalog programs by adopting the *Closed World Assumption (CWA)*, which, in this context, reads as follows:

If a fact is not derivable from a set of Datalog clauses, then the negation of that fact is true.

For example if, after computing the SGC relation, the tuple $\langle LUCY, JOHN\rangle$ is not found, the fact $\neg sgc\ (lucy, john)$ – that is, Lucy is not a child of John – is inferred.

The CWA applied to Datalog clauses allows the deduction of negative facts, but not their use within the Datalog rules in order to deduce some new facts. For instance, in Relational Algebra, all the pairs of persons who are not same generation cousins are specified as: $NONSGC = (PERSON \times PERSON) - SGC$. Accordingly, one would like to write:

$$r_3:\ nonsgc(X, Y):-person(X), person(Y),\ \neg sgc(X, Y).$$

The language *Datalog*$^{\neg}$ has the same syntax as Datalog, but here negated literals are allowed in the rule bodies. For safety reasons, all the variables occurring within a negated literal must also occur in a positive literal of the body. Without delving into semantic details, note that unfortunately, because of recursion, the computation of Datalog$^{\neg}$ programs is not as straightforward as that of a pure Datalog program; indeed, by simply applying the *EPP* and the INFER algorithm to a recursive Datalog$^{\neg}$ program, one may incur into a contradiction, since some negative facts that are inferred at step n of the computation might be derived as positive at some step $n + k$. Intuitively, consider the program composed by rules r_1, r_2, r_3, and think of the set of same generation cousins derived at the first computation step. Suppose that $sgc(lucy, john)$ has not been derived; then, at the second step, $\neg sgc(lucy, john)$ may be derived by applying r_3; yet, it might be that $sgc(lucy, john)$ is derived from r_1, r_2 at some later step $k(k > 2)$.

The most common policy used to avoid such problems is only allowing Datalog$^{\neg}$ programs which are *stratified* [7], according to the following intuition: when evaluationg a rule with one or more negative literals in the body, *evaluate first the predicates corresponding to these negative literals*. Then, the CWA is "locally" applied to these predicates. Consider the example above: since the *sgc* predicate appears in negative form in rule r_3, it is first evaluated by applying only rules r_1,r_2 (the "first stratum" of the program); then, once the whole extension of *sgc* has been computed, all the pairs of persons who are not in the SGC relation can be derived (actually by difference).

However, one can intuitively guess that not necessarily all the Datalog programs can be stratified in this way, that is, it may be possible that there is another rule r_4 which in turn contains the predicate *nonsgc* in negative form, and so on and so forth. More formally, define the *Dependency Graph* $DG(P) = \langle N(P), E(P)\rangle$ of a Datalog$^{\neg}$ program P as follows: $N(P)$ is the set of predicates p occurring in the rule heads of P, while an edge $\langle p,q \rangle$ belongs to $E(P)$ if the predicate symbol q occurs positively or negatively in some rule whose head predicate is p. Moreover, $\langle p,q \rangle$ is labeled by ¬ if there is at least one rule in P with head predicate p, whose body contains a negative occurrence of q.

A Datalog$^{\neg}$ program P is *stratified* iff DG(P) does not contain any cycle involving an edge labeled by¬. If P is stratified, it is quite easy to construct a stratification of P [1,5,14], that is, a sequence of subprograms $P_0 = EDB$, $P_1,\ldots,P_n$ of P such that $P_0 \cup P_1 \cup \ldots \cup P_n = P$ and, by evaluating them separately and in order from P_0 to P_n, and by applying the CWA to P_k when computing P_{k+1}, the result does not contain any contradiction. Note that stratifications are not unique, that is, if the condition on the $DG(P)$ is satisfied, P can be stratified in several different ways. It is easy to see that the sample program $P = \{r_1,r_2,r_3\}$ is stratified, and that a stratification is $P_0 = EDB$, $P_1 = \{r_1,r_2\}$, $P_2 = \{r_3\}$.

Much further work has been done on the semantics of negation and of non-monotonic programs [1]. Semantics based on various kinds of partial models, like the *stable models* [12] and the *well-founded models* [10] are often studied. An example of more recent work on the subject is [3], where the new concept of soft stratification, based on a new bottom-up query evaluation method based on the Magic Set approach, is proposed.

Key Applications

The research on deductive databases was concentrated in the decade between the mid-eighties and the mid-nineties. This work, and all logic-based approaches to database problems, constitute the foundational experience for speculation that have lead to a number of results in different fields. The field of active databases is one interesting example of the application of the theoretical foundations of Datalog. An active database system is a DBMS endowed with active rules, i.e., stored procedures activated by the system when specific events occur. The processing of active rules is characterized by two important properties: termination and confluence. In [8], a set of active rules is translated into logical clauses, taking into account the system's execution semantics, and simple results about termination and determinism available in the literature for deductive rules are transferred to the active evaluation process. Another, more recent application is the integration of Databases with the Semantic Web, an interesting example of which is the *SWRL (Semantic Web Rule Language)* [15], a proposal combining sublanguages of the OWL Web Ontology Language with the rule-based paradigm. SWRL is (roughly) the union of Horn logic and OWL, where rules are of the form of an implication between an antecedent (body) and consequent (head), with a semantics very similar to that of Datalog.

Synonyms

Query execution engine; Relational query processor; Query engine

Definition

The query processor in a database management system receives as input a query request in the form of SQL text, parses it, generates an execution plan, and completes the processing by executing the plan and returning the results to the client.

Key Points

In a relational database system the query processor is the module responsible for executing database queries. The query processor receives as input queries in the form of SQL text, parses and optimizes them, and completes their execution by employing specific data access methods and database operator implementations. The query processor communicates with the storage engine, which reads and writes data from the disk, manages records, controls concurrency, and maintains log files.

Typically, a query processor consists of four sub-components; each of them corresponds to a different stage in the lifecycle of a query. The sub-components are the query parser, the query rewriter, the query optimizer and the query executor [3].

The parser initially reads the SQL text, renames the table references to the *schema.table* template, and validates the structure. As a second step, it uses the database catalog to check the existence of the referenced tables, as well as ensuring that the user who submitted the specific query has the appropriate privileges for the particular operation on the particular data. If everything succeeds, the output from the parser is a data structure understood internally by both the rewriter and the optimizer. This data structure is handed over to the query rewriter.

The query rewriter modifies the query without changing its semantics. The rewriter replaces references to views as references to base tables, simplifies arithmetic expressions, and applies logical transformations to predicates. After the query is parsed and rewritten (and before it is passed on to the optimizer), the system checks a cache of execution plans of recently optimized queries for an execution plan for the specific query in order to avoid the (usually expensive) optimization phase.

The optimizer generates an efficient execution plan for answering a specific query. The decision on which specific access method or database operator implementation will be used relies heavily on the statistics kept by the system and the selectivity estimation. The output of the optimizer is the query execution plan. In the common case, the query plan is an interpretable dataflow directed acyclic graph, where each node is a specific implementation of a database operation. There are some systems where the optimizer generates directly executable machine code, such as in Daytona [2]. The optimizer can choose from many techniques that can speed up the execution of a query. For example, it may decide to generate a plan where multiple threads or processes work in parallel to answer a specific query. Such an execution strategy works well especially if the machine where the system is running contains multiple processors. Query optimization is the responsibility of a fairly sophisticated software module [1,3,4].

Although the query plan describes in detail the various operations needed for the execution of the query, it is the query executor that contains the algorithms for accessing base tables and indexes, as well as various database operator execution algorithms. The objective of the query executor is to execute the plan as fast as possible and return the answer to the client. The query optimizer and query executor are tightly coupled together. The query executor determines which algorithms implement the plans generated by the optimizer. For instance, if a query executor supports only Hash and Sort-Merge joins, then the optimizer is restricted to producing plans that use only those two join implementations.

Typically, query executors employ the *iterator* model, a simple and intuitive way to filter data. Each operator is implemented as a subclass of the iterator class, using as interface functions such as `init()`, `get_next()`, and `close()`. An iterator can be used as input to any other iterator, thereby enabling universal handling of iterators or iterator combinations by the system, regardless of the particular function they implement. However, recently researchers argue that the overhead of processing data in a tuple-at-a-time, iterator-based fashion leads to inefficient execution of queries when running on modern hardware and deep memory hierarchies [5].

There are many interpretations of what constitutes a query processor. The query executor is the subcomponent that does the "real" job of answering a query. It pulls the data out of the database and employs the various data manipulation algorithms towards them. Thus, a frequent misinterpretation is to consider the query processor and query executor as being synonyms.

Query transformations

Definition

Query rewriting is one of the initial phases of query processing. After the original query is parsed and translated into an internal representation, query rewrite transforms it to an equivalent one by carrying out a number of optimizations that are independent of the physical state of the system. Typical transformations include un-nesting of subqueries, views expansions, elimination of redundant joins and predicates and various other simplifications.

Key Points

Query rewriting is one of the phases of query processing. It refers to the application of a number of transformations to the original query in order to produce an equivalent optimized one. Such transformations do not depend on the physical state of the system (such as the size of the relations, the system workload, etc). They are usually based on well-defined rules that specify how to transform a query expression into a logically equivalent one.

The goal of query rewriting is threefold: (i) the construction of a standardized starting point for query optimization (standardization), (ii) the elimination of redundancy (simplification), and (iii) the construction of expressions that are improved with respect to evaluation performance (amelioration).

To satisfy this goal, common responsibilities of the query rewriter include:

- View expansion
- Logical rewriting of predicates. For example, improving the match between expressions and the capabilities of index-based access methods
- Various semantic optimizations such as elimination of redundant joins and predicates
- Sub-query flattening

Typically, query rewriting is performed after parsing the original query. It can be thought of as either being the first part of query optimization or as an independent component preceding the query optimizer and the generation of the alternative execution plans. Rewriting is particularly important for complex queries, including queries with many sub-queries or many joins.

Query translation; Query mapping

Definition

Given a source query Q_s over a source schema and a target query template over a target schema, query translation generates a query that is *semantically closest* to the source query and *syntactically valid* to the target schema. The semantically closest is measured by a closeness metrics, typically defined by precision and/or recall of a translated query Versus a source query over a database content. Syntax validness indicates the answerability of a translated query over the target schema. Therefore, the goal of query translation is to find a query that is answerable over the target schema and meanwhile retrieves the closest set of results as the source query would retrieve over a database content.

Historical Background

Query translation is an essential problem in any data integration system and has been studied extensively in the database area. Since a data integration system needs to integrate many different sources, query translation is thus needed to mediate heterogeneous query capabilities presented by those sources. A source typically only accepts and processes queries of certain formats. Such restrictions on acceptable queries form the query capability of the source. For instance, a Web database may only accept queries through their Web query interfaces, a relational database may accept SQL queries, and a legacy system may only accept selection queries over certain attributes through their wrappers.

Foundations

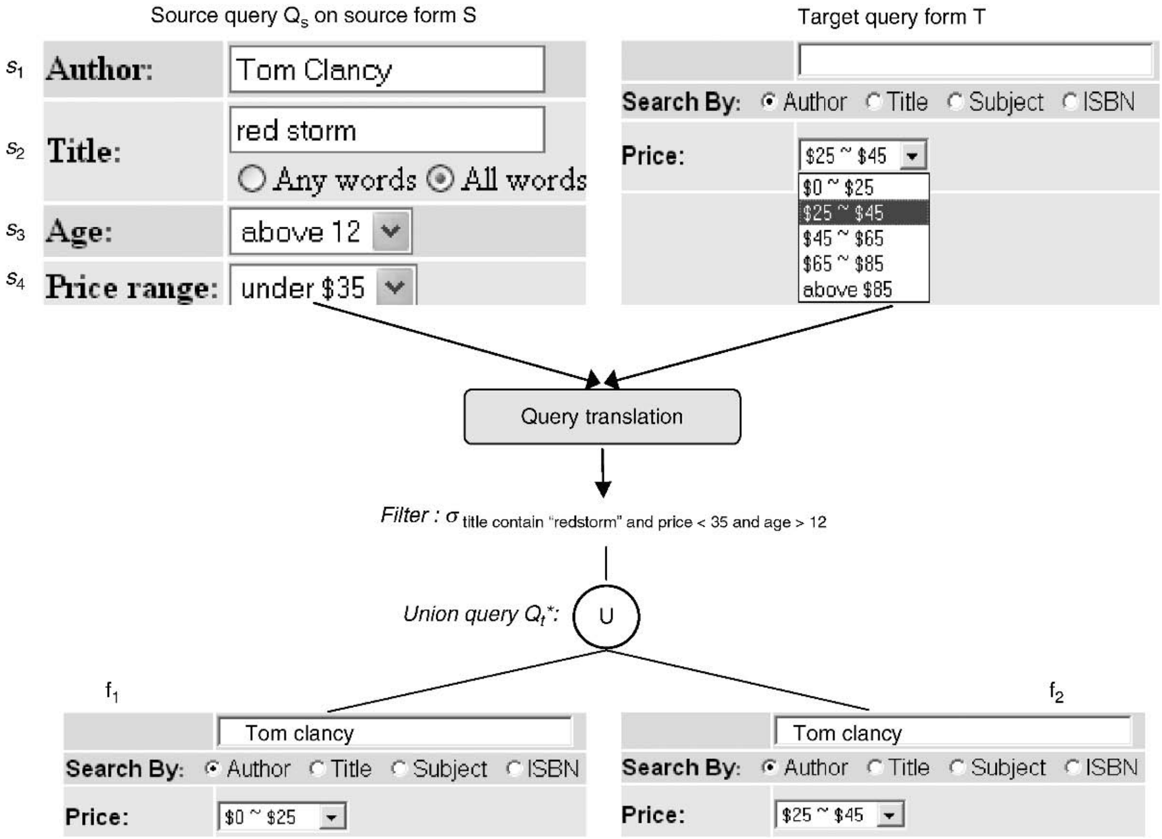
To represent query capabilities, different description languages have been proposed. Vassalos [13] proposes p-Datalog, a datalog-like language for describing query capabilities. Halevy [8] uses capability records to describe, for accepted queries, their binding requirements of input parameters and the attribute name of output parameters. Rajaraman [12] proposes query templates in the format of parameterized queries to specify binding patterns of acceptable queries. Similarly, Zhang [15] uses predicate templates and form templates to represent query capabilities of Web databases through Web query interfaces. As an example, Fig. 1 shows two query forms with different query capabilities. The source query form S accepts conjunctive queries over four predicates: such as s_1 : [`author`; *contain*; Tom Clancy], s_2 : [`title`; *contain*; red storm], s_3 : [`age`; $>$; 12], and s_4 : [`price`; $\leq$; 35], i.e., $Q_s = s_1 \wedge s_2 \wedge s_3 \wedge s_4$. A target query form T supports predicate templates on `author`, `title`, `subject`, `ISBN` one at a time with an optional template on predicate price.

More specifically, the heterogeneity of query capabilities can be categorized into three levels:

Attribute Heterogeneity

Two sources may query a same concept using different attribute names. For instance, the source schema S in Fig. 1 supports querying the concept of reader's age, while the target schema T does not. Also, S denotes book price using price range, while T using price.

Q



Source query Q_s on source form S
s_1 Author: Tom Clancy
s_2 Title: red storm
○ Any words ● All words
s_3 Age: above 12
s_4 Price range: under $35
Target query form T
Search By: ● Author ○ Title ○ Subject ○ ISBN
Price: $25 ~ $45
$0 ~ $25
$25 ~ $45
$45 ~ $65
$65 ~ $85
above $85
Query translation
Filter : $\sigma_{\text{title contain "redstorm" and price < 35 and age > 12}}$
Union query Q_t^*:
U
f_1
Tom clancy
Search By: ● Author ○ Title ○ Subject ○ ISBN
Price: $0 ~ $25
f_2
Tom clancy
Search By: ● Author ○ Title ○ Subject ○ ISBN
Price: $25 ~ $45

Query Translation. Figure 1. Form assistant: A translation example.

Predicate Heterogeneity

Two sources may use different predicates for the same concept. For instance, the price predicate in T has a different set of value ranges from those of S. As a result, a translated target predicate can only be as "close" to the source predicate as possible. Therefore, a closeness metrics needs to be introduced to set up a goal of translation. For instance, a *minimal subsumption* translation requires that a translated target query subsume the source query with fewest extra answers.

Query Structure Heterogeneity

Two sources may support different sets of valid combinations of predicates. In the above example, the target schema T only supports queries on one of the four attributes `author`, `title`, `subject` and `ISBN` at a time with an optional attribute `price`. Therefore, T cannot query author and `title` together, while S can.

The goal of query translation is to generate an appropriate query expressed upon the target schema T. Such a query, as Fig. 1 shows, in general, consists of two parts: a *union query* Q_t^* which is a union of queries upon the target schema to retrieve relevant answers from a target database, and a *filter* σ which is a selection condition to filter out false positives retrieved by Q_t^*. To minimize the cost of post processing, i.e., filtering, translation aims at finding a union query Q_t^* that is as "close" to the source query Q_s as possible so that it retrieves fewest extra answers. Q_t^* in Fig. 1 is such a query.

To realize the translation, query translation needs to reconcile the heterogeneities at the three levels – attribute, predicate and query. Techniques have been studied extensively for addressing the heterogeneity at each level.

Schema Matching for Attribute Heterogeneity

Schema matching (e.g., see the survey of [11]) focuses on mediating the heterogeneity at the attribute level. Recent schema matching approaches follow two different forms – pairwise matching and holistic matching. The pairwise matching approaches (e.g., [3,7]) take two schemas as input, and find best attribute matchings between the two. The holistic matching approaches, pursued by, e.g., [5,6,14], take a collection of schemas as input and generate a set of matchings over all these schemas. Different approaches suit different application settings. The holistic matching approaches are suitable for applications that would dynamically query a large scale of sources simultaneously, while the pairwise matching approaches are suitable for applications that query a small set of pre-configured sources.

Predicate Mapping for Predicate Heterogeneity

Predicate mapping focuses on addressing the heterogeneity at the predicate level. Existing solutions can be categorized into two categories: static predicate mapping mechanism and dynamic predicate mapping mechanism. The static predicate mapping mechanism works with a set of pre-configured data sources. It predefines mapping knowledge between a source schema and a target schema. In such scenarios, it is common, e.g., as [1] studies, to use pairwise rules to specify the mapping. Figure 2 gives some example rules that encode the mapping knowledge required for translation in the example of Fig. 1.

In contrast, the dynamic predicate mapping mechanism works with dynamically discovered sources in a domain. It does not encode the mapping knowledge for specific sources, but instead defines common domain-based translation knowledge that handles most sources in a domain. Such a system may use rules to encode domain knowledge or alternatively may use a search-driven mechanism to dynamically search for the best mapping. Such a search-driven mechanism "materializes" the semantics of a query as results over a database. For instance, to realize rule r_3 in Fig. 2 in the search mechanism, the dynamic mechanism projects both the source and target predicates onto an axis of real numbers, and thus compares their semantics based on their coverage. Finding the closest mapping thus naturally becomes a search problem – to search for the ranges expressible in the target form that minimally cover the source predicate.

Query Rewriting for Query Structure Heterogeneity

Capability-based query rewriting focuses on mediating the heterogeneity at query structure level. Most query rewriting works [4,8,9,10,12] are studied for data integration systems following a *mediator-wrapper* architecture, where a global mediator integrates local data sources through their wrappers. Query rewriting specifically studies the problem of how to mediate a "global" query (from the mediator) into "local" subqueries (for individual sources) based on their query capabilities. There are two basic approaches for addressing query rewriting in data integration system – *global as view* (GAV) and *local as view* (LAV). In global as view, each relation in the mediated (global) schema is defined as a view over schemas of local data source. Query rewriting in GAV is straightforward – simply replacing relation names in a query (over global schema) with their view definitions will yield a valid rewriting of query (over local schemas). In contrast, in local as view, each relation of a local schema is defined as a view over the mediated global schema. Query rewriting in LAV is thus to find a query plan or query expression which uses only views (i.e., local schemas) to answer queries over global schema. In particular, this problem is often abstracted as *answering queries using views*. For a thorough survey of related techniques for answering query using views, please refer to [4].

Key Applications

Query translation is a key component in any data integration system. The broad range of applications for data integration gives rise to the diverse applications of query translation. Two examples are:

Vertical Integration Systems

A vertical integration system integrates information from multiple pre-configured sources (usually in the same domain of data), and thus requires translating queries from a unified query interface to individual data sources. As data sources are usually pre-configured, such a system usually replies on static query translation mechanism such as [1] to handle translation with predefined source knowledge.

r_1 [author; *contain*; \$t] → *emit:* [author; *contain*; \$t]
r_2 [title; *contain*; \$t] → *emit:* [title; *contain*; \$t]
r_3 [price; *under*; \$t] → **if** \$t ≤ 25, *emit:* [price; *between*; 0,25]
elif \$t ≤ 45, *emit:* [price; *between*; 0,25] ∨ [price; *between*; 25,45]
......

Query Translation. Figure 2. Example mapping rules of source *S* and target *T*.

Meta Querying Systems

A meta querying system, e.g., [2], integrates dynamically selected sources relevant to user's queries, and on-the-fly translates user's queries to these sources. As sources are dynamically discovered without predefined source knowledge, such a system needs a dynamic query translation mechanism such as [15] which handles translation without relying on source-specific knowledge.

Quorum Systems

Marta Patiño-Martinez
Universidad Politecnico de Madrid, Madrid, Spain

Definition

Replication is a technique that provide scalability and high availability by introducing redundancy. This entry focuses on full replication for simplicity, that is, each node (site) has a copy of the entire database. Therefore, the terms nodes and replicas are used interchangeably. Replication increases performance (scale-out) as access to the data can be distributed across the replicas. Furthermore, the data remains available as long as some replicas are accessible. The most common approach is to execute all write operations (updates) at all replicas in order to keep them consistent while read operations are executed at a single replica. For read-intensive workloads this achieves the desired scalability. However, this approach, known as read-one/write-all (ROWA), has poor availability for write operations (writes cannot operate once a single replica fails) and does not provide scalability under write-intensive workloads. Quorum systems address both of these issues. They reduce the number of copies involved in write operations at the cost of increasing the number of copies involved in read operations. Reducing the number of copies to be accessed implies increased availability, tolerance of network partitions, reduced communication costs and the possibility of balancing the load among replicas.

In order to preserve data consistency of write operations, and a read and a write operation on the same data item must overlap at least at one replica. For that, each operation has to execute on a subset of replicas called a quorum. A *quorum system* over a set of nodes $\mathcal{N} = \{N_1,...N_n\}$ is defined as a collection $\mathcal{S}$ of subsets $S_i \subseteq \mathcal{N}$ with pair-wise non-null intersection. This means, for each $S_i, S_j \in \mathcal{S}$, $S_i \cap S_j \neq \emptyset$. Each subset $S_i \subseteq \mathcal{N}$ is called a *write quorum.* A write operation on a data item of the database must be executed in a write quorum. The requester asks all sites in the quorum for permission. If all of them grant permission, the write operation is executed at all nodes in the quorum. Data items are tagged with versions. If a write operation succeeds in a write quorum S_i, all nodes in S_i set the version of the affected data item to the same value, namely a value higher than any current version among the nodes in the quorum. The non-empty intersection property guarantees that only one quorum can make a decision at a time. That is, if two concurrent write operations on the same data item ask for permission to two write quorums, at least one node is member of both write quorums and gives permission to only one of the write operations. Read operations are executed on a *read quorum*, a set of sites $R_j \in \mathcal{N}$ such that $\forall S_i \in \mathcal{S}, S_i \cap R_j \neq \emptyset$. The requester of the read operation executes the read at all the sites of the read quorum, which return the value read and the version. The requester selects the value corresponding to the highest version. Since a read quorum intersects with all write quorums, it is guaranteed that at least one of the versions read is the latest one.

Historical Background

Quorum systems for data replication were proposed concurrently by [13] and [6] in order to provide availability despite individual node failures and network partitions. *Majority* quorum (also known as *quorum consensus*) [13] exploits the concept of majority to guarantee the intersection property. A quorum can be any majority of nodes. *Weighted voting* [6] generalizes majority by assigning votes to each site and defining a quorum to be a majority over the total number of votes in the system. An overview of early quorum systems is given in [4].

Maekawa [9] initiated a research line for increasing the scalability of quorum systems by reducing their size (in the order of $O(\sqrt{n})$). After this seminal work a large number of quorum systems exploiting different schemes have been proposed, mainly in the nineties. Extensive surveys on quorum systems can be found in [11,7].

Many of the proposed quorum systems exploit geometrical properties to satisfy the intersection property. *Grid quorums* arrange sites as a grid and then define read and write quorums as rows and columns to enforce their intersection. Grids quorums can be rectangular [5] or can have other shapes, such as triangles [11]. Grid quorums were generalized into hierarchical grid quorums by [8]. Another popular way to arrange sites are trees. Tree quorums were introduced by [1].

Quorums have been extended to tolerate Byzantine (arbitrary) failures requiring the intersection of two quorums to be bigger than one. Such quorums have been termed Byzantine quorums [10].

The properties of quorums have been studied extensively, especially availability and scalability. Optimal availability for sites with homogeneous failure probability were studied in [2,3,12]. Scalability (also known as load) has been first studied for symmetric update processing (all the sites in the write quorum fully execute the update transaction or operation) in [11], and then under asymmetric update processing (only one site executes the operations, the others only apply the changes) in [7].

Foundations

There are two basic ways to define quorum systems, plain (or exclusive) quorums and read/write quorums. Read/write quorums allow reduction of cost of read operations by exploiting the knowledge of whether an operation is a read or a write. They are more adequate for data replication where this knowledge is typically exploited. Plain quorums, or just quorums, are typically defined for mutual exclusion purposes, but can also be used for data replication by using exclusive quorums for both reads and writes.

A set system $\mathcal{S}$ is a collection of subsets $S_i \subseteq \mathcal{N}$ of a finite universe $\mathcal{N}$. A quorum system defined over a set of sites $\mathcal{N}$ is a set system $\mathcal{S}$ that fulfils the following property: $\forall S_i, S_j \in \mathcal{S},\ S_i \cap S_j \neq \emptyset$. Given a quorum system $\mathcal{S}$, each $S_i \in \mathcal{S}$ is a quorum. A read-write quorum system, over the set of sites $\mathcal{N}$, is a pair (R,W) where W is a quorum system (write quorums), and R a set system (read quorums) with the following property: $\forall\ W_i \in W,\ \forall\ R_j \in R,\ W_i \cap R_j \neq \emptyset$.

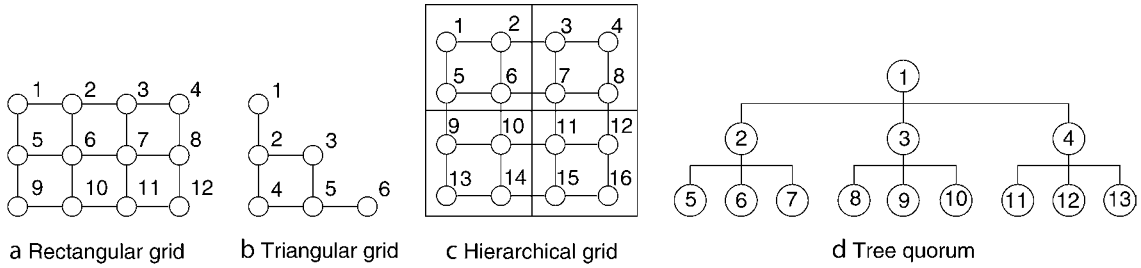
Quorum Types and Their Sizes

For scalability purposes it is beneficial to keep both read and write quorums as small as possible. Furthermore, in order to distribute the load fairly, each node should ideally participate in the same number of quorums. In the following, n denotes the number of nodes in $\mathcal{N}$.

Majority In the majority quorum system [13] read and write quorums must fulfill the following constraints (wq and rq stand for the write and read quorum sizes): $2 \cdot wq > n$ and $rq + wq > n$. The minimum quorum sizes satisfying these constraints are: $2 \cdot wq = n+1$ and $rq + wq = n+1$ and therefore, $wq = \lfloor \frac{n}{2} \rfloor + 1$ and $rq = \lceil \frac{n}{2} \rceil = \lfloor \frac{n+1}{2} \rfloor$. The ROWA approach can be seen as an extreme case of majority, in which $rq=1$ (a single replica is read) and $wq = n$ (all replicas are written). An example of a majority quorum system for three sites (1,2,3) with $rq = wq = 2$ is: {{1, 2}, {2, 3}, {1, 3}}. The majority quorum system is fair since each node has the same probability to be part of a quorum. In weighted majority [6], each site has a non-negative weight (votes). A write quorum consists of nodes such that the sum of their votes is more than half of the total number of votes. A read quorum consists of nodes that have at least half of the total number of votes. Assigning votes allows to adjust to heterogeneous environments where nodes have different processing power and availabilities.

Grids Another family of quorums is grid quorums. The simplest form of grid quorum is the rectangular grid [5]. A rectangular grid quorum organizes n sites in a grid of r rows and c columns (i.e., $n = r \cdot c$). Figure 1a depicts a 3 × 4 rectangular grid. A read quorum consists of accessing an element of each column of the grid ($rq = c$). A write quorum consists of a full column and one element from each of the remaining columns ($wq = r + c - 1$). In the quorum system of Fig. 1a {1,10,7,12} would be a read quorum and {2,6,10,5,3,8} a write quorum. The rectangular grid with the optimal (smallest) quorum size is the square. In this case, $rq = \sqrt{n}$ and $wq = 2 \cdot \sqrt{n} - 1$.

A variation of rectangular grids are *hierarchical grids* [8]. For instance, 16 sites can be configured into a two-level-grid with 2 × 2 grids at each level (Fig. 1c).



Quorum Systems. Figure 1. Different quorum systems.

A hierarchical grid organizes sites into a multi-level hierarchy, such that they reside on the leaves of this hierarchy, while other levels are represented by logical nodes. Each node at level i of the hierarchy (beside leaves) is defined by a rectangular $m \times n$ grid of nodes at level $i+1$. Two constructions are used to build quorums: row covers and full rows. A row cover is formed recursively by selecting a set of $(i+1)$-level nodes where each node pertains to a different row of the grid. A full row is formed recursively by selecting at level i a set of $(i+1)$-level nodes all pertaining to a single row of the grid. A read quorum consists of a row cover. A write quorum consists of the union of a full row and a row cover. A read quorum would be $\{1,6,7,8\}$ and a write quorum would be $\{1,5,6,7,8,10,14\}$. For square grids, this results in a read quorum size of $\sqrt{n}$ and a write quorum size of $2 \cdot \sqrt{n} - 1$, i.e., identical to its non-hierarchical counterpart.

Another way to arrange a grid quorum is a *triangular grid* [11]. Sites in a triangular grid are arranged in d rows such that row i $(1 \le i \le d)$ has i elements (Fig. 1b). A write quorum is defined as the union of one complete row and one element from every row below the full row. Therefore, the quorum size is always d. Read quorums are either a write quorum or an element from each row. In Fig. 1b a sample quorum would be $\{2,3,5\}$.

Triangle quorums are not fair since nodes that are higher in the triangle are more likely to be part of a quorum. In contrast, both rectangular and hierarchical grid quorums are fair.

Trees Another important family of quorum systems is tree quorums. Tree quorums were introduced in [1]. Similar to grid quorums, tree quorums are arranged as a logical structure over the nodes in order to reduce quorum sizes. The nodes are organized into a tree of height h and degree d, i.e., each inner node in the tree has d children. Figure 1d shows a tree with $d=h=3$. A *tree quorum* $q = \langle l, b \rangle$ over a tree with height h and degree b is a tree of height l and degree b constructed as follows. Read and write quorums have the same structure. The quorum contains the root of the tree and b children of the root. Then, recursively for each selected child, b of its children have to be selected, and so on, until a depth l is reached. In the case all nodes are accessible the quorum forms a tree of height l and degree b. If some node is inaccessible at depth h' from the root, the node is replaced by b tree quorums of height $l-h'$ starting from the children of the inaccessible node. In order to guarantee intersecting quorums, quorums must overlap both in height and degree. A read quorum $rq = \langle l_r, b_r \rangle$ and write quorum $wq = \langle l_w, b_w \rangle$ overlap if $l_r + l_w > h$ and $b_r + b_w > d$. Two write quorums overlap if $2 \cdot l_w > h$ and $2 \cdot b_w > d$. Tree quorums are generally not fair since nodes that are closer to the root take part in more quorums.

Depending on the values of l and b, different tree quorum systems can be defined. The most well-known is the *ReadRoot* in which a write quorum $wq = \langle h, d/2 + 1 \rangle$, i.e., at each level in the tree a majority of nodes needs to be accessed while a read quorum is $rq = \langle 1, (d+1)/2 \rangle$. That is, all reads go to the root. If the root fails, reads go to the next level while writes cannot be performed anymore. More availability is provided by *MajorityTree* where a majority approach is used both for the degree and height parameters. That is, a read quorum is $rq = \langle (h+1)/2, (d+1)/2 \rangle$ and a write quorum is $wq = \langle h/2 + 1, d/2 + 1 \rangle$. This increases the availability of write operations (since write quorums can be built without the root) but also the access costs of read operations. For the tree depicted in Fig. 1d, {1, 2, 3} is a read and a write quorum, or, if the root is down, {2, 5, 6, 3, 8, 9}.

Availability

Availability of quorums has also been studied extensively. Barbara and Garcia-Molina [3] demonstrated that majority is the most available quorum system for homogeneous failure probabilities (all sites have the same failure probability), if the failure probability p is higher than 0.5. Later, it was shown in [12] that for $p<0.5$ monarchy (all access goes to a single node) was the most available quorum system. When the failure probabilities are heterogeneous, the most available quorum system is weighted majority. The computation of the optimal weights has been provided for the different cases: all sites with $p>0.5$ [14] and the general case in which $0<p<1$ [2]. An extensive comparative study of the availability of different quorum systems is presented in [12].

Experimental Results

A comparison of the performance of quorum systems has been performed by [7,11]. In [7], two different forms of update processing were considered. Using symmetric update processing all the nodes in the write quorum fully execute update transactions (i.e., update operations). In contrast, asymmetric processing lets one node execute the operation while the others only apply the changes. As applying changes typically requires less resources than fully executing the operation, asymmetric processing imposes less load per write operation on the system than symmetric processing. Figure 2 compares the scalability of ROWA, majority and rectangular grids using the analytical model from [7]. The x-axis shows the the fraction of writes ($w = 1.0$ means 100% write operations, $w = 0.0$ means 100% reads). The y-axis shows the total number of nodes (replicas). The z-axis shows the scalability (how many times the throughput of a single-node system is multiplied by the replicated system). The first row of figures shows the performance for symmetric update processing. The scalability is generally very poor, especially for majority and grid. The second row shows results for asymmetric update processing when applying writes has 15% of the costs of fully executing the operation. Scalability

improves substantially. Majority and grid quorums can improve over ROWA for write-intensive workloads, but at the cost of performing worse in read-intensive environments.

Key Applications

One of the main applications of quorum systems is data replication. However, they are also used for other decentralized control protocols such as distributed mutual exclusion, distributed consensus, Byzantine replication, and group membership.

Future Directions

One of the main open issues with data replication based on quorum systems is how to manage efficiently collections of objects such as tables. Quorum systems might work reasonably well for accesses to individual objects. However, the access of collections of objects has not yet been adequately addressed. When accessing collections of objects the system is forced to collect all the instances of the collection from a read quorum to obtain the latest version of every object and only then, it becomes possible to select the subset of objects from the collection (typically by means of a predicate as in a SELECT statement). This compilation of the full collection from all the sites in the quorum at a single site ruins the performance and scalability of the quorum approach.

Randomization Methods to Ensure Data Privacy

ASHWIN MACHANAVAJJHALA, JOHANNES GEHRKE
Cornell University, Ithaca, NY, USA

Synonyms

Perturbation techniques

Definition

Many organizations, e.g., government statistical offices and search engine companies, collect potentially sensitive information regarding individuals either to publish this data for research, or in return for useful services. While some data collection organizations, like the census, are legally required not to breach the privacy of the individuals, other data collection organizations may not be trusted to uphold privacy. Hence, if U denotes the original data containing sensitive information about a set of individuals, then an untrusted data collector or researcher should only have access to an *anonymized* version of the data, U^*, that does not disclose the sensitive information about the individuals. A randomized anonymization algorithm R is said to be a *privacy preserving randomization method* if for every table T, and for every output $T^* = R(T)$, the privacy of all the sensitive information of each individual in the original data is provably guaranteed.

Historical Background

This is a brief survey of state of the art randomization methods. The reader is referred to the classical survey by Adam and Wortman [1] for a more comprehensive description of older randomization techniques.

Existing literature can be classified based on whether the individuals sharing the data trust the data collector or not. The untrusted data collector scenario is discussed first. Randomization methods have been historically used to elicit accurate answers to surveys of sensitive `yes/no` questions. Respondents may be reluctant to answer such questions truthfully when the data collector (surveyor) is untrusted. Warner's classical paper on *randomized response* [17] proposed a simple technique, where each individual i independently randomized the answer as follows: i answers truthfully with probability p_i, and lies with probability $(1 - p_i)$. Randomized response intuitively ensures privacy since no individual reports the true value. However, Warner did not formalize this intuition.

Subsequent works [7,2] generalized the above randomized response technique to other domains. Evfimievski et al. [7] studied the problem where individuals share itemsets (e.g., a set of movies rented) with an untrusted server (e.g., an online movie rental company) in return for services (e.g., movie recommendations), and they proposed a formal definition of privacy breaches. They invented a provably private randomization technique where users submit independently randomized itemsets to the server. They also proposed data reconstruction algorithms to help the server mine association rules from these randomized itemsets, and experimentally illustrated the accuracy of the reconstruction techniques. The above methods are called *local randomization techniques* since every individual perturbs his/her data locally before sharing it with the data collector.

In the trusted data collector scenarios, while the individuals trust the data collector, they may not trust any third party with whom their data is shared. Hence, randomization methods have been proposed to help privately share the collected data. These techniques can be broadly categorized into *input randomization* and *output randomization* techniques. Input randomization techniques publish a perturbed version of the table; queries are answered using the perturbed data. Output randomization techniques, on the other hand, execute queries on the real data, and return perturbed answers.

One thread of work on input randomization techniques was initiated by Agrawal and Srikant [3]. They proposed an input randomization technique wherein 0-mean random noise is added to the numeric attributes of each individual in the table. The algorithm was experimentally shown to be utility preserving. Nevertheless, Kargupta et al. [10] and Huang et al. [9] showed that adding noise independently to each record in the table does not guarantee privacy.

Yet another thread of work involves publishing synthetic data that has the same properties as the original data, but preserves privacy. Synthetic data generation is a very popular technique in the statistics community, and real applications (like OnTheMap [13]) publish sensitive information using this technique. First proposed by Rubin [16], these techniques build a statistical model using a noise infused version of the data, and then generate synthetic data by randomly sampling from this model. While much research has focused on deriving variance and confidence estimators from synthetic data, only recently has the privacy of these techniques been formally analyzed [12,15].

Among output randomization techniques, the SULQ framework proposed by Blum et al. [5] stands out since it has provable guarantees of privacy. Here, numeric query answers are perturbed by adding Laplace noise. Unlike in input perturbation techniques, privacy is guaranteed if and only if the number of queries that are answered is sub-linear in the number of entities in the table. Nevertheless, Blum et al. show that a large number of useful data mining tasks can be performed using this framework. However, exploratory research could be hindered in this framework, since the researchers need to formulate their queries before seeing the data.

Foundations

Local Randomization Techniques

Let U be the original data and let D_U be its (potentially multi-dimensional) domain. Each record $u \in U$ corresponds to the sensitive information of a distinct individual. Each u is independently randomized using a perturbation matrix **A**. The entry $\mathbf{A}[u, v]$ describes the transition probability $\Pr[u \rightarrow v]$ of perturbing a record $u \in D_U$ to a value v in the perturbed domain D_V. This random process maps to a Markov process, and the perturbation matrix **A** should therefore satisfy the following properties:

$$\mathrm{A} \geq 0, \qquad \sum_{v \in D_V} \mathbf{A}[u, v] = 1 \ \forall_u \in D_U \tag{1}$$

Privacy

Since each record $u \in U$ is perturbed independent of the rest of the records, it is sufficient to reason about the privacy of each record separately. A *privacy breach* [7] is said to occur if for some predicate ϕ of an individual's private information, the prior belief in the truth of ϕ is very different from the posterior belief in its truth after seeing the randomized record $R(u)$. More precisely, an *upward* (ρ_1, ρ_2) *privacy breach* with respect to a predicate ϕ occurs if

$$\begin{aligned}&\exists u \in U, \exists v \in Dv, \text{ s.t.,}\\ &\Pr[\phi(u)] \leq \rho_1 \text{ and } Pr[\phi(u)|R(u) = v] \geq \rho_2\end{aligned} \tag{2}$$

Similarly, a *downward* (ρ_1, ρ_2) *privacy breach* with respect to a predicate ϕ occurs if

$$\begin{aligned}&\exists u \in U, \exists v \in Dv, \text{ s.t.,}\\ &\Pr[\phi(u)] \geq \rho_1 \text{ and } \Pr[\phi(u)|R(u) = v] \leq \rho_2\end{aligned} \tag{3}$$

A randomization method R is defined to be γ*-amplifying* if

$$\forall v \in D_V, \ \forall u_1, u_2 \in D_U, \ \frac{Pr[u_1 \rightarrow v]}{Pr[u_2 \rightarrow v]} \leq \gamma \tag{4}$$

Evfimievski et al. [8] showed that a local randomization method that is γ-amplifying permits a (ρ_1, ρ_2) privacy breach if and only if

$$\frac{\rho_2}{\rho_1} \cdot \frac{1 - \rho_1}{1 - \rho_2} \geq \gamma \tag{5}$$

Algorithms

Randomized Response: Warner's randomized response technique [17] can be instantiated in this model as follows. Each entry $u \in U$ is a *yes/no* answer given by a distinct individual to a sensitive question Q (e.g., *"Have you ever used illegal drugs?"*). Hence, D_U ={0,1}. In order to preserve privacy, each individual flips a coin with bias p, and answers honestly if the coin lands heads and lies otherwise. The perturbation matrix is the 2 × 2 matrix with $\mathbf{A}[0,0] = \mathbf{A}[1,1] = p$ and $\mathbf{A}[0,1] = \mathbf{A}[1,0] = (1 - p)$.

Given n such perturbed answers, the aggregate answer can be estimated as follows. Let π be the fraction of the population for which the true response to Q is *yes* . Then the expected proportion of *yes* responses is

$$\Pr[\text{yes}] = \pi \cdot p + (1 - \pi) \cdot (1 - p) \tag{6}$$

$$\text{Hence, } \pi = \frac{\Pr[\text{yes}] - (1 - p)}{2p - 1} \tag{7}$$

If m out of the n individuals answered *yes* , then the following $\hat{\pi}$ is an unbiased estimator for π.

$$\hat{\pi} = \frac{\frac{m}{n} - (1 - p)}{2p - 1} \tag{8}$$

Warner also proposed a second randomization technique wherein, instead of lying with probability $(1 - p)$, the respondent answers the question Q honestly with probability p and answers a different innocuous question Q_I with probability $(1 - p)$. For instance, with probability p, the respondent truly answers if she had used illegal drugs, and with probability $(1 - p)$, the respondent flips a coin with bias α and answers *yes* if the respondent got a head. In this case, the probability that the answer to Q_I is *yes* is α. Hence, if m out of the n individuals answered *yes* , then the following $\bar{\pi}$ is an estimator for π.

$$\Pr[\text{yes}] = \pi \cdot p + \alpha \cdot (1 - p) \tag{9}$$

$$\pi = \frac{\Pr[\text{yes}] - (1 - p) \cdot \alpha}{p} \tag{10}$$

$$\bar{\pi} = \frac{\frac{m}{n} - (1 - p) \cdot \alpha}{p} \tag{11}$$

Typically, the innocuous question method is better than the former method, since the estimator $\bar{\pi}$ has a smaller variance than $\hat{\pi}$ when the probability of answering the correct question p is not too small.

Itemset Randomization

Itemset randomization is a useful tool that allows users to privately share their (e.g., shopping) histories with a centralized server in return for recommendation services. Let $\mathcal{I}$ represents the set of all items (e.g., products bought by at least one of the users). Then each entry $u \in U$ corresponds to a set of items $\mathcal{I}_u \subseteq \mathcal{I}$. Suppose, for simplicity, all the itemsets $\mathcal{I}_u$ are assumed to have the same number of items, say m. The server wants to learn the *frequent itemsets*, i.e., itemsets $A \subseteq \mathcal{I}$ whose support $\left(sup(A) := \frac{|\{u \in U | A \subseteq \mathcal{I}_u\}|}{|U|}\right)$ is $\geq s_{min}$. The following *Select-a-Size* algorithm, with parameters ρ and $\{p[j]\}_j{}^m$=0, is used to randomize itemsets.

- Select an integer $j \in [1,m]$, with probability $p[j]$.
- Select a simple random sample of size j of $\mathcal{I}_u$, called $\mathcal{I}'_u$.
- For every $a \in \mathcal{I} - \mathcal{I}_u$, add a to $\mathcal{I}'_u$ with probability ρ.

Evfimievski et al. [8] proved sufficient conditions on the parameters, ρ and $\{p[j]\}_j{}^m$=0, in order for this algorithms to be γ-amplifying while simultaneously maximizing the utility of the randomization method (e.g., maximizing the number of original items retained in the randomized itemset, $|I_u \cap I_u'|$). Algorithms for recovering the original data from the randomized itemsets and unbiased estimators for the mean and the covariance of these estimates are provided in [8].

Output Perturbation Techniques

Again let U be the original data. Output perturbation techniques execute queries on the real data, and then return perturbed answers. More precisely, if Q is a query on the data U, and R is the perturbation algorithm, $R(Q(U))$ is returned as the answer. In any such technique, there needs to be a limit on the number and the type of queries that can be posed to the database; for instance, answering the same query Q a large number of times discloses the exact answer to Q.

Privacy

Recall that each record in U corresponds to a distinct individual, and that the value of every record in U is independent of the other records. If each query accesses only one record in the table, then output perturbation essentially reduces to local randomization and the privacy breach analysis can be used.

When a query Q accesses multiple records ($U_Q \subseteq U$), however, one cannot reason about the privacy of a single record $u \in U$ (and hence, the privacy of an individual i) in isolation from the rest of the records $U_Q - \{u\}$. Moreover, depending on the amount of prior information known about U_Q, the extent of u's disclosure varies. For instance, if u is, say, the salary of Betty, Q is the query returning the total salary of women in the table, and the adversary knows that Betty is the only woman in the department ($|U_Q| = 1$), then disclosing $Q(U)$ discloses the value of u completely.

Differential privacy [6] can be used to quantify privacy in this case. Answering a query $Q(.)$ using $R(Q(.))$ is ε- *differential private* if for every pair of original tables U_1 and U_2 that differ in the value of a single record u, and for every possible answer A,

$$\left|\log\left(\frac{\Pr[R(Q(U_1)) = A]}{\Pr[R(Q(U_2)) = A]}\right)\right| \leq \epsilon \tag{12}$$

Intuitively, the above definition preserves privacy as follows. Consider a worst-case adversary who knows the exact values of all the records in $U - \{u\}$ and who is attempting to discover the value of record u_i. Now, if α_S denote the adversary's prior belief that $u \in S$ ($S \subseteq D_U$), then after seeing the answer $R(Q(U))$, the adversary's posterior belief β_S conditional on his knowledge of the rest of the records in the table is bounded by,

$$\alpha_S / e^{\epsilon} \leq \beta_S \leq e^{\epsilon} \times \alpha_S \tag{13}$$

Algorithms

The SULQ framework, introduced by Blum et al. [6], answers aggregate queries by adding random noise. Let Q be a function $D_U{}^n \rightarrow \mathfrak{R}$ The *sensitivity* of query Q, is the smallest number $S(Q)$, such that

$$\begin{aligned} &\forall U_1, U_2 \text{that differ in one record,} \\ &|Q(U_1) - Q(U_2)| \leq S(Q) \end{aligned} \tag{14}$$

Let Lap(λ) denote the *Laplace* distribution which has a density function $h(y) \propto \exp(-|y|/\lambda)$. Suppose a query $Q(U)$ posed to a database U is answered using $Q(U) + Y$, where $Y \sim \text{Lap}(S(Q)/\varepsilon)$. This perturbation scheme satisfies ε-differential privacy. For every U_1,U_2 that differ in only one record u,

$$\begin{aligned} \frac{\Pr[Q(U_1) + Y = x]}{\Pr[Q(U_2) + Y = x]} &= \frac{h(x - Q(U_1))}{h(x - Q(U_2))} \\ &= \frac{\exp(-|x - Q(U_1)| \times \epsilon / S(Q))}{\exp(-|x - Q(U_2)| \times \epsilon / S(Q))} \end{aligned} \tag{15}$$

$$\leq \exp(\epsilon \times |Q(U_1) - Q(U_2)| / S(Q)) = \exp(\epsilon) \tag{16}$$

This technique is useful when the amount of noise added is small; i.e., when the Q has low sensitivity. Examples of queries with low sensitivity are histograms, linear aggregation queries.

Input Perturbation Techniques

Most research is exploratory; the output perturbation techniques can be inconvenient, since researchers must specify queries before seeing the data. Input perturbation techniques on the other hand publish a perturbed version of the data that the researchers can then directly query. Though the two techniques seem different, technically they are the same; input perturbation uses a single perturbed query over the data, namely the sanitization algorithm. Dwork et al. [6] and Kifer et al. [11] show that in many cases publishing perturbed answers to multiple queries gives more utility than publishing a single perturbed dataset like in input perturbation.

Privacy

A simple technique to perturb the data is to independently add 0-mean noise to each attribute of each record. Let V be a noise matrix, then the perturbed data is $U_p = U + V$. The random noise added to each cell ($v \in V$) is usually either a uniform random variable in $[-\alpha,\alpha]$ or distributed as a Gaussian with 0 mean and a known variance. The privacy of such a scheme is unclear; in fact, Kargupta et al. [10] and Huang et al. [9] showed that the very accurate estimates of the original data can be recovered from such additively perturbed data due to dependencies inherent in U. For instance, suppose an adversary knows that all the records in U have the same value, say z. Then, additive randomization does not guarantee any privacy; the mean of the perturbed data accurately estimates z if there are enough records in U.

Additive randomization can be broken using Principal Components Analysis (PCA). Suppose the data has m dimensions and is perturbed by adding noise independently to each dimension. Usually, different attributes in the data are correlated; hence, it can projected onto a smaller number, $p < m$, of dimensions. The first principle component (PC) of the data is the direction, e_1, along which the data has the highest variance. The i^{th} PC, e_i, is a vector orthogonal to the first $(i - 1)$ PC's with the largest variance. These vectors are the eigenvectors of the covariance matrix of the data. In correlated data, only the variances along p directions are large. However, for the random data, the variances are the same along all directions. The variances of the perturbed data are roughly the sum of the variances of the original data and the random noise. Hence, by dropping $(m - p)$ directions along which the perturbed data has the least variance, while much information is not lost about the original data, a $(1 - p/m)$ fraction of the noise added is removed; this might lead to privacy breaches.

Algorithms

In order to guarantee privacy, the noise added should be correlated to the data. This is ensured by *synthetic data generation*. Here, a statistical model is generated from a noise infused version of the existing data, and synthetic data points are sampled from this model. Noise is introduced into the synthetic data on two counts: the noise infused prior to building the model, and the noise due to random sampling.

Different algorithms for generating synthetic data can be created by varying the synthetic model that is built using the data. One simple technique is based on Dirichlet resampling [12]. Let H denote the histogram of U, i.e., $H=\{f(v)| \, v \in D_U, f(v) = \text{multiplicity of } v \text{ in U}\}$, and let R denote the noise histogram. Then the statistical model is $D(H + R)$, where D denotes the Dirichlet distribution. Synthetic data is generated as follows. Draw a vector of probabilities, X, from $D(H + R)$, and generate m points according to the probabilities in X. The above process is mathematically equivalent to the following resampling technique. Consider an urn with balls marked with values $v \in D_U$ such that the number of balls marked with v equals the sum of the frequency of v in U and the frequency of v in the noise histogram. Synthetic data is generated in m sampling steps as follows. In each sampling step, a ball, say marked v, is drawn at random and two balls marked v are added back to the urn. In this step, the synthetic data point is v.

Machanavajjhala et al. [12] characterized the privacy guaranteed by this algorithm in terms of noise distribution. Specifically, they showed that in order to guarantee ε-differential privacy, the frequency of every $v \in D_U$ in the noise histogram should be at least $m/(e^{\varepsilon} - 1)$. For large m and small ε the noise required for privacy overwhelms all of the signal in the data and renders the synthetic data completely useless. Such large requirements of noise is due to the following worst case requirement of differential privacy. Consider a scenario where an adversary knows that U contains exactly one record u_i that takes either the value v_1 or v_2. Now suppose that in the output sample, every record takes the value v_1. If m is large, then the adversary's belief that $r_u = v_1$ is close to 1. In order to guard against such adversaries, differential privacy requires a large amount of noise. However, the probability that such synthetic data is output is negligibly small. This can be remedied using a weaker (ε, δ)-probabilistic differential privacy definition, where an algorithm is private if it satisfies ε-differential privacy for all outputs that are generated with a cumulative probability of at least (1 − δ). Under this weaker definition, the Dirichlet resampling technique is private with much smaller noise requirements.

Barak et al. [4] propose a solution to publish marginals of a contingency table (i.e., a histogram) using the SULQ framework. Publishing a set of noise infused marginals is not satisfactory; such marginals may not be consistent, i.e., there may not exist a contingency table that satisfies all these marginal contingency tables. Barak et al. solve this problem by adding noise to a small number of Fourier coefficients; any set of Fourier coefficients correspond to a (fractional and possibly negative) contingency table. They show that only a "small" number of Fourier coefficients are required to generate the required marginals, and hence only a small amount of noise (proportional to the size of the marginal domain) is required. The authors employ a linear program solution (in time polynomial in the size of multidimensional domain) to generate the final non-negative integral set of noise infused marginals.

Rastogi et al. [14] propose the $\alpha\beta$ algorithm for publishing itemsets. It is similar to the select-a-size randomization operator. Given an itemset I that is a subset of the domain of all items D, the $\alpha\beta$ algorithm creates a randomized itemset V by retaining items in I with probability $\alpha + \beta$ and adding items in $D - I$ with probability β. This algorithm satisfies a variant of ε-differential privacy. Moreover, the authors show that for queries $Q : 2^D \rightarrow \mathbb{R}$, $Q(I)$ can be estimated as follows:

$$\hat{Q}(I) = (Q(V) - \beta Q(D))/\alpha \qquad (17)$$

where $Q(V)$ and $Q(D)$ are the answers to the query Q on the randomized itemset V and the full domain D, respectively. $\hat{Q}(I)$ is shown to provably approximate Q (I) with high probability.

Key Applications

Privacy preserving techniques have been used in Census applications and various web-applications.

The Dirichlet resampling based synthetic data generation technique is used in the web-based OnTheMap Census application that plots worker commute patterns on the U.S. map to study workforce indicators [13]. Warner's randomized response has been used in eliciting responses to sensitive survey questions.

Future Directions

One common property of all provably private randomization methods is that the probability of perturbing a value $u \in D_U$ to every value $v \in D_V$ (the perturbed domain, which is usually the same as D_U) should be positive. As shown by Machanavajjhala et al. [12], this causes a problem when the size of the domain is very large. For instance, in the On The Map [13] application, the domain D_U is the set of census blocks on the U.S. map and there are about 8 million such blocks. However, given a destination, there is only a few hundred workers commuting to it. Hence, even if a small amount of noise is added to each block on the map, spurious commute patterns will arise in the synthetic data. All of the techniques discussed in this article should be revisited in the context of real scenarios with sparse data.

Range Query

Mirella M. Moro

Synonyms

Range search; Range selection

Definition

Consider a relation *R* with some numeric attribute *A* taking values over an (ordered) domain *D*. A *range query* retrieves all tuples in R whose attribute A has values in the interval $[low, high]$. That is, $low \leq R.A \leq high$. The range interval may be closed as above, open (e.g., $low < R.A < high$), or half-open in either side (e.g., $low < R.A \leq high$). A range query can be one-sided (e.g., low $\leq R.A$ retrieves all tuples with R.A value greater or equal to *low*). When $low = high$ the range query becomes an *equality* (or *membership*) query.

Key Points

Range queries involve *numeric* (or numerical) attributes. These are attributes whose domain is totally ordered and thus a query interval (e.g., *[low, high]*) can be formed. In contrast, attributes whose domain is not naturally ordered are called *categorical* (or *nominal*). Range queries correspond to selections and are thus amenable to indexing. The standard access method for a range query on some attribute A is a B+-tree built on the values of attribute A. Since the B+-tree maintains the order of the indexed values in its leaf pages, a range query is implemented as a search for the leaf page with the lower value of the range interval, followed by the accessing of sibling pages until a page that contains the higher value of the range interval is reached. The above discussion considers the one-dimensional range search. Multidimensional range queries are also important. A typical example is the *spatial range query* that retrieves all objects which fall within (or intersect, overlap, etc.) a region (a rectangle specified by ranges in each dimension). Such multidimensional range queries are typically indexed by R-trees.

Aggregation and threshold algorithms for XML; Approximate XML querying; Top-k XML query processing

Definition

When querying collections of XML documents with heterogeneous or complex schemas, existing query languages like XPath or XQuery with their exact-match semantics are often not the perfect choice. Such exact querying languages will typically miss many relevant results that do not conform to the strict formulation of the query.

Top-k query processing for XML data, which focuses on finding the k top-ranked XML elements to an XPath (or XQuery) query with full-text search predicates, is a particularly appropriate query model for querying semi-structured data when the actual content or structure of the underlying data is not fully known. Challenges in processing top-k queries over XML data include scoring individual answers based on how closely they match the query, supporting IR-style vague search over both content and structure, and ranking the k best answers in an efficient manner.

Historical Background

Non-schematic XML data that comes from many different sources and inevitably exhibits heterogeneous structure and annotations in the form of hierarchical tags and deeply nested XML elements often cannot be adequately searched using pure database-style query languages like XPath or XQuery. Typically, queries either return too many or too few results using only Boolean search predicates. Rather, the ranked-retrieval paradigm needs to be called for, with relaxable search conditions, various forms of similarity predicates on tags and contents, and quantitative relevance scoring. The information retrieval (IR) community has historically focused on scoring documents based on how closely they match a user's keyword query. Intense research on applying IR techniques to XML data has started in the early 2000's and has meanwhile gained considerable attention. Recent IR extensions to XML query languages such as XPath 1.0 Full-Text or the NEXI query language used in the INEX benchmark series [5] reflect this emerging interest in IR-style ranked retrieval over semi-structured data. So far, various work on scoring answers to XML queries have focused on adapting IR-style scoring techniques from unstructured text to the semi-structured world, see, e.g., [2,5,11]. On the IR side, some foray into adding structure to standard IR search has taken place before the advent of XML [13]. The popularity of XML provides an opportunity to combine efforts led separately by both the DB and IR communities and provide robust techniques to query semi-structured data.

Threshold Algorithms

The method of choice for efficient processing of top-*k* similarity queries is the family of threshold algorithms (TA), most notably presented by Fagin et al. [8] and originally developed for multimedia databases and structured records stored in relational database systems (RDBMS). These algorithms rely on making dynamic choices for scheduling index lookups during query execution in order to prune low-scoring candidate items as early as possible. They typically scan precomputed index lists for text terms or attribute values of structured records in descending order of local (i.e., per-term) scores and aggregate these scores for the same data item into a global score, using a monotonic score aggregation function such as (weighted) summation. Based on clever bookkeeping of score intervals and thresholds for the top-*k* matches, these index scans can often terminate early, namely as soon as the final top-*k* results can be safely determined, and thus the algorithm often only has to scan short prefixes of the inverted lists. In contrast to the heuristics adopted by many Web search engines, these threshold algorithms compute exact results and are provably optimal in terms of asymptotic costs.

XML and IR

Efficient evaluation and ranking of XML path conditions is a very fruitful research area. Solutions include various forms of structural joins, multi-predicate merge joins, the staircase join based on index structures with pre- and postorder encodings of elements within document trees [10], and holistic twig joins [6]. The latter, also known as path stack algorithm, is probably the most efficient method for twig queries using a combination of sequential scans over index lists stored on disk and linked stacks in memory. However, these approaches are not dealing with uncertain structure and do not support top-*k*-style threshold-based early termination.

IR on XML data has become popular in recent years. Some approaches extend traditional keyword-style querying to XML data [7,11], introduced full-fledged XML query languages with rich IR models for ranked retrieval [9,19], or developed extensions of the vector space model for keyword search on XML documents. FleXPath [4] was among the first approaches to combine this theme with full-text conditions over search predicates. Meanwhile, various groups have started adding IR-style keyword conditions to existing XML query languages. TeXQuery is the foundation for the W3C's official full-text extensions to XPath 2.0 and XQuery 1.0. TIX and TAX are query algebras for XML that integrate IR-style query processing into a pipelined query evaluation engine. TAX furthermore comes with an efficient algorithm for computing structural joins. Here, the results of a query are scored subtrees of the data, and TAX already provides a threshold operator that drops candidate results with low scores from the result set. TOSS is an extension of TAX that integrates ontological similarities into the TAX algebra.

XIRQL [9], a pioneer in the field of ranked XML retrieval, presents a path algebra based on XQL, an early ancestor of W3C's XQuery, for processing and optimizing structured queries. It combines Boolean query operators with probabilistically derived weights for ranked result output, thus carrying the probabilistic IR paradigm over to the XML case. Finally, XXL [19], specifies a full-fledged, SQL-oriented query language for ranked XML-IR with a high semantic expressiveness that made it stand apart from the Boolean

XQL and XPath language standards being predominant at that time. For ranked result output, XXL leverages both a standard IR vector space model and an ontology-oriented similarity search for the dynamic relaxation of structure and term conditions. TopX [17], the actual successor of XXL, on the other hand, focuses on a smaller, XPath-like, subset of the XXL query language which allows for a radically different query processing architecture that outperforms XXL in terms of efficiency by a large margin.

Foundations

Applying the TA paradigm for inverted index lists to XML ranked retrieval is not straightforward. In a data-centric XML setting, a ranking of query results to a query is typically induced by defining some form of structural similarity, whereas in a more text-centric view (with a rich mixture of XML tags and text contents), ranking is derived from IR-style text relevance measures, or a combination of structural similarity and text relevance. More precisely, the XML-specific difficulties arise from the following challenges:

Query Processing and Index Structures: Relevant intermediate results to a mixture of structural and content-related search conditions must be tested as to whether they satisfy the path conditions of the query, and this may incur repetitive and expensive *random access* to large, disk-resident index structures. Furthermore, instead of enforcing conjunctive query processing, it is desirable to relax path conditions and rather rank documents by a combination of content scores and an additional degree to which the structural query conditions are satisfied. *Incremental path evaluations* are required when the index structures are accessed mostly using efficient *sequential disk access* in order to limit or entirely avoid the more expensive random accesses. Yet all incremental updates to candidate score bounds during the query processing need to stay monotonic, in order to guarantee a correct algorithmic basis for top-*k* query evaluation with early candidate pruning.

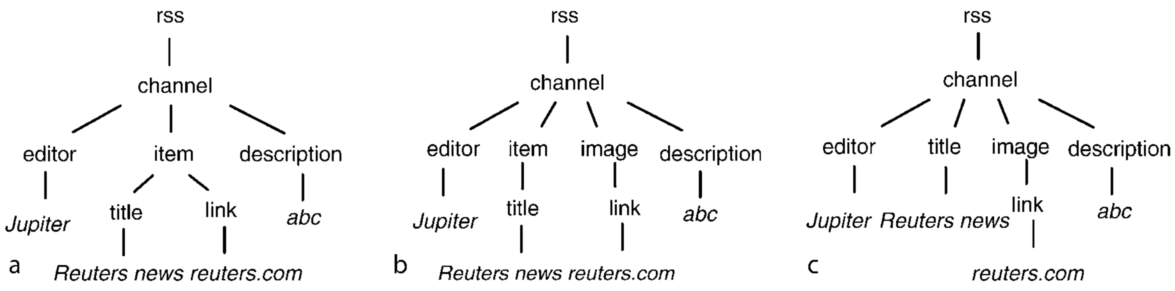
IR Scoring Models and Vague Search: Existing IR scoring models for text documents cannot be directly carried over to the XML case, because they would not consider the specificity of content terms in combination with hierarchical elements or attribute tags. For example, the term "transactions" in a bibliographic data set should be viewed as specific (and lead to a high score) when occurring within elements of type section or caption but be considered less informative within tags like journalname. Furthermore, it should be possible to relax search terms and, in particular, tag names, using tree editing operations, or ontology- and thesaurus-based similarities. For example, a query for a book element about "XML" should also consider a monograph element on "semi-structured data" as a relevant result candidate.

Result Granularity: Scores and index lists refer to individual XML elements and their content terms, but from an IR point-of-view it is desirable to aggregate scores at the document level and return the most relevant XML subtrees, up to the entire XML document, as results. Thus, the query evaluation has to weigh *different result granularities* against each other dynamically in the top-*k* query processing, and the relevance scoring model should consider XML-specific ranking aspects such as *exhaustiveness* and *specificity* when choosing the most suitable result granularity to address the user's information need.

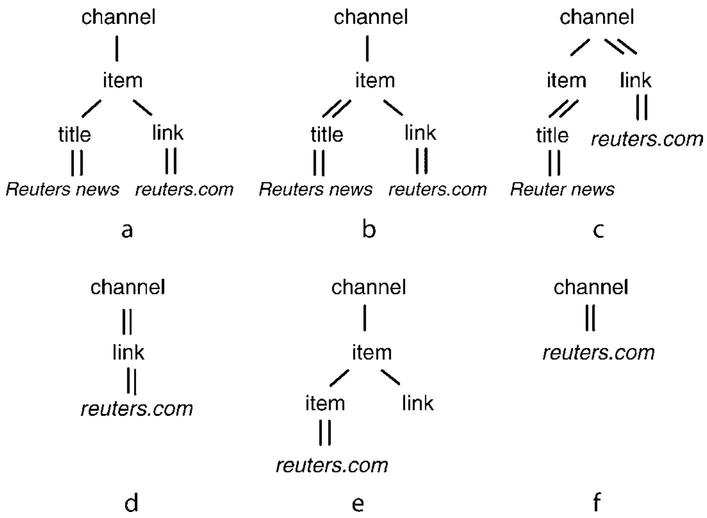
Scoring Structure

Structural similarity is considered in the sense that documents can qualify even if they do not satisfy all path conditions, i.e., if there were too few results otherwise. For dynamically relaxing tag names and structural relationships of tags in path queries, various tree editing operations can be employed, such that only the most similar matches in the collection are returned.

XML data can typically be represented as forests of node-labeled trees. Figure 1 shows a database instance containing fragments of heterogeneous news documents. Figure 2 gives examples of several queries drawn as trees: the root nodes represent the returned answers, single and double edges represent the descendant and child axes, respectively, and node labels stand for names of elements or keywords to be matched. Hence, different queries match the different news documents in Fig. 1. For example, query (a) in Fig. 2 matches document (a) exactly, but would neither match document (b) (since link is not a child of item) nor document (c) (since item is entirely missing). Query (b) matches document (a), also since the only difference between this query and query (a) is the descendant axis between item and title. Query (c) matches both documents (a) and (b) since link is not required to be a child of item while query (d) matches all documents in Fig. 1. Intuitively, it makes sense to return all three news documents as candidate matches, suitably ranked



Ranked XML Processing. Figure 1. Heterogeneous XML database example.



Ranked XML Processing. Figure 2. Query tree patterns and relaxations.

based on their similarity to query (a) in Fig. 2. Queries (b), (c), and (d) in Fig. 2 correspond to *structural relaxations* of the initial query (a) as defined in [4]. In the same manner, none of the three documents in Fig. 1 matches query (e) because none of their title elements contains *reuters.com*. Query (f), on the other hand, is matched by all documents because the scope of *reuters.com* is broader than in query (e). It is thus desirable to return these documents suitably ranked according to their similarity to query (e).

In order to achieve the above goals, [4] defines query relaxations, including *edge generalization* (replacing a child axis with a descendant axis), *leaf deletion* (making a leaf node optional), and *subtree promotion* (moving a subtree from its parent node to its grandparent). These relaxations capture approximate answers but still guarantee that exact matches to the original query continue to be matches to the relaxed query. For example, query (b) can be obtained from query (a) by applying edge relaxation to the axis between `item` and title and still guarantees that documents where title is a child of item are matched. Query (c) is obtained from query (a) by composing edge generalization between item and title and subtree promotion (applied to the subtree rooted at link). Finally, query (d) is obtained from query (c) by applying leaf deletion to the nodes *ReutersNews*, title and item. Query (d) is a relaxation of query (c) which is a relaxation of query (b) which is in turn a relaxation of query (a). Similarly, query (f) in Fig. 2 can be obtained from query (e) by a combination of subtree promotion and leaf deletion. Other works have considered additional query relaxation such as *node renaming*, *node generalization*, *node insertion*, and *node deletion* [1,9,15,16]. The use of schema knowledge can reduce the number of possible relaxed queries by ignoring relaxations that are guaranteed not to lead to additional matches [16].

Amer-Yahia et al. [3] presented strategies to assign scores to query relaxations. These strategies are based on the traditional *tf* · *idf* measure derived from IR-style ranking of keyword queries against an unstructured document collection. The *twig scoring* method introduced in [3] computes the score of an answer taking occurrences of *all* structural and content-related (i.e., keyword) predicates in the query. For example, a match to query (c) would be assigned an *inverse document frequency* score, *idf*, based on the fraction of the number of channel nodes that have a child item with a descendant title containing the keyword *ReutersNews* and a descendant link that contains the keyword *reuters.com*. Such a match would then be assigned a *term frequency* score, *tf*, based on the number of query matches for the specific channel answer.

Scoring Text

A variety of IR-style scoring functions has been proposed and adopted for XML retrieval, ranging from the classic vector space model with its *tf* · *idf* family of scoring approaches, typically using *Cosine* measure for score aggregations, over to the theoretically more sound *probabilistic scoring models*, with *Robertson & Sparck-Jones* and *Okapi BM25* being the most widely used ranking approaches in current IR benchmark settings such as TREC or INEX, up to even more elaborated *statistical language models*. An important lesson from text IR is that the influence of the term and document frequency values, *tf* and *df* – in the following referred to as their element-specific counterparts *ftf* and *ef*, should be sub-linearly dampened to avoid a bias for short elements with a high term frequency of a few rare terms. To address these considerations, the TopX engine, presented by Theobald et al. [17,18], adopts the empirically very successful Okapi BM25 probabilistic scoring model to a generic XML setting by computing individual relevance models for each element type occurring in the collection.

For a typical NEXI query pattern of the form $q = // A[\text{about}(.//, t_1, \ldots, t_m)]$, the following *relevance score* is computed for an element *e* with tag name A:

$$score(e,q) = \sum_{i=1}^{m} \frac{(k_1+1)ftf(t_{i,}e)}{k + ftf(t_i,e)}$$

$$.\log\left(\frac{N_A - ef_A(t_i) + 0.5}{ef_A(t_i) + 0.5}\right)$$

$$\text{with } K = k_1\left((1-b) + b\frac{length(e)}{avg\_length_A}\right)$$

Here, $ftf(t_i, e)$ models the *relevance* of a term t_i for an element's *full content*, i.e., the frequency of t_i in all the descending text nodes of element *e*; while $ef_A(t_i)$ models the *specificity* of t_i for a particular element with tag name A by capturing how many times t_i occurs under a tag A across the whole collection having N_A elements with this tag name.

That is, this extended BM25 model computes a separate relevance model for each term t_i with respect to its enclosing tag name A, thus maintaining detailed element frequency statistics $ef_A(t)$ of each individual tag-term pair that occurs in the collection. It provides a smoothed (i.e., dampened) influence of the *ftf* and *ef* components, as well as a compactness-based normalization that takes the average length of each element type into account. Note that the above function also includes the tunable parameters k_1 and b just like the original BM25 model that now even allows for fine-tuning the influence of the *ftf* components and the length normalization for each element type individually – if desired. For an about operator with multiple keyword conditions as used in the NEXI query language of the INEX benchmark series (or similarly for ftcontains in the XPath 2.0 Full-Text specification), that is attached to an element *e* with tag name A, the aggregated score of *e* is simply computed as the sum of the element's scores over the individual tag-term conditions. For path queries with more than one structural tag condition or with multiple full-text operators, the content scores of each element can be combined with the structural scores described above.

Various extensions for more specific full-text predicates such as keyword proximity and phrase matching, as well as incorporating ontological concept similarities for query expansion, have been proposed in the literature – some of which are leaving some interesting research questions for a top-*k*-style query processor, since most of the more sophisticated proximity- or graph-based compactness measures inherently lead to non-monotonic score aggregation functions.

XML Top-k Query Evaluation Techniques

Combining Structure Indexes and Inverted Lists: Kaushik et al. [12] proposed one of the first, exact-match, top-*k* algorithms for XML by employing various path index operations as basic steps for non-relaxed evaluations of branching path queries. Their strategy combines two forms of auxiliary indexes, a *DataGuide*-like path index for the structure whose extent identifiers are linked to an inverted index for processing relevance-ranked keyword conditions. The index processing steps are then invoked within a TA-style top-*k* algorithm, involving eager random access to these inverted index structures.

XRank: Among the most prominent IR-related approaches for ranked retrieval of XML data is XRank [11]. It generalizes traditional link analysis algorithms such as *PageRank* for authority ranking in linked Web collections and conceptually treats each XML element as an interlinked node in a large element graph. Then the *element rank* of an XML element corresponds to the authority weight computed over a mixture of containment edges, obtained from the XML tree structure, and hyperlink edges, obtained from the inter-document XLink structure, similar to the HTML case. XRank may indeed return deeply nested elements but merely supports conjunctive keyword search; it does not yet support structured and/or path query languages such as XPath. For efficient retrieval of multi-keyword queries, it also uses inverted lists sorted in descending order of element ranks and sketches the usage of standard threshold algorithms for pruning the search space.

FlexPath: FlexPath [4] integrates structure and keyword queries and regards the query structure as templates for the context of a full-text keyword search. The query structure (as well as the content conditions) can be dynamically relaxed for ranked result output according to predefined tree editing operations when matched against the structure of the XML input documents. The FlexPath query processor already comprises the usage of top-*k*-style query evaluations for a slightly modified, XPath-like, query language that later evolved as part of the official W3C Full-Text extensions to XPath 2.0 and XQuery 1.0. Like [12], it uses separate index structures for storing and retrieving the structural and content-related conditions of an XPath 2.0 Full-Text query; it may thus require a substantial amount of random access to disk-resident index structures for resolving the final structure of a result candidate.

Whirlpool: The Whirlpool system introduced by Marian et al. [14] provides a flexible architecture for processing top-*k* queries on XML documents *adaptively*. Whirlpool allows partial matches to the same query to follow different execution plans, and takes advantage of the top-*k* query model to make dynamic choices during query processing. The key features of Whirlpool are: (i) a partial match that is highly likely to end up in the top-*k* set is processed in a prioritized manner, and (ii) a partial match unlikely to be in the top-*k* set follows the cheapest plan that enables its early pruning. Whirlpool provides several adaptivity policies and supports parallel evaluation; details on experimental results can be found in [14].

TopX: The biggest challenge in further accelerating full-text query evaluations over large, semi-structured data collections lies in finding appropriate encodings of the XML data, for indexes that can be read *sequentially* in big chunks directly from disk when the collection (or index) no longer fits into the main memory of current machines. Thus, the TopX engine [17,18] operates over a *combined inverted index* for content- and structure-related query conditions by precomputing and materializing joins over tag-term pairs, the most common query patterns in full-text search. This simple precomputation step makes the query processing more scalable, with an encoding of the index structure that is easily serializable and can directly be stored sequentially on disk just like any inverted index, for example using conventional B^+-tree indexes or inverted files.

At query processing time, TopX scans the inverted lists for each tag-term pair in the query in an interleaved manner, thus fetching large element blocks into memory using only sorted access to these lists and then iteratively joining these blocks with element blocks previously seen at different query dimensions for the same document. Using pre-/postorder tree encodings [10] for the structure, TopX only needs a few final random accesses for the potential top-*k* items to resolve their complete structural similarity to a path query. An extended hybrid indexing approach using a combination of DataGuide-like path indexes and pre-/postorder-based range indexes can even fully eliminate the need for these random accesses – however at the cost of more disk space.

TopX further introduces pluggable extensions for *probabilistic candidate pruning*, as well as a *probabilistic cost-model* for adaptively scheduling the sorted and random accesses, that help to significantly accelerate query evaluations in the presence of additional, precomputed index list statistics such as index list selectivities, score distribution histograms or parameterized score estimators, and even index list (i.e., keyword) correlations. For *dynamic query expansions* of tag and term conditions, TopX can incrementally merge the inverted lists for similar conditions obtained from an exchangeable background thesaurus such as *WordNet* or *OpenCyc*. Thus, TopX provides a whole toolkit of specialized top-*k* operators for efficient full-text search, including *incremental merge operators* for dynamic query expansion and *nested top-k operators* for high-dimensional phrase expansions.

Key Applications

Scalable, Web-Style Search over Semi-structured Collections: Efficient IR over large Web collections will remain one of the most challenging applications for XML-top-*k* query processing with full-text search, with an ever-increasing demand for scalability, interactive runtimes, and vague search involving dynamic query relaxation and/or expansion over heterogeneous collections or unknown schemata.

INEX Benchmark Series: INEX provides a comprehensive forum for IR research on semi-structured data, that goes beyond using the formerly prevalent synthetic data collections such as XMark or XBench for evaluating retrieval quality in true IR-style settings, with a variety of subtasks, XML-IR-specific evaluation metrics, and peer assessments of retrieval results [5].

Future Directions

Graph Top-k: Current XML-top-*k* algorithms are restricted to XML data trees. Future work could focus on further generalizing the scoring approach, in order to handle cycles arising from inter- or intra-document XLinks, with the need to still derive tight and accurate bounds for early candidate pruning. This may involve efficient index structures for arbitrary graphs and potentially non-monotonic score aggregation functions to incorporate graph compactness measures such as *Steiner trees.*

More XQuery: Similarly, current work has only focused on implementing various subsets of the XPath query language. Providing top-*k*-style bounds and pruning thresholds for more complex XQuery constructs such as *loops* and *if-cases* would be an intriguing issue for future work.

Experimental Results

Extensive experiments can be gleaned from the various approaches presented in the literature, see, e.g., [3,4,12,14,17].

Raster Data Management and Multi-Dimensional Arrays

Peter Baumann
Jacobs University, Bremen, Germany

Synonyms

Array databases; Raster databases

Definition

In this enry, the management of raster data is described based on the concept of an array database system. An array database system is a database system that supports the array (also called raster) data structure, as understood in programming languages: a homogeneous collection of data items where each item has a coordinate associated, and coordinates sit at grid points in a rectangular, axis-parallel subset of the Euclidean space $\mathbf{Z}^d$ for some $d > 0$.

Such arrays convey a very regular structure with a well-defined neighborhood relation between its cells, which requires suitable storage structures. Frequently, operations on cells are applied simultaneously to large contiguous portions of arrays, such as overlaying two equally-sized images; efficient query processing needs to provide support for such patterns. Finally, arrays tend to be very large, with single objects frequently ranging into Terabyte and soon Petabyte sizes; for example, today's earth and space observation archives grow by Terabytes a day.

Query language support for arrays consists of array primitives which can be nested as in standard SQL, and preferably integrated into SQL. Once sufficiently declarative query languages are available, query optimization and parallelization can be applied which has been proven to accelerate array evaluation up to orders of magnitude. Storage management must give efficient access to large arrays and sub-arrays thereof. Due to the large sizes, compression often is applied, but some high-volume applications still require storage hierarchies.

Today, an important application domain is Web services on geo raster data, such as 1-D environmental sensor time series, 2-D satellite images, 3-D x/y/t image time series (Fig. 1), 3-D x/y/z exploration data, and 4-D x/y/z/t climate simulation data. Other spatio-temporal applications can be found, e.g., in the Life Sciences. *On-line analytical processing* (OLAP) and Statistical Databases consider arrays as well, often combining the time dimension with abstract axes such as sales and products.

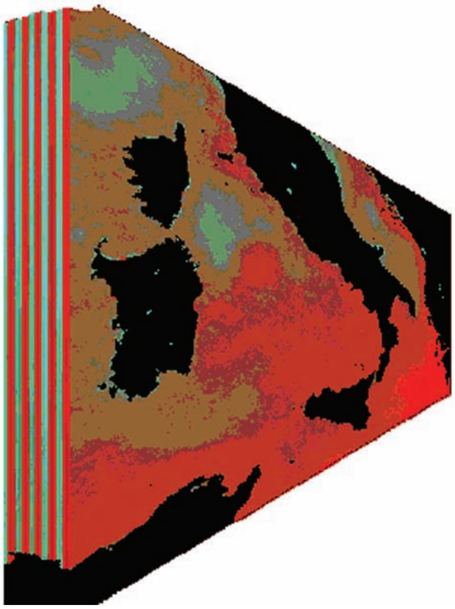
Historical Background

The array paradigm is not directly supported by the relational data model. Therefore, two different approaches have traditionally been pursued to achieve array support: BLOBs and OLAP data *cubes*.

Imagery in Array Databases

If stored in databases, image pixel matrices go into BLOBs (Binary Large OBjects), linearized and encoded in some data exchange format, and result in a byte string whose semantics is unknown to the database system. The database system, therefore, cannot provide any array operation aside from reading and writing the complete BLOB. As a consequence, for many potential application domains, users believe that databases cannot support their raster data, and they still tend to develop their own file-based services in an ad-hoc manner.

The requirement for further array processing capabilities distinguishes array databases from multimedia databases and imaging systems. Array databases are different from multimedia databases which analyze images using some built-in algorithms to obtain



Raster Data Management and Multi-Dimensional Arrays. Figure 1. Retrieval result from a 3-D x/y/t satellite image time series data cube on sea surface temperature; original data cube contains about 10,000 satellite images (image: rasdaman screenshot, data: NASA/DLR).

feature vectors. Subsequently, search is performed on the feature vectors, not the images. Array databases, conversely, do not attempt to interpret the raster data, but always operate on the cell values themselves.

Likewise, array databases are different from image processing and understanding systems. Imaging systems offer elaborate functionality, however are not constrained to excessively large images in relation to main memory size. Array databases, conversely, constrain themselves in functionality to remain safe in evaluation, but aim to have no object size limit.

Statistics Data in Array Databases

Statistical data are usually modeled as OLAP data cubes. Today, the main paradigm is Relational OLAP (ROLAP) where each data item, together with its coordinates, is stored in a so-called fact table in a relational DBMS. This explains why ROLAP is suitable only for very sparse data, where listing only valid points together with their coordinates represents an efficient compression scheme.

Relational query operators, extended with specific data cube operators, provide powerful analysis capabilities on such data cubes.

A Unified View

Although treated differently, both images (here understood to have any spatio-temporal dimensions, not just 2-D x/y axes) and data cubes share characteristics to a large extent. Both consist of a data structure mapping n-D coordinates with rectangular boundaries into a value space. Operations also convey similarities, as the following examples show: Subsetting (cutting out sub-cubes) is known in both worlds, and an OLAP roll-up from days to weeks is equivalent to scaling an image by a factor of seven using linear interpolation.

Actually the main difference motivating different treatment lies in a data property. Statistical data tend to be very sparse, typically only up to 5% of the data cube holds values of interest. Image data, on the other hand, tend to be 100% dense.

Some authors [7] argue that OLAP data cubes are not strictly arrays because, in the case of categorical axes (in OLAP called measures), the neighborhood relation between points does not induce a strict ordering. Others [2] subsume data cubes under the array paradigm, for example because categorical measures ultimately are mapped to integer coordinates during physical modeling.

History and Current State

A first important step beyond BLOBs was accomplished with PICDMS [4] where a 2-D array query language, still procedural and without suitable storage support, has been introduced. A declarative n-D array query language with an algebraic foundation and a suitable architecture, which is implemented and in operational use, has been presented in [2,1]. Marathe and Salem present a 2-D database array language [8]. In [4] nested relational calculus is extended with multidimensional arrays, obtaining a model called NCRA and a query language derived from it, AQL. Both seem to be more theoretically motivated and aim in particular at complexity studies for array addressing. Mennis et al. [9] introduce 3-D map algebra, a framework suitable for handling 2-D and 3-D geo raster data.

While OLAP is a well established business today, arrays are considered by industry only recently. ESRI's ArcSDE and Oracle's GeoRaster cartridge offer tiled storage of 2-D maps with mainly spatial subsetting support; the rasdaman system offers n-D full query support.

Foundations

The collection paradigm in databases encompasses sets, bags, lists, and arrays. The array concept forms a separate, distinct information category. While it might be emulated, e.g., by nested lists, this will not lead to usable query concepts (e.g., for slicing a data cube along all its axes), nor can this be a basis for efficient implementations.

Consequently, all database aspects need to be reconsidered for array support, including conceptual modeling (what are appropriate operations?), storage management (how to manage objects spanning many disk blocks, if not several media?), and query evaluation (what are efficient and optimizable processing strategies?).

Conceptual Modeling

Formally, an array a is a function a: $X \rightarrow F$ where X is a finite axis-parallel hypercube in Euclidean space $\mathbf{Z}^d$ for some $d > 0$ and F is some algebra. Let X be the array's domain, F its cell type, and the individual locations $x \in X$ carrying some value $f \in F$ the array's cells.

Following good practice in databases, an array query language should be declarative and safe in evaluation. Declarative in this context means that there is no explicit iteration sequence over an array (or part of it) during evaluation – conceptually, all cells should be inspected simultaneously. This opens up avenues for efficient storage and evaluation patterns, and query optimization in general (see below). Avoiding explicit iterations also contributes to be safe in evaluation, i.e., every query is evaluated in a finite number of (finite-time) steps.

Actually it turns out that a wide range of practically relevant operations can be expressed using only a few primitives [2]. The MARRAY operator creates an array over some given domain and sets its cells by evaluating an also given expression at each cell location. An application of the MARRAY operator has the general form

marray *index-range-specification*
values *cell-value-expression*

where *index-range-specification* defines the resulting array's domain and binds an iteration variable to it. In *cell-value-expression* the value of the cells are determined for each cell coordinate; this expression may or may not use the current value of the iteration variable, e.g., to read out cells from some given array. The first example, domain subsetting, makes use of this addressing by copying the values of cells within the cutout region from the original array into the new array.

Example: "A cutout of array *a* specified by the corner points (100,100) and (200,300)."

marray *p* in [100:200,100:300]
values *a*[*p*]

In the query language this particular application pattern of MARRAY can be abbreviated as

a[100:200,100:300]

Aside from copying cells as above, the resulting array can also have new values assigned which may or may not depend on other arrays.

Example: "Array *a* (which is known to be of size 1024 × 768), with intensity reduced by a factor of 2." Auxiliary function dom(*a*) returns the domain of *a*, over which the query has to iterate:

marray *p* in dom(*a*)
values *a*[*p*]/2

Such operations are abbreviated in the query language by applying the operation on hand directly to the array, in the example obtaining:

a/2

All unary and binary operations on cells can thus be lifted to become array operations.

Example: "Array *a*'s values where they are above threshold *t*, and 0 otherwise."

$(a > t) * a$

In this example, Boolean and arithmetic operations are combined. Similar to many programming languages, Boolean results from the comparison are interpreted as 0 and 1 for the subsequent multiplication.

The CONDENSE operator aggregates cell values into one scalar result, similar to SQL aggregates. Its application has the general form

condense *condense-op*
over *index-range-specification*
using *cell-value-expression*

where, like with MARRAY before, *index-range-specification* indicates the array index domain to be iterated over and binds a variable to it. Similarly, *cell-value-expression* represents an expression to be evaluated for each index range coordinate. The additional element, *condense-op*, specifies the aggregating operation used to combine the cell value expressions into one single value.

Example: "The sum of all values in *a*."

condense+
over p in sdom(a)
using $a[p]$

This is abbreviated as *add_cells*(a); further predefined condensers include *count_cells*(), minimum, maximum, and quantifiers.

Histogram computation demonstrates nesting of these operations.

Example: "A histogram of 256 buckets over 8-bit greyscale array *a*."

marray n in [0:255]
values count_cells($a = n$)

The inner expression, $a = n$, is an application of the formerly introduced "lifted" operation. For each coordinate p of a, the comparison $a[p] = n$ is performed, yielding a Boolean array.

The SORT operator allows slicing of an array along one of its axes and reordering of slices according to some sorting criterion.

By embedding this into a set-oriented model with array-valued attributes one can write queries over sets of arrays. The next example assumes a table *BrainActivationMaps* where one of the attributes, named *data*, is an array. The data array might contain processed scans of human brains indicating activity like electrical flow, temperature, blood pressure, etc. Note that for the query it does not matter whether the *data* array is, say, 2-D or 3-D. This way queries can be kept rather generic.

Example: "Tuple identifier and histogram of all those *BrainActivationMaps* tuples where the average data intensity exceeds threshold 127."

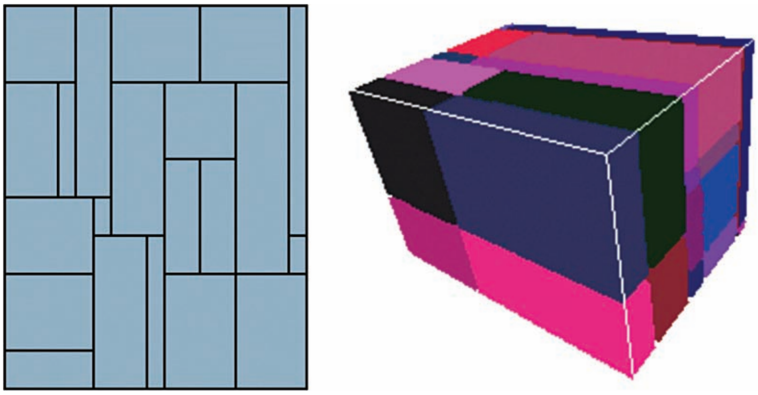
select *id*,
marray n in [0:255]
values *count_cells*(*bam.data* = n)
from *BrainActivationMaps* as *bam*
where *avg_cells*(*bam.data*) > 127

Such languages allow formulating statistical and imaging operations which can be expressed analytically without using loops. In [6] it has been proven that the expressive power of such array languages in principle is equivalent to relational query languages with ranking.

Physical Modeling

In almost all practically relevant scenarios, array objects are by orders of magnitude larger than disk blocks. The foremost task for an array storage manager is to preserve spatial proximity on disk. For n-D data this obviously is impossible to achieve on a linear storage space, hence approximations need to be employed. One such technique is tiling, adopted from imaging. Tiling (also called chunking) partitions an n-D cube into a set of non-overlapping n-D subcubes (Fig. 2), each of which is stored in a BLOB in the traditional manner. The partitioning pattern can be chosen freely, which opens up a wide space for storage optimization. In the most simple case, equally sized tiles are employed where the tile size is chosen suitably for the disk and bus specs; an advanced alternative is to determine an optimal tile distribution with individual tile proportions and sizes for a given query set.

A spatial index, such as the R-Tree, helps to quickly determine the tiles affected by a query, which usually is a *range query*. As opposed to spatial (i.e., vector) databases the situation is simple: the target objects, which



Raster Data Management and Multi-Dimensional Arrays. Figure 2. Sample tiling of 2-D and 3-D arrays.

have a regular box structure, partition a space of known extent. Hence, almost any spatial index will perform decently.

Often compression of tiles is advantageous. Still, in face of very large array databases tertiary storage may be required, such as tape robots [10,11].

Query Evaluation

A tile-based storage structure suggests a tile-by-tile processing strategy. Indeed a large class of practically relevant queries can be evaluated by inspecting a tile stream, rather than loading the whole source object into main memory. Additionally, for some query types such as condensers, tile streaming can be terminated prematurely.

It turns out that array query evaluation times typically are CPU bound, except for the very rare cases where only domain subsetting and no processing is required. The reason lies in the large number of array cells to be processed per query. Preliminary results show that query parallelization by assigning tiles to different CPUs yields promising performance gains [5].

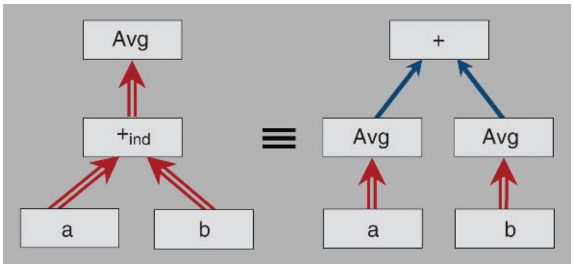
Query Optimization

Array queries lend themselves well towards *query optimization*. Currently only heuristic optimization is reasonably understood, but shows good results. Consider the query

select *avg_cells*$(a + b)$
from a, b

Figure 3 shows an equivalence rule which can speed up evaluation: substituting the left-hand side array expression with the right-hand side yields

select *avg_cells*(a) + *avg_cells*(b)
from a, b



Raster Data Management and Multi-Dimensional Arrays. Figure 3. Algebraic equivalence rule "*avg_cells* (*m1* + *m2*) ≡ *avg_cells*(*m1*) + *avg_cells*(*m2*)."

This query involves two array traversals and two (negligible) scalar operations. Bottom line, three array traversals have been reduced to two this way.

Key Applications

In many cases where some phenomenon is sampled or simulated, the result is a rasterized data set. Given the high volumes and multi-faceted retrieval arising, there is a remarkably wide application domain for array databases. Briefly, it can be summarized as sensor, image, and statistics data in the widest sense. Exemplarily geo and life sciences will be inspected next.

Earth Sciences

By far, the most important and visible application domain for large-scale array information systems is geospatial raster data, with high public visibility through novel, user-friendly interaction techniques like the Virtual Globes of NASA WorldWind (worldwind.arc.nasa.gov) and GoogleEarth (earth.google.com).

The Open GeoSpatial Consortium (OGC, www.opengeospatial.org), in collaboration with ISO, OASIS, W3C and others, provides standards for open, interoperable geo Web service interfaces. OGC develops a family of modular geo service standards, of which the Web Coverage Service (WCS) suite is particularly relevant for raster data (there also called coverage data). It offers basic subsetting services, scaling, and reprojection. This static request type is augmented with a coverage processing language in the Web Coverage Processing Service (WCPS) Implementation Specification [3].

A typical WCPS request computes the Normalized Difference Vegetation Index (NDVI), which computes a measure of the degree of vegetation for each pixel. For a multi-spectral satellite image *s* with near-infrared channel *nir* and red channel *red*, the NDVI is defined as:

NDVI(s) = ($s.nir$ - $s.red$)/($s.nir$ + $s.red$)

The result is a real value between -1 and +1; the closer it is to +1, the higher is the likelihood for vegetation. For some server object *LandsatScene* (note that WCPS lists single objects and does not operate on sets like database languages) an 8-bit greyscale NDVI image is specified as follows:

for *s* in (*LandsatScene*)
return
encode((char) (255 * (*s.nir* - *s.red*)/(*s.nir* + *s.red*) + 1), "TIFF")

Life Science

Human Brain Imaging In human brain imaging, the research goal is to understand the relations between brain structure and its function. In experiments, human subjects have to perform some mental task while activity parameters such as brain temperature, electrical activity, and oxygen consumption are measured by PET or fMRI CAT scans. The resulting 3-D x/y/z data cubes have a resolution of 1 mm and an overall volume in the Megabyte size. In a computationally expensive warping operation, the brain images get normalized against some chosen standard brain so that organs always sit at known voxel coordinates (Fig. 4 left). In the end, a brain image set as large as possible is desired to achieve high statistical significance.

Traditionally, feature search is the only property through standard SQL on structured and semi-structured data; specialized tools can perform search on single images or small sets thereof. With array databases, thousands of experiments each with large image sets can be searched by brain feature. The brain organs can be registered as voxel masks (Fig. 4 right). The query types arising mainly perform standard statistics per brain.

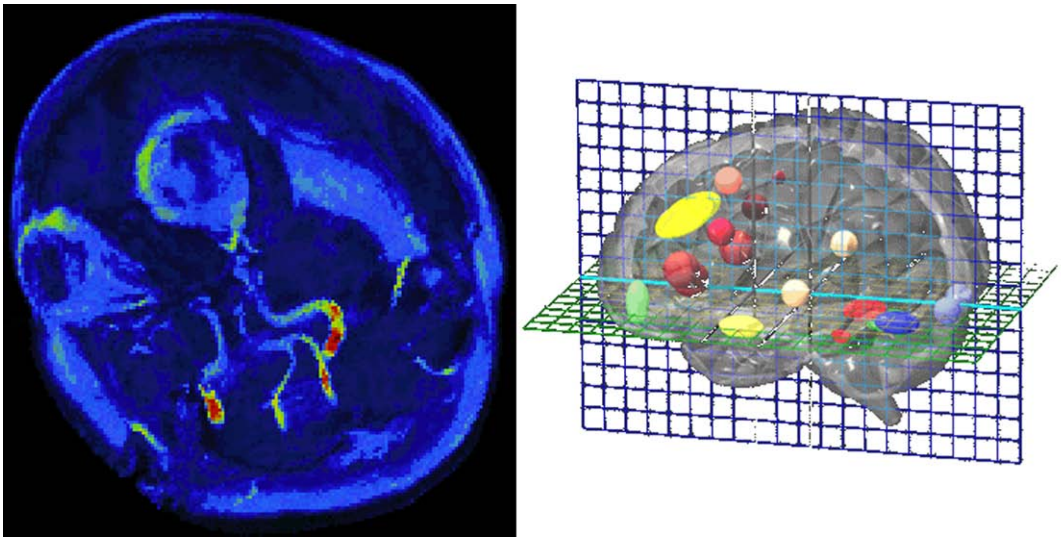
Example: "A parasagittal view of all scans containing critical Hippocampus activations, TIFF-coded." Positional parameter $1 denotes the slicing position, $2 the intensity threshold value, $3 the confidence, as chosen by a user through some browser interface.

select tiff(*ht*[$1, *:*, *:*])
from *HeadTomograms* as *ht*, *Hippocampus* as *mask*
where count_cells(*ht* > $2 and *mask*)/count_cells(*mask*) > $3

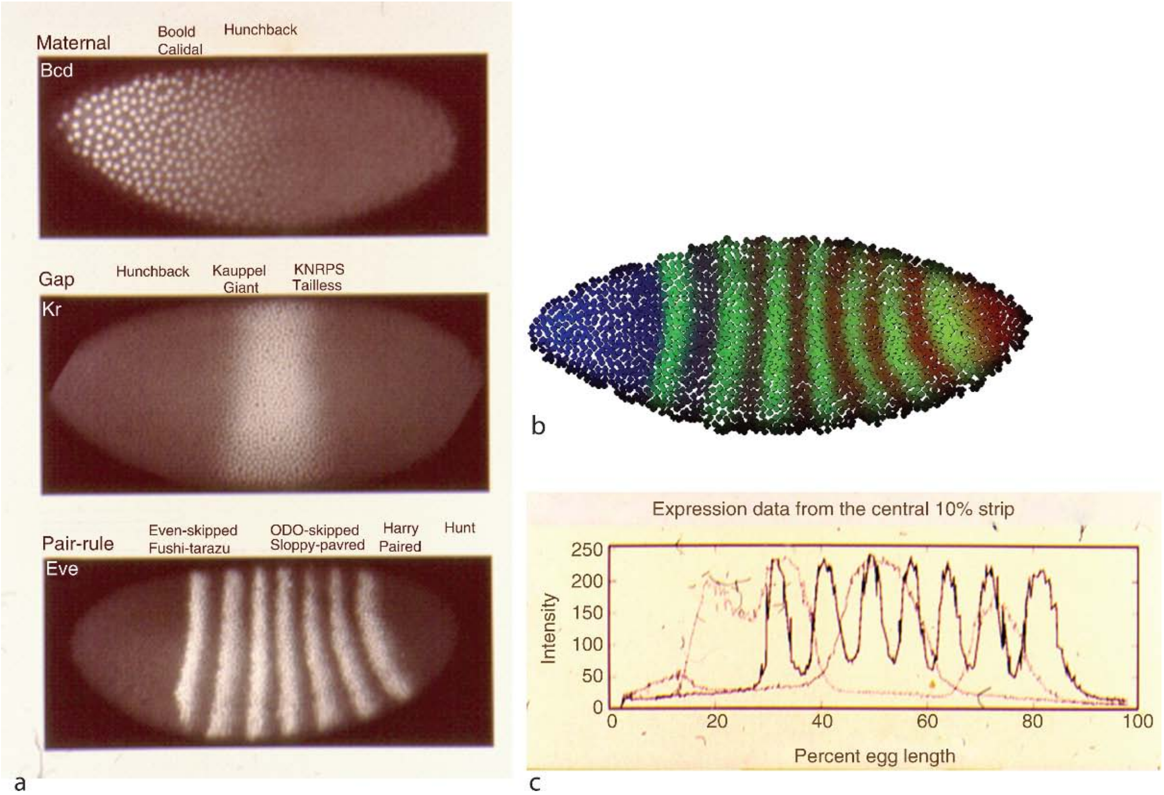
Gene Expression Analysis Gene expression is the activity of reading out genes for reproduction in a living body. The research goal in gene expression analysis is to understand how and when genes express to become manifest in the phenotype. One step towards this is to understand the spatio-temporal expression patterns in a well-known research object, the fruit fly Drosophila melanogaster.

The staining process delivers activity patterns (Fig. 5 left). It is common to combine three gene images into one by randomly assigning them to the red, green, and blue channel, resp. (Fig. 5 top right). Traditionally, diagrams like Fig. 5 bottom right are constructed.

Array queries allow searching the resulting 4-D x/y/z/t activity cube and generate, among others, the views researchers are used to. A gene expression database might contain 4-D objects where the first dimension lists the fruitfly genes in some chosen order and the other three spatial dimensions allow addressing into the fruitfly body. Then, a query can slice these 4-D cubes and recombine these slices into the aforementioned RGB overlay.



Raster Data Management and Multi-Dimensional Arrays. Figure 4. Human brain activation map (left) and brain organ masks (right).



Raster Data Management and Multi-Dimensional Arrays. Figure 5. Gene activity maps for a fruitfly embryo (left), overlay into RGB (top right), slice aggregating activity over the 10% central strip of a snapshot (bottom right).

Example: “Genes $1, $2, and $3 at time $4, as RGB images.”

```
select jpeg({1c,0c,0c}*e[$1, *:*, *:*, $4]
+{0c,1c,0c}*e[$2, *:*, *:*, $4]
+{0c,0c,1c}*e[$3, *:*, *:*, $4])
from EmbryoImages as e
where oid(e) = 193537
```

Future Directions

Array databases are in their infancy, with many inviting research avenues. On a conceptual level, a unified algebraic array theory seems promising which is to unify (dense) image handling with (sparse) statistical and OLAP handling. Advanced query optimization deserves further investigation, with topics like cost-based optimization and complex array addressing schemes (such as filter kernels). Physical tuning parameters are not yet fully understood in their effects and interplay. Finally, further experience in as many applications as possible is desirable for a better understanding of the relevant query patterns. The ultimate goal is to establish arrays as first-class database citizens.

Real and Synthetic Test Datasets

Thomas Brinkhoff
Institute for Applied Photogrammetry and
Geoinformatics (IAPG), Oldenburg, Germany

Synonyms

Spatio-temporal data generator; Spatio-temporal benchmarking

Definition

In the area of mobile and ubiquitous data management, real and synthetic test datasets are used for experimental investigations of performance and robustness.

Typical applications are the examination of access methods for spatio-temporal databases and the simulation of mobility for location-based services. Besides synthetic and real datasets, combinations of these two types of data are often used that integrate a predefined infrastructure.

Historical Background

Beginning in the mid 1990s, the development of algorithms and data structures for spatio-temporal data took place of the research in the field of pure (geo-) spatial applications. Previous spatial test datasets were not sufficient for investigating the performance and robustness of those algorithms and data structures. Consequently, first data generators for spatio-temporal test datasets were published in the end of the 1990s.

Foundations

Comprehensible performance evaluations are an important requirement in the field of mobile and ubiquitous data management. This demand covers the preparation and use of well-defined test datasets and benchmarks enabling the systematic and comprehensible evaluation and comparison of algorithms and data structures in this area.

In experimental investigations, synthetic data following some statistical distributions as well as data from real-world applications are used as test datasets. The use of *synthetic datasets* allows testing the behavior of an algorithm or of a data structure under exactly specified conditions or in extreme situations. In addition, for testing the scalability, synthetic data sets are often suitable. However, it is difficult to assess the performance of real applications by employing synthetic data. The use of *real datasets* tries to solve this problem. In this case, the selection of the data is crucial. For non-experts it is often difficult to decide whether a dataset reflects a "realistic" situation or not. Furthermore, real datasets are typically connected with a special type of application. For example, a dataset recording cars driving within a city may have completely different properties than the traffic in rural areas or the movement of vehicles in battlefields.

In the area of mobile and ubiquitous data management, *infrastructure-based dataset generators* have become popular. These generators compute moving objects that are restricted by some infrastructure like a network or prohibited areas. The infrastructure may be a real-world dataset or completely artificial. The number, distribution, speed and other properties of the moving objects are influenced by the infrastructure as well as by parameters specified by the user of the generator. Dataset produced by infrastructure-based dataset generators are a compromise between real and synthetic datasets in respect of realism on the one hand and of controllability on the other hand.

Synthetic Datasets

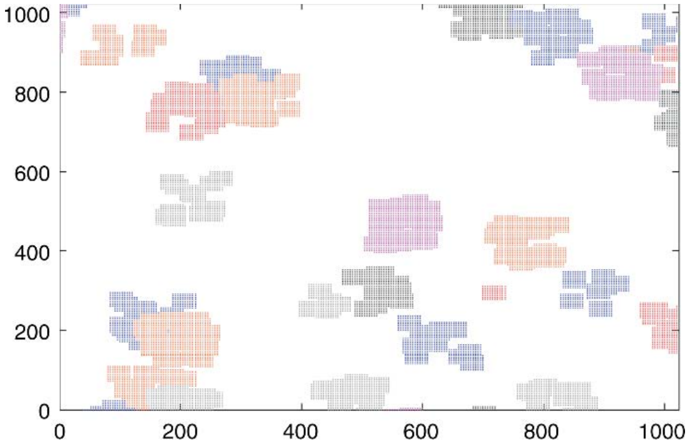
A prominent example for a program providing synthetic spatio-temporal test datasets is the *GSTD (Generate SpatioTemporal Data)* algorithm by Theodorides, Silva and Nascimento [8]. The basic idea of this algorithm is to start with a distribution of point or rectangular objects, e.g., a uniform, a Gaussian or a skewed data distribution. These objects are modified by computing positional and shape changes using parameterized random functions. If a maximum time stamp is exceeded, an object will become invalid. If an object leaves the predefined spatial data space, different approaches can be applied: the position remains unchanged, the position is adjusted to fit into the data space, or the object re-enters the data space at the opposite edge of the data space. In order to create more realistic movements, a later version of the GSTD algorithm considers rectangles for simulating an infrastructure: each moving object has to be outside of these rectangles.

The *Oporto generator* by Saglio and Moreira [7] is designed for a specific scenario: fishing at sea. The generator supports different object types, which allow modeling different behavior. In order to generate smooth movements, objects of one type may be attracted (e.g., fish by plankton) or repulsed by objects of other types (e.g., ships by stormy areas).

G-TERD (Generator for Time-evolving Regional Data) by Tzouramanis, Vassilakopoulos and Manolopoulos [9] generates two-dimensional raster data (see Fig. 1). The user can control the behavior of the generator by defining parameters and statistical models. The parameters influence the color, the maximum speed, size and rotation of the moving regions. Other moving or static objects may have impact on the speed and on the direction of a moving object.

Real Datasets

There exist many spatio-temporal datasets in the WWW [6]. Very often GPS positions of cars or other vehicles like buses, trains or bikes are recorded. An example is the INFATI dataset from the Aalborg University [3]. It represents a collection of spatio-temporal



Real and Synthetic Test Datasets. Figure 1. Raster regions generated by G-TERD.

data that was collected for a project about intelligent speed adaptation. The dataset contains the GPS tracks of about two dozen cars equipped with GPS receivers and logging equipment.

Other popular objects are animals equipped with active satellite tags, e.g., whales, sharks and turtles. The recordings of weather phenomena like hurricanes and the orbits of satellites can also be used as spatio-temporal test datasets.

The section "Data Sets" of this entry gives a small overview on real datasets that are provided for download.

Datasets from Infrastructure-Based Generators

The *Network-based Generator* by Brinkhoff [1] is based on the observation that the motion of objects is often restricted by a network. Examples are streets, railways, air corridors or waterways. Therefore, the generator computes moving objects according to a network that is provided by a file or by a spatial database (see Fig. 2). For each edge of the network, a speed limit and a maximum capacity can be defined. If the number of objects traversing an edge at the same time exceeds the specified capacity, the speed limit on this edge may decrease. In addition, each moving object has a (maximum) speed. The computations of the number of new objects per time stamp, of the start location, of the length of a new route and of the location of the destination are done by time-dependent Java functions that can be overloaded by the user of the generator. This concept allows modeling daily commuting and rush hours. The route of a moving object is computed at the time of its creation. However, the fastest path may change over the time by the motion of other objects and of other influences. Therefore, the re-computation of a route is triggered by events depending on the travel time and on the deviation between the current speed and the expected speed on an edge.

The *City Simulator* by Kaufman, Myllymaki, and Jackson [4] is a scalable, three-dimensional model city that enables the creation of dynamic spatial data simulating the motion of up to one million moving objects. The data space of the city is divided into different types of places that influence the motion of the moving objects: roads, intersections, lawns and buildings are such places that define together a city plan (see Fig. 3). Each building consists of an individual number of floors for modeling the third dimension.

SUMO (Simulation of Urban Mobility) [5] developed by Institute of Transport Research at the German Aerospace Center and the Center for Applied Informatics (ZAIK) is open-source software for traffic simulation. Its objective is to support the traffic research community with a common platform for testing and comparing models of vehicle behavior, traffic light optimization, routing etc. Therefore, the car movement model of SUMO is much more evaluated than the models of the other generators.

Key Applications

The primary field of application of the presented test datasets is the evaluation of spatio-temporal databases, but also in other fields the datasets are used. According to Citeseer and the ACM Portal, applications cover (among others) the evaluation of spatio-temporal data structures, the analysis of spatio-temporal queries

and of mobility patterns, the simulation of wireless environments by mobile agents, the design of (web) server architectures for moving objects, and the test of car-to-car communication.

Future Directions

It can be expected that spatio-temporal test datasets will be more often used for evaluations of sensor networks, peer-to-peer communication and positioning techniques.

Time-constrained transaction management

Definition

Real-time transaction processing focuses on (i) enforcing time constraints of transactions, i.e., meet time constraints on invocation and completion, and (ii) ensuring temporal consistency of data, i.e., data should be valid/ fresh at the time of usage.

The successful integration of time-cognizant behavior and transaction processing into a database system is generally referred to as a real-time database system (RTDB).

Historical Background

The area of real-time transaction processing has emerged from the need for real-time systems, which often are safety-critical, to handle large amounts of data in a systematic fashion, and the increasing expectation of non-critical applications that have used conventional databases but are now needed to deal with "soft" real-time data applications, e.g., multimedia. Real-time systems have traditionally managed data in an ad hoc manner, i.e., system developers have stored and manipulated data in regular data structures resident in the application code. This approach does not scale well as applications increase in complexity and in their needs for managing large amounts of data. Conventional databases, however, are considered inadequate for handling real-time requirements. Conventional databases impose a throughput-centric design, e.g., maximizing average throughput, and is thus not concerned about the specific outcome of a transaction (in fact, transactions are considered equally important). Furthermore, conventional databases are general-purpose transaction processing system design to be satisfy the needs of a multitude of non-real-time applications. In contrast, a predominant part of the real-time systems are very resource limited, normally these systems have a couple of orders of magnitude less resources, e.g., primary memory, and are not using hard disks. Thus, system functionality need to be tailored to application-specific needs to accommodate a minimum footprint and overcome different architectural assumptions and data requirements.

Note that the term real-time has many connotations in industry and in the general literature it is often used interchangeably to denote that something is fast. This differs from the notion used here, where real-time is synonymous to the notion of predictability. The notion of real-time indicates that the correctness of a result depends not only on the logical result of its computation but also on the time at which the result is derived. Thus, the system correctness depends both on the functional and temporal behavior of the system execution. The temporal behavior is tightly connected to the time constraints associated with transactions and data, e.g., deadlines. This requires that a transaction management system needs to enforce that the timeliness of transactions and data, in turn requiring that scheduling and concurrency control algorithms are time-cognizant.

Examples of real-time applications are control systems, multimedia, to air-traffic control, and as evident, these applications differ in their real-time requirements, complexity, and the type of data they manage. In order to maintain external/internal correctness, real-time systems have to respond to input stimuli and by an actuator, i.e., produce an output result/action within a finite and sufficiently small time bound. These systems must feature predictability, i.e., the ability to show that the system meets the specified requirements under various conditions the system is expected work under [11].

Several research platforms have developed, e.g., ARTS-RTDB & BeeHive (both from University of Virginia, USA), COMET (Linköping University, Sweden), DeeDS (University of Skövde, Sweden), REACH (Technical University of Darmstadt, Germany), Rodain

(University of Helsinki, Finland), and STRIP (Stanford University, USA).

Foundations

Real-transaction processing systems operate under and are benchmarked against different performance goals, correctness criteria, and assumptions applications than throughput-centric systems. The performance metrics adopted for real-time transaction processing system reflect that real-time transactions have time constraints on the execution, and the validity of the data. These requirements impose constraints on the system, which is reflected in the performance metrics used for measuring the timeliness of the system, in addition to conventional metrics for measuring consistency. Typical performance metrics, out of which several originate from the area of real-time systems, include deadline miss ratio of transactions, tardiness/lateness of transactions, cost/effects due transactions missing their deadlines, data temporal consistency (external and logical). The requirements of timeliness can exceed that of consistency and isolation, i.e., it might be more important to deliver a result of adequate precision/quality in time than delivering an exact result late. This implies that correctness of a result can be traded for timeliness by relaxing consistency (referring to ACID properties).

Transaction Model

Real-time transactions are typically characterized along the dimensions of the temporal scope, criticality, and transaction type.

The temporal scope of a transaction is typically described by an arrival time a_i, a release time r_i, a (worst case) execution time e_i, and a deadline d_i, where the following conditions hold (the times are expressed as absolute variables): $a_i \leq r_i < d_i$, $r_i + e_i \leq d_i$. A system is, thus, considered schedulable if it can be shown that all transactions can meet their deadlines.

Real-time transactions can be categorized given the criticality and the stringency of meeting their deadlines and the notions of hard, firm, and soft deadlines are generally used. A hard deadline is critical and, thus, the transaction must always complete within the deadline. Missing a hard deadline will have severe or even cataclysmal consequences. In contrast, firm and soft deadlines are used to for transactions when it system can tolerate occasional time constraint violations. The distinction between them is in the utility of completing a task after its deadline; a soft deadline indicates there is often value of completing the task albeit late. A firm deadline indicates that there is no value for late completion and tardy transactions, i.e., tasks running beyond their deadline, can thus be aborted to minimize resource usage.

Transactions may have precedence constraints that put constraints on the relative order of execution among transactions.

The temporal consistency of a data object has two parts: *absolute consistency*, which reflects the state of an external environment and how that state is reflected in the database, and *relative consistency*, which concerns the consistency among data elements used to derive other data. Thus, absolute consistency (a.k.a. external consistency) is necessary to ensure that a system's view of the external environment (e.g., the controlled system) is consistent with the actual state of the environment. Relative consistency (a.k.a. logical consistency) ensures that only valid data is used to derive new data. To express temporal consistency, a real-time data object o_j is annotated with an absolute validity interval avi_j denoting the time length and a timestamp ts_j when the data object was last updated/sampled. The data object is considered valid in the time interval $[\mathrm{ts}_j, \mathrm{ts}_j + \mathrm{avi}_j]$.

To define the notion of a relative validity interval *rvi*, a *relative consistency set R* is introduced for each derived data object, which contains the set of data objects used for its derivation. Furthermore, each such set is has a relative validity interval denoted R_{rvi}. A data object o_j is temporally consistent if the following two conditions hold: (i) $(t + ts_j) \leq avi_j$ (absolute consistency) and (ii) (assume R is the set for o_j) for all $\mathrm{o}_k \in R | \mathrm{ts}_j - \mathrm{ts}_k | \leq R_{rvi}$.

Concurrency Control

A conventional non-real-time two-phase-locking scheme (2PL) is prone to priority inversion, unknown blocking times, and deadlocks, making it infeasible in a real-time context. Priority inversion occurs when a high-priority transaction is blocked due to a resource locked by a low-prioritized transaction. Thus, the high-priority transaction experiences blocking delays that can jeopardize this timeliness. Several 2PL variants have been developed to overcome these deficiencies, and the most well-known scheme is two-phase-locking with high priority resolution (2PL-HP). Consider the case a transaction T_R is requesting a lock, which is held by another transaction T_H. In 2PL-HP, T_R will abort T_H if the priority of T_R exceeds that of T_H; otherwise T_R will wait until T_H completes. There are additional schemes that deploy more elaborate conditions to avoid that a process is aborted unnecessarily, e.g., considering the remaining execution time of T_R and the needed execution time of T_R.

In real-time optimistic concurrency control (OCC), transactions execute in three stages: read, validation, and write. In the read stage, transactions read and update data items freely, storing their updates into private workspaces. Note that the updates of a transaction stored in the private workspaces are installed as global copies in the write stage (i.e., after the transaction is validated). In the validation stage, a validating transaction may conflict with ongoing transactions. Depending on the transaction characteristics, there are several real-time conflict resolution mechanisms for the validation [5], i.e., a validating transaction may commit, abort, or be "put on the shelf" to wait for the conflicting transactions.

In priority-wait conflict resolution mechanism [5], which is demonstrated to have superior performance for OCC, a transaction that reaches validation and finds higher priority transactions in its conflict set is "put on the shelf", that is, it is made to wait and not allowed to commit immediately. This gives the higher priority transactions a chance to make their deadlines first. After all conflicting higher priority transactions leave the conflict set, either due to committing or due to aborting, the on-the-shelf waiter is allowed to commit. Note that a waiting transaction might be restarted due to the commit of one of the conflicting higher priority transactions.

Distributed Real-Time Transaction Processing The distributed transaction execution model for a real-time two-phase commit protocol is presented next. A commonly adopted sub-transaction model has been presented [4] in which there is one process, called the master, which is executed at the site where the transaction is submitted, and a set of other processes, called cohorts, which execute on behalf of the transaction at the various sites that are accessed by the transaction. Cohorts are created by the master sending a STARTWORK message to the local transaction manager at that site. This message includes the work to be done at that site and is passed on to the cohort. Each cohort sends a WORKDONE message to the master after it has completed its assigned data processing work. The master initiates the commit protocol (only) after it has received this message from all its cohorts. Within the above framework, a transaction may execute in either sequential or parallel fashion. The distinction is that cohorts in a sequential transaction execute one after another, whereas cohorts in a parallel transaction execute concurrently.

Real-Time Two-Phase Commit The master implements the classical two-phase commit protocol [3] to maintain transaction atomicity. In this protocol, the master, after receiving the WORKDONE message from all its cohorts, initiates the first phase of the commit protocol by sending PREPARE (to commit) messages in parallel to all its cohorts. Each cohort that is ready to commit first force-writes a prepare log record to its local stable storage and then sends a YES vote to the master. At this stage, the cohort has entered a prepared state wherein it cannot unilaterally commit or abort the transaction, but has to wait for the final decision from the master. On the other hand, each cohort that decides to abort force writes an abort log record and sends a NO vote to the master. Since a NO vote acts like a veto, the cohort is permitted to unilaterally abort the transaction without waiting for the decision from the master.

After the master receives votes from all its cohorts, the second phase of the protocol is initiated. If all the votes are YES, the master moves to a committing state by force-writing a commit log record and sending COMMIT messages to all its cohorts. Each cohort, upon receiving the COMMIT message, moves to the committing state, force-writes a COMMIT log record, and sends an ACK message to the master. On the other hand, if the master receives one or more NO votes, it moves to the aborting state by force-writing an abort log record and sends ABORT messages to those cohorts that are in the prepared state. These cohorts, after receiving the ABORT message, move to the aborting state, force-write an abort log record and send an ACK message to the master. Finally, the master, after receiving ACKs from all the prepared cohorts, writes an end log record and then "forgets" the transaction (by removing from virtual memory all information associated with the transaction).

A real-time two-phase commit protocol such as PROMPT (Permits Reading Of Modified Prepared data for Timeliness) [6], works differently from traditional two-phase commit protocol in that transactions requesting data items held by other transactions in the prepared state are allowed to access this data. That is, prepared cohorts lend their uncommitted data to concurrently executing transactions (without releasing the update locks) in the optimistic belief that this data will be committed. If the lender is aborted later, the borrower is also aborted since it has utilized dirty data. On the other hand, if the borrowing cohort completes its local data processing before the lending cohort has received its global decision, the borrower is "put on the shelf", that is, it is made to wait until either the lender receives its global decision or its own deadline expires, whichever happens earlier. In this case, the borrower can only commit if the lender commits.

In contrast to centralized databases where transactions that validate successfully *always* commit, a distributed transaction that is successfully locally validated might be aborted later because it fails during global validation. This can lead to "wasteful" aborts of transactions–a transaction that is locally validated may abort other transactions in this process. If this transaction is itself later aborted during global validation, it means that all the aborts it caused during local validation were unnecessary.

Key Applications

The number of real-time applications that handle real-time data is large. Thus, a range of applications that manage data with temporal constraints is given in the following.

- *Air-traffic control systems.* This system is used to monitor air-traffic around an airport, which requires continuous monitoring of aircraft positions and weather data, as well as (non-real-time) data of different aircraft types.
- *Control system.* A specific case is an engine control system, which approximately uses readings of twenty sensors, and these sensor values are fundamental in the computation of 400 other variables, where the validity of the derived data is a function of the sensed value. Derived data is used control the mixture of fuel and air in the ignition, as well as diagnostics.
- Wireless networking systems for retrieval of subscriber information such as service subscription and device location stored in Home Location Register (HLR) as well as billing information in the case of prepaid phone calls. For example, the network communication protocols have various timers for call delivery that may cause connection failure if information is not retrieved before a transaction deadline.

Future Directions

The increasing number of applications that handle large amounts of real-time data calls for a strong support from the underlying transaction processing system to satisfy timeliness and consistency requirements. The development of time-cognizant concurrency control and scheduling algorithms has provided a foundation for real-time transaction processing systems. There are several challenging areas where progress would be conducive to enforce the predictability, and below a few examples are provided

- The underlying assumption which most real-time scheduling approaches build upon is the knowledge of the worst-case execution times of the transactions, either a priori to the system starts its execution or they are made available upon their arrival to the system. The dynamic nature of transaction workloads can cause the system to experience transient overloads. Techniques that are shown to effectively manage the uncertainty of execution times or can measure tight and not overly conservative worst case execution times would increase schedulability and resource utilization, as well as techniques for resolving and minimizing the effects of transient overloads.
- *Extended transaction models supporting relaxed ACID properties.* Enforcement of ACID in real-time applications has shown to be costly, jeopardize timeliness, and does not utilize the potential parallelism that can be exploited by relaxation of the ACID properties. This has resulted in the development of, e.g., epsilon-serializability and the notion of data similarity. There is a need for additional application-centric consistency that would capture the tolerance of the applications and the presence of multiple models coexisting in parallel.
- *Transaction scheduling for guaranteeing data temporal consistency.* There is need to maintain coherency between the state of the environment and data used in applications such as control systems.

For example, in order to react to abnormal situations in time, it is necessary to monitor the environment continuously. Such requirements pose a great challenge for maintaining the freshness of data while scheduling transactions to meet their deadlines.

- The notion of data precision and data confidence are becoming increasingly important in real-time applications, i.e., data is annotated with additional attributes to represent the confidence in the data value, (i.e., the level of trust in how the data was derived) and the precision/accuracy of the data. It is unclear how these two notions can be effectively used as decision parameters for concurrency control and schedulability.

Recall

Ethan Zhang[1,2], Yi Zhang[1]
[1]University of California, Santa Cruz, Santa Cruz, CA, USA
[2]Yahoo! Inc., Santa Clara, CA, USA

Definition

Recall measures the coverage of the relevant documents of an information retrieval (IR) system. It is the fraction of all relevant documents that are retrieved. Consider a test document collection and an information need Q. Let R be the set of documents in the collection that are relevant to Q. Assume an IR system processes the information need Q and retrieves a document set A. Let $|R|$ and $|A|$ be the numbers of documents in R and A, respectively. Let $|R \cap A|$ denote the number of documents that are in both R and A. The *recall* of the IR system for Q is defined as $R = |R \cap A| / |R|$.

Key Points

Precision and recall are the most frequently used and basic retrieval performance measures. Many other standard performance metrics are based on the two concepts.

Receiver Operating Characteristic

Pang-Ning Tan
Michigan State University, East Lansing, MI, USA

Synonyms

Operating characteristic; Relative operating characteristic; ROC

Definition

Receiver operating characteristic (ROC) analysis is a graphical approach for analyzing the performance of a classifier. It uses a pair of statistics – true positive rate and false positive rate – to characterize a classifier's performance. The statistics are plotted on a two-dimensional graph, with false positive rate on the x-axis and true positive rate on the y-axis. The resulting plot can be used to compare the relative performance of different classifiers and to determine whether a classifier performs better than random guessing.

Historical Background

ROC analysis was originally developed in signal detection theory to deal with the problem of discriminating known signals from a random noise background [11]. It was first applied to the radar detection problem to quantify how effective targets such as enemy aircrafts can be identified according to their radar signatures. In the 1960s, ROC analysis was applied to experimental psychology and psychophysics [6]. The approach has subsequently found its application in a variety of areas including radiology, epidemiology, finance, weather forecasting, and social sciences. In machine learning, the benefits of using ROC analysis for evaluating and comparing the performance of classifiers was first demonstrated by Spackman [14]. The approach was brought to the attention of the data mining community by Provost and Fawcett [12], who proposed the idea of using a convex hull of ROC curves to compare multiple classifiers in imprecise and changing environments.

Foundations

Predictive accuracy has traditionally been used as the primary evaluation measure for classifiers. However, its limitation is well-documented, particularly for data sets with skewed class distributions [12]. ROC analysis provides an alternative way for measuring performance by examining the trade-off between the successful detection of positive examples and the misclassification of negative examples. The approach was originally developed for binary classification problems, where each example is assigned to either a positive or a negative class. When applying the classifier to a given example, four possible outcomes may arise: (i) true positive (TP), when a positive example is classified correctly, (ii) true negative (TN), when a negative example is classified correctly, (iii) false positive (FP), when a negative example is misclassified as positive, and (iv) false negative (FN), when a positive example is misclassified as negative. These outcomes can be tabulated in a 2 × 2 table known as the confusion matrix, as shown in Table 1.

An ROC graph is constructed by examining the true positive rate and false positive rate of a classifier. The true positive rate (TPR), also known as hit rate or sensitivity, corresponds to the proportion of positive examples that are correctly labeled by the classifier, whereas the false positive rate (FPR), also known as false alarm rate, corresponds to the proportion of negative examples that are incorrectly labeled. Mathematically, these statistics are computed from a given confusion matrix as follows:

$$\mathrm{TPR} = \frac{\mathrm{TP}}{\mathrm{TP} + \mathrm{FN}} \tag{1}$$

$$\mathrm{FPR} = \frac{\mathrm{FP}}{\mathrm{FP} + \mathrm{TN}} \tag{2}$$

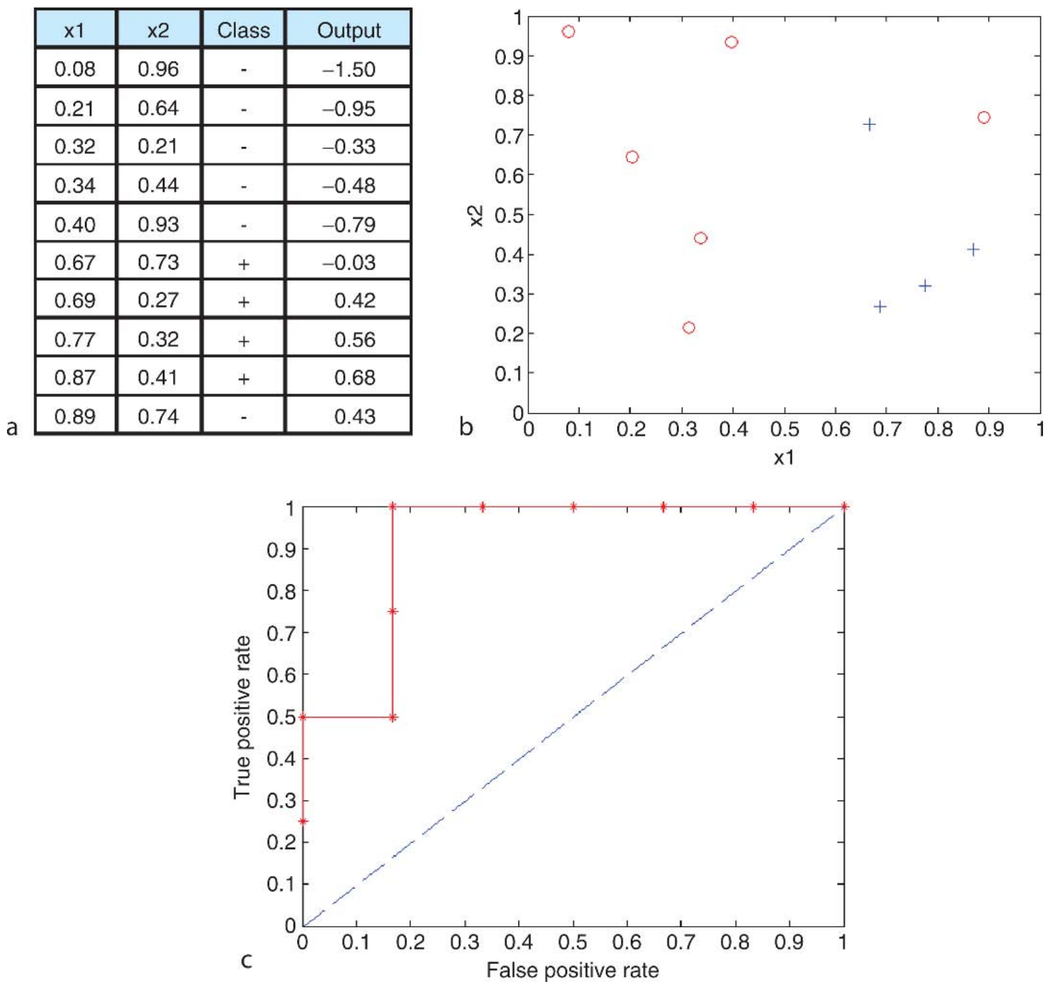
The number of points in an ROC graph depends on the type of output produced by the classifier. A classifier that produces a discrete-valued output is mapped to a single point in the ROC graph because there is only one confusion matrix. Other classifiers such as naïve Bayes and neural networks can produce numeric-valued outputs to indicate the degree to which an example belongs to the positive class. A threshold must be specified to determine the class membership – if the classifier's output exceeds the threshold, the example is assigned to the positive class. Each threshold setting leads to a different point in the ROC graph. By varying the threshold, a piecewise linear curve, known as the ROC curve, is formed. For example, the solid line in Fig. 1c shows the ROC curve obtained by varying the threshold on classification outputs produced by a neural network classifier.

There are several critical points in the diagram that are of practical significance. The critical point (FPR = 0, TPR = 0) corresponds to an extremely conservative classifier, i.e., one that assigns every example to the negative class. In contrast, the critical point (FPR = 1, TPR = 1) corresponds to a classifier that liberally declares every example to be positive. Since the ideal classifier corresponds to the critical point (FPR = 0, TPR = 1), points closer to the upper-left corner of the ROC graph are generally better classifiers. A random classifier, on the other hand, produces points that reside along the diagonal line connecting the bottom-left to the upper-right corner of the ROC graph, as shown by the dashed line in Fig. 1c. For example, a classifier that randomly assigns one-fourth of the examples to the positive class has TPR = 0.25 and FPR = 0.25.

Receiver Operating Characteristic. Table 1. Confusion matrix for a 2-class problem

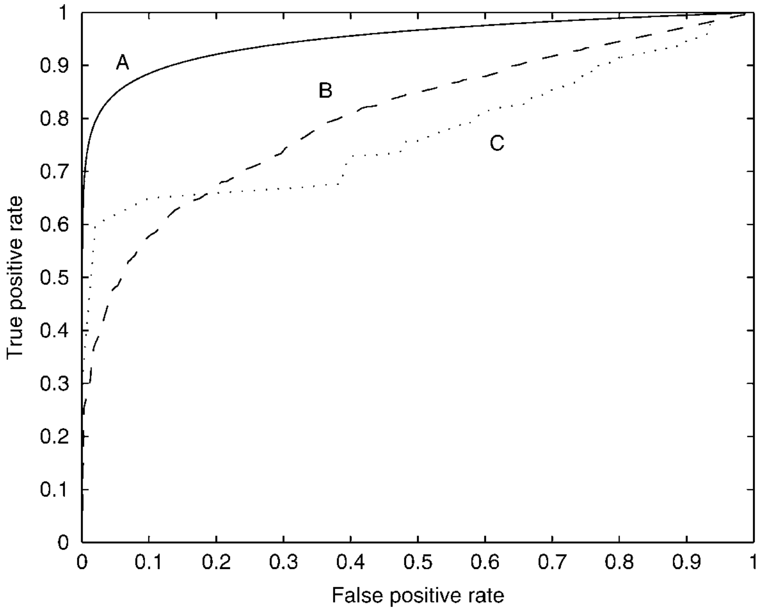
		Predicted Class	
		+	−
Actual Class	+	TP	FN
	−	FP	TN

An ROC curve X dominates another ROC curve Y if X lies above and to the left of Y. The more dominant the ROC curve, the better the classifier is. For example, Fig. 2 shows that classifier A is better than classifiers B and C because it has a more dominant ROC curve. In practice, however, one seldom finds an ROC curve that completely dominates other ROC curves. Instead, one would find different ranges of FPR values in which one classifier is better than another. For example,



x1	x2	Class	Output
0.08	0.96	-	–1.50
0.21	0.64	-	–0.95
0.32	0.21	-	–0.33
0.34	0.44	-	–0.48
0.40	0.93	-	–0.79
0.67	0.73	+	–0.03
0.69	0.27	+	0.42
0.77	0.32	+	0.56
0.87	0.41	+	0.68
0.89	0.74	-	0.43

Receiver Operating Characteristic. Figure 1. ROC curve for a two-dimensional data set classified using a single layer neural network.



Receiver Operating Characteristic. Figure 2. Performance comparison of classifiers using ROC curve.

in Fig. 2, classifier C is better than B when FPR below 0.2 or above 0.95. Therefore, Provost and Fawcett [12] introduced the ROC convex hull (ROCCH) method to combine the ROC curves from a set of classifiers to obtain the most dominant ROC curve. The convex hull can be used to identify ranges of FPR values in which a classifier is potentially optimal.

Although an ROC curve provides a visual display of a classifier's performance, it is often useful to summarize the curve into a single metric to estimate the overall classifier's performance. By analyzing the statistical properties of the metric [10], this provides a quantitative way to determine whether the observed difference in performance of two classifiers is statistically significant. Examples of ROC-derived metrics include area under ROC curve (AUC), slope intercept index, and the ROC break-even point. AUC is also equivalent to the Wilcoxon-Mann-Whitney statistic [7], thus allowing us to compute its statistical properties such as standard error and confidence interval.

In addition to ROC curves, there are alternative ways to visualize the performance of a classifier such as precision-recall curves [2] and cost curves [3]. A precision-recall curve plots the tradeoff between precision, which is the fraction of examples classified as positive that are actually positive, against recall, which is equivalent to true positive rate. Davis and Goadrich [2] has shown that a curve that dominates in the ROC space also dominates in the precision-recall space. Nevertheless, an ROC curve may not effectively capture important differences between classifiers when applied to data sets with skewed class distributions. For example, the confusion matrices shown in Table 2 have very similar TPR and FPR values even though their precision values are very different. The ROC representation also does not commit to any particular cost function or class distribution. As a result, it does not convey information such as the misclassification costs and class probabilities for which a classifier performs better than another. To overcome this limitation, Drummond and Holte [3] proposed the idea of using cost curves to explicitly represent the cost information.

Receiver Operating Characteristic. Table 2. Confusion matrices to illustrate the difference between ROC and precision-recall curves

(a)		Predicted Class	
		+	–
Actual Class	+	35	5
	–	25	435
(b)		Predicted Class	
		+	–
Actual Class	+	35	5
	–	5	455

A cost curve plots the expected cost of a classifier against a probability cost function which is defined as follows:

$$\text{Probability Cost Function} = \frac{P(+)C(-|+)}{P(+)C(-|+) + P(-)C(+|-)} \quad (3)$$

where $P(+)$ and $P(-)$ are the prior probabilities of each class, $C(-|+)$ is the cost of misclassifying a positive example as negative, while $C(+|-)$ is the cost of misclassifying a negative example as positive.

Key Applications

ROC analysis has been successfully applied to many application domains including psychology (in the studies of perception to resolve the issue of sensory threshold) [15], radiology (to distinguish between subjective judgment and objective detectability in imaging systems) [9], and epidemiology [13]. In addition to classification problems, ROC analysis is also applicable to other ranking problems such as recommender systems, information retrieval, and anomaly detection.

Future Directions

Most of the previous work on ROC analysis are limited to binary class problems. For multi-class problems, the analysis is more complicated as the confusion matrix is no longer a simple 2 × 2 table. An obvious way to extend the approach is to generate a different ROC graph for each class. However, with this approach, the ROC analysis is no longer insensitive to the class distribution [4]. Furthermore, combining the AUC statistics from multiple ROC graphs remains an open problem.

Another research direction that has attracted considerable interests in recent years is designing classification algorithms that directly optimize the area under ROC curve, or equivalently, the Wilcoxon-Mann-Whitney statistic. For instance, Cortes and Mohri [1] showed that, under certain conditions, the objective function optimized by the RankBoost algorithm is identical to AUC. New algorithms have also been developed to incorporate AUC into decision tree induction [5] and support vector machines [8].

Definition

Record linkage is a computational procedure for linking each record *a* in file *A* (e.g., a file masked for disclosure protection) to a record *b* in file *B* (original file). The pair (*a*, *b*) is a match if *b* turns out to be the original record corresponding to *a*.

Key Points

Record linkage techniques were created for data fusion and to increase data quality. However, they have also found an application in measuring the risk of identity disclosure in statistical disclosure control. In the SDC context, it is assumed that an intruder has an external dataset sharing some (key or outcome) attributes with the released protected dataset and containing additionally some identifier attributes (e.g., passport number, full name, etc.). The intruder is assumed to attempt to link the protected dataset with the external dataset using the shared attributes. The number of matches gives an estimation of the number of protected records whose respondent can be re-identified by the intruder. Accordingly, disclosure risk is defined as the proportion of matches among the total number of records in *A*.

There are two main types of record linkage used to measure identity disclosure in SDC: distance-based record linkage and probabilistic record linkage.

Distance-based record linkage consists of linking each record *a* in file *A* to its nearest record *b* in file *B*. Therefore, this method requires a definition of a distance function for expressing *nearness* between records. This record-level distance can be constructed from distance functions defined at the level of attributes. Construction of record-level distances requires standardizing attributes to avoid scaling problems and assigning each attribute a weight on the record-level distance. A straightforward choice is to use the Euclidean distance, but other distances can be used.

The main advantages of using distances for record linkage are simplicity for the implementer and intuitiveness for the user. Another strong point is that subjective information (about individuals or attributes) can be included in the re-identification process by properly modifying distances.

The main difficulty of distance-based record linkage consists of coming up with appropriate distances for the attributes under consideration. For one thing, the weight of each attribute must be decided and this decision is often not obvious. Choosing a suitable distance is also especially difficult in the cases of categorical attributes and of masking methods such as local recoding where the masked file contains new labels with respect to the original dataset.

Like distance-based record linkage, probabilistic record linkage aims at linking pairs of records (*a*, *b*) in datasets *A* and *B*, respectively. For each pair, an index is computed. Then, two thresholds *LT* and *NLT* in the index range are used to label the pair as linked, clerical or non-linked pair: if the index is above *LT*, the pair is linked; if it is below *NLT*, the pair is non-linked; a clerical pair is one that cannot be automatically classified as linked or non-linked and requires human inspection. When independence between attributes is assumed, the index can be computed from the following conditional probabilities for each attribute: the probability $P(1|M)$ of coincidence between the values of the attribute in two records *a* and *b* given that these records are a real match, and the probability $P(0|U)$ of non-coincidence between the values of the attribute given that *a* and *b* are a real unmatch.

To use probabilistic record linkage in an effective way, one needs to set the thresholds *LT* and *NLT* and estimate the conditional probabilities $P(1|M)$ and $P(0|U)$ used in the computation of the indices. In plain words, thresholds are computed from: (i) the probability $P(LP|U)$ of linking a pair that is an unmatched pair (a *false positive* or *false linkage*) and (ii) the probability $P(NP|M)$ of not linking a pair that is a match (a *false negative* or *false unlinkage*). Conditional probabilities $P(1|M)$ and $P(0|U)$ are usually estimated using the EM algorithm.

Definition

Record matching is the problem of identifying whether two records in a database refer to the same real-world entity. For example, in Fig. 1, the customer record *A*1 in Table *A* and record *B*1 in Table *B* probably refer to the same customer, and should therefore be matched. (The example in Fig. 1 was adapted from an example in [21].) As Fig. 1 suggests, the same entity can be encoded in different ways in a database; this phenomenon is fairly common and occurs due to a variety of natural reasons such as different formatting conventions, abbreviations, and typographic errors. Record matching is often studied in the following setting: Given two relations *A* and *B*, identify all pairs of matching records, one from each relation. For the two tables in Fig. 1, a reasonable output might be the pairs (*A*1,*B*1) and (*A*2,*B*2). In some settings of the record matching problem, there is a constraint that each record of table *A* be matched with at most one record of table *B*. This asymmetric setting is typically used when records in table *B* are "clean" and those of table *A*, "dirty." The record matching problem is closely related to the *deduplication* problem. The focus of record matching is to identify pairs of matching records while that of deduplication is to partition records so that records in the same partition refer to the same entity. In practice, the output produced by record matching is inaccurate; it is not an equivalence relation and does not correspond to a natural partitioning. The above distinction between record matching and deduplication is often ignored and the two terms are used synonymously.

Historical Background

Record matching has a rich history dating back to the work by Newcombe and others [16] in 1959. Fellegi and Sunter [10] formalize the intuition of Newcombe and others. Specifically, they cast the record matching problem as a classification problem that can be stated as follows: Given a vector of *similarity scores* between attribute values for a pair of records, classify the pair as a *match* or a *nonmatch*. For a given attribute, a similarity score indicates how similar the two records are on that attribute. A simple similarity measure assigns a score 1 if the records agree on the attribute and 0 otherwise. More sophisticated similarity measures are discussed subsequently. Fellegi and Sunter [10] use a naive Bayes classifier, but subsequent work has considered other kinds of classifiers such as decision trees [7] and SVMs [3]. The classifiers are typically trained using learning examples comprising of a set of record pairs, each labeled as a match or a non-match [3,7,10]. One of the problems with this approach is that learning examples required to train an accurate classifier are hard to generate, since they should not be either obvious matches or obvious non-matches. Sarawagi and Bhamidipaty [17] address this problem and propose an approach based on active learning to interactively identify useful learning examples. Jaro [13] and Winkler [20] propose an alternate approach where the classifier is learned in an unsupervised setting without learning examples using a variant of EM (expectation maximization) algorithm.

A large class of work on record matching has focused on more sophisticated measures of similarity between attribute values of records. As mentioned above, these form the basis for classifying record pairs as a match or a nonmatch. A variety of classic similarity functions such as edit distance and variants [5] and cosine similarity with

Record Matching. Figure 1. Record matching example.

tf-idf (term frequency-inverse document frequency) weights [8] have been used for record matching. Jaro [12] proposes a more domain specific similarity measure designed for people names. Sarawagi and Bhamidipaty [17] propose using a weighted linear combination of simple similarity functions such as those mentioned above, and present techniques for learning the weights using training examples. Bilenko and Mooney [3] present a generalization of edit distance whose parameters can be learnt from a large text corpus. Arasu and others [1] present a framework for *programmable similarity*, where a similarity function can be programmed to be sensitive to synonymous words or phrases such as Robert and Bob or US and United States.

Another body of work on record matching has focused on efficiency issues. For large inputs, it is impractical to exhaustively consider all pairs of records and check if they are a match or not. Hernandez and Stolfo [11] present the *sorted neighborhood approach*, which linearly orders all the records based on a carefully selected key and considers only pairs of records that are close to each other in the linear ordering. McCallum and others [15] present an approach based on *canopies*, which are overlapping clusters of the input records. Only pairs of records within a cluster are checked for a match. Chaudhuri and others [6] identify *set-similarity join* as a useful primitive for large scale record matching.

Foundations

String Similarity

Most record matching approaches are based on the observation that two matching records have similar values for their attributes. For example, the records A2 and B2 have similar names and similar addresses and the same age, and are therefore likely to be matches. The similarity between two values is typically determined using a *similarity function* that takes two values and produces as output a number that quantifies the similarity of the values. String similarity functions that quantify the similarity between two strings are particularly relevant for record matching since many attributes in record matching are textual in nature. One of the earliest and well-known string similarity measure is *edit distance* or *Levenshtein distance*. The edit distance between two strings $s1$ and $s2$ is defined as the smallest number of edit operations required to produce $s2$ from $s1$, where an edit operation is an insertion, deletion, or substitution at the character level. For example, the edit distance between Martinez and Marteenez is 2 since one can derive the second string from the first using one substitution and one insertion. Edit distance is often a poor fit for record matching since two strings representing different entities can have small edit distance (e.g., 148th Ave NE and 147th Ave NE) and two strings representing the same entity, a large edit distance (e.g., 148th Ave NE and 148th Ave Northeast).

An alternate approach that works well for some domains is to treat strings as a bag of words (or *tokens*) and use a token-based similarity function such as *cosine* or *jaccard* (defined below). For a string s, let $Tokens(s)$ denote the set of tokens in s. For a token t, let $w(t)$ denote the *weight* of token t. The weight of a token represents its "importance" for the purposes of computing similarity. The jaccard similarity of two strings s_1 and s_2 is defined as:

$$\frac{|\ Tokens(s_1) \cap Tokens(s_2)\ |}{|\ Tokens(s_1) \cup Tokens(s_2)\ |}$$

For a set S, $|S|$ denotes the weighted cardinality of S, i.e., the sum of weights of the tokens in B. The cosine similarity between two strings s_1 and s_2 is defined as:

$$\frac{||\ Tokens(s_1) \cap Tokens(s_2)\ ||_2}{||\ Tokens(s_1)\ ||_2 \cdot ||\ Tokens(s_2)\ ||_2}$$

For a set S, $||S||_2$ is defined as $\sqrt{\sum_{t \in S} w(t)^2}$. Token-based similarity functions differ from edit distance in two aspects: First, they ignore the ordering of tokens; for example, `148th Ave NE` represents the same bag of tokens as `NE 148th Ave`. This feature is desirable in some domains. For example, the list of authors appears before the title string in some citations and after the title in other citations. An order-sensitive similarity function would produce a low similarity score for two citation strings referring to the same publication but with different author-title orderings. Second, token-based similarity functions are not sensitive to intra-token edits. Two tokens are considered different even if they are textually very similar. As mentioned earlier, this feature is useful in domains such as addresses where, for example, two street names can differ by a single character. Token-based similarity functions enable weighting of tokens to capture their relative importance. A commonly used weighting scheme is the idf-based one, where the weight $w(t)$ of a token t is defined to be $log(N/N_w)$, where N is the number of records in a reference table and N_w denotes the number of records in the reference table containing the token t. With idf-based weighting, the similarity of the pair (`Applecross Rd`, `Applecross Road`) would be higher than the similarity of the pair (`Applecross Rd`, `Maltby Rd`) although both pairs have one token that is common to the two strings in the pair. This happens since the idf-weights of the rarer words `Applecross` and `Maltby` are higher than the weights for the common words `Road` and `Rd`. A related class of similarity functions is obtained by tokenizing strings to their character-level n-grams instead of words. For example, the set of 2-grams of the string `Applecross` is: `{Ap, pp, pl, le, ec, cr, ro, os, ss}`. These similarity functions share some characteristics with edit distance since they can capture intra-word edits, but they are not as order sensitive as edit distance.

A variety of other domain specific similarity functions have been used for record matching. These are covered in depth in the survey by Elmagarmid and others [9] and the tutorial by Koudas and others [14].

Record Matching

Let R and S denote the input tables of record matching. The record matching problem can be viewed as a binary classification problem, where a given pair of records (r, s), $r \in R$ and $s \in S$, has to be classified either as a *match* or a *nonmatch*. A slight variant, not discussed here, is to consider a third category *possible match* consisting of hard-to-classify pairs that require manual inspection. One common approach for record matching is to train a standard binary classifier using learning examples consisting of a set of record pairs prelabeled as a match or nonmatch. The original Fellegi and Sunter approach uses a naive Bayes classifier and is discussed below. Other kinds of classifiers such as SVMs [3] and decision trees [7] have also been used.

Fix a record pair $(r, s) \in R \times S$. Define a *similarity vector* $\overline{x} = [x_1,..., x_n]$, where each x_i denotes the similarity between r and s on some attribute A. The similarity can be computed using one of the functions discussed earlier (for string attributes). It can also be a simple binary value based on equality, i.e., $x_i = 1$ if r and s agree on the attribute and 0, otherwise. Let M denote the event that the pair (r,s) is a match and U the event that it is a nonmatch. Using Bayes rule, one gets

$$Pr(M|\overline{x}) = \frac{Pr(\overline{x}|M)Pr(M)}{Pr(\overline{x})}$$

$$Pr(U|\overline{x}) = \frac{Pr(\overline{x}|U)Pr(U)}{Pr(\overline{x})}$$

Therefore, $Pr(M|\overline{x}) \geq Pr(U|\overline{x})$ whenever,

$$\frac{Pr(\overline{x}|M)}{Pr(\overline{x}|U)} \geq \frac{Pr(U)}{Pr(M)}$$

The expression $\ell(\overline{x}) = Pr(\overline{x}|M)/Pr(\overline{x}|U)$ is called the *likelihood function*. The construction of the naive Bayes classifier assumes that x_i and x_j, $i \neq j$, are conditionally independent given M or U, implying:

$$Pr(\overline{x}|M) = \prod_{i=1}^{n} p(x_i|M)$$

$$Pr(\overline{x}|U) = \prod_{i=1}^{n} p(x_i|U)$$

The probabilities $p(x_i|M)$ and $p(x_i|U)$ can be estimated using the learning examples, which can be used to estimate $Pr(\overline{x}|M)$ and $Pr(\overline{x}|U)$ using the expressions above. It is harder to estimate $Pr(U)$ and $Pr(M)$. A simple approach is to empirically pick a threshold

T and classify the pair (r, s) as a match if $\ell(\overline{x}) \geq T$ and a nonmatch otherwise.

A simple classifier that has performance advantages over more sophisticated machine-learning (ML) classifiers is the *threshold-based* classifier. Here, the record pair (r, s) is classified as a match if the similarity vector $\overline{x}$ satisfies:

$$(x_1 \geq T_1) \wedge (x_2 \geq T_2) \wedge \cdots \wedge (x_n \geq T_n)$$

where $T_1,...,T_n$ are thresholds that can be learned using labeled examples or set manually based on domain expertise. Record matching based on a threshold-based classifier can be performed efficiently using the string similarity join primitive discussed below. Chaudhuri and others [4] show that the record matching accuracy of union of several threshold-based classifiers is comparable to that of state-of-art ML classifiers.

A related approach, sometimes called *distance-based* [19] record matching, is to define a distance measure between two records by suitably combining the similarity (distance) scores of the attributes of the two records. A pair (r, s) is considered a match if the distance between r and s is smaller than a given threshold value. This approach is also easily extended to the asymmetric version of record matching where each record in R is constrained to match at most one record in S: For each record r in R, the record in S with the smallest distance to r is selected as a match.

More details of the other approaches used for record matching can be found in the survey by Elmagarmid et al. [9].

Performance

For large input tables R and S, it is impractical to consider every pair of records $(r, s) \in R \times S$ and classify them as a match or a nonmatch. Therefore, an important challenge in record matching is to identify the matching pairs without exhaustively considering every pair in $R \times S$. An important primitive for efficient record matching is *string similarity join*: Given two tables R and S, identify all pairs of records $(r, s) \in R \times S$ such that the string similarity of $r.A$ and $s.B$ is above some specified threshold, where the string similarity is measured using one of the similarity functions mentioned earlier. A string similarity join can be used to heuristically identify promising matching candidates, which can then be subjected to more complex classification. The string similarity join primitive can also be used to perform record matching based on the threshold-based classifier discussed above [4].

Since many of the string similarity measures such as jaccard and cosine are set-based, a more foundational primitive is *set-similarity join* [6]. A set-similarity join conceptually takes two collections of sets U and V as input and outputs all pairs of sets $(u, v) \in U \times V$ having high set-similarity. String-similarity joins can be evaluated using set-similarity joins as a primitive even for many non-set based similarity functions such as edit distance. A simple algorithm for set-similarity join involves building an inverted index over the collection V. The inverted index efficiently retrieves for any given element e all sets in V containing e. For each set u in U, the inverted index is used to retrieve all sets v in V that share one or more elements with u; the pair (u, v) is then produced as output if its satisfies the set-similarity join condition. More efficient algorithms for set-similarity joins are presented in [2,18].

Key Applications

The primary application of record matching is data cleaning. The presence of duplicate records in a database adversely affects the quality of the database and its utility for analysis and mining. Another related application of record matching is data integration. The same real-world entity is often represented differently in other databases being integrated, and record matching is necessary to evolve a common representation for the entity. Another application of record matching is to measure the risk of identity disclosure in statistical disclosure control (SDC) [19]. In the SDC context, a dataset A (for public release) is produced from a source dataset B by masking values for identity protection. The goal of this step is to make it hard for an adversary to link a record in A to the record in B from which it was generated. The number of records in A that can be matched to records in B using the record matching techniques discussed above gives an estimate for disclosure risk of the released dataset A. Distance-based record matching is often used for this purpose.

Redundant Arrays of Independent Disks

Kenichi Wada
Hitachi Limited, Tokyo, Japan

Synonyms

Array; Disk array; Storage array; RAID

Definition

A set of disks from one or more commonly accessible disk subsystems is combined with a body of control software in which part of the physical storage capacity is used to store redundant information about user data stored on the remainder of the storage capacity. The redundant information enables regeneration of user data in a storage emergency in which a disk in the array or an access path fails.

Key Points

The term *RAID* was adopted from the 1988 SIGMOD paper "A Case for Redundant Arrays of Inexpensive Disks (RAID)." In the paper, RAID refers to a group of storage schemes that divide and replicate data among multiple disks to provide better performance, cost and power consumption rate with reasonable availability comparing with conventional Single Large Expensive Disk (SLED) used for Mainframe. Currently, the term of "independent" is usually used rather than "inexpensive" because SLED becomes obsolete.

A number of standard schemes have evolved which are referred to as *levels*. Originally, five RAID levels were conceived, but many more variations have evolved. Currently, there are several sublevels as well as many non-standard levels.

The two key concepts in RAID are striping, and error correction using parity. The striping of RAID means dividing user data into fixed length blocks (striping units). The error correction using parity conceals one disk failure in an array of disks from the host computer and user data lost by one disk failure is regenerated using the parity.

Original five RAID levels are as follows:

1. Level 1: Mirrored disk. Two or more identical copies of data are maintained on separate disks.
2. Level 2: Using Hamming Code and striping with small striping unit (each read or write spread across all disks in an array). During read or write, on the fly ECC is adopted using Hamming Code in order to conceal some number of disk failures in an array.
3. Level 3: Using parity and striping with small striping unit (each read or write spread across all disks in an array). If one disk fails in an array, data on the failed disk are regenerated using corresponding parity and data on other disks in the array.
4. Level 4: Using parity and striping with large striping unit (small read or write can fit in one disk). One disk in an array is allocated to store the parity and user data is striped across remaining disks.
5. Level 5: Using parity and striping with large striping unit (small read or write can fit in one disk). Parity and user data is striped across all disks in an array.

In addition to these 5 levels, Level 0 is often used to represent arrays using striping without data redundancy in which fixed-length sequences of virtual disk data addresses are mapped to sequences of member disk addresses in a regular rotating pattern.

Reference Knowledge

Chintan Patel, Chunhua Weng
Columbia University, New York, NY, USA

Definition

Reference knowledge is the knowledge about a particular part of the world in a way that is independent from specific objectives, through a theory of the domain [2]. Different knowledge bases reuse or extend subsets of the reference knowledge for application specific tasks.

Key Points

Developing knowledge bases is a laborious process involving domain experts, knowledge engineers and computer scientists. To minimize this effort, often the core theory and concepts of a given domain are represented in a reference knowledgebase that are reused or extended by other application specific knowledge bases. Consider for example, in the biomedical domain, the Foundational Model of Anatomy [3] is considered a reference knowledge base for representing anatomy terms that can be used for representing the mouse anatomy.

One of the important advantages of using reference knowledge bases is that they provide interoperability [1] across the applications using the knowledge. The applications that heavily reuse or extend the reference knowledge achieve higher levels of interoperability.

The reference knowledge bases are generally developed without any application requirements or objectives. The reference knowledge imposes a rigid set of constraints on representing the application specific or local knowledge base. Such constraints sometimes conflict with the application or turn out to be difficult to implement or maintain, hence impeding the use of reference knowledge. Secondly, the reference knowledge bases tend to be very large [1] and creating subsets appropriate for small applications is challenging.

Region Algebra

Matthew Young-Lai
Sybase iAnywhere, Waterloo, ON, Canada

Definition

A region algebra is a collection of operators, each of which returns a set of regions as a result and takes as arguments one or more sets of regions. A *region* of a string is a pair of natural number positions (s,e) that correspond to the substring starting at s and ending at e. A position is a count of bytes, characters, or words from the beginning of the string.

Choosing a set of operators defines a particular region algebra. Operators are chosen for efficiency as well as utility. For example, if regions correspond to structure elements such as chapters and sections in a document, then many operators for querying structure conditions are useful and can be implemented efficiently. One example of such an operator is $\mathit{containedIn}(X,Y)$ which takes two sets of regions X and Y and returns the subset of regions in X that are contained in some region of Y, i.e., $\{(s_x, e_x) \in X \mid \exists (s_y, e_y) \in Y\,(s_x \geq s_y) \wedge (e_x \leq e_y)\}$. A similar operator is $\mathit{contains}(X,Y)$ which returns the subset of regions in X that contain some region of Y, i.e., $\{(s_x, e_x) \in X \mid \exists (s_y, e_y) \in Y\,(s_x \leq s_y) \wedge (e_x \geq e_y)\}$.

Another defining characteristic of a particular region algebra is the restrictions that apply to the sets of regions.

If sets are unrestricted, then a string of length n has $\binom{n}{2}$ regions. This means that the worst case cost of evaluating a single operator cannot be linear in the length of the string. Thus, region algebras are often defined with restrictions on the nesting or overlap of regions in a set.

Historical Background

The first use of a region algebra for text search was in the PAT system [10]. The operators in PAT assume the use of a PAT array (also known as a suffix array) as the underlying implementation. This data structure can provide sets of matches for various lexical patterns (e.g., find all positions corresponding to a given substring of the text). It can also filter matches based on frequency or length conditions (e.g., return only the most frequent words matching a substring). The query language includes operators for dynamically combining matches into regions – a very flexible capability. It also provides set operators such as *union* and *difference* and structure operators such as *including*. Thus, it is a good example of the idea of using a region algebra to mix structure and content operations in text search. The system makes a distinction between sets of regions and sets of points which means that it does not completely fit the definition of a region algebra. Its operators are typed in that their arguments and return values must be either sets of regions or sets of points. This means that the language is not fully compositional. Also, region sets are not allowed to include nesting or overlapping regions which causes semantic problems. For example, when an operator such as *union* results in overlapping regions, only the start points are returned.

Burkowski describes a region algebra for combined content and structure search in text [2,1]. It treats both single words and structure elements spanning many words uniformly as regions. Thus it avoids the problems that result from distinguishing points and regions. Like PAT, region sets do not include nesting or overlapping regions. Later extensions to this work allow regions to overlap which is just as efficient [3]. An advantage of overlapping regions is that it makes the ability to dynamically define regions outside of a fixed hierarchical structure even more flexible and useful. The earlier papers by Burkowski describe simple structure operations such as *containing*, simple content operators for selecting words, and ranking operators based on inverse document frequency from traditional information retrieval. Later work explores ranking for information retrieval in more depth [6].

Jaakkola continues the pattern of imposing fewer restrictions on region sets [7,8]. Sets are allowed to nest and overlap arbitrarily, abandoning the guarantee of linear size relative to the length of the string. However, the maximum depth of nesting tends to be constant in most data, and independent of the length of the data. This is true, at least, when talking about structure in text documents where region algebras are usually applied. Therefore, allowing arbitrary sets gives even more flexibility while not abandoning efficiency in practice.

Compared to relational algebra, there has been relatively little work exploring expressiveness or optimization issues with region algebras. Many systems make an informal effort to balance expressiveness with efficiency. For many useful algebras, the operators are restricted enough that the efficiency of evaluating arbitrary compositions is obvious without need of formal proof. Some work does explore more general issues. For example, Consens and Milo examine equivalence testing and whether operators like direct inclusion can be efficiently supported [4,5]. Young-Lai and Tompa look at characterizing operators that allow the possibility of efficient evaluation [12].

Foundations

The operators of a region algebra can combine and select regions. An important question, however, is where the regions originate. The most flexible approach is to scan the string for matches at every query. These matches can then be treated as regions and further manipulated using the algebra. In principle, any type of pattern language can be used for scanning. For example, it is possible to search for simple substrings, for regular expressions, or for words (possibly with linguistic processing such as stemming or lemmatization). It is also possible to parse the string with a grammar and return structures as regions. This is useful for data such as programming language source code where a well-defined grammar exists. For a scanning operation such as parsing with a grammar, the functionality of the parser starts to overlap with what can be accomplished with the region algebra. In fact, it is possible to use appropriately defined region algebra operators to simulate the process of parsing a string of tokens with a grammar.

If a string is too long to efficiently scan at every query, then regions can be pre-computed and stored persistently. This means making choices before-hand about what queries to support, and involves a tradeoff between flexibility and space. For example, consider storing a list of regions for every unique word. It is possible to apply a stoplist of common words to save space, but then it is impossible to search for phrases involving these stop words. There is also a tradeoff between efficiency and flexibility. For example, consider stemming the input by converting all forms of a word such as "stemming," "stemmed," and "stemmer" to the root word "stem." This does not reduce the number of stored regions (ignoring for the moment the fact that it can reduce the total space requirement in some compressed representations). However, it reduces the flexibility since it is no longer possible to search for just one of the forms. On the other hand, it increases the efficiency of searching for all forms together since there is no need to combine separate lists. Overall, choosing what regions to pre-compute means predicting the types of queries that need to be supported.

Various representations are possible for persistently stored regions. The simplest is a collection of unordered lists. Given that region lists generated by scanning are ordered by position in the string, however, it makes sense to store them in that order. This can be done in a flat file which allows sequential access or binary searching. Alternatively, it can be in an index structure such as a B-tree which allows more efficient searches and updates. Ordered representations allow the possibility of particularly efficient compression using various techniques.

For a non-nesting set of regions, there is a single, unique sort order. For a set of regions with nesting there are two possible sort orders. That is, regions may ordered primarily by either *s* or by *e*. The choice has some effect on evaluation strategies for expressions that compose multiple operators. If regions are stored persistently, then a single sort order must be chosen. Of course, a physical operator can be provided to convert between the two orderings, although this is not possible in linear time and constant memory. Note that considering such an operator part of the algebra itself implies modifying the definition to use lists of regions with physical order properties rather than sets of unordered regions. Alternatively, one can make a distinction between the logical algebra that works with un-ordered sets, and the physical operators that are used for optimization and evaluation.

One way to avoid choosing between the two possible sort orders in persistent storage is to only index non-nested regions. This is less of a limitation than it might appear since it is easy to generate nested regions dynamically given two lists of endpoints. For example, it is possible to index the start and end tags for nested sections in a text in separate lists. The tags themselves have a unique order since they are not nested. A physical operator can scan and merge the two lists of tag regions, pushing the start tags onto a stack and popping the stack at every end tag. This results in a region list ordered primarily by *e*. A very similar operator can be used to dynamically generate regions that contain two words of interest. In this case, there is no natural pairing of word occurrences and the result may be as big as the cross product of the two lists. A useful solution is to define the operator so that it discards all but the shortest regions in the cross product, or equivalently, those that do not contain another nested region.

Given operands that are stored in an ordered list representation, there are many useful operators such as *contains* and *containedIn* that can be evaluated by scanning both lists and performing a type of merge join. This produces an ordered result that can then be used as an input to another operator. If an algebra consists exclusively of operators that can be evaluated with such merge strategies, then it is possible to evaluate arbitrarily composed expressions with very little query optimization effort and relatively good efficiency. A simple strategy is to evaluate the operator with the two smallest available inputs at each step until all operators in the tree are finished. Intermediate results can be buffered.

There are many ways to improve on this basic strategy. Some of them are implied by viewing the problem as an instance of relational query optimization and have not been explicitly described in the context of region algebras. For example, it is possible to consider additional physical operators such as index nested loop join. This can be used in the above strategy when joining a small operand with a larger one. Rather than scan the entire large operand, the join operator performs a binary search or index lookup within the large operand for each region in the small operand.

It is also possible to consider optimizing an entire query rather than making a local, greedy decision at each step about which operator to evaluate next. This implies the need to determine equivalences between expressions, to consider different physical evaluation plans based on these equivalences, and to choose between the plans. The choice must involve estimating the costs of physical plans which is a difficult problem in general. However, it may admit heuristic or approximate solutions that do well in practice as is the case with relational query optimization.

There are some inherent limitations of the region model. One has to do with the limited information contained in a region. Given just numeric endpoints, it is easy to tell whether two given regions overlap or nest. However, nothing is known about their relationship with other regions that may exist. For example, given two regions *a* and *b* such that *a* contains *b*, there is no way to tell if *a* directly contains *b* meaning that there is no region *c* in the system such that *a* contains *c* and *c* contains *b*. Ignoring the possibility of constraints that may allow this to be inferred, the only way to know if this is the case is to search every other region list. This is likely to be inefficient.

By definition, operators in a region algebra are also excluded from referring to the content of a region. Thus, it is not possible to define an operator that takes the region endpoints and goes back to the original string to check some condition. Note that this is related to the issue of which regions have been indexed in a string. If there is a set of regions for "stem," an operator cannot check the string to see which of those regions were really the word "stemmed." However, even if there are separate region lists for "stem" and "stemmed," it is not possible to look up the value of words that follow "stem" in the text.

Of course, both of these limitations can be overcome by extending from regions to arbitrary tuples of information. To solve the direct containment problem, it is possible to store a third number *depth* with each region that indicates its nesting level. Then *b* is directly contained in *a* if it is contained in *a* and its depth is higher by one. Similarly, it is possible to add a text column to a region to store the word that follows the region and carry it with subsequent intermediate results. Essentially then, it is possible to consider extending to a full relational model. However, the region columns in such an extended model might admit the possibility of useful physical operators not generally provided in relational systems. For example, many region algebra operators can be executed with list merges but cannot be formulated as joins with equality conditions.

Another general limitation of region algebras has to do with the use of regions as a structure model. Consider a collection of region sets where each set has an associated type or label. This can represent arbitrarily nested structures in a strictly non-overlapping hierarchy. It can also represent multiple independent hierarchies over the same string. It can represent overlapping structures which goes beyond what is possible with a strict hierarchy. One thing that it cannot do is represent an arbitrary graph structure. For example, if regions are mapped to nodes in a graph, and there is an edge between any two nodes that overlap, then not all graphs are possible. For example, this can represent a chain of nodes with edges between them, but cannot add an edge from the first node in the chain to the last node without adding other edges at the same time. This limitation applies even if using regions only to encode a structure without requiring that the endpoints correspond to physical locations in a contiguous string.

Key Applications

A region algebra can be used as a query language for searching structured or semi-structured text, for searching structured or semi-structured data encoded in a text format such as SGML or XML, or for information retrieval. Alternatively, it can be used as an underlying model for query optimization or execution for some other query language.

As a query language, a region algebra can also serve as a component of a larger text processing task. One example is structure recognition where features such as composability and a loose structure model give advantages over alternatives such as grammars [11]. Other examples include constraint definition, outlier finding, and editing by example [9].

Regulatory Compliance in Data Management

Radu Sion
Stony Brook University, Stony Brook, NY, USA

Definition

Regulatory compliance in data management refers to information access, processing and storage mechanisms designed according to regulations governing their respective data types and semantics. For example, in the United States, health-related data falls under the incidence of the Health Insurance Portability and Accountability Act (HIPAA) and any associated data management systems need to provide compliance to HIPAA requirements, including data retention and secure deletion assurances. Such compliance has potential for far reaching impact in the design of data processing semantics, from relational ACID properties to complex query processing and index optimization.

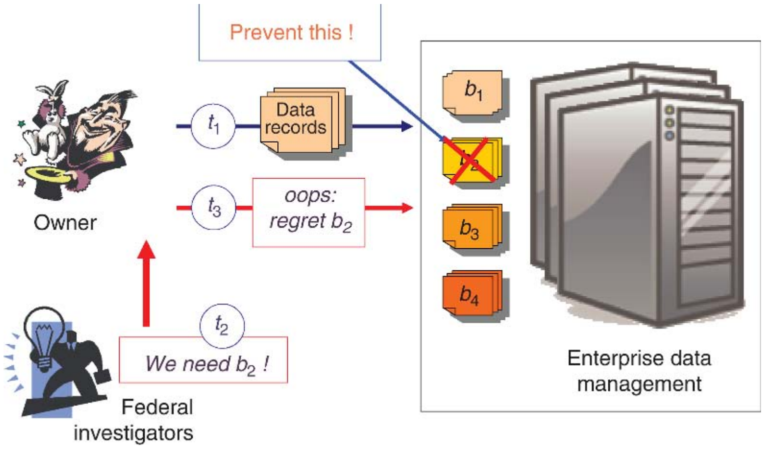
Historical Background

Modern digital societies and markets increasingly mandate consistent procedures for the access, processing and storage of information. In the United States alone, over 10,000 such regulations can be found in financial, life sciences, health-care and government sectors, including the Gramm–Leach–Bliley Act (1999), the Health Insurance Portability and Accountability Act (1996), and the Sarbanes–Oxley Act (2002). A recurrent theme in these regulations is the need for regulatory – compliant data management as an underpinning to ensure data confidentiality, access integrity and authentication; provide audit trails, guaranteed deletion, and data migration; and deliver Write Once Read Many (WORM) assurances, essential for enforcing long-term data retention and life-cycle policies.

Foundations

Overview

Over 10,000 regulations govern the management of documents in the United States alone [8], in financial, life sciences, health-care industries, and the government. These regulations impose a wide range of policies, ranging from information life-cycle management (e.g., mandatory data retention and deletion) to audit trails and storage confidentiality. Examples include the Gramm–Leach–Bliley Act [6], Health Insurance Portability and Accountability Act [13], Federal Information Security Management Act [14], Sarbanes–Oxley Act [15], Securities and Exchange Commission rule 17a-4 [12], Department of Defense Records Management Program under directive 5015.2 [9], Food and Drug Administration 21 CFR Part 11 [11], and the Family Educational Rights and Privacy Act [10]. In Europe, the Directive 95/46/EC of the European Union on the protection of personal data, provides privacy and security guarantees for personal information [3]. In addition, many



Regulatory Compliance in Data Management. Figure 1. WORM prevents history "re-writing".

countries have their own data protection laws. For example, in the United Kingdom, the Data Protection Act of 1998 [1] regulates, among other information, personal health-care records. It requires mandatory disposal of electronic records after retention period, accuracy of information, logging any changes, and strict confidentiality.

While each regulation has its own unique characteristics, certain assurance features can be found throughout:

Guaranteed data retention. To address this requirement, the goal of compliant data management is to support Write Once Read Many (WORM) semantics: once written, data cannot be undetectably altered or deleted before the end of their regulation-mandated life span, even with physical access to its hosting server.

Secure deletion. Once data has reached the end of its lifespan, it can (and in some cases must) be deleted. Deleted records should not be recoverable even with unrestricted access to the underlying medium; moreover, after data is deleted, no hints of its existence should remain on the server, even in the indexes. The term *secure deletion* is used to describe this combination of features.

Compliant data migration. Retention periods are measured in years. For example, national intelligence information, educational records, and certain health records have retention periods of over 20 years. To address this requirement, compliant data management needs *data migration* mechanisms that allow information to be transferred from obsolete to new storage media while preserving its associated security guarantees.

Litigation holds. Even if a data record has reached the end of its lifespan, it should remain fully accessible if it is the subject of current litigation.

In addition to these features, a common thread running through many of these regulations is the perception of powerful insiders as the primary adversary. These adversaries have superuser powers coupled with full access to the storage system hardware. This corresponds to the perception that much recent corporate malfeasance has been at the behest of CEOs and CFOs, who also have the power to order the destruction or alteration of incriminating records. Since the visible alteration or destruction of records is tantamount to an admission of guilt in the context of litigation, a successful adversary must perform their misdeeds *undetectably.*

Regulatory Compliant Commercial Systems

As the ability to control data retention is an essential requirement to be found in a majority of regulations, systems aimed at providing WORM assurances have been brought to the market by virtually all major storage vendors, including companies such as IBM [5], HP, EMC [2], Hitachi Data Systems Zantaz, StorageTek, Sun Microsystem Network Appliance and Quantum Inc. [7]. A set of representative instances are discussed in the following.

Tape-based WORM

Due to the favorable cost-per-MB ratio of tape-based storage in the past, it was a natural choice for massive data storage in commercial enterprise deployments (where regulatory compliance is of concern). Thus storage vendors started offering tape-based WORM mechanisms first. The Quantum DLTSage predictive, preventative and diagnostic tools for tape storage environments [7] are a representative instance. The WORM assurances of the tape systems are provided under the assumption that only Quantum tape-readers are deployed. "DLTSage WORM provides features to assure compliance, placing an electronic key on each cartridge to ensure WORM integrity. This unique identifier cannot be altered, providing a tamper-proof archive cartridge that meets stringent compliance requirements to ensure integrity protection and full accessibility with reliable duplication." [7]. Such systems however, are subject to a set of impractical assumptions. Given the nature of magnetic tape, an attacker can easily dismantle the plastic tape enclosure and access the underlying data on a different customized reader, thus compromising its integrity. Relying on the physical integrity of a "plastic yellow label" to safe-guard essential enterprise information is likely unacceptable in any medium to high-stake commercial scenarios.

Optical-Disk WORM

Optical (compact) disk (CD) media has been around experimentally since 1969 and commercially available since 1983. Given the prohibitive costs of high-powered lasers in small form factors, in the early days, most CD devices were only capable of reading disk information. As the technology matured, write-once (and later read-write) media appeared. Optical WORM-disk solutions rely on the irreversible physical primitive write effects to ensure the inability to alter existing content. However, with ever increasing amounts of information being produced and requiring constant low-latency accessibility in commercial scenarios, it is challenging to deploy a scalable optical-only WORM solution. Moreover, optical WORM disks are plagued with other practical issues such as the inability to fine-tune WORM and secure deletion granularity (problems partially shared also by tape-based solutions). Moreover, as the WORM disks do not provide any strong security features (due to bulk-production requirements) any optical WORM solutions are vulnerable to simple data replication attacks as discussed above. Optical WORM also perform relatively poorly in the price-performance measurements because current technology is somewhat under-sized for the volumes of data associated with compliance. Sony's Professional Disk for Data optical disk system, for example, holds only 23 GB per disk side. Nevertheless, because it is faster than tape and cheaper than hard disks, optical WORM storage technology is often deployed as a secondary, high-latency storage medium to be used in the framework of a hard disk-based solution. Care needs to be taken in establishing points of trust and data integrity when information leaves the secured hard disk store for the optical media.

Hard Disk-based WORM

Magnetic disk recording currently offers better overall cost and performance than optical or tape recording. Moreover, while immutability is often specified as a requirement for records, what is required in practice is that they be "term-immutable", i.e., immutable for a specified retention period. Thus almost all recently-introduced WORM storage devices are built atop conventional rewritable magnetic disks, with write-once semantics enforced through software ("soft-WORM").

EMC Centera. The EMC Centera Compliance Edition [2] is a content addressed storage (CAS) solution that also offers regulatory compliance capabilities. Each data record "has two components: the content and its associated content descriptor file (CDF) that is directly linked to the stored object (business record, e-mail, etc.). A digital fingerprint derived from the content itself is the content's locator (content address). The CDF contains metadata record attributes (e.g., creation date, time, format) and the object's content address. The CDF is used for access to and management of the record. Within this CDF, the application will assign a retention period for each individual business record. Centera will permit deletion of a pointer to a record upon expiration of the retention period. Once the last pointer to a record has been so deleted, the object will be eliminated" [2], and, in the Plus version, also "shredded" (from the media). Given its software-only nature, these mechanisms are vulnerable to simple software or physical direct disk-access attacks like described above. Data integrity can be easily compromised.

Hitachi message archive for compliance. Similarly, Hitachi Data Systems provide the Data Retention Utility, a software-based "virtual" WORM mechanism for mainstream Hitachi storage systems. The system allows customers to "lock down archived data, making it non-erasable and non-rewritable for prescribed periods, facilitating compliance with governmental or industry regulations".

IBM LockVault compliance software. IBM offers multiple soft-WORM solutions. The LockVault compliance software is a layer that operates on top of IBM System Storage N series to provide "disk-based regulatory compliance solutions for unstructured data".

IBM system storage archive manager. The IBM Tivoli Storage Manager is part of the IBM TotalStorage Software [5] and provides certain software data retention protection. It "makes the deletion of data before its scheduled expiration extremely difficult. *Short of physical destruction to storage media or server, or deliberate corruption of data or deletion of the Archive Manager database*, Archive Manager will not allow data [...] to be deleted before its scheduled expiration date." However, it is not desirable to base the functioning of the regulatory compliance mechanism on the correct behavior of the main system. After all, the compliance mechanism's main role is to guarantee exactly such fault-less behavior. The main adversary of concern in regulatory settings is *exactly* one with incentives for data corruption and physical compromise attacks.

Network appliance snaplock compliance/enterprise software. The NetApp SnapLock software suite is designed to work on top of NetApp NearStore and FAS storage systems. It provides soft-WORM assurances, "preventing critical files from being altered or deleted until a specified retention date". As opposed to other vendors, NetApp SnapLock supports open industry standard protocols such as NSF and CIFS.

Sun StorageTek compliance archiving software. Sun also offers soft-WORM assurances through its StorageTek Compliance Archiving Software . The software runs on top of the Sun StorageTek 5320 NAS Appliance to "provide compliance-enabling features for authenticity, integrity, ready access, and security".

Security Properties

The design of compliance data management is extremely challenging due to the conflict between security, cost-effectiveness, and efficiency. For example, the requirement to find requested information quickly means in practice data must be indexed. But trustworthy indexing of compliance data is a challenging problem, as it is easy to tamper with traditional indexes stored on WORM. Further, trustworthy indexes will make it very hard to delete all traces of documents that are past their retention periods, as required by certain regulations. Yet another complicating factor is the decades-long retention periods required by many regulations; it is unrealistic to expect data to reside on the same device for so long. One of the main challenges of such an endeavor lies in securing the system against attack by insiders with superuser powers, and in balancing the conflicting requirements for trustworthiness, high performance, and low cost.

Current regulatory compliant data management systems constitute an important step in the right direction. These systems however, are unfortunately fundamentally vulnerable to faulty behavior or illicit adversaries with incentives to alter stored data, as they rely on enforcement primitives – such as software and/or simple hardware device-hosted on/off switches – ill-suited to their target (insider) adversarial setting.

Achieving a secure, cost-effective, and efficient design when the insider is the adversary is extremely challenging. To defend against insiders, processing components that are both tamper-resistant and *active*, such as general – purpose trustworthy hardware are needed. By offering the ability to run logic within a secured enclosure, such devices allow fundamentally new paradigms of trust. Trust chains spanning untrusted and possibly hostile environments can now be built by deploying secure tamper-resistant hardware at the storage components' site. The trusted hardware can run certified logic; close proximity to data coupled with tamper-resistance guarantees allow an optimal balancing and partial decoupling of the efficiency/security trade-off. Assurances can now be both efficient and secure.

However, trusted hardware devices are not a panacea. Their practical limitations pose a set of significant challenges in achieving sound regulatory-compliance assurances. Specifically, heat dissipation concerns under tamper-resistant requirements limit the maximum allowable spatial gate-density. As a result, general-purpose secure coprocessors (SCPUs) are often significantly constrained in both computation ability and memory capacity, being up to one order of magnitude slower than host CPUs. Such constraints mandate careful consideration in achieving efficient protocols. Direct implementations of the full processing logic *inside* the SCPU are bound to fail in practice due to lack of performance. The server's main CPUs will remain starkly under-utilized and the entire cost-proposition of having fast untrusted main CPUs and expensive slower secured CPUs will be defeated. Efficient protocols need to access the secure hardware sparsely, asynchronously from the main data flow.

Recently, Hsu et al. [4] analyzed some of the principal requirements for trustworthy "content immutable storage" (CIS) of electronic records and identified a set of principles, including: (i) increasing the cost and conspicuity of any attack against the system, (ii) focusing on end-to-end trust, rather than single components, (iii) using a small trusted computing base, isolate trust-critical modules and make them simple, verifiable and correct, (iv) using a simple, well-defined interface between trusted and untrusted components, and (v) trust, but verify every component and individual operation.

Key Applications

Recent compliance regulations are intended to foster and restore humans trust in digital information records and, more broadly, in our businesses, hospitals, and educational enterprises. As increasing amounts of information are created and live digitally, compliance data management will be a vital tool in restoring this trust and ferreting out corruption and data abuse at all levels of society.

Future Directions

Future research will need to explore novel regulatory compliant data management solutions that address the appropriate insider adversary. Numerous technical challenges are associated with such an endeavor, including designs for SCPU overhead-minimizing techniques for expected transaction loads, amortized commitment schemes to enforce write-once-read-many (WORM) semantics at the throughput rate of the servers ordinary processors, while benefiting from existing work on compliance indexing to create efficient indexes secured by novel cryptographic constructs such as fast short-lived signatures. Compliant data migration mechanisms will likely require backwards-compatible, inter-device trust chains and fast re-encryption techniques.

Relational Algebra

VAL TANNEN
University of Pennsylvania, Philadelphia, PA, USA

Definition

The operators of the relational algebra were already described in Codd's pioneering paper [2]. In [3] he introduced the term *relational algebra* and showed its equivalence with the tuple relational calculus.

This entry details the definition of the relational algebra in the *unnamed perspective* [1], with selection, projection, cartesian product, union and difference operators. It also describes some operators of the *named perspective* [1] such as join.

The flagship property of the relational algebra is that it is equivalent to the (undecidable!) set of domain independent relational calculus queries thus providing a standard for *relational completeness.*

Key Points

Fix a countably infinite set $\mathbb{D}$ of constants over which Σ-*instances* are defined for a relational schema Σ.

The relational algebra is a *many-sorted* algebra, where the sorts are the natural numbers. The idea is that the elements of sort n are finite n-ary relations. The *carrier* of sort n of the algebra is the set of finite n-ary relations on $\mathbb{D}$ If f is a many-sorted k-ary operation symbol that takes arguments of sorts $n_1,\ldots,n_k$ (in this order) and returns a result of sort n then its type is written as follows: $f : n_1 \times\ldots \times n_k \rightarrow n_0$, and this is simplified to n for nullary ($k = 0$) operations. Bold letters $\mathbf{x}$, $\mathbf{y}$ used for tuples and x_i for the i'th component of $\mathbf{x}$. The operations of the algebra, with their types and their interpretation over the relational carriers are the following:

constant-singletons $\{c\} : 1(c \in \mathbb{D})$.

selection1 $\sigma^n_{ij} : n \rightarrow n$ $(1 \leq i < j \leq n)$ interpreted as $\sigma^n_{ij}(R) = \{\mathbf{x} \in R \mid x_i = x_j\}$

selection2 $\sigma^n_{ic} : n \rightarrow n$ $(1 \leq i \leq n, c \in \mathbb{D})$ interpreted as $\sigma^n_{ic}(R) = \{ \mathbf{x} \in R | x_i = c \}$

projection $\pi i^{\mathrm{n}}_1\ldots ik : n \rightarrow k$ $(1 \leq i_1,\ldots,i_k \leq n$, not necessarily distinct) interpreted as $\pi^n_{i_1\ldots i_k}(R) = \{x_{i_1},\ldots, x_{i_k} \mid \mathbf{x} \in R\}$

cartesian(cross-) product $\times^{mn} : m \times n \rightarrow m + n$ interpreted as $\times^{mn}(R, S) = \{x_1,\ldots,x_m, y_1,\ldots,y_n \, | \mathbf{x} \in R \wedge \mathbf{y} \in S\}$

union $\cup^n : n \times n \rightarrow n$ interpreted as $\cup^n(R, S) = \{\mathbf{x} | \mathbf{x} \in R \vee \mathbf{x} \in S\}$

difference $-^n : n \times n \rightarrow n$ interpreted as $-^n(R, S) = \{\mathbf{x} | \mathbf{x} \in R \wedge \mathbf{x} \notin S\}$

Relational algebra *expressions* are built, respecting the sorting, from these operation symbols, using the relational schema symbols *as variables.*

Note that an obvious operation, intersection, is missing. Of course, intersection can be defined from union and difference, by De Morgan's laws. Interestingly, intersection is also definable just from cartesian product, selection, and projection. Other useful operations are definable also.

Given a relational schema Σ, a relational algebra *query* is an algebraic expression constructed from the symbols in Σ and the relational algebra operation symbols. Given a database instance $\mathcal{I}$ as input, such a query e returns a relation $e(\mathcal{I})$ as output. For example if R, S are binary, the expression $\pi_{2414}(\sigma_{13}(R \times S)) - (R \times R)$ defines a query that returns a 4-ary relation (omit the operation's superscripts because they can usually be reconstructed and use infix notation for the binary operations). Clearly, each of the operations of the relational algebra maps finite instances to finite relations, and more importantly, it is easily seen that *relational algebra queries are domain independent.* Moreover, there exists an (easily) computable translation that takes any relational algebra query into an equivalent domain independent FO (first-order) query.

The converse of this last fact is the main "raison d'être" for the relational algebra. However, because the set of domain independent FO queries is not decidable, it is not possible to define an effective translation just for these queries. Instead, define a "translation" for *all* FO queries, such that domain independent FO queries are indeed translated to equivalent relational algebra queries. Recalling the notation $q(\mathcal{I}/D)$ gives

Theorem

There exists a total computable translation that takes any FO query q into a relational algebra query e such that for any instance $\mathcal{I}$, gives $e(\mathcal{I}) = q(\mathcal{I}/adom(\mathcal{I}) \cup adom(q))$ (and for domain independent queries the right-hand side further equals $q(\mathcal{I})$.

The key to the proof is the observation that active domains can be computed in the relational algebra.

This result justifies Codd calling a query language *relationally complete* whenever it has the expressive power of the relational algebra. However, it is necessary to note that the relational algebra also inherits the negative results about first-order logic: it is undecidable whether there exists some instance on which a given query returns a non-empty answer (satisfiability) and it is undecidable whether two queries are equivalent.

The presentation above assumes that the relational symbols have just arity. This is the so-called *unnamed perspective* [1] and it is convenient for theoretical investigations. The practical descriptions of the relational model, e.g., [4], use the *named perspective*[1] in which a set of *attributes* is fixed and each relation is organized vertically by a finite set of them. For such as relation, a tuple is function from its attributes to constants. The relational algebra operators in the named perspective are similar to the ones above except that attributes are used instead of the integers identifying components of tuples. Complications arise with cartesian product when the two relations have attributes in common. Thus, in the named perspective an additional operator is needed for the *renaming* of a relation's attributes. On the positive side, using attributes leads to an nice generic definition of *natural join*, and operation that generalizes both cartesian product (when attribute sets are disjoint) and intersection (when attribute sets are identical) and which has many elegant properties.

Definition

The relational database model was proposed by Codd in [2] where he assumed that its "data sublanguage" would be based on the predicate calculus (FOL) and where he introduced various algebraic operations on relations. Only in [3] did he introduced the terms *relational algebra* and *relational calculus*.

Later, it became customary to talk about the *domain relational calculus* (detailed below), which is closely related to the syntax of first-order logic and has quantified variables ranging over individual constants, and about the *tuple relational calculus* which is in fact the one given by Codd in [3] and whose variables range over tuples of constants. The two calculi are equivalent, via easy back and forth translations. However, both calculi allow the formulation of *domain dependent* queries which are inappropriate for database languages. While domain independence is undecidable, it is possible to define decidable sublanguages of *safe* queries which are themselves domain independent and such that any domain independent query is equivalent to a safe one.

Key Points

A *relational (database) schema* is a finite first-order vocabulary consisting only of relation symbols. In fact, relational formalisms also permit constants so it is necessary to fix a countably infinite set $\mathbb{D}$ of constants and work with formulae over the first-order vocabulary $\Sigma \cup \mathbb{D}$ where Σ is a relational schema. Also, the set $\mathbb{D}$ is taken as the sole *universe of discourse* for the interpretation of formulae. A *relational (database) instance* for a given schema Σ (a Σ-*instance*) is a first-order structure whose domain, or universe, is $\mathbb{D}$ and in which the relation symbols are interpreted by *finite* relations, while the constants are interpreted as themselves.

For a given schema Σ , a *domain relational calculus query* (a.k.a. first-order query) has the form $\{\langle e_1,\dots,e_n\rangle \mid \varphi\}$ where $e_1,\dots,e_n$ are (not necessarily distinct) variables or constants and φ is a first-order formula over the vocabulary $\Sigma \cup \mathbb{D}$ with equality such that the all free variables of φ occur among $e_1,\dots,e_n$. The *inputs* of the query are the Σ-instances. For each input $\mathcal{I}$, the *output* of the query $q \equiv \{\langle e_1,\dots,e_n\rangle \mid \varphi\}$ is the n-ary relation

$$q(\mathcal{I}) = \{\langle \bar{\mu}(e_1),\dots,\bar{\mu}(e_n)\rangle \mid \\ \textit{assignment } \mu \textit{ such that } \mathcal{I}, \mu \models \varphi\}$$

Let $\mathcal{I}$ be an instance. The *active domain* of $\mathcal{I}$, notation $adom(\mathcal{I})$, is the set of all elements of $\mathbb{D}$ that actually appear in the relations that interpret Σ in $\mathcal{I}$. While $\mathbb{D}$ is infinite, $adom(\mathcal{I})$ is always finite. Moreover, given a query $q \equiv \{\langle e_1,\dots,e_n\rangle \mid \varphi\}$ $adom(q)$ is denoted by the (finite) set of constants that occur in φ or among $e_1,\dots,e_n$. One expects that the instance $\mathcal{I}$ together with the query q completely determines the output $q(\mathcal{I})$. In particular, only the elements in $adom(\mathcal{I}) \cup adom(q)$ can appear in the output. However, this is not the case for all first-order queries. For example, the outputs of $\{x \mid \neg R(x)\}$ or $\{\langle x,y\rangle \mid R(x) \vee S(y)\}$ are in fact infinite! More subtly, the following query is also problematic: $\{x \mid \forall y R(x,y)\}$. Here the output contains only elements from $adom(\mathcal{I})$ but whether a tuple is in the output or not depends on the set of elements that y ranges over. These queries are "dependent on the domain." More precisely, for any instance $\mathcal{I}$ and any D such that $adom(\mathcal{I}) \cup adom(q) \subseteq D \subseteq \mathbb{D}$, denote by $q(\mathcal{I}/D)$ the output of the query q on the input structure obtained by restricting the domain to D. A query q is *domain independent* if for any $\mathcal{I}$ and any D_1,D_2 where $adom(\mathcal{I}) \cup adom(q) \subseteq D_i \subseteq \mathbb{D}, i = 1, 2$ one has $q(\mathcal{I}/D_1) = q(\mathcal{I}/D_2)$. It is generally agreed that in a reasonable *query language*, all the queries should be domain independent. Therefore, general first-order queries do not make a good query language. Worse, it is undecidable whether a first-order query is domain independent [1]. So how does one get a reasonable query language? It is possible (in several ways) to define decidable *safety* restrictions on general first-order formulae such that the safe queries are domain independent and moreover for any domain independent query there exists an equivalent safe query [4,1]. The safety restrictions tend to be complicated and have little practical value. A better idea is the *relational algebra*.

Clearly, not all functions that map instances to relations are meanings of first-order queries. However, the meanings of first-order queries are all *generic*, i.e., invariant under bijective renamings of the constants in $\mathbb{D} \setminus adom(q)$. Conversely, a function f that maps instances to relations and is generic is said to be *first-order definable* (a.k.a. definable in the relational calculus) if there exists a first-order query q whose semantics is f (contrast this with the definability within a given structure described in FIRST-ORDER LOGIC: Semantics). A well-known example of function that is not first-order definable is taking the *transitive closure* of a binary relation.

Codd's *tuple relational calculus* [4,3] differs from the domain relational calculus in that its variables range over tuples and its terms are either constants or of the form $t.k$ where t is a variable and k is a positive integer selecting one of the components of the tuple (for example if t is assigned to (a,b,c) then the meaning of $t.2$ is b).

Relational database

Definition

The *Relational Model* describes data as named relations of labeled values. For example, customer ID's can relate with customer names and addresses in the relational model as *Customer*: {<(*CustomerID*, *11111*), (*Name*, *Pat*), (*Address*, *12 Maple*)>, <(*CustomerID*, *22222*), (*Name*, *Tracy*), (*Address*, *44 Elm*)>}. In this example, there is a name for the relation – *Customer*; label-value pairs – e.g., (*CustomerID*, *11111*), which provide the labeled values; and tuples – e.g., <(*CustomerID*, *11111*), (*Name*, *Pat*), (*Address*, *12 Maple*)>, which are the tuples of the named relation.

Usually, the relations of the relational model are viewed as tables. Figure 1 shows an example of several relations viewed as tables. Together, they constitute a relational database. The first table in Fig. 1 is the table view of the relation described in the previous paragraph.

Besides their structures, tables in the relational model also have constraints. Typical constraints include key constraints (e.g., *CustomerID* values must be unique), type constraints (e.g., *DateOrdered* values must be of type *Date*), and referential integrity constraints (e.g., the *CustomerID* values in table *Order* must refer to existing *CustomerID* values in table *Customer*).

Historical Background

Codd's seminal paper [2] introduced the relational model as a model based on *n*-ary relations. The seminal paper also introduces normal forms for relations and a query language for relations. In perspective, Codd essentially showed how to apply fundamental concepts in set theory to form the relational data model, the foundation of relational databases.

Several textbooks describe the relational data model. Widely read descriptions are in the textbook by Elmasri and Navathe [3] and the textbook by Silberschatz, Korth, and Sudarshan [5], both of which appear in their fifth edition. A few textbooks focus solely on the relational model and treat it from a theoretical perspective [1,4].

Foundations

The relational model can be viewed in several ways: (i) intuitively, (ii) conceptually, (iii) as an implementation description, and (iv) formally. Each view satisfies different user needs.

Intuitive View

Figure 1 shows three tables that together model a simple item-order application. An intuitive description of the relational model has the following characteristics:

- A group of tables stores the data of an application, and together the tables constitute a relational database (e.g., the tables in Fig. 1).

Customer	(CustomerID	Name	Address)
	11111	Pat	12 Maple
	22222	Tracy	44 Elm

Item	(ItemNr	Description)
	X11-222	Ball
	Y33-444	Game
	Z11-555	Book

Order	(OrderNr	CustomerID	ItemNr	DateOrdered	NrOrdered)
	123-1	11111	Y33-444	12 May	1
	114-7	22222	X11-222	10 May	5
	114-7	22222	Y33-444	10 May	5

Relational Model. Figure 1. Sample named relations of labeled data viewed as tables in the relational model.

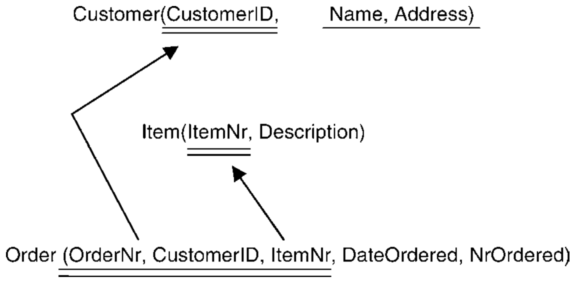
- Each table has a name (e.g., *Customer* for the first table in Fig. 1).
- Each table has labeled column headers (e.g., *CustomerID*, *Name*, and *Address* for the first table in Fig. 1).
- Each table has data for each column header (e.g., *Pat* and *Tracy* for the *Name* column of the first table in Fig. 1).
- The rows of each table constitute a record for the table (e.g., <*11111*, *Pat*, *12 Maple*> for the first row in the first table in Fig. 1).
- Each record asserts a fact that relates the table name, column headers, and record values (e.g., the first row of the first table in Fig. 1 asserts that a *Customer* exists whose *CustomerID* is *11111*, whose *Name* is *Pat*, and whose *Address* is *12 Maple*).
- Each value belongs to a specified domain, a defined set of possible values (e.g., *CustomerID* values are five-digit numbers).
- A key uniquely identifies each record (e.g., in Fig. 1 *CustomerID* uniquely identifies customers and the triple *OrderNr*-*CustomerID*-*ItemNr* uniquely identifies a line item in an order).
- Values link records in different tables (e.g., in Fig. 1 the value *11111* links the customer whose *CustomerID* is *11111* with the orders for that customer by recording the *CustomerID* in the same record as the *OrderNr*).
- For these cross-table linkages to make sense, referenced values must exist (e.g., in Fig. 1 an order record references customers by *CustomerID*'s; thus, any *CustomerID* value recorded in the *Order* relation must exist in the *Customer* relation).

Conceptual View

In a conceptual view of the relational model, the focus is on the conceptual schema of each table. The collection of table schemas for all the tables constitutes the relational database schema.

Figure 2 shows a schematic view of the relational database schema for the database in Fig. 1. A *relational schema* is a named template for a set of *n*-tuples with the following features.

- The schema has a name – *Customer*, for example, in Fig. 2.
- The schema has *n* attribute names, one for each component of the *n*-tuples being represented. The *n* attribute names must all be different so that they form a set. The attribute names are usually just called attributes. In Fig. 2 the *Customer* schema has three attributes: *CustomerID*, *Name*, and *Address*.



Customer(CustomerID, Name, Address)
Item(ItemNr, Description)
Order (OrderNr, CustomerID, ItemNr, DateOrdered, NrOrdered)

Relational Model. Figure 2. Schematic of table headers.

- The schema has key constraints. An attribute (or a set of attributes) whose value (or values) uniquely determine at most one tuple is a key. One of these keys is the primary key; often there is just one key, which therefore is the primary key. In the schematic view, underlines designate keys; double underlines designate primary keys. In the *Customer* schema in Fig. 2, *CustomerID* is the primary key, and the pair *Name*-*Address* is another key.
- The schema has referential integrity constraints. This prevents referencing objects that do not exist. In the example in Fig. 2, the customers referred to in the *Order* table must exist in the *Customer* table, and the items referred to must exist in the *Item* table. Almost always, the referring attribute refers to a key, usually the primary key. Thus, the referring attribute is called a foreign key – a key in another table. When an attribute is a foreign key, the values for the attribute in the *n*-tuples for the table must be a subset of the values for the attribute in the *m*-tuples of the referenced table. Schematically, as Fig. 2 shows, an arrow is drawn from a foreign key to a key. In the example, the customer IDs in the *Order* tuples must be a subset of the customer IDs in the *Customer* tuples, and the item numbers in the order tuples must be a subset of the item numbers in the *Item* tuples.
- Optionally, the schema may also have domain specifications for the attributes. For example, customer IDs may always be five-digit numbers. If so, "*CustomerID*: *five-digitnumber*" could be written as a note in the schematic diagram in Fig. 2.
- Optionally, the schema may also have additional information. Additional constraints or notes may

be written – for example, a note to say that the *DateOrdered* should be initialized as today's date.

Implementation View

The language used to express implementation views is called a Data-Definition Language (DDL). Figure 3 shows an example for the sample customer-order application in Fig. 1. The DDL in Fig. 3 is SQL, a standard commercial database language for specifying, updating, and querying a database.

SQL allows database developers to declare relations for the database and constraints over and among these relations. The SQL syntax provides a way to declare these basic relational-model features as follows.

- A developer declares a schema for a table with a *create table* declaration. The developer must provide a name for the table, and then must declare each of the table's attributes. *Customer* is the name for the first table declared in Fig. 3.
- A developer declares an attribute by giving its name and then listing the constraints that apply to the attribute. The attributes in the *Customer* table declared in Fig. 3 are *CustomerID*, *Name*, and *Address*.
- A developer declares domain constraints for an attribute by giving a type declaration. In Fig. 3 the type declaration for *CustomerID* is *numeric* (5), declaring that customer IDs are 5-digit numbers. SQL provides various types such as numbers, strings, dates, time, and money. Type declarations are unfortunately not uniform across all database systems.
- A developer declares key constraints for an attribute either by stating that it is the *primary key* or that it is *unique* – a key but not the primary key. In Fig. 3 *CustomerID* in the first table schema and *ItemNr* in the second table schema are primary keys.
- A developer declares foreign-key constraints for an attribute with a *references* clause. The *references* clause designates the table in which the referenced attribute is found. When the attribute in the referenced table has the same name as the attribute in the referencing table, this simple declaration is sufficient. If the name is different, then the *references* clause must also include the name of the attribute being referenced. In Fig. 3, *CustomerID* in the *Order* table references *CustomerID* in the *Customer* table, and *ItemNr* references *ItemNr* in the *Item* table. These foreign-key constraints ensure that the *CustomerID* and *ItemNr* values in the *Order* table refer to existing values in the *Customer* and *Order* tables.
- When constraints involve multiple attributes, SQL provides syntax that allows a developer to declare these constraints in a separate entry in a table declaration. Thus, as Fig. 3 shows, a developer can declare that the attribute combination consisting of *Name* and *Address* constitutes a key for the *Customer* table, and that the attribute combination consisting of *OrderNr*, *CustomerID*, and *ItemNr* constitutes the primary key for the *Order* table. The SQL syntax also provides for multiple-attribute foreign keys. Thus, although neither necessary nor even desirable in the example in Fig. 3, the attributes *Name* and *Address* could be added to the *Order* table and a foreign-key constraint could then be declared as *foreign key* (*Name*, *Address*) *referencesCustomer* (*Name*, *Address*).
- Typical additional constraints declarable with SQL include null constraints and check constraints. Null constraints let developers decide whether null values can or cannot appear as values for attributes. Values for primary-key attributes may never be null; other attributes require a *not null* designation (otherwise they can have null values). Check constraints let developers add conditions that must hold. For example, a developer can declare that *NrOrdered* can be neither negative nor zero by adding the constraint *check*($NrOrdered > 0$) to the *NrOrdered* attribute in the *Order* table in Fig. 3.

```
create table Customer (
    CustomerID numeric(5) primary key,
    Name varchar(20),
    Address varchar(25),
    unique (Name, Address)
    );

create table Item (
    ItemNr char(7) primary key,
    Description varchar(50)
    );

create table Order (
    OrderNr varchar(10),
    CustomerID numeric(5) references Customer,
    ItemNr char(7) references Item,
    DateOrdered date,
    NrOrdered smallint,
    primary key (OrderNr, CustomerID, ItemNr ),
    );
```

Relational Model. Figure 3. SQL implementation schemas.

Formal View

The formal view of the relational model captures the essence of a relational schema in terms of mathematical concepts. The definition is based on the concepts of sets, relations, and functions.

A *relational schema* R is a non-empty set of attribute names $R = \{A_1, A_2,...,A_n\}$. Usually an "attribute name" as just called an "attribute." Further, as a notational convenience, when an attribute name is a single letter, the set notation is reduced by dropping the braces, commas, and spaces. Thus, a *relational schema* R is a non-empty set of attributes $R = A_1A_2...A_n$. Each attribute A has a domain, denoted $dom(A)$, which is a set of values.

A relation is always defined with respect to a relational schema. The notation $r(R)$ denotes that relation r is defined with respect to a relational schema R and is read "r is a relation on schema R" or just "r on R" when the context is clear. A *relation* is a set of n-tuples, $\{t_1,..., t_k\}$, where n is $|R|$, the cardinality of R. Let schema R be $A_1A_2...A_n$. Then, an *n-tuplet* for a relation $r(R)$ is a function, from R to the union of domains $D = dom(A_1) \cup dom(A_2) \cup ... \cup dom(A_n)$, with the restriction that $t(A_i) \in dom(A_i)$, $1 <= i <= n$.

A relation is usually written as a table – the table in Fig. 4, for example. In Fig. 4 the relation r has relational schema $R = AB$. To declare the attribute domains, assume $dom(A)$ is $\{a, b, c\}$ and $dom(B)$ is $\{0,...,9\}$. The set of n-tuples for r is the set of discrete functions $\{\{(A, a), (B, 1)\}, \{(A, b), (B, 1)\}, \{(A, b), (B, 2)\}\}$.

Another way to view the relational model formally is to view it as an interpretation in first-order logic. In this view of the relational model each relation r, whose schema has n attributes, is an n-place predicate. An *interpretation* for a first-order language consists of (1) a non-empty domain D of values, which under the unique name assumption each represent themselves, and (2) for each n-place predicate, an assignment of *True* or *False* for each possible substitution of n values from D.

As an example, consider the relation in Fig. 4. To see this relation as an interpretation, let $r(x, y)$ be a two-place predicate. The domain D is {a, b, c, 0, 1, 2, 3, 4, 5, 6, 7, 8, 9}. *True* is assigned to the substitutions $(x = a, y = 1)$, $(x = b, y = 1)$, and $(x = b, y = 2)$ and *False* is assigned to all other substitutions.

r =	A	B
	a	1
	b	1
	b	2

Relational Model. Figure 4. Sample table for illustrating the formal definition.

Most often in this first-order-logic view, the "closed world assumption" is used to conveniently assign *True* and *False* to each substitution. The "closed world assumption" states that whatever is not *True* is *False*, and thus only the *True* facts need to be recorded. This, then, reduces to the equivalent of just giving a table such as the one in Fig. 4 – the rows in the table represents the substitutions for which the predicate is *True* and the only substitutions for which the predicate is *True*.

In a first-order-logic view of the relational model, it is also possible to express constraints. For the table in Fig. 4, for example, the constraint that A should be a key can be expressed by the closed formula $\forall x_1 \forall y_1 \forall x_2 \forall y_2 (r(x_1, y_1) \wedge r(x_2, y_2) \wedge x_1 = x_2 \Rightarrow y_1 = y_2)$. This does not hold for the table in Fig. 4, however, since the second and third tuples have $x_1 = x_2$, but $y_1 \neq y_2$. A check constraint stating that the values in the B column must all be less than 5 can be expressed as $\forall x \, \forall y (r(x, y) \Rightarrow y < 5)$. This constraint does hold in the table in Fig. 4.

For an interpretation for a first-order language, when all the closed formulas hold, the interpretation is said to be a *model*. Database instances in which all constraints hold are therefore models – models of the world they represent.

Key Applications

Relations, stored in relational databases, are widely used in industry. Indeed, their combined usage constitutes a mega-billion-dollar industry. Relational databases range from relatively small databases used as backends to web applications such as "items for sale" to relatively large databases used to store corporate data.

Relationships in Structured Text Retrieval

Mounia Lalmas
Queen Mary, University of London, London, UK

Definition

In structured text retrieval, the relationship between text components may be used in ranking components relative to a given query.

Key Points

In a structured text document, there exists a relationship between the document components. In the context of XML retrieval, the relationships between elements are provided by the logical structure of the XML mark-up. An element, unless it is the root element (the document itself), has a parent element, which itself may have a parent element. Similarly, non-leaf elements have children elements, and so on. Considering relationships between elements appears to be beneficial for XML retrieval. For instance, in a collection of scientific articles, it is reasonable to assume that the "abstract" of an article is a better indicator of what the article is about than a "future work" section in the same article. The challenge in XML retrieval is what types of relationship should be considered, and how this information can be used to score elements according to how relevant they are for a given query. In the contextualization approach [1], considering the "root element – element" relationship to rank an element in addition to the element own content has shown to improve retrieval effectiveness [2,3].

Relative Operating Characteristic

▶ Receiver Operating Characteristic (ROC)

Relative Time

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

Viewing a temporal database as a collection of time-referenced (or timestamped) facts, a time reference in such a database is called *relative* if its value is dependent of the context. For example, this context can be the current time, *now*, or it can be another instant.

Key Points

The relationship between times can be qualitative (before, after, etc.) as well as quantitative (3 days before, 397 years after, etc.). If quantitative, the relationship is specified using a time span.

Examples: "Mary's salary was raised yesterday," "it happened sometime last week," "it happened within 3 days of Easter, 2005" "the Jurassic is sometime after the Triassic," and "the French revolution occurred 397 years after the discovery of America".

The simplest example of a relative timestamp is a period that starts at a time in the past and extends to *now*, such as (2005, *now*). As the clock ticks, this period gets longer.

Exhaustivity; Specificity; Topical-hierarchical relevance

Definition

Relevance is the extent to which some information is pertinent, connected, or applicable to the matter at hand. It represents a key concept in the fields of documentation, information science, and information retrieval.

In information retrieval, the notion of relevance is used in three main contexts. Firstly, an algorithmic relevance score is assigned to a search result (usually a whole document) representing an estimated likelihood of relevance of the search result to a topic of request. This relevance score often determines the order in which search results are presented to the user. Secondly, when the performance of information retrieval systems is tested experimentally, the retrieved documents are assessed for their actual relevance to the topic of request by human assessors (topic experts). A binary relevance scale is typically used to assess the relevance of the search result, where the relevance is restricted to be either zero (when the result is not relevant to the user request) or one (when the result is relevant). Thirdly, in experiments involving users (or in operational settings) a broader notion of relevance is often used, with the aim of expressing the degree to which the retrieved documents are perceived as useful in solving the user's search or work task.

In structured text (XML) retrieval, the search result is typically an XML element, and the relevance score assigned by an XML retrieval system again represents an estimated likelihood of relevance of the search result to the topic of request. However, when the results are subsequently assessed for relevance, the binary relevance scale is not sufficient, primarily due to the hierarchical relationships that exist among the elements in an XML document. Accordingly, in XML retrieval one or more relevance dimensions (each with a multi-graded relevance scale) have been used to assess the relevance of the search result.

Key Points

In traditional information retrieval experiments where whole documents are retrieved, a fairly simple notion of relevance may suffice for most purposes [1]. The challenge in XML retrieval is that the relevance assessments must capture not only whether the retrieved elements are relevant, but also how they relate to one another.

The different relevance definitions for XML retrieval have mainly been investigated by the INitiative for the Evaluation of XML Retrieval (INEX). In 2002, the INEX relevance definition comprised two relevance dimensions named *topical relevance* and *component coverage*. This relevance definition has not been used by INEX since then, partly because of the vague terminology used for the names of the two relevance dimensions, and partly because it has been subsequently shown that the INEX 2002 assessors did not fully comprehend component coverage. In 2003 and 2004, the two INEX relevance dimensions were named Exhaustivity and *Specificity*, which respectively reflect the extent that an element *covers* and is *focussed on* aspects of an information need represented by the topic of request. The two INEX relevance dimensions used four grades to assess the relevance of an element (either its exhaustiveness or its specificity): "none," "marginally," "fairly," and "highly." The grades from each dimension were then combined into a single 10-point relevance scale.

From 2005 onwards, a highlighting assessment procedure is used at INEX to gather relevance assessments for the XML retrieval topics. As a result, the INEX relevance definition was simplified such that only three Exhaustivity values were assigned to a relevant element, while the *Specificity* of the relevant element was measured on a continuous relevance scale and computed automatically as the ratio of highlighted to fully contained text. From 2006 onwards, relevance in INEX is defined only according to the notion of *Specificity*, where the continuous relevance scale is used to assess the relevance of retrieved elements.

The experience of both assessors and users is important when defining relevance in XML retrieval. An interactive track was established at INEX in 2004 to investigate the behavior of users when elements of XML documents (rather than whole documents) are presented as answers. The interactive track was run again at INEX in 2005 and 2006, comprising various tasks and different XML document collections [2].

A *topical-hierarchical* relevance definition was used by the INEX Interactive tracks in 2005 and 2006, which comprises two relevance dimensions and a five-point nominal relevance scale [2,3]. An analysis of the feedback gathered from users participating in the INEX 2005 Interactive track showed that users did not find the five-point scale to be very hard to understand [3]. Furthermore, a mapping between the five-point relevance scale (used by users) and the continuous *Specificity* scale (used by the expert assessors) can easily be established [3], which allows for a better understanding of the definition of relevance in XML retrieval.

Definition

The relevance feedback technique expands the initial query by taking into account relevance assessments on documents by the user. Relevance feedback techniques aim to improve the retrieval accuracy and to better satisfy the user information need.

Key Points

The relevance feedback algorithms may use explicit (e.g., user labels), implicit (e.g., click-through data) or blind (e.g., pseudo relevance documents) relevance information for the feedback purpose.

A classical relevance feedback algorithm based on the Vector Space model was proposed by Rocchio in 1971 [1].

Relevance Feedback for Content-Based Information Retrieval

XIN-JING WANG, LEI ZHANG
Microsoft Research Asia, Beijing, China

Definition

Relevance feedback (RF) [5,2] is an on-line approach which tries to learn the users' intentions on the fly. It leverages users to guide the computers to search for relevant documents. An RF mechanism has two components: a learner and a selector. At every feedback round, the user marks (part of) the images returned by the search engine as *relevant* or *irrelevant*. The learner exploits this information to re-estimate the target of the user. This information is used both quantitatively (retrieving more documents like the relevant documents) and qualitatively (retrieving documents similar to the relevant ones before other documents). With the current estimation of the target, the selector chooses other images that are displayed by the interface of the search engine; then the user is asked to provide feedback on these images during the next round. The process of RF is usually presented as a cycle of activity: an IR system presents a user with a set of retrieved documents; the user indicates those that are relevant; and the system uses this information to produce a modified version of the query. The modified query is then used to retrieve a new set of documents for presentation to the user. This process is known as an iteration of RF which ends until the user is satisfied.

Historical Background

RF is a powerful tool which is traditionally used in text-based information retrieval systems. It was introduced to CBIR during mid-1990s [4], with the intention of bringing the user into the retrieval loop and reducing the "semantic gap" between what queries represent (low-level features) and what the user thinks.

Early approaches assumed the existence of an ideal query point that, if found, would provide the appropriate answer to the user. These approaches belong to the family of query point movement (QPM) methods, for which the task of the learner consists in finding, at every round, a better query point together with a re-weighting of the individual dimensions of the description space.

Recent work on RF often relies on support vector machines (SVM). With SVMs, generally the data is first mapped to a higher-dimensional feature space using a non-linear transform kernel, then is classified in this mapped feature space using maximum margin strategy [6].

Foundations

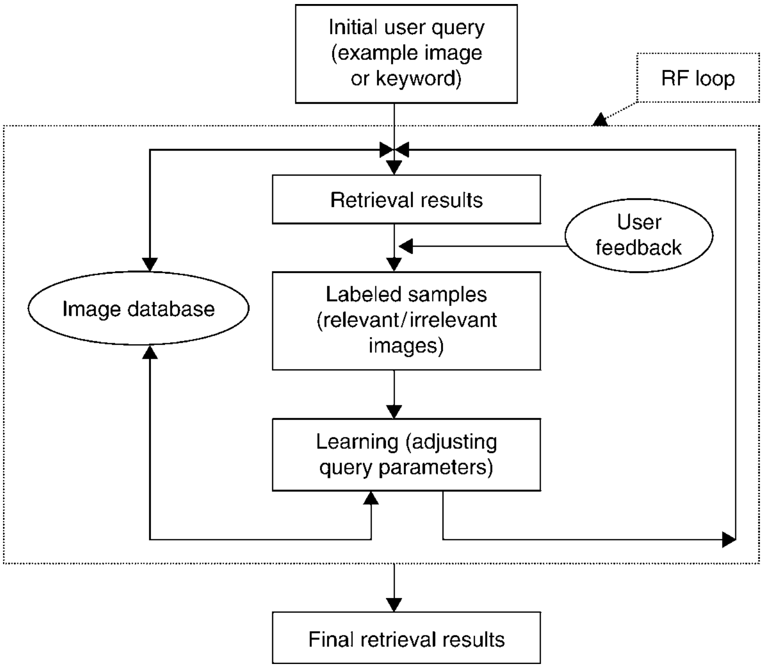
General Assumptions

Before developing relevance feedback mechanisms for content-based image retrieval, it is necessary to understand some general assumptions underlying. According to [2], the assumptions are as the following:

1. The discrimination between relevant and irrelevant images must be possible with the available image descriptors.
2. There are some relatively simple relations between the topology of the description space and the characteristics shared by the images that the user is searching for.
3. Relevant images are a small part of the entire image database.
4. While some of the early work on RF assumed that the user could (and would be willing to) provide a rather rich feedback, including relevance notes for many images, currently the assumption is that this feedback information is scarce. The user will only mark a few relevant images as positive and some very different images as negative.

Figure 1 shows the flowchart of a typical Content-based image retrieval process with relevance feedback [3]. Based on the above general assumptions, a typical scenario for relevance feedback in content-based image retrieval is as below [3,9]:

1. The system provides initial retrieval results given query examples;
2. User judges the above results as to what degree, they are relevant (positive examples) or irrelevant (negative examples) to the query.



Initial user query (example image or keyword)
RF loop
Retrieval results
User feedback
Image database
Labeled samples (relevant/irrelevant images)
Learning (adjusting query parameters)
Final retrieval results

Relevance Feedback for Content-Based Information Retrieval. Figure 1. CBIR with RF.

3. Machine learning algorithm is applied to learn a new ranking model based on the user's feedback. Then go back to (2).

Steps (2)–(3) are repeated till the user is satisfied with the results.

Step (3) is comparably the most important step and different approaches can be used to learn the new query. A few generally adopted approached are introduced in the following.

Re-Weighting Approaches

A typical approach in step (3) is to automatically adjust the weights of low-level features to accommodate the users' need, rather than asking the user to specify the weights as adopted in earlier content-based image retrieval systems. This re-weighting step dynamically updates the weights embedded in the query (not only the weights to different types of low-level features such as color, texture, shape, but also the weights to different components in the same feature vector) to model the high-level concepts and perception subjectivity [4].

Query Point Movement Approaches

Another method is called query-point-movement (QPM) [3]. It improves the estimation of the query point by moving it towards the positive examples and away from the negative examples. A widely adopted query point removing technique is called the Rocchio's formula [1] (see (1) below):

$$Q' = \alpha Q + \beta\left(\frac{1}{N_{R'}} \Sigma_{i \in D'_R} D_i\right) - \gamma\left(\frac{1}{N_{N'}} \Sigma_{i \in D'_N} D_i\right) \quad (1)$$

In (1), Q and Q' are the original query and updated query, respectively, and D'_R and D'_N are sets of the positive and negative images returned by the user, and $N_{R'}$ and $N_{N'}$ are the set sizes. α, β and γ are weights.

Machine Learning Approaches

Machine learning techniques are also widely used. As mentioned previously, support vector machine (SVM) is used to capture the query concept by firstly applying the kernel trick which projects images onto a hyperspace and then separates the relevant images from irrelevant ones using maximum margin strategy. The advantages of adopting SVM are that (i) it has high generalization ability, and (ii) it works for small training sets.

Another step-forward approach is proposed by Tong and Chang [8] called SVM active learning, which was reported to be able to effectively use negative and non-labeled samples, and learn the query concept faster and with better accuracy.

Since manually labeling images is tedious and expensive, training image set is usually very small. This is called the small sample problem. To handle this problem, some researchers proposed boosting methods, e.g., Discriminant-EM (D-EM) [7], which boosts the classifier learnt from the limited labeled training data.

Decision-tree learning methods such as C4.5, ID3 were also used in RF loop to classify the database images into relevant and irrelevant.

Key Applications

Relevance feedback approach can help not only content-based image retrieval, but also applications like image annotation, segmentation, etc.

Future Directions

There are still many research work on adopting relevance feedback to content-based image retrieval [2]:

1. It is better to exploit prior information, such as domain-specific similarity, clustering, context of session, etc., in the RF mechanisms.
2. The impact of the data and of the policy of the user on both the learner and the selector must be addressed.
3. How to scale up RF to handle very large image databases is an important issue which was not extensively studied.

Relevance Feedback for Text Retrieval

Olga Vechtomova
University of Waterloo, Waterloo, ON, Canada

Synonyms

RF

Definition

Relevance feedback (RF) is a process by which the system, having retrieved some documents in response to the user's query, asks the user to assess their relevance to his/her information need. The user's relevance judgements are then used to either adjust the weights of the query terms, or add new terms to the query (query expansion).

Key Points

Searchers may have difficulties in finding the words and phrases (terms) to express their information needs accurately and completely. They may also use different words in the queries than the words used by the authors of documents. On the other hand, searchers tend to know relevant information when they see it. In other words, it may be easier for them to tell which documents are relevant, instead of formulating a detailed query.

A typical relevance feedback process consists of the following steps: the user formulates and submits an initial query to an information retrieval system, which retrieves a ranked list of documents. Documents are typically presented in the ranked list in some surrogate form, for example, as document titles, abstracts, snippets of text, query-biased, or general summaries. The user then reads the contents of the documents that seem promising. After reading each document, the user is expected to indicate to the system whether it is relevant or not to his/her information need. After the user has judged some documents as relevant, either the system, or the user initiate the process of query expansion or query term reweighting. The relevance feedback process can be iterative.

When relevance feedback is used for reweighting, the weights of the user-entered query terms are adjusted based on their occurrence in the judged documents. For example, in the probabilistic model [2], terms are reweighted based on their presence in the documents judged relevant to give a more accurate estimation of the probability of the document's relevance to the query.

Relevance feedback has consistently yielded substantial gains in performance in experimental settings when used for query expansion. In this case, documents judged relevant by the searcher are used as the source of new terms to be added to the query. Many term selection methods have been proposed for query expansion following relevance feedback. The general idea behind all such methods is to select terms that discriminate between relevant and nonrelevant documents, and are useful in retrieving previously unseen relevant documents, e.g., [1,2].

A related process is known as pseudo-relevance or blind feedback (BF). The difference from RF is that instead of asking the user to indicate the relevance of a document, the system assumes that *n* top ranked documents are relevant. An advantage of BF over RF is that it requires less cognitive effort on the part of the user. The performance of BF, however, depends on the performance of the user's query. If the documents in the top ranks are nonrelevant, then query expansion or query term reweighting will deteriorate the performance.

Another technique is implicit relevance feedback (IRF), where the system infers the user's interest in the documents based on his/her behavior with respect to the IR system. A detailed study analyzing the utility of IRF was conducted by [4].

The adoption of relevance feedback in its traditional form by the web search engines has been limited. A study of the use of relevance feedback in the Excite search engine is reported in [3].

Database replication; Data replication protocols; Cluster database replication

Definition

In database replication, each data item has several physical copies, also called replicas, that are distributed over different nodes (sites). In case of full replication, each data item has a copy on each site. In this case, the term replica can also refer to a node hosting a copy of the entire database. *Replica control* is in charge of translating the read and write operations that clients submit on the logical data items into operations on the physical data copies. The goal is to keep a consistent state among all the replicas and to provide a consistent view of the data to the client. Replica control extends concurrency control in order to coordinate the execution of concurrent transactions at different replicas.

Historical Background

Replica control in databases has been studied since the 1980's. Early approaches mostly explored distributed locking and had their main focus on providing high availability and enforcing strong consistency in the advent of site failures and network partitions [3]. In particular, the correctness criterion 1-copy-serializability requires the execution in a replicated system to be equivalent to a serial execution over a non-replicated database.

In the 1990's a seminal paper from Gray et al. [7] criticized existing database replica control protocols providing analytical evidence of the lack of scalability due to the high deadlock probabilities when the number of replicas increases. This paper raised a new wave of research around data replication searching for scalable approaches. Some of these approaches explore weaker levels of consistency (e.g., [2,6,15]). Others aim at maintaining strong levels of consistency while still offering good scalability (e.g., [1,8,11]), sometimes relying on powerful abstractions such as group communication. Snapshot isolation has been explored as a new isolation level [5,9,14] to allow for more concurrency in the replicated system. A considerable effort has been undertaken to optimize those parts of replication control that have a large impact on the performance. Both kernel based replication solutions (e.g., [8,11] as middleware-based replication tools (e.g., [1,9,14] have been developed. Different solutions have been developed for LAN and WAN environments.

All these efforts have led to a wide range of replica control protocols. Which one to choose for a specific scenario depends on the environment and the application requirements. A trade-off between correctness, performance, generality, and potential of scalability is nearly always unavoidable.

Foundations

Replica control algorithms and their implementations can be categorized by a wide range of parameters.

Architecture

One aspect of replica control is *where* the protocol is implemented. It can be implemented within the database what is known as *kernel-based* or *white box* approach (e.g., Postgres-R [8] and the database state machine [11]). A client connects to any database replica which then coordinates with the other replicas. Typically, replica control is tightly coupled with the concurrency control mechanism of the database system.

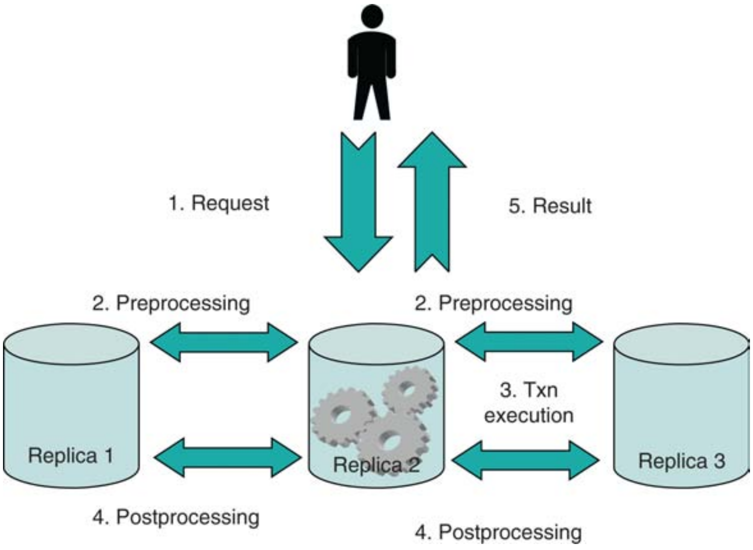
Alternatively, replica control can be implemented outside the database as a *middleware* layer (e.g., [1,9,10,14,15]). Clients connect to the middleware that appears as a database system. The middleware then controls the execution and directs the read and write operations to the individual database replicas. This can be instrumented in two ways: (i) A *black-box approach* uses standard database systems to store the database replicas [1,14,15]; (ii) A *gray-box* approach expects the database system to export some minimal functionality that can be used by the middleware for a more efficient implementation of replica control, e.g., providing the tuples that a transaction has updated so far in form of a writeset [10]. A middleware-based approach typically has its own concurrency control mechanism which might partially depend on the concurrency control of the underlying database systems. There might be a single middleware component (centralized approach), or the middleware might be replicated itself. For example, the middleware could have a backup replica for fault-tolerance. Other approaches have one middleware instance per database replica, and both together build a replication unit.

Replica Control Phases

A replica control protocol has to control the execution of transactions during regular operation (no failure), while failures occur, and during recovery (failed sites with stale data replicas rejoin the system or new sites are added to the system). As shown in Fig. 1, the execution of a transaction during regular operation may have a number of phases (adjusted from [12]):

1. *Client connection*. The client interacts with the database through a client proxy (such as a JDBC or an ODBC driver, or the database client API). The client connects to the replicated database by invoking the client proxy connection method. In the middleware approach, the client connects to the middleware (or one of the middleware instances if they are replicated). In the kernel-based approach, it connects to one of the database replicas. Connecting to a replicated database may require some mechanism to enable *replica discovery* in a transparent way (such as a well-known registry or IP multicast). With this, the client can connect to the database independently of which replicas are currently available. If transparency is required, i.e., the client application should not be aware of replication, then replica discovery can be hidden in the client proxy.
2. *Request submission*. The client submits a request via the client proxy that forwards it to the middleware or database replica to which it is connected.
3. *Pre-processing coordination*. Some protocols require sending requests to all replicas. As a result, the replica to which the client is connected might forward the request to one, some or all replicas. This phase may also be used for other purposes such as distributed concurrency control or load-balancing.
4. *Request processing*. The request is processed by one or more replicas.
5. *Post-processing coordination*. Once a request is processed some protocols perform concurrency control tasks, propagate changes, aggregate results from a quorum, or guarantee atomicity by executing a two-phase commit protocol or another termination protocol.
6. *Result return*. The result of the request is sent back to the client proxy that returns it to the client.

A request can be either an entire transaction (consisting of one or multiple read and write operations), or an operation within a transaction. In the latter case, phases 2–6 may be repeated for each operation and for the final commit of a transaction (as in distributed locking [3]). Moreover, the order of the last two phases could be reversed, i.e., first a result is sent to the client and after that, some coordination takes place.



Replica Control. Figure 1. Replica control phases.

Replica control protocols are implemented in the preprocessing phase, in the post-processing phase or in both of them. five phases are independent of the architecture of the replicated database (replica control is implemented as a middleware layer, either centralized or distributed, or is a kernel based implementation).

Mapping Approaches

One of the main tasks of replica control is to map read and write operations on logical data items to operations on the physical data copies such that replicas eventually converge to the same value and reads see consistent data. With ROWA (read-one-write-all) protocols, read-only operations are processed at a single replica, while write operations are executed at all replicas. The extension to ROWAA (read-one-write-all-available) protocols aims at handling site failures. However, in case of network partitions ROWAA might result in two partitions executing transactions. In contrast, quorum-based replica control can handle both site and network failures. Both read and write operations need to access a quorum of replicas. Any two write quorums, and each read and write quorum have to overlap in at least one replica in order to guarantee data consistency and consistent read operations.

Correctness Criteria

One of the main aspects of replica control is the correctness criterion to be supported. Several, relatively strong correctness criteria extend the notion of isolation from a non-replicated database to a replicated setting. *1-copy correctness* states that the replicated data should appear as one logical non-replicated database. Depending on the isolation level used in the non-replicated execution different correctness criteria can be defined. In a non-replicated database, *serializability* guarantees that the concurrent execution of transactions is equivalent to a serial execution. *1-copy-serializability* [3] (1CS) extends this notion and guarantees that the concurrent execution of transactions over the replicated database is equivalent to a serial execution over a non-replicated database. Non-replicated database systems usually offer more relaxed forms of isolation, such as the ANSI isolation levels or snapshot isolation. 1-copy-snapshot-isolation has been defined as a correctness criterion for a replicated database (e.g., [9], and several replica control protocols consider snapshot isolation (e.g., [5,9,14]).

Weak consistency models do not require 1-copy correctness. Depending on the consistency level, clients might read replicas that are stale, that is, have not yet applied the latest updates, or copies might even diverge if different replicas are allowed to concurrently apply conflicting updates [16]. The degree of staleness or divergence might be bound.

Concurrency Control

In cases where *1-copy* correctness is required, distributed concurrency control is needed to enforce the correctness criteria by restricting the execution of concurrent conflicting transactions. That is, many replica control protocols extend concurrency control to a replicated system.

Concurrency control protocols can be either optimistic or pessimistic. A *pessimistic* approach restricts concurrency to enforce consistency across replicas. The easiest way consists in executing all update transactions sequentially in the same order at all sites, what would provide 1CS trivially. Other protocols increase concurrency by exploiting knowledge about the data that will be accessed. With this information, transactions accessing disjoint data sets can be executed in parallel while those that potentially access common data are executed sequentially. The granularity of data can be at different levels, such as tables, tuples or conflict classes (i.e., data partitions). Pessimistic replica control protocols are implemented in the pre-processing phase. *Optimistic* approaches, in contrast, execute potentially conflicting transactions concurrently. Only when the transaction has completed execution, a validation phase (also known as certification) takes place. It checks whether the transaction being validated conflicts with concurrent transactions. If there is a conflict, some transaction must be aborted. A standard mechanism to guarantee serializability is to abort the validating transaction if the set of data items it read during execution overlaps with the set of data items written by a concurrent transaction that already validated. With snapshot isolation, a transaction fails validation if it wrote some data item that a concurrent, already validated transaction also wrote.

Processing Update Transactions

Another important feature of replica control is how update transactions are processed. With *symmetric update processing* each update transaction is fully executed at all replicas. In contrast, *asymmetric update* *processing* executes update transactions at one site (or subset of sites) and then, the resulting changes (known as *writeset*) are propagated to the rest of the replicas. Some protocols [1] lie in between, being symmetric at the statement level, but asymmetric at the transaction level. That is, if an update transaction contains both write and read statements, the read statements are executed at one site while write statements are executed at all sites. Asymmetric update processing has typically much less overhead than symmetric update processing and thus, allows for better scalability in update-intensive environments [8].

Timepoint of Synchronization

As described earlier, a client typically connects to one replica and submits its transactions to this replica. An important question is *when* this replica coordinates with other replicas to guarantee data consistency. In *eager* (aka synchronous) protocols, coordination takes place before the transaction commits locally. Typically, this means that the replica sends the changes (asymmetric processing) or the operation request (symmetric processing) and the concurrency control component decides on a serialization order for this transaction before it commits. In contrast, with *lazy replication* (aka asynchronous), updates are asynchronously propagated after the transaction commits. Lazy replication usually applies asymmetric processing. The propagation can be done immediately after the commit, periodically, or be triggered by some weak consistency criteria such as freshness. With lazy replication, transaction execution has usually no preprocessing coordination phase, and phases five and six are switched. This means, the results are first returned to the client, and then, the post-processing phase is run. Eager replication usually results in longer client response times since communication is involved but can more easily provide strong consistency.

Who Executes Transactions

Primary copy replication requires that all update transactions are executed at a given site (the primary) (e.g., [5,14,15]). The primary propagates the changes to the other replicas (secondary replicas). Secondaries are only allowed to execute read-only transactions themselves. In order to be able to forward read-only transactions to secondaries and update transactions to the primary, the system must be aware at the start time of a transaction whether it is read-only or not (e.g., through a tagging mechanism). If update transactions can be executed at any site, the replica control protocol follows an *update everywhere* approach (also referred to as *update anywhere*). An alternative to primary copy replication and update everywhere is based on partitioning the database items such that each partition has a primary, but different partitions may have different primaries (e.g., [4,10]). This avoids that the primary becomes a bottleneck under write-intensive workloads. However, it is only suitable for applications where the database can be partitioned such that each transaction only accesses data of one partition.

Degree of Replication

A further dimension is the *degree of replication*. In *full replication* every data item is replicated at each site. At the other extreme, in a *distributed database* each data item is stored at only one site and there is no replication. In partial replication each data item is replicated at a subset of nodes.

Coordination Steps

Another aspect considers the number of coordination steps, and thus, the number of message rounds, per transactions. Some protocols use a constant number of message rounds, while others require a linear number of message rounds, depending on the number of (write) operations within the transaction (e.g., in distributed locking). In the former case, the pre-processing and/or the post-processing phases are executed once for each transaction. In the latter case, these phases are executed per (write) operation.

Furthermore, some replica control protocols require a coordination protocol among the replicas in order to decide the outcome of a transaction (*voting termination*), similar to a distributed commit protocol. In others, each replica decides by itself deterministically about the outcome of a transaction (*non-voting termination*).

In early eager approaches, atomicity was achieved by running a commit protocol, such as two-phase-commit, at the end of transaction. This was not only time-consuming by itself but also required that all sites had completely executed the transaction before the transaction was committed at any site. In more recent approaches, atomicity is often achieved by other means such as reliable multicast that provides the required failure atomicity. Even in eager approaches where the participating sites agree on a serialization order before the transaction commits at any site, this allows the user to receive the commit outcome before the transaction is actually executed at all replicas.

Restrictions

Another point to consider when analyzing replica control protocols are the possible constraints they set on the kind of transactions that are supported. Some protocols only allow single statement transactions (known as auto-commit mode in JDBC). Other protocols allow several statements within a transaction, but they have to be known at the beginning of the transaction. This is typically implemented using stored procedures (or prepared statements in JDBC) [1,10]. The more general protocols do not have any restriction on the number of statements a transaction contains [8,9,14].

Other Aspects

Replica control also needs to work correctly in the case of failures and when new or repaired replicas are added to the system. Replica control can also be affected by the implementation of self-* properties or autonomic behavior.

Another crucial feature of replica control is the environment for which it is designed. Many approaches target local area networks (LAN) where the bandwidth is high and partitions are rare. Some approaches have explored how to attain acceptable response times in wide area networks (WANs). Other kinds of networks have also been explored such as mobile networks and peer-to-peer networks. There are specific entries for all them.

Key Applications

Replica control is always needed if replicated data is updated. In particular, in database replication, where updates occur in the context of transactions, replica control is also needed to guarantee transactional correctness.

Future Directions

An important future direction is to combine replica control with modern multi-tier and service-oriented architectures. Providing high availability and scalability for a multi-tier architecture is a non-trivial task. It implies replicating all the tiers to avoid single points of failure and performance bottlenecks. In this setting, guaranteeing consistency is very challenging, especially in the face of failures. Some initial work has already been started in this direction [13] and future developments are expected along this line.

Replica Freshness

Alan Fekete
University of Sydney, Sydney, NSW, Australia

Divergence control; Freshness control; Incoherency bounds

Definition

In a distributed system, information is often *replicated* with copies of the same data stored on several sites. Ideally, all copies would be kept identical, but doing this imposes a performance penalty. Many system designs allow replicas to lag behind the latest value. For some applications, it is acceptable to use out-of-date copies, provided they are not too far from the true, current value. *Freshness* refers to a measure of the difference between a replica and the current value.

Historical Background

The tradeoff between consistency and performance or availability is an old theme in distributed computing. In the database community, many researchers worked on ideas connected with explicitly allowing some discrepancy between replicas during the late 1980s and early 1990s. Early papers identified many of the diverse freshness measures discussed here, from groups at Princeton, Bellcore and Stanford [1,10,11]. A mixed model that integrated freshness limits of several kinds was Pu's epsilon-serializability [6,7]. TACT is a more recent mixed model, introduced by Yu and Vahdat [12]. Much of the research since the 1990s focused on optimization decisions to improve the performance of a system with slightly stale replicas. Many different system assumptions and metrics to optimize have been considered. Among influential papers are [4,5,9]. Research continues on defining different models which bound the staleness of replicas. Unlike earlier work, the focus has recently been on setting bounds which relate to the clients' view of divergence, rather than to the underlying state of the replicas. Röhm et al. designed a system with transaction-level client-defined staleness limits for read-only transactions, within the framework of 1-copy serializability [8]. Guo et al. suggested SQL extensions to express query-specific limits on the perceived staleness and inter-object drift [3], and later developed a theory to express these constraints even when stale reads are allowed within update transactions [2].

Foundations

Consider a distributed system, where information is stored at multiple sites, connected by a communications network. If several sites all store values that are intended to represent the same information in the real world, one can call these copies or *replicas*; it is usual to write x^A to represent the replica at site A of the logical data item x. At any instant, the true or current value of the logical item is the value assigned to x in the most recent non-aborted update of x. The ideal, of course, has this value stored in every replica, always (or at least, at any instant when a read operation can occur). This is possible using traditional eager replication (see entry on Traditional Concurrency Control for Replicated Databases). However, many systems prefer to propagate updates lazily, and to allow replicas or cached copies that are not completely up-to-date, as described in the entry on Optimistic Replication and Resolution. While there are many applications that can tolerate data that is not current, there are usually limits on the application's tolerance for inaccuracy. Thus many system designs allow for a bound to be placed on how far a replica can diverge from the true value; such a bound expresses a constraint on the *freshness* of the replica. This entry describes some of the main ideas that have been proposed to quantify the freshness of replicas.

The focus here is on the properties that define what is allowed, rather than on implementation details that control how these bounds are enforced. For example, some system designs have a single master replica, which always has the true value, while in others the most up-to-date information is sometimes found in one copy and sometimes in another. However, the definitions can be stated without concern for this issue. Another axis of variation is whether the bounds have to apply always, or only when a replica is used in a query. Some papers give a numeric value for freshness or precision (which should be high), others measure staleness or imprecision. This paper uses measures where a low value is better, so zero means that the replica is completely up-to-date.

Value-Based Divergence

Suppose the logical data item comes from a numeric domain such as real numbers. In that case, one can just use the metric on the values themselves. For example, if the true current value is 10.5 and a replica has the value 9.2, then the divergence of that replica is measured as 1.3. In some proposals, the interest is in the value-based divergence between two replicas, even if neither has the current true value. If each replica is within δ of the true value, the difference between any pair of replicas is bounded above by 2δ.

Delay-Based Staleness

For some applications, a useful measure of tolerance for imprecise data is to quantify how recently the data was correct. For example, when a person moves house, the post-office will often redirect mail that had the former address, for a short period. Thus staleness can be measured by how long the replica has to wait before learning of an update that has occurred. For example, suppose the true value was 9.2 until time 100, and which time the value was updated to 10.5; if at time 103 a replica still contains 9.2, one says it is stale by 3 time units. Where the values are representing a real-world quantity, and the quantity can't change by more than v units each time interval, then a bound of δ on the delay implies a bound of $v\delta$ on the value divergence.

Many system designs can't determine, at a replica, how stale it is. Instead they keep a timestamp with each value, indicating when that update instruction was first applied. If they bound the difference between the timestamp and the current time, they also bound the staleness. Suppose one wants to keep delay below 5 time units; one can say that this holds at time 103, if the replica contains a value whose timestamp is 98 or greater. However, the argument does not work in reverse: even at time 103, a replica with timestamp 93 might be stale by less than $103 - 93 = 10$, depending on when the next update occurred after time 93. One says that a value has a valid period, which is a half-closed interval from the time at which the value first appeared in an update, until just before the next update occurred which changed the value.

Measures of Missed Updates

In many system designs, only a subset of updates are propagated to the replica (in order to save bandwidth). This motivates a definition where one measures how many updates occurred on the logical item, without being recorded (yet) at the replica. For example, suppose the logical item is updated from 9.2 to 10.5 at time 100, and then to 10.1 at time 102, and then to 9.6 at time 104. A replica with value 9.2 at time 103 has missed 2 updates that have occurred by that time. This definition can be related to a delay-based measure if the updates come periodically, as is common for sensor readings.

Inter-Object Consistency Drift

When a query reads several logical objects, one might bound the drift between the versions seen in the two reads. For example, if a query examines copies of the temperature and humidity from a sensor, the user might care that the two measurements were taken at almost the same time, because the humidity affects the accuracy of the thermometer. Suppose a replica x^A contains a value whose valid period is the interval $[T,U)$ and y^B contains a value valid in the interval $[V, W)$. Measure the drift between the replicas, as the smallest separation between the valid intervals; this is zero if $[T,U) \cap [V,W) \neq ø$, and otherwise it is $min(|V - U|, |T - W|)$. A drift bound of zero is called a "snapshot" condition, as all the data examined must come from a common state of the database.

Transaction Semantics

Often, each update and each query is a separate operation. However, several updates or several queries can be placed in a single transaction. In 1-copy serializability (q.v.), all the operations in a transaction have to appear to take place together, but a transaction with reads may be serialized in the past, and so one might desire a common maximum delay for all the reads done in that transaction. A different approach is taken in epsilon-serializability. Here one ascribes a numeric measure to each of the various situations of divergence between the value read and the correct value, and adds up the divergence measure seen in each read, there is then a bound on the total divergence accumulated during the reads in a given query transaction.

Mixed Measures

Each of the definitions of freshness seems to work for some applications but not for others. Thus the TACT model has separate bounds of each measure which must be applied to all the logical data items within a user-specified grouping of items. For example, a particular logical item might require that whenever it is read, it is separated from the true value by no more than 1.5 in numeric value, it is stale by no more than 10 in delay, and it must be missing no more than 3 updates done at the master.

Key Applications

The commercial database platforms generally offer best-effort update propagation, rather than giving applications guaranteed bounds on freshness. Thus the properties described here are usually found in research prototypes or special-purpose data management, for example in cache management for web content or sensor data.

Future Directions

The ideas of replica freshness reappear in new domains, where applications might be able to tolerate some imprecision and where there is a high cost to keeping data up-to-date. For example, somewhat stale data might be used in a sensor network, or delivered in dynamic web page content. Many of these ideas are being generalized, in a broad research agenda that deals with uncertain or imprecise data.

Replicated Database Concurrency Control

Bettina Kemme
McGill University, Montreal, QC, Canada

Replica and concurrency control

Definition

In a replicated database, there exist several database servers each of them maintaining a (partial) copy of the database. Thus, each logical data item of the database has several physical copies or replicas. As transactions submit their read and write operations on the logical data items, the *replica control* component of the replicated system translates them into operations on the physical data copies. The *concurrency control component* of the replicated system controls the execution order of these operations such that the global execution obeys the desired correctness criteria. For a tightly coupled system with strong consistency requirements, 1-copy-serializability is the standard correctness criterion, requiring that the concurrent execution of transactions on the replicated data has to be equivalent to the serial execution of these transactions over a logical copy of the database. Thus, a global concurrency control strategy is needed. For loosely coupled systems with weak consistency requirements, each database server uses its local concurrency control mechanism. Inconsistencies are only resolved later via reconciliation techniques.

Key Points

Global concurrency control strategies for replicated databases can be centralized or distributed. In a centralized solution, there is a single or main concurrency control module which could be installed on one of the database servers or in an independent component (e.g., a middleware layer between clients and the individual database servers). This single scheduler decides on the global execution order. Using this architecture, standard concurrency control methods found in non-replicated database systems can be easily extended to the replicated environment. However, the single module becomes a single point of failure, and might lead to considerable message overhead. In a distributed solution, each database server has its own concurrency control component, and the different components have to work in a coordinated fashion in order to guarantee the correct global execution order.

The standard strict two-phase-locking (2PL) protocol can be extended very easily to a replicated system. In a centralized solution, there is no real difference to a non-replicated database. Before an operation on a data item is issued, a lock for this data item has to be acquired and all locks are released at commit time. In a distributed solution, each local lock manager performs strict 2PL. The difference is that locks are now set on the physical copies and not on the logical data item. As many replica control algorithms follow the read-one-copy/write-all-copies strategy it means that a write operation on a data item will lead to write locks on all database servers holding a copy of the data item. With this, a distributed deadlock might occur that involves only a single data item.

Optimistic concurrency control mechanisms are attractive in a replicated database system since they allow a transaction to be executed first locally at only one database server. Only at commit time, the modified data items are propagated to the other replicas and a validation phase checks whether a proper global execution order can be found. This keeps the communication overhead low.

In general, communication is an important issue in a replicated database. An option is to take advantage of advanced communication primitives, e.g., multicast protocols that provide delivery guarantees and a global total order of all messages. As all available database servers receive all messages in the same total order, this order can be used as a guideline to determine at each site locally the very same global serialization order.

Data Replication; Duplication

Definition

Replication (or data replication) is the process to make copy of a collection of data. Copied data made by replication is referred as replica (or data replica).

Replication can be categorized by data type to be copied. Most DBMSs support database replication for high availability or parallel transaction processing. Some filesystems support filesystem replication for high availability or workload distribution. Filesystem replication is commonly used in distributed filesystems. Volume replication can be processed by Logical Volume Manager, Filesystem or Storage system.

Most replication techniques try to keep replicas consistent and updated so that in case of system failures, the replica can be used to recover from the failure with minimal data loss.

Key Points

During data replication, original data is usually copied on an ongoing basis. The goal of this data replication is to provide high availability. There are two types of data replication in terms of data copy method: synchronous and asynchronous. Synchronous replication guarantees, "zero data loss" by means of atomic write operations (i.e., a write either completes on both sides or not at all). A write is not complete until there is acknowledgment for both original and replica. Most applications wait for a write transaction to complete before proceeding with further work, so synchronous replication may lower overall performance considerably.

In asynchronous replication, a write is complete as soon as the original is updated. The replica is usually updated after a small lag. This decreases write costs, but "zero data loss" is not guaranteed.

Data replication can be categorized by the layer of doing it. In case of Server-based replication, some entity (e.g., DBMS, Filesystem, Logical Volume Manager, and Application) in a server performs replication. Most Database replication and filesystem replication falls into this category.

Appliance-based replication is another category. Some appliance in a network connecting servers and storage systems makes replication. Most storage virtualization appliances have volume replication functions. File virtualization appliances may provide filesystem replication.

Storage-based replication is done by storage system. Block storage can provide volume replication and file storage such as NAS can provide filesystem replication.

Replication Based on Group Communication

FERNANDO PEDONE
University of Lugano, Lugano, Switzerland

Definition

Database replication based on group communication encompasses protocols that implement database replication using the primitives available in group communication systems. Most commonly, these replication protocols ensure strong data consistency (e.g., serializability, snapshot isolation), which translates into ordering requirements on the data operations. Protocols not based on group communication primitives should implement this ordering from scratch, typically in some ad hoc manner. Implementing ordering guarantees is not an easy task, notably in the presence of failures since it is usually difficult to determine the state a failed site was in when the crash occurred. Group communication primitives offer message reliability and ordering properties that simplify the design of replication protocols. As a consequence, database replication protocols based on group communication are usually highly modular.

Historical Background

Group communication was introduced in the 1980s. The Isis system pioneered work on group communication primitives that provide strong guarantees in the presence of failures [4], a concept that builds on the earlier abstraction of process groups to support one-to-many communication. Database replication based on group communication was introduced in the 1990s.

To understand how group communication influenced database replication, the first step is to provide a brief account of how group communication is related to replication in distributed systems in general. Many fault-tolerant distributed systems aiming at strong consistency are implemented according to the state-machine replication approach [10,15], sometimes called active replication. (Notice that while [15] extends state-machine replication to the context of failures, the concept was introduced in [10] for environments in which failures could not occur.) Essentially, the state-machine replication approach can be decomposed into two requirements, which orchestrate the dissemination of operations to replicas:

Agreement. Every non-faulty replica receives every operation.
Order. Every non-faulty replica processes the operations it receives in the same relative order.

Assuming that each replica can be made to behave as a state machine, when provided with the same operations in the same order, all replicas will produce the same results. The problem is then how to ensure the agreement and order properties. It turns out that group communication systems provide primitives that guarantee these properties. Thus, it comes perhaps as no surprise that group communication has become a basic building block for implementing state-machine replication, and fault-tolerant distributed systems.

Two observations from the mid-1990s help understand how group communication came into play in database replication. First, it was pointed out that transactions in replicated databases share common properties with group communication primitives [14]. For example, transaction isolation translates into ordering requirements among requests, a property typically available in group communication systems. Likewise, transaction atomicity is usually referred to as agreement in group communication systems. Second, it was shown that mechanisms typically used to provide strong consistency in distributed databases are inappropriate in replicated scenarios. For example, distributed two-phase locking has an expected deadlock rate that grows with the third power of the number of replicas [7]. The underlying argument from these results follows from the fact that out of order requests may get entangled, increasing the chances of deadlocks, a shortcoming that group communication primitives can easily solve.

As a consequence, researchers started looking at database replication protocols based on primitives that provide guarantees similar to those found in transactional systems.

Foundations

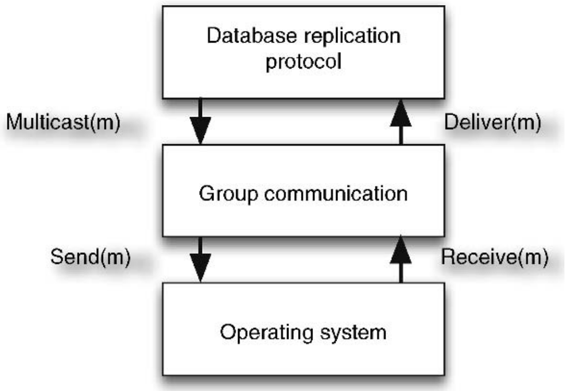
How can group communication help design database replication protocols? To answer this question group communication primitives are discussed and then a framework is presented to reason about the usefulness of these primitives in database replication. A recurrent approach to replication based on group communication is the deferred update model, which is presented next. In this discussion, unless stated otherwise, servers are assumed to have a full copy of the database.

Group Communication Primitives

The abstraction of groups (of servers) acts as a logical addressing mechanism in a replicated system, allowing the degree of replication and the identity of the individual servers to be ignored. For example, a group can abstractly represent the servers that replicate the database. Moreover, group communication primitives provide one-to-many communication with various powerful semantics, and hide much of the complexity of maintaining the consistency of the system and handling failures of replicated servers.

Group communication is usually characterized by two primitives: multicast(m, g) allows a message m to be forwarded to the members of group g; the message is passed to the application by means of the deliver (m) primitive. Multicast and deliver are implemented on top of simpler communication primitives (i.e., providing weaker guarantees). A multicast message is delivered to the application after the members of the group the message is addressed to have interacted, possibly exchanging point-to-point messages, to implement the properties ensured by the group communication (see Fig. 1).

Group communication primitives typically provide *message atomicity*: if a server in g delivers m, then every



Replication Based on Group Communication. Figure 1. Group communication primitives.

non-faulty server in g should also deliver m. Notice that if a server is down when a message m is multicast, it will not be able to deliver m (i.e., the server is faulty). If the server later recovers, it should deliver all messages it has missed. This is done using a state transfer mechanism, by which a recovering server receives the missed state from operational severs before it resumes its execution. State transfer is transparent to the application and implemented by the group communication system.

Another property typically ensured by group communication primitives concerns *message ordering*. Two such properties are *first-in-first-out (FIFO)* and *total order*. FIFO ensures that messages multicast by the same sender are delivered in the order they are multicast, that is, if a server executes multicast(m, g) followed by multicast(m', g), all non-faulty servers in g will deliver m first and then m'. Total order guarantees that all messages, regardless of the sender, are delivered in the same order by all non-faulty servers. If server s executes multicast(m, g) and server s' executes multicast(m', g), then m and m' should be delivered in the same order. Notice that FIFO is not a special case of total order. With total order, if a server multicasts m followed by m', the destinations can deliver m' before m, as long as they all deliver m and m' in the same order. Both properties can be combined in a *FIFO total order* property.

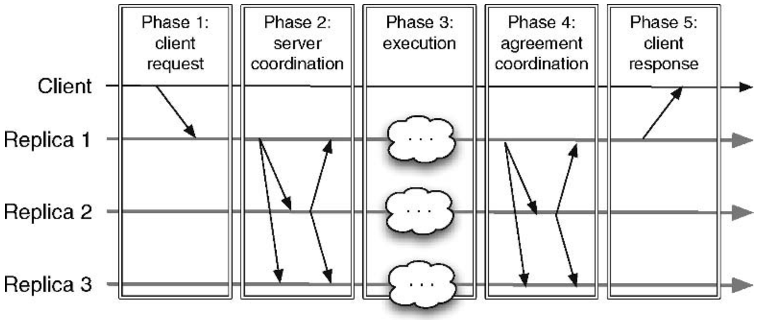
Groups can be *static* or *dynamic*. Static groups do not change their membership during the execution, although members can crash and later recover. Dynamic groups adapt the membership according to the state of their members, operational or crashed. Dynamic groups use a sequence of views, $v_0(g), v_1(g), \ldots, v_i(g), \ldots$, to manage membership. Each view $v_i(g)$ defines the composition of g at some time t, i.e., the members of the group that are operational at time t. Whenever a server in some view $v_i(g)$ is suspected to have crashed, or some server wants to join, a new view $v_{i+1}(g)$ is installed, which reflects the membership change.

Group communication primitives for dynamic groups can guarantee properties relating views to multicast messages. One such property is *sending view delivery*, according to which a message can only be delivered in the context of the view in which it was multicast. This means that if a server multicasts message m while in view $v_i(g)$, then m can only be delivered before view $v_{i+1}(g)$ is installed.

The following sections use two multicast primitives with different properties: abcast(m, g) ensures message atomicity and total order in the context of static groups; vscast(m, g) assumes dynamic groups and guarantees message atomicity, FIFO ordering, and sending view delivery properties. In both cases, messages are delivered to the application using deliver(m).

A Functional Model for Database Replication

Replication protocols can be generically decomposed into five phases, as shown in Fig. 2 [16]. Some protocols may skip some phases, while others may apply some of the phases several times during the execution of transactions. In Phase 1 the client contacts one or more database replicas to submit its requests. Phase 2 involves coordination among servers before executing requests. (Notice that message exchanges in Fig. 2 are illustrative only; different communication protocols may present different message patterns.) The actual execution of a request takes place in Phase 3; one or more servers may be involved in the execution of the operation. In Phase 4 servers agree on the result of the execution, usually to ensure atomicity, and in Phase 5 one or more servers send the result to the client. There



Replication Based on Group Communication. Figure 2. A functional model for database replication.

are basically two parts in which group communication primitives can help: during *server coordinaton* (Phase 2) and *agreement coordination* (Phase 4).

Database replication protocols can be *eager* or *lazy*, according to when update propagation takes place; and *update everywhere* or *primary copy*, according to who performs the updates. Group communication has traditionally been used by eager protocols, both in the case of update everywhere and primary copy. Some eager approaches are briefly reviewed next; a more detailed account can be found in [16].

Distributed two-phase locking (D2PL) is a traditional mechanism to coordinate servers during transaction execution. In replicated scenarios, implementing D2PL with point-to-point communication may lead to many distributed deadlocks [7]. If lock requests are propagated to servers using abcast, however, total order is ensured, and the probability of deadlocks is reduced [2]. In such a protocol, the client submits its requests to one database server (Phase 1) which abcasts them to all servers (Phase 2). Upon delivering the request, servers should make sure that conflicting locks are obtained in a consistent manner (Phase 3). Once the servers have executed the operation they send the response to the client (Phase 5). Commit and abort requests are processed like any other operation and so there is no need for agreement coordination (Phase 4). Notice that Phases 1–3,5 may be executed multiple times, once per request. If transactions can be predefined (e.g., storage procedures), then they can be abcast to all servers as a single request, and then Phases 1–3,5 are executed only once per transaction [3,11].

The deferred update approach is another form of eager update-everywhere replication mechanism based on group communication. In this case, the client selects one database server and submits all its requests to this server, without communicating with other servers (Phase 1). During the execution of the transaction, there is no synchronization among servers (i.e., no Phase 2), and only the selected server executes the transaction (Phase 3). Read-only transactions are committed locally by the selected server. Update transactions are propagated to all servers at commit time using abcast. The delivery of a terminating update transaction triggers a certification procedure used to ensure consistency. If the transaction passes the certification test its updates are committed against the database (Phase 4). Only then the reply is sent to the client (Phase 5). Several group communication-based replication protocols follow this approach, which is discussed in more detail in the next section.

Eager primary copy replication can also take advantage of group communication primitives. In this case clients interact only with the primary copy during the execution of the transactions (Phase 1). Therefore, there is no Phase 2. After the primary executes a request it sends the result to the client (Phase 3 executed by the primary only). Several requests from the client may be executed against the primary copy until commit is requested, at which point the primary communicates the new database state (e.g., redo logs) to the secondary copies (Phase 4). The secondaries apply the modifications to their local database. Communication between the primary and the secondaries is through vscast. FIFO ordering ensures that updates from the primary are received in the order they are sent. Sending view delivery guarantees correct execution in case of failure of the primary. For example, if the primary fails before all secondaries receive the updates for a certain request and another replica takes over as new primary, vscast ensures that updates sent by the new primary will be properly ordered with regard to the updates sent by the faulty primary.

Deferred Update Database Replication Protocols

Database replication protocols based on the deferred update technique, sometimes called certification-based protocols, are optimistic in that transactions execute on a single server without synchronization among servers. Abcast ensures that at termination transactions are delivered in the same order by all servers. The total order property together with a deterministic certification test guarantee that all servers agree on which transactions should be committed and which ones should be aborted.

The precise way in which the certification test is implemented and the information needed to implement it depend on the consistency criterion. Two typical consistency criteria are serializability and snapshot isolation. Serializability specifies that a concurrent execution of transactions in a replicated setting should be equivalent to a serial execution of the same transactions using a single replica. With snapshot isolation, transactions obtain at the beginning of their execution a “snapshot” of the database reflecting previously committed transactions; a transaction can commit as long as its writes do not intersect with the writes of the transactions that committed since the snapshot was taken.

The certification test may require transaction readsets and writesets. Transaction readsets and writesets refer to the data items the transaction reads and writes during its execution (e.g., the primary keys of the rows read or written). Let $RS(T)$ and $WS(T)$ denote, respectively, the readset and writeset of transaction T, and let $CC(T)$ be the set of transactions that executed concurrently with T. There are different ways to define the concurrent transactions set; typically, the set contains the transactions that committed after T started its execution, but before T itself committed. The propositions below abstractly define the conditions for committing a transaction according to serializability and snapshot isolation, respectively.

Serializability. T can commit if and only if $\forall T' \in CC(T) : RS(T) \cap WS(T') = \emptyset$
Snapshot isolation. T can commit if and only if $\forall T' \in CC(T) : WS(T) \cap WS(T') = \emptyset$

There are two general ways in which certification can be implemented in order to ensure serializability: with and without explicit information about transaction readsets. If information about data items read by the transaction is available, both the readsets and the writesets, together with the actual updates, are abcast to all servers as part of the termination of T. Upon delivering this message, each server individually evaluates the condition for serializability and determines whether T can be committed. When certifying T, each server builds $CC(T)$ based on transactions previously delivered, and in doing so, the test can be implemented deterministically, guaranteeing that all servers reach the same decision concerning committing transactions [12].

Certification without transaction readsets can be performed with an additional communication step among servers [9]. In the following, read operations are assumed to be performed before write operations. When a transaction requests to commit, only its writeset and the actual updates are abcast to all servers. After delivering the message, the server that executed the read operations tries to execute all write operations of the terminating transaction. Ongoing local transactions with read locks that conflict with the terminating transaction's write locks require special care: If the transaction has not been abcast yet, it is simply locally aborted; otherwise an abort message is abcast to all servers. Once the terminating transaction has acquired all its write locks, a commit message is abcast to all servers, which upon delivery commit the transaction.

Snapshot isolation can be implemented with a single round of messages (i.e., one abcast per transaction only) without readsets [9]. At commit time the writeset and the updates of a committing transaction are abcast to all servers. Each server executes the certification test and decides individually whether the transaction can commit or not.

Key Applications

Database replication protocols based on group communication are usually used to guarantee high availability for OLTP applications. Some of the existing protocols have been proved to provide good scalability under read-intensive workloads. Given the frequent assumption that each participating server should have a full copy of the database (i.e., full replication), scalability under write-intesive workloads is limited.

Future Directions

Replication based on group communication has been a hot topic of research in the past years. Several protocols have been proposed, a few implemented, and some made available for free download. While the main tradeoffs are known now, some problems are still open.

One open problem concerns how to structure group communication-based database replication protocols. According to whether changes in the database engine are required or not, there are two possibilities: kernel- and middleware-based architectures. Kernel-based protocols (e.g., [12,9]) take advantage of internal components of the database to increase performance in terms of throughput, scalability, and response time. For the sake of portability and heterogeneity, however, replication protocols should be independent of the underlying database management system. Even if the database internals are accessible, modifying them is usually a complex operation. As a consequence, middleware-based database replication (e.g., [6,13]) has received much attention in the last years. Such solutions can be maintained independently of the database engine, and can potentially be used in heterogeneous settings. Kernel-based protocols, on the other side, have more information about the data accessed by the transactions (e.g., readsets), which may result in more concurrency or less abort rate or both. In order to make its complexity more manageable, some efforts have tried to standardize kernel-based protocols [1].

Another problem subject to further investigation is partial replication. Full replication protocols have limited scalability under update-intensive workloads [8]. This is not a specific limitation of existing protocols, but an inherent characteristic of fully replicating the database on each server. Each new server added to a fully replicated system allows more clients to connect and submit transactions. If such transactions update the database, they will add load to every individual server. Partial replication does not suffer from the same problem since the degree of replication of each data item can be controlled. Thus, servers can be added to the system, improving the performance of data mostly read and without increasing the load of existing servers. It is not obvious how to implement partial replication in the context of group communication though and few proposals have considered it so far (e.g., [5]).

Replication for High Availability

Bettina Kemme
McGill University, Montreal, QC, Canada

Synonyms

Fault-tolerance; Backup mechanisms

Definition

Replication is a common mechanism to increase the availability of a data service. The idea is to have several copies of the database, each of them installed on a different site (machine). Using replication, the data remains available as long as one site is running and accessible. Fault-tolerance is related to availability. A system is considered fault-tolerant if it continues to work correctly despite the failure of individual components. Replicating data and processes over several sites, the failure of any individual site can be masked since the tasks executed by the failed site can be transferred to one of the available sites. The terms high availability and fault-tolerance are often used interchangeably. However, fault-tolerance is stronger than a high availability solution since it expects the fault-tolerant system to behave exactly as a system where components never fail. This requires to make failures transparent to clients and typically means that all data copies have to be consistent at all times. This is difficult to achieve in systems where network connectivity is not always guaranteed. There, a high availability solution might allow users to access locally available data copies although it is possible that they do not reflect the latest updates.

Historical Background

High availability and fault-tolerance have received attention in many different communities covering high available hardware, fault-tolerant software systems and data availability. Redundancy is one of the major mechanisms to achieve the desired goal.

In the database community, looking for high availability solutions was the main reason to start research into database replication [3], while replication for scalability and performance were only explored later. The research community has mainly focused on the maintenance of transactional properties despite various kinds of failures. Apart from mere correctness, there exist many implementation alternatives that can have a large impact on the performance of the system, and current major database systems have developed a wide range of high availability solutions with different trade-offs.

Data availability has also been explored in many other data centric domains such as file systems [10, 12], mobile systems [6] or fault-tolerant processes [4].

Foundations

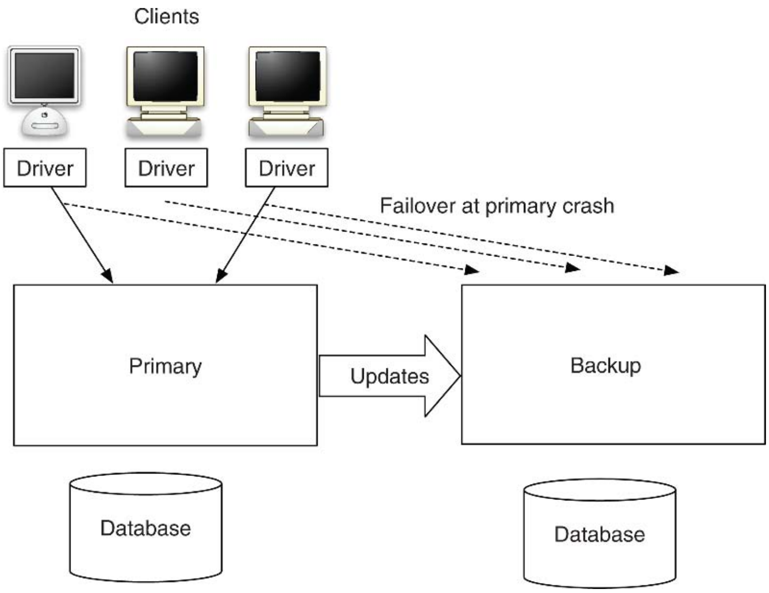
This entry focuses solely on availability for database systems. However, many of the issues and solutions discussed here are also valid outside the database domain.

Basic Fault-Tolerance Architecture

This discussion first looks at the case when a database system crashes. In this case, it does not perform any further actions and the data is no more available. Only after restart and recovery it becomes again operational. As the recovery procedure can take considerable time, a fault-tolerance solution maintains more than one copy of the database. In the following, the terms replica and site refer to a machine running a database management instance and controlling a copy of the complete database.

A fault-tolerance replication architecture has to tackle several issues. Firstly, when data is updated the data copies have to be kept consistent, resulting in additional measures, and thus *overhead during normal processing when no failures occur*. Secondly, when a replica fails, a *failover procedure* has to reconfigure the system. Thirdly, after a failure, the failed replica or a new replica have to be started and added to the system in order to handle future failures. For this, the joining replica has to receive the current state of the database from the available replicas. This third step is referred to as *replica recovery.*

As the most common fault-tolerance architecture uses primary-backup replication (Fig. 1) the following



Replication for High Availability. Figure 1. Primary-backup architecture.

discussion focuses on this architecture. There is one primary replica and one or more backup replicas in the system. All clients are connected to the primary replica which executes all transactions. In the case the primary fails, the clients have to be reconnected to one of the backups which takes over the tasks of the primary.

Execution While No Failures Occur The primary executes all transactions and decides on a serialization order (via the concurrency control module). At specific timepoints, the replication module of the primary replica propagates updates to the backup replica(s). Each backup replica applies the changes in an order that conforms to the serialization order determined by the primary.

Propagation can be done in several ways. In a *2-safe* approach, the changes performed by a transaction are propagated before the transaction commits, and an agreement protocol, such as a 2-Phase-Commit protocol, guarantees atomicity (the transaction either commits or aborts at all participating replicas). In a *1-safe* approach, the primary can commit a transaction before update propagation is completed.

1-safe propagation is faster than 2-safe propagation. However, if the primary fails after committing a transaction but before propagating its changes then the transaction is lost because the backup that becomes the new primary has no information about it. Neither atomicity nor durability of the transaction is given. Recovery of this transaction can be complex. In other context, 1-safe propagation is also often referred to as lazy, asynchronous or optimistic replication, while 2-safe propagation is often referred to as eager or synchronous replication.

There are several other design choices in regard to propagation. For instance, a message could be sent per update operation, per transaction or even per set of transactions. Furthermore, the update message could contain the physically changed records (e.g., taken from the log used for local recovery) or the update statement.

Changes can be applied at the backup at different timepoints. A backup is called *hot-standby* if it immediately applies any changes it receives to its own local database. Therefore, at the time of the failover, the backup is immediately operational and can accept client requests. However, it requires a powerful backup because of the high overhead during normal processing. A *cold-standby* defers applying the changes, e.g., to a timepoint when it is idle or when it actually becomes the new primary at failover time. This results in low overhead during normal processing. Thus, a cold-standby could be a less-expensive machine. However, failover will likely take longer and performance will be compromised until the powerful machine has completed recovery and can become again the primary.

Failover If there is more than one backup, an agreement protocol can be used to decide which of the backups takes over as new primary.

As part of the failover procedure, the clients have to be reconnected to the new primary. This reconnection is typically implemented within the driver software (e.g., JDBC driver) running on the client side (see Fig. 1). The driver is connected to the primary but knows the backup(s). When it looses connection to the primary, it connects to the backups to see who is the new primary.

Furthermore, the new primary, if is has not yet done so, has to apply all the changes of committed transactions that it received from the old primary before the crash. It aborts transactions for which it has already received some information but not all. A difficult issue is the handling of transactions that were active at the time of the failure. If the client had not yet submitted the commit request, the driver can simply throw an abort exception for this transaction before it connects to the new primary. This is correct since independently of being 1-safe or 2-safe, the new primary has neither committed nor is involved in a 2PC for this transaction. It is up to the client to resubmit the transaction (as would be the case for transactions involved in deadlocks). A different situation arises if the application program has already submitted the commit request, and the driver is waiting for the confirmation from the primary when the failure occurs. In this case, the transaction might already be committed at the backups. The driver has to ask the new primary for the outcome of the transaction and inform the client accordingly with a commit confirmation or an abort exception.

Replica Recovery Replica recovery is the task of integrating a new or failed replica into the replicated system. The recovery procedure can be performed *online* or *offline*. In offline recovery, transaction processing is halted in the system, the joining replica receives the accurate state of the data, and then transaction processing can resume. The problem is that availability is compromised. Online recovery, in contrast, performs recovery without stopping transaction processing in the rest of the system.

Data transfer strategies. There are several possibilities to provide a recovering replica with the latest state of the database [6]. One possibility is to transfer the entire database state to the recovering replica. This approach is simple but leads to unnecessary data transfer if large parts of the data did not change during the downtime of the recovering replica. Thus, an alternative solution first determines for each data item, whether this data item was actually changed during the downtime. Only if this is the case, the current version is transferred to the recovering replica. While this might decrease the size of data to be transferred it needs additional measures during normal processing and recovery to determine the changed objects. Instead of the data items, one can also transfer the log with all updates that the recovering replica has missed. Then, the recovering replica applies these missing updates to its database. The later two approaches are only possible for failed replicas that later recover while completely new replicas need a complete state transfer.

Recovery Procedure. A failed replica or a new replica typically joins as a backup. It can become the primary once recovery has completed (e.g., if it is the most powerful machine). The joining replica can receive the state from the primary or from another backup.

Using online recovery, the state transfer takes place concurrently to transaction processing at the primary. Thus, one has to make sure that the recovering replica does not miss any transactions. That is, for a given transaction, the updates performed by this transaction at the primary are either reflected by the state transfered through recovery, or are propagated by the primary to the new backup after recovery has completed.

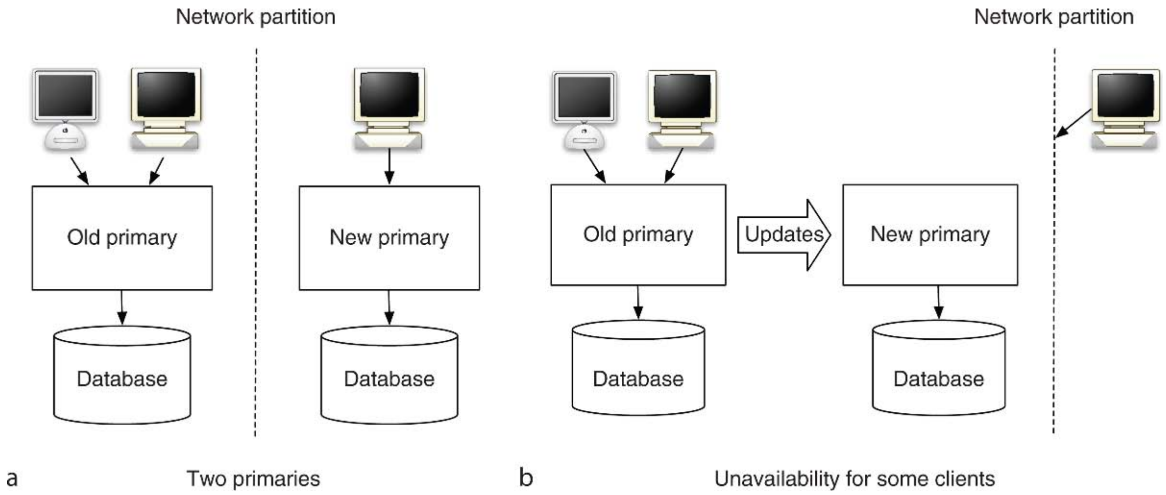
Combining Scalability and Fault-Tolerance

Many recent approaches exploit replication for both scalability and fault-tolerance by allowing transaction execution to be distributed across all available replicas (typically a LAN cluster). The protocols follow a read-one-write-all-available (ROWAA) replication strategy [2] where read operations are executed at one replica (which allows load-balancing) and write operations are executed at all replicas that are currently available (to keep copies consistent). In fact, the primary-backup approach is also a ROWAA approach but all clients are connected to the primary and transactions are only executed there. In these cluster replication solutions [9], when a replica fails, it is excluded from the system. Clients served by the replica are transferred to available replicas, and writes are only performed on the remaining available replicas. Failover is complicated by the fact of ongoing transaction execution during the failover period.

Network Partitions

Site crash is not the only failure type that can occur. A network problem might (temporarily) partition the replicas, allowing each replica to only communicate with a subset of other replicas. Network partitions occur seldom in LANs but are common in WANs or wireless networks. They are often transient and only hold for short periods of time. In general, it is impossible for a replica to determine whether another replica that is not reachable has failed, is currently not connected, or is simply slow and overloaded making it temporarily non-responsive. A correct fault-tolerance solution needs to work correctly despite this ambiguity. Standard primary-backup replication does not work correctly if network partitions occur. Figure 2 depicts two cases. When a network partition occurs between primary and backup (Fig. 2a), the backup and all clients within the partition of the backup will suspect the primary to have failed leading to both partitions having one primary serving local clients. If only clients but not the backup are disconnected from the primary (Fig. 2b), the system continues to run correctly, but from the disconnected clients' point of view, the system is unavailable.

Quorums One major approach to handle network partitions is to use quorums [7,13]. A read operation has to access a read quorum of replicas while a write operation has to access a write quorum of replicas. A quorum could, e.g., be the majority of replicas. Quorums are defined such that any two write operations on the same data item access at least one common replica. This is needed to serialize write operations and assure that any given write quorum has at least one replica with the latest version of the data item. Each read quorum must overlap with each write quorum. Therefore, each read operation is guaranteed to read at least one replica with the latest version. The beauty of



Replication for High Availability. Figure 2. Network partitions. (a) Two primaries. (b) Unavailability for some clients.

quorums is that they handle both replica failures and network partitions in the same way. It does not matter whether a client cannot reach a particular replica because it is down or disconnected, as long as the client can access a quorum of replicas, the operation can succeed. Recovery does not need any particular actions. While a replica is down it will not participate in any operations. Once it restarts it can be accessed and build part of a quorum. However, its data versions are outdated. Thus, any read operation will not read the data versions of this replica but the most current one from other replicas in the quorum. When the replica participates in a write quorum for a data item, the write operation will automatically update the value of the data item to the latest version.

Despite these attractive properties, quorums have not been used in database systems so far because of the complexity of handling database operations (e.g., complex SELECTs) on a quorum of replicas. The entry *Quorum Systems* discusses quorums in detail.

A possibility is to combine the strengths of ROWAA and quorums [1]. A connected group of replicas processes transactions according to ROWAA if the group fulfills a quorum requirement. A quorum is defined so that it is impossible that two partitioned groups of replicas can fulfill the quorum requirement. Group membership is dynamically adjusted whenever failures, restarts or network reconfigurations occur.

1-Safe (Lazy) Replication in WANs A further approach to address network partitions is to trade data accuracy with availability. It generally follows the ROWAA technique and performs update propagation lazily after commit (i.e., 1-safe). Each read operation only needs to access one copy of the data item, typically the one that is the closest. Thus, queries are usually fast and high availability is given since only one replica needs to be reachable.

For update transactions, one approach is to still have a primary replica and execute all update transactions at the primary. The primary then propagates the updates to all available secondary replicas sometime after commit. Having a single primary for update transactions allows for a globally correct serialization order. Propagating lazily allows the primary to commit a transaction without caring whether the other replicas are available. However, the secondaries can have outdated data, and thus local read operations might read stale data. Furthermore, if a client cannot reach the primary, its update transactions cannot be executed.

A second approach allows an update transaction to execute and commit at any replica, typically the closest, (update everywhere). This provides high availability for update transactions. However, data copies might diverge requiring some form of conflict detection and reconciliation, and read operations can read inconsistent data. Still, for many WAN applications, this is the only feasible option. Also, in mobile environments with planned periods of disconnection, this is the only way to provide availability to the mobile units.

In these lazy strategies, recovery is done incrementally. When a site wants to propagate an update but cannot reach a replica, it stores the update locally on persistent storage. When the replica is again available, the update will be propagated. That is, propagation is typically done via a persistent queue guaranteeing that an update is propagated and applied exactly once despite transient failures.

Other Failure Types

There exist other failures that are not considered here. For instance message loss can be handled by the underlying communication system.

Key Applications

Basically all commercial database systems provide a high availability solution based on primary-backup replication. Furthermore, other data replication strategies are also often supported and can be deployed for high availability and performance reasons. Most businesses that have update intensive workloads and require 24/7 availability deploy one or more of these solutions.

Outside the database domain, lazy (1-safe) replication is used both for fast local access and availability by file systems [10,12], web-servers [11] and cooperative applications such as distributed calendars.

Replication for fault-tolerance has also become popular in application servers. They represent the middle-tier in modern mutli-tier architectures, and maintain various kinds of data such as session information or cached versions of data stored in persistent storage. The challenges are similar as in pure database replication as the access to this data is transactional [5,14].

Future Directions

As applications are built increasingly on component-based architectures, combining software and hardware from many different vendors, it becomes a challenging task to assure that the system as a whole provides fault-tolerance. According to the end-to-end paradigm, the levels closest to the application might be the only ones able to completely implement the required level of fault-tolerance. On the other hand, lower levels might be able to ensure fault-tolerance more efficiently.

Replication for Scalability

Scale out; Cluster replication; Scalable database replication

Definition

One of the main uses of data replication is to increase the scalability of databases. The idea is to have a cluster (of possibly inexpensive) nodes, to replicate the data across the nodes, and then distribute the load among them. In order to be scalable, the more nodes are added to the system, the higher the achievable throughput should be. The scale reached today is on tens of nodes (i.e., below 100 nodes). Communication is not an issue since CPU and IO overheads are dominant. The approach in the last years has been to learn from the traditional approaches but change some fundamentals so that the limitations of these traditional approaches are avoided.

In order to attain scalability each transaction should not be fully processed by every replica. This depends on how transactions are mapped to replicas. For read only transactions, it is easy to avoid redundant processing since they can be executed at any single replica. Update transactions are more challenging, since updates should be reflected at all replicas where there are copies of the updated data items. This should be achieved in an atomic way across the replicated system what makes scalability challenging. Under the traditional approaches, atomicity was attained by means of distributed locking (for isolation) and two-phase-commit (for failure atomicity), what resulted in solutions lacking scalability.

A second aspect introduced by updates is their overhead. With symmetric update processing no scalability is achieved for updates, since all replicas pay the cost of fully executing the transaction. However, for asymmetric processing some scalability is possible, since only one replica pays the cost of fully executing the transaction, whilst the others just pay the cost of propagating and installing the resulting updated tuples. Another of the major factors that impact the scalability is the degree of replication. Under full replication, all replicas keep a full copy of the database. This means that an update transaction executed at one of the replicas should propagate the resulting updated tuples to all other replicas. This update propagation overhead increases its relative weight with an increasing number of replicas, what inherently limits the scalability. Some research efforts pursue partial replication to overcome the scalability limit of full replication.

There are a number of additional factors that influence scalability. One of such factors is the consistency being provided. The traditional consistency criterion for replicated databases, 1-copy-serializability, constrains the potential concurrency therefore limiting the scalability. A lot of research has targeted to relax consistency in order to increase the scalability.

Historical Background

Traditional textbook approaches for data replication [3] were concerned with consistency and did not provide any scalability. The paper from Gray et al. [9] provided analytical evidence of this lack of scalability triggering a large body of research performed during the last decade on scalable database replication.

One set of approaches that aim at attaining scalability were based on lazy replication [8,4]. In order to provide consistency, some of these lazy approaches constrained update propagation to attain 1-copy-serializability [4].

A second batch of research explored scalable eager (synchronous) replication. The seminal approaches in this direction were Postgres-R [12] and the database state machine [17]. These approaches explored optimistic concurrency control under a white box (or kernel-based) replication approach and triggered the research performed in the last decade around scalable data replication. Due to the complexity of white box approaches, middleware-based replication was proposed to simplify the engineering of replication. The seminal approach to middleware-based replication was Middle-R [22,16] that explored scalable pessimistic replica control. The middleware approach from Middle-R became very popular and today it is one of the main approaches to engineer database replication [1,20,15,5]. Middleware approaches took two different flavors, those based on group communication [22,16,15] and those based on schedulers [1,5,20].

Another batch of research has looked at trading off some consistency in favor of scalability. There are two main families within this batch: those stemming from lazy approaches and those coming from eager replication. On the lazy replication side, consistency was relaxed through the concept of freshness. Freshness quantifies consistency, e.g., by the potential number of missed updates [8]. On the eager replication side, consistency was relaxed by resorting to isolation levels lower than serializability. The most popular one has been snapshot isolation [13] provides full 1-copy correctness (1-copy-snapshot-isolation, 1CSI) for snapshot isolation replicated databases. 1CSI is provided by a number of replication protocols both under update-everywhere [13] and primary-copy [20]. Another consistency criterion proposed based on snapshot isolation is Generalized Snapshot Isolation (GSI) [7]. It enables queries to see older snapshots that are prefix consistent. More recently, snapshot isolation has also been exploited in the context of lazy approaches in [6] and also for multi-tier architectures [18].

The fourth batch of research has tried to overcome the lack of scalability of full replication. The paper [11] demonstrated analytically the scalability limits of full replication. Two ways to overcome this inherent scalability limitation are quorum-based replication and partial replication. Quorum-based replication can improve the scalability for extreme update workloads, but introduces a number of technical problems, the most important ones related to the scalability of predicate reads [11]. Partial replication approaches have aimed at improving scalability by limiting the number of copies of each data item [21,19].

Foundations

One of the uses of database replication is to increase the scalability of the system. The use of data replication to scale is also known as *scale-out* approach, in which the scalability increases by adding new nodes. This contrasts with the *scale-up* approach in which a system scales by substituting the current node with a more powerful computer. This section discusses the major factors that influence scalability of data replication, namely: how to attain atomicity, the mapping of transactions to replicas, and the consistency criterion.

Attaining Atomicity and Isolation

The traditional way to attain transactional properties in data replication [3] was based on using distributed locking to serialize transactions in the same order (isolation at replicated level) and using two-phase-commit (2PC) to guarantee that either all replicas commit the transaction or none (failure atomicity). Gray et al. [9] showed analytically the lack of scalability of traditional approaches. Basically, distributed locking has a probability of deadlock that increases exponentially with the number of transactions and 2PC does not scale and produces high response times. Two trends were followed to escape from the bottlenecks of traditional approaches. Lazy protocols commit transactions without waiting for transaction update propagation, that is, updates are propagated lazily or asynchronously with respect to transaction commit at the replica that processed the transaction. Alternatively, eager protocols propagate transaction updates atomically using alternative ways to enforce atomicity more scalable than 2PC.

Lazy protocols have mainly resorted to two approaches to attain some levels of consistency: primary-copy (aka single-master) and multi-master data replication. The *primary-copy* approach simplifies the consistency problem by enabling updates only at a single replica known as primary. All the other replicas, known as secondaries, only allow the execution of read-only queries. In this way, the consistency problem boils down to installing the updates from the primary in FIFO order or a more relaxed order that guarantees the same relative order of conflictive transactions. A popular replication protocol providing primary-copy is [20].

Primary-copy replication has its bottleneck in the primary that has to fully process all update transactions. As an alternative, *multi-master* replication has been proposed in which update transactions can be processed by any replica. Different approaches have been adopted for multi-master replication. In some approaches the way update transactions are propagated is constrained to guarantee high levels of consistency [4]. In others consistency is relaxed by providing quantitative levels of consistency such as freshness. A more detailed discussion on freshness is provided later in this text. Leganet is one of the systems with a lazy replication protocol providing freshness [8].

Eager protocols aim at high levels of qualitative consistency. Most eager protocols are either based on group communication or on a scheduler. *Approaches based on group communication* use atomic multicast to enforce atomicity in a more scalable way than 2PC. Atomic multicast provides failure atomicity by guaranteeing that all or none of the replicas receive messages and also guarantees that all replicas receive the messages in the same relative order. In this way, each replica is able to schedule the messages containing updates in an order consistent with respect to the common total order. There are a number of data replication protocols based on group communication such as Postgres-R [12], database state machine [17], and Middle-R [16,13].

The *scheduler-based approach* has also been proposed for attaining consistency in eager protocols. The idea is to use a node as transaction scheduler. This scheduler is in charge of enforcing consistency. It labels transactions with a sequence number and forwards them to the replicas. In this way, replicas are able to order conflictive transactions in the same way and atomicity can also be enforced by preventing gaps in the transaction processing. Some of the database replication systems based on scheduler are conflict-aware data replication [1] and C-JDBC [5].

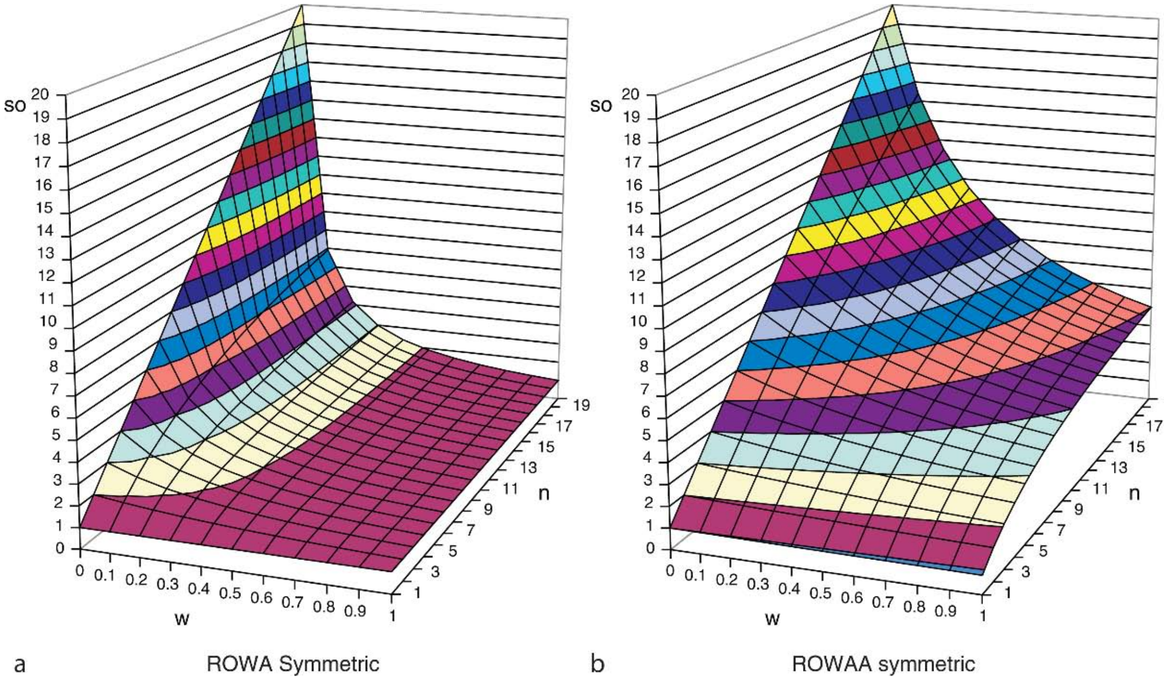
Transaction Mapping

The mapping of transactions to replicas is crucial in attaining scalability. There are several issues related to the transaction mapping: which replicas processes read-only transactions (queries), how update transactions are processed, and how many copies of each data item are kept.

The first issue is *how read-only transactions (queries) are managed*. Since queries only read data, for fully replicated systems it becomes possible to execute queries at any single replica, whilst update transactions are fully executed at all replicas. This mapping is known as read-one write-all-available approach (ROWAA) [3]. It enables to scale under read workloads, since for reads the load is shared among replicas. However, this approach fails to scale even with a small percentage of update transactions [11]. ROWAA has been used by the early replication protocols that are surveyed in [3].

The second issue is *how update transactions are processed*. Update transactions can be executed at only one of the replicas, as far as the other replicas get the resulting updates and install them. This mapping is known as *asymmetric update processing*, in contrast with *symmetric update processing* in which update transactions are fully executed by all replicas. This mapping also enables sharing the load introduced by update transactions, enabling scalability with update workloads [11].

Figure 1 compares the scalability of symmetric and asymmetric processing under ROWAA. The x-axis shows the fraction of writes (1.0 = 100% writes), the y-axis shows the number of nodes. The z-axis shows the scale-out, i.e., how many times the throughput of a single-node system is multiplied by the replicated system. Figure 1 shows that symmetric processing only achieves a high scale-out for very low values of w. With asymmetric processing, assuming that installing updates has around 15% of the costs of executing



Replication for Scalability. Figure 1. Scalability of symmetric and asymmetric processing (wo = 0.15 for asymmetric).

the update transaction itself ($wo = 0.15$), the scale-out is relatively high even for higher update rates.

A different mapping that has been proposed to further increase the scalability of update workloads is based on quorum systems. Quorum systems enable to write just in a subset of the replicas (write quorum). This has the associated tradeoff that reads should also be performed on a subset of replicas (read quorum). Quorums can compete with ROWAA when the percentage of updates in the workload is very high (80–100%) [11]. However, they only work for transactions accessing individual objects. When combined with collections of objects such as tables, queries become too expensive for being practical.

The third issue is *how many copies of each data item are kept (aka degree of replication)*. The paper [11] demonstrated analytically the scalability limits of full replication as a function of the ratio of the cost of fully executing the transaction and installing the resulting updates termed write overhead, *wo*.

With typical write overheads of 0.15 and below, the scalability becomes very reasonable for a few tens of nodes. However, full replication does not scale beyond that. The reason is that the overhead introduced by the update propagation and installation consumes higher and higher fractions of the capacity of the full system what finally is translated in consuming any extra additional capacity to process updates from the existing replicas.

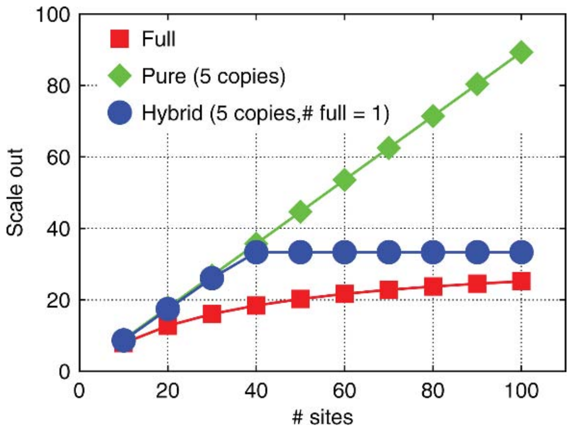
The alternative to scale beyond the limits of full replication is to use partial replication. Partial replication, however, also introduces other challenges. If there is no single replica with the full database, what is called pure partial replication, transactions become inherently distributed. As an alternative, if there is application knowledge available, it can be exploited to guarantee that there will be at least a replica that can execute a transaction fully locally. A potential solution is to have hybrid partial replication in which there are some replicas containing the full database and some replicas storing a fraction of the database. The former enables to avoid distributed transactions, and the latter enables to scale. Unfortunately, this approach, although it scales significantly better than full replication, reaches a limit of scalability. This limit is reached when the full replicas are saturated with update installation from partial replicas (even if they do not process any local transaction). The way to scale beyond hybrid partial replication is to use pure partial replication, what implies to be able to process replicated distributed transactions in an efficient way. The scalability of partial replication, both hybrid and pure, has been studied recently both analytically and empirically [21].

Figure 2 compares the scale-out of full replication, pure partial replication where each data item has five copies equally distributed among the nodes, and hybrid replication where one node has a copy of the entire database, and each data item has a total of five copies. The update workload in this case is 20% one can clearly see, that only pure replication has no scalability limit while the others are limited by the fact that all updates have to be performed on all copies, and there is at least one server that has copies of all data items.

Consistency Criterion

Another of the major factors influencing the scalability of replication is the consistency criterion. Some replication protocols provide a qualitative consistency. These protocols are usually *eager* protocols in which replica control is tightly integrated with update propagation to guarantee the qualitative consistency criterion. Other protocols have aimed at *quantitative consistency*, typically *lazy* protocols. In lazy protocols replica control is more relaxed and typically offers quantitative consistency, and in some cases simply eventual consistency.

Qualitative consistency for data replication provides a formal definition of the attained consistency. The consistency criterion can be seen as the extension of the



Replication for Scalability. Figure 2. Scalability of full versus partial data replication.

isolation concept of centralized systems to a replicated setting. Isolation formalizes the consistency for concurrent executions in a centralized system. The replication consistency criterion extends this formal notion to the consistency of the concurrent transaction execution in a replicated system. The traditional criterion for replicated databases has been 1-copy-serializability (1CS) [3]. This criterion states that the concurrent execution of a set of transactions in a replicated system should be equivalent to the execution in a serializable centralized system. 1CS has been the only criterion used till very recently. 1CS, as its centralized counterpart, serializability, constrains the potential concurrency in the system by making reads and writes conflicting. Constraining the potential concurrency is harmful for scalability (even for performance in a centralized system) since it might prevent to fully utilize the available capacity in the replicated system. In order to overcome the scalability limitation of 1CS, some researchers have explored snapshot isolation (SI) as isolation notion on which to build a replication consistency criterion. 1-copy snapshot-isolation [13] (1CSI) provides the notion of 1-copy correctness underlying in 1CS for a SI database. That is, the concurrent execution of a set of transactions in a replicated system should be equivalent to a centralized (1-copy) execution in a centralized SI database. The main advantage of SI is that reads and writes do not conflict. The only conflicts are between writes on the same tuples that are rare in most applications. 1CSI enables replica control protocols that are based on SI databases. This means that they do not have contention problems due to read-write conflicts, what results in higher scalability. Snapshot isolation is currently being used for different replica control protocols, lazy primary-copy replication [20], eager update-everywhere [13], lazy replication [6], and application server replication [18].

Quantitative consistency aims at increasing the scalability by relaxing the consistency enabling queries to see outdated data bounded quantitatively. It is typically used in lazy propagation schemes. Freshness criteria bound how much the value a query reads differs from the actual value of the data item. Freshness, e.g., could bound the number of updates a query has missed or the time since the copy read was last updated. The concept of freshness has been exploited by many different systems, and has been used in the context of primary-copy [20], multimaster [8], or application server replication [2]. The entry *Consistency Models for Replicated Data* provides a more detailed discussion on the different qualitative and quantitative consistency levels that exist.

Key Applications

Database replication has a wide number of applications. In principle any database that reaches saturation can be substituted by a replicated database to scale out. *Enterprise data centers* are certainly one of the main targets of database replication in order to scale for high loads typical of these systems. *Web farms* hosting dynamic content require the use of a database for storing it. In this kind of systems the main bottleneck is precisely the database and therefore, it can benefit from replicated databases. Grid systems are able to scale for applications based on the paradigm of bag of tasks, problems that can be split in a myriad of small subproblems that can be solved independently. In some cases, some grid applications require database access that is what finally becomes the bottleneck of the system. By employing a replicated database as a *data grid*, these grid applications can increase their scalability. A recent and increasingly important trend is *Software as a Service (SaaS)*. In this new paradigm, applications are hosted at a remote data center such as Google. SaaS aims for providing transparent scalability by means of self-provisioning. In this way, the hosted application can increase the number of replicas as needed depending on the received load and paying only for the resources it needs. SaaS platforms require an underlying scalable storage system such as a replicated database. Another area in which database replication is becoming a competitive solution is edge computing. *Edge computing* aims at moving web contents closer to clients located at the edge of Internet. Centralized solutions to edge computing are not adequate since distant clients observe high latencies. With edge computing, the contents is cached or replicated at data centers geographically close to the client to mask the latency. Early approaches only managed to reduce the latency of static contents. Recently, it has been shown that by using database replication in wide area networks it becomes possible also to mask the latency for dynamic contents [23].

Definition

Modern middleware systems are commonly used in multi-tier architectures to enable separation of concerns. For each tier, a specific component container is provided, tailored to its mission, web interface, business logic, or persistent storage. Data consistency across tiers is guaranteed by means of transactions. This entry focuses on the main three tiers: web, application server, and database tiers.

Middleware systems are at the core of enterprise information systems. For this reason they require high levels of availability and scalability. Replication is the main technique to achieve these two properties. First middleware replication approaches addressed the replication of individual tiers and focused initially on providing availability and later, on scalability. However, an integral approach is needed to provide availability and scalability of multi-tier systems. Replicating an individual tier increases its availability and might increase its scalability as well. However, replicating a single tier is not sufficient for providing data availability and scaling for the whole system; the non-replicated tiers eventually become a single point of failure and/or a potential bottleneck. A potential solution is to combine independently replicated tiers. However, due to their independent replication, they are not aware of the replication of each other; this results in inconsistency problems in the event of failures.

Recent research has introduced new approaches to replication of multi-tier architectures. The two main replication architectures are horizontal and vertical replication. In horizontal replication, the tiers are replicated independently, then measures are taken to make at least one of them aware of the other to deal in a consistent way with failures and failovers. In vertical replication, a set of tiers (typically the application and database tiers) are replicated as a unit, and the replication logic is encapsulated in the upper tier (typically the application server). Another important aspect of replication of multi-tier systems is related to the definition of the correctness criterion, i.e., the conditions a replicated multi-tier architecture should fulfill in order to provide consistency. There are two important criteria in this area, namely, exactly-once semantics and 1-copy correctness.

Historical Background

The first wave of research on the replication of multi-tier architectures focused solely on the availability of individual tiers, mainly the application server and database tiers. In the first wave, the theoretical basis for process replication was set [22]. The state machine approach was proposed to guarantee the consistency of replicated servers. This approach stated that a server could be consistently replicated by guaranteeing that all server replicas receive the requests in the same order and the server deterministically processed them. This determinism requirement was interpreted as the server had to be sequential, which was too restrictive for real servers that are multi-threaded in nature.

The efforts on the database tier concentrated on how to attain data consistency in the advent of failures and how to characterize data consistency. These initial efforts led to lock-based data replication approaches. These approaches were not scalable but they enabled the development of correctness criterion. The criterion characterizing correctness was 1-copy-serializability, i.e., replication should be semantically transparent, the replicated database should allow only those executions that had an equivalent in a non-replicated (1-copy) system.

A second wave of research on middleware replication addressed the fault-tolerance of real systems in the context of CORBA, which led to the (fault-tolerant) FT-CORBA standard. These approaches were based on the theoretical foundations of the state machine and tried to solve the difficulties of engineering replication in real middleware systems [2,7,16]. A new line of research opened in this wave enabled the use of the state machine approach for multi-threaded servers. A seminal paper [11] showed that it was possible to devise a scheduler that can guarantee deterministic behavior of multi-threaded servers. Later approaches studied how to increase the potential concurrency [3].

The efforts on the database tier focused on how to attain scalability. Some approaches relaxed consistency in the quest for scalability relying on lazy replication approaches (see the entry *Replication for Scalability* for a deeper view) [5,17]. Other approaches aimed at attaining scalability while preserving full consistency [1,12,18,19]. The three later approaches leveraged group communication to provide consistency in any failure scenario.

The third wave of research on middleware replication focused on dealing with specific aspects of multi-tier architectures, more concretely, on how to deal with transactional processing in a consistent way, the consistency criteria, and how to attain scalability. The issue of the lack of transactional consistency in replication approaches for multi-tier architectures was then raised [8]. In the context of FT-CORBA, it was studied how to connect a replicated CORBA application server with a shared database guaranteeing exactly once semantics [25], therefore providing the same semantics as the non-replicated system. Also in the J2EE context transactional consistency has been studied. First approaches replicated session state in the application server replicas sharing a common database [24] and enforced transactional consistency in this context.

More recently, replication of multiple tiers has also been studied, e.g., in a vertical replication approach [21]. That is, an application server and database server pair is the replication unit. Database servers are centralized and are not aware of the replication. The application server encapsulates the replication logic transparently to the database. The application server replicas interact among them to enforce consistency (i.e., 1-copy-serializability). Additionally, in this approach transactions are not aborted in the advent of failures from the client perspective, that is, it provides high transaction availability. Another recent approach has considered the issue of replicating application servers accessing multiple databases [14]. In this approach a primary-backup model is adopted. Clients interact with the primary application server. The most general case in which the application server accesses multiple databases is considered. This case is more complex since it involves dealing with two-phase-commit (2PC) and the failover of the 2PC coordinator (the transaction manager of the application server). The primary application server accesses multiple databases to process client requests. When the client transaction ends, 2PC is started and coordinated by the primary application server. The primary checkpoints session state as well as transaction management information to the backups. The approach is able to handle the primary failure and enforce transaction consistency for distributed transactions, providing transaction manager (2PC coordinator) failover.

On the correctness side, it was studied how to guarantee exactly once semantics in multi-tier architectures in which the application server tier is stateless [9]. That is, how to guarantee transaction atomicity and exactly once semantics in the advent of a failover in replicas of stateless application servers. A thorough study of the different approaches for multi-tier replication that guarantee transactional consistency was presented in [13].

On the database tier, the third wave of research has focused on boosting the scalability beyond a few tens of replicas attained in the second wave. Two aspects were mainly addressed: How to overcome the scalability limits of 1-copy-serializability and full replication. 1-copy-serializability limits significantly the potential concurrency of the system which had an impact on the attainable scalability. This resulted in approaches based on a more relaxed consistency criterion, 1-copy-snapshot-isolation [15]. The scalability limits of full replication were studied analytically in [10] which led to the exploration of partial replication. Partial replication has resulted in boosting the scalability of full data replication [23], although it has some complexities such as how to deal with data partitioning and distributed transactions.

Nowadays, integral approaches for the replication of multi-tier architectures are becoming common. Research in the area is aiming at enhancing the scalability of the seminal approaches to replication of multi-tier systems. More concretely [4] studies how to replicate the application server tier with a shared database and boost the scalability by relaxing data currency through freshness constraints. Another recent approach is looking at the scalable replication of application server and database tiers [20]. In order to overcome the scalability bottleneck of serializability, this approach is based on 1-copy-snapshot isolation. Additionally, it deals for the first time with the issue of the cache consistency at the application server for relaxed isolation levels, in particular, for snapshot isolation.

Foundations

This section reviews the main replication approaches for the different tiers. Both approaches (replicating a single tier and replicating multiple tiers) will be considered.

The web tier is simple to replicate due to its stateless nature. On the other hand, it has to deal with a very specific aspect that lies in the availability and scalability of the connectivity to the Internet. This has resulted in multiple approaches to virtualize URLs and IP addresses. IP virtualization enables providing transparent failover since the client sees a single logical IP despite the fact that two physical IPs might get involved in the processing of its requests upon a failover. IP virtualization also enables to provide transparent load balancing since a network switch can transparently route requests to a logical IP to different physical IPs to balance the load across different sites. A thorough survey on the replication of the web tier can be found in [6].

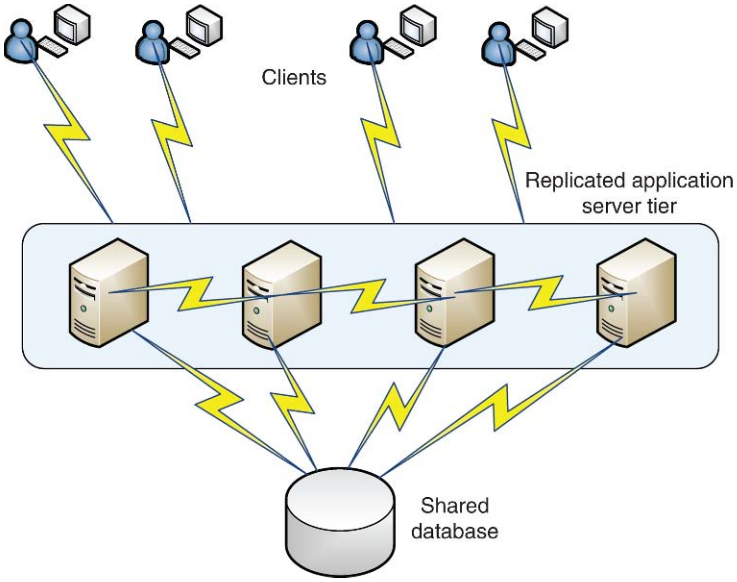
The replication of the application server tier is more challenging due to its stateful nature and also due to its support for transactional processing. It is possible to distinguish between replication for availability and replication for scalability. Replication for availability aims at providing fault-tolerance but typically without taking care of scalability, even providing negative scalability (a performance below the one of the non-replicated server). Replication for scalability, in addition to providing availability, it is able to increase the system capacity by increasing the number of replicas.

Replication for availability approaches rely on the state machine approach [22]. The state machine replication is based on two basic principles: (i) All replicas receive requests in the same global order; (ii) Each replica behaves deterministically and then, given the same input request sequence produces the same output sequence. Therefore, replication protocols for availability rely on a method for ordering client requests in the same order at all replicas to attain the required global order, typically, using group communication and total order multicast. Then, they remove the non-determinism from the application. In this class, it is possible to find all the efforts around FT-CORBA such as Eternal [16].

One of the main sources of non-determinism is multi-threading. Most of the approaches simply tackle with single-threaded (sequential) servers to guarantee determinism. However, multi-threading is a necessary feature for real-world servers. Some research has been conducted in how to guarantee determinism of replicas in the presence of multi-threading [3,11]. This research has produced different multi-threading schedulers that enforce deterministic scheduling enabling the replication of multi-threaded servers. The seminal approach [11] showed that by using a deterministic scheduler and setting a deterministic method to schedule requests integrated in the deterministic scheduler it became possible to guarantee the determinism of multi-threaded servers. Later on some other deterministic schedulers have been proposed aiming at increasing the real concurrency [3].

An important issue that needs to be dealt with in the replication of application servers is how to preserve transactional consistency [8]. The paper [9] proposes e-transactions to preserve consistency and identifies exactly once semantics as a key consistency criterion for replication of transactional multi-tier architectures. e-Transactions also provide a protocol for satisfying exactly-once semantics for replicated stateless application server tiers with a shared database (see Fig. 1). Exactly-once semantics states that each transaction should be executed exactly once despite failures and re-executions due to failovers.

A more evolved approach [24] deals with the replication of stateful application servers also with a shared database. In this approach, the relationship between request and transaction is not constrained to be 1 to 1 as in e-transactions, instead, it can be arbitrary. That is, it can be 1:1, N:1, and 1:N. In [24] it is proposed a protocol providing exactly-once semantics [9] despite failures. The protocol intercepts database accesses labeling them with a global sequence identifier and the associated client and request identifier. Each database requests is multicast to the other replicas with the associated information. In the advent of a failure of the primary replica of the application server, a backup replica will take over. Those clients that have not received a reply to their last request will resubmit it to the new primary. The new primary will execute resubmitted requests intercepting the requests submitted to the database. This interception takes care of executing the database requests in the same order as in the old primary in order to guarantee a



Replication in Multi-Tier Architectures. Figure 1. Horizontal replication with a replicated application server tier and a shared database.

deterministic execution and exactly once semantics. New requests will be delayed till the requests received from the former primary are replayed.

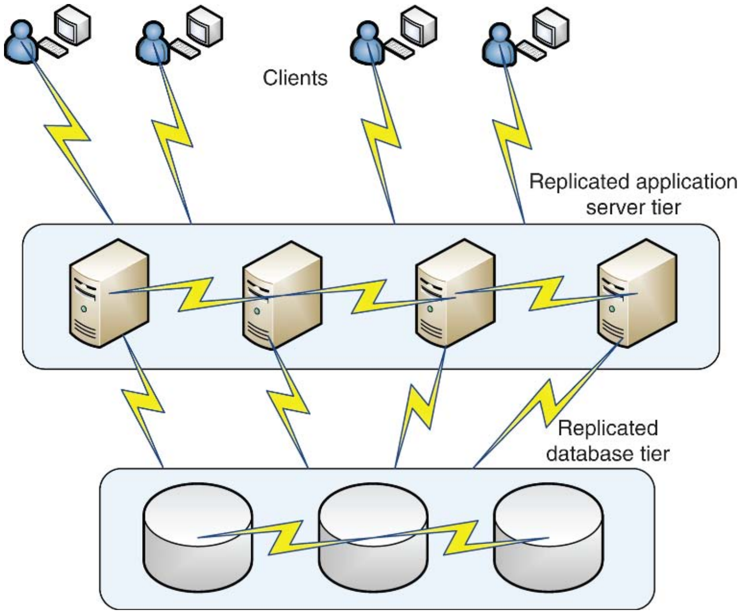
All the aforementioned approaches deal exclusively with the replication of the application server tier, which results in the database becoming a single point of failure and performance bottleneck. More recently, research has been conducted to deal with the replication of both the application server and database tiers guaranteeing consistency despite failures. Two alternative architectures have been considered: horizontal and vertical replication [13].

In horizontal replication each tier is replicated independently (see Fig. 2). However, the integration of two independently replicated tiers results in inconsistency problems in the advent of failures [13]. In order to avoid inconsistencies the replicated tiers sholud become aware of each other to handle failovers consistently. However, this is typically unrealistic since it implies the cooperation of two different vendors very often competitors in the market. [13] proposes two solutions to attain consistent failover by incorporating awareness of replication in only one of the two tiers, either the application server or the database tier.

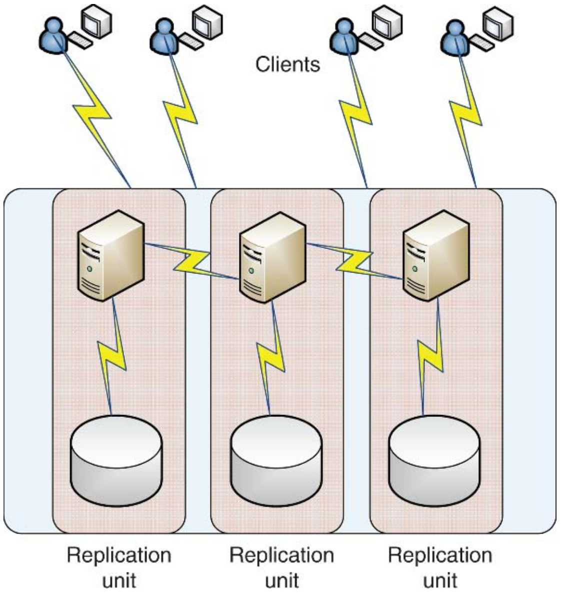
Vertical replication lies in taking as replication unit an application server - database server pair [21] (see Fig. 3). The database server is not aware of the replication. The application server encapsulates all the replication logic. In the vertical replication approach [21] both changes to session (session beans in the context of J2EE) and persistent state (entity beans in the context of J2EE) are captured. The two kinds of changes are propagated to the backup replicas at the end of each client request to provide *highly available transactions*, that is, transactions that do not abort despite failovers.

Both horizontal and vertical replication architectures are also used to attain scalability. Horizontal replication has mainly focused on replicating the middleware tier to replicate sessions while sharing a single database. In these approaches, consistency is attained through the shared database that serializes concurrent database accesses from different replicas. The replication of sessions enables to increase the scalability of applications in which the bottleneck is located in the application server, they are CPU intensive (e.g., image processing). However, these approaches fail to scale when the bottleneck is on the database, which is the most common case in practice.

Vertical approaches have aimed at increasing the scalability independently of whether they are application server or database intensive whilst providing strong consistency [4,20]. To date there are two different approaches to scalable vertical replication: [20] that provides strong consistency and [4] that provides relaxed consistency.



Replication in Multi-Tier Architectures. Figure 2. Horizontal replication with two replicated tiers.



Replication in Multi-Tier Architectures. Figure 3. Vertical replication. Replicated application server and database tiers.

[4] uses a master-slave approach and aims at scaling read-intensive workloads. The master processes all update transactions that get reflected in the underlying database and takes care of propagating a sequence of committed updates to the slaves. Each slave updates the cache and also commits the updates to the database in commit order. Read-only queries can be executed at any replica and can read stale data. The system can be configured to set the staleness or freshness upon which each transaction should be executed.

On the other hand, [20] is an update-everywhere approach (all replicas can process update transactions) and aims at scaling both read and write workloads. Unlike [4,20], provides strong consistency, namely, 1-copy-snapshot-isolation. [20] firstly provides a consistency criterion for application server caching, named cache-transparency. An application server is cache-transparent if it allows the same executions as the application server with the cache disabled. Cache transparency extends the isolation notion of databases to a multi-tier architecture. This is crucial since current application servers may work incorrectly with databases running on some relaxed isolation levels, such as, snapshot isolation. Secondly, it guarantees 1-copy correctness for the multi-tier server which provides replication transparency. [20] builds on 1-copy-snapshot isolation to obtain higher scalability levels since 1-copy-serializability has some strict scalability limits as discussed earlier. Basically, [20] uses multi-versioning in the cache of the application server replicas that is synchronized with the snapshots of the underlying database and among replicas in order to provide cache and replication transparency, respectively.

Reputation and Trust

Zoran Despotovic
NTT DoCoMo Communications Laboratories Europe,
Munich, Germany

Synonyms

Feedback systems; Word of mouth

Definition

Trust means reliance on something or someone's action. As such, it necessarily involves risks on the side of the subject of trust, i.e., trustor. The main goal of a trust management system is to reduce the involved risks. Reputation systems present a possible solution to do that. They use relevant information about the participants' past behavior (feedback) to encourage trustworthy behavior in the community in question. The key presumptions of a reputation system are that the participants of the considered online community engage in repeated interactions and that the information about their past doings is informative of their future performance and as such will influence it. Thus, collecting, processing, and disseminating the feedback about the participants' past behavior is expected to boost their trustworthiness.

Key Points

The goal of a reputation system is to encourage trustworthy behavior. It is up to the system designer to define what trustworthy means in her specific setting. There are two possible ways to do this: *signaling and sanctioning reputation systems*. In a signaling reputation system, the interacting entities are presented with signals of what can go wrong in the interactions if they behave in specific ways. Having appropriate signals, the entities should decide what behavior is most appropriate for them. An important assumption of the signaling reputation systems is that the involved entities do not change their behavior in response to a change of their reputation. As an example, the system may just provide a prospective buyer with indications of the probability that the seller will fail to deliver a purchased item. This probability is the main property of the seller. It can change with time, but independently of the seller's reputation.

The other possibility is *sanctioning reputation systems*. The main assumption they make is that the involved entities are aware of the effect the reputation has on their benefits and thus adjust their behavior dynamically as their reputation changes. The main task of a reputation system in this case is to *sanction* misbehavior through providing correlation between the feedback the agent receives and the long-run profit she makes.

Request Broker

Aniruddha Gokhale
Vanderbilt University, Nashville, TN, USA

Synonyms

Object request broker; Event broker; Storage broker

Definition

A Request Broker is a software manifestation of the Broker architectural pattern [3] that deals primarily with coordinating requests and responses, and managing resources among communicating entities in a distributed system. A Request Broker is usually found as part of middleware, which are layers of software that sit between applications, and the underlying operating systems, hardware and networks.

Historical Background

The mid to late 1980s established the TCP/IP protocol suite as the *de facto* standard suite of protocols for building networked applications. Contemporary operating systems provided a number of application programming interfaces (APIs) for network programming. The famous among these were the *socket* API that were tailored towards building TCP/IP-based applications. This era also saw the widespread use of killer TCP/IP-based applications, such as the File Transfer Protocol (FTP).

Despite the success of the socket API to build distributed applications, there were a number of challenges involved in developing these applications. First, the socket API was tedious to use and incurred a number of accidental complexities stemming from the use of type-unsafe C-language data types. Second, application programmers were responsible for handling the marshaling and demarshaling of the data types transferred between the communication entities, which involved a number of challenges. Notable among these were the need to address the byte ordering, and word size and padding issues arising from the heterogeneity in the hardware architectures. Third, server applications were able to provide only one primary functionality due to the lack of an object-oriented service abstraction. Finally, client applications had to explicitly bind to a location-dependent service, which made the applications inflexible and brittle.

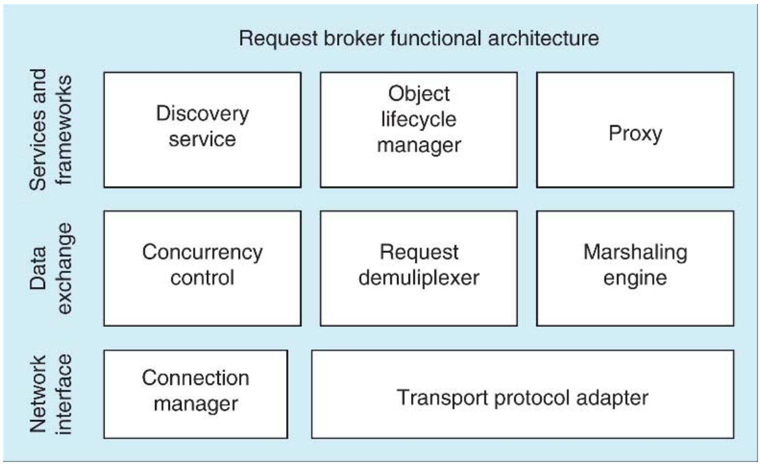
Every distributed application that was developed had to reinvent the wheel and address these complexities. There was a compelling need to overcome these challenges by factoring out the commonly occurring patterns of network programming and provide them within reusable frameworks. This led to the notion of middleware [1,2], which provide reusable capabilities in one or more layers of software that sit between the application logic, and the operating systems, hardware and networks. A Request Broker is at the heart of such a middleware and performs a number of functions on behalf of the applications.

Request Brokering capabilities at the middleware layer started appearing with the advent of the Remote Procedure Call (RPC). Sun RPC was among the earlier middleware platforms that illustrated Request Brokers. Others that emerged thereafter included the Distributed Computing Environment (DCE), the Common Object Request Broker Architecture (CORBA), Java Remote Method Invocation (RMI), Distributed Component Object Model (DCOM) and .NET Remoting.

Foundations

A Request Broker implements the Broker architectural pattern [3]. The primary objectives of a request broker are to decouple clients and servers of a distributed application and provide reusable services, such as concurrency management, connection management, seamless transport-level networking support, data marshaling, and location transparency. Figure 1 illustrates the commonly found functional blocks [5] in a Request Broker discussed below.

- *Proxy* – A Request Broker allows the separation of interface from implementation thereby decoupling the client of a service from the implementation of the service. A service is often described using interface definition languages to define the interfaces, the operations they support and data types that can be exchanged. Versioning of interfaces can also be provided within these descriptions. A proxy gives an illusion of the real implementation to the client.
- *Discovery services* – A Request Broker manages service discovery on behalf of clients. Some form of a service description, such as a URL or service name, is used by the broker to lookup a potentially remote implementation that offers the service. The broker will return to the client application a handle to the external service in the address space of the client so that the client can seamlessly invoke services on the handle via the Proxy. Depending on whether *pass by reference* or *pass by value* semantics are used, the execution of client requests may occur remotely on the server machine or locally in the client's address space, respectively.
- *Marshaling engine*– A Request Broker often specifies an encoding scheme or a serialization format for representing application data. Often there exist tools that read the interface descriptions of services and synthesize code that can marshal and unmarshal all the data types that are defined as serializable in the interface descriptions. This tool-generated code, which is usually called a *stub*, is linked into the fabric of the Request Broker, which manages data marshaling and unmarshaling on behalf of the application.
- *Concurrency control* – A server application may require finer-grained control on concurrency for scalability and performance. Request Brokers often provide sophisticated concurrency control mechanisms, such as *thread pools*, to handle application requests in a scalable and concurrent manner.
- *Object lifetime manager* – A server application may host multiple different services to optimally utilize resources. Often these services are provided in the form of objects implemented in a programming language. The Request Broker must manage several objects simultaneously in the system according to the policies dictating their lifetimes, e.g., transient or persistent. Other policies that tradeoff between memory footprint and performance include the *activate-on-demand* policy, which activates a service only on demand and for the duration of the request. This conserves resources but impacts performance.
- *Request demultiplexing and dispatching* – A broker may manage several hundreds of objects at a time. When requests arrive at a server, they must be efficiently demultiplexed and dispatched to the right object implementation.
- *Connection management and Transport Adapter* – Since applications are distributed they must communicate over different networking protocols. Request Brokers often enable applications to



Request Broker. Figure 1. Request broker functional architecture.

configure the choice of protocol to use for communication. For example, the unpredictable behavior of TCP/IP will not suffice for real-time applications in which case special transport protocols must be used. But the application must be shielded from these differences. Transport adapters [4] can provide these capabilities. For the transport protocol used, appropriate connection management capabilities are required. For example, connections may need to be purged periodically to conserve resources.

Apart from the functional architecture, a taxonomy of the capabilities provided by a Request Broker can be developed along the following orthogonal dimensions.

(1) *Communication models* – This dimension includes different classifications, such as (i) Remote Procedure Calls (RPC) versus Message Passing; (ii) Synchronous versus Asynchronous communications; (iii) Request/Response versus Anonymous Publish/Subscribe semantics; (iv) Client/Server versus Peer-to-Peer.

(2) *Location transparency* – This dimension includes mechanisms, such as object references or URLs, used by the Request Broker to hide the details of the service.

(3) *Type system support* – This dimension includes the richness of the data types that can be exchanged between the communicating entities, and the semantics of data exchange. For example, Request Brokers can support passing objects by value or by reference or both.

(4) *Interoperability and portability* – This dimension includes the degree of heterogeneity supported by the Request Brokers. For example, technologies such as CORBA are both platform- and language-independent, which makes them widely applicable but requires complex mapping between the platform- and language-independent representations to platform- and language-specific artifacts. Often this impacts the richness of data types that can be exchanged. On the other hand some technologies are language-dependent, e.g., Java RMI, or platform-dependent, e.g., DCOM and .NET Remoting.

(5) *Quality of service (QoS) support* – This dimension includes the capabilities provided by the Request Broker to support different QoS requirements of applications. Some brokers may be tailored to support real-time support while others are customized for persistence and transaction support.

Key Applications

Request Brokers are at the heart of distributed computing, and span a wide range of application domains including telecommunications, finance, healthcare, industrial automation, retail, grid computing, among others. Request Brokers with enabling technologies to support real-time applications have also been used to build distributed real-time and embedded systems found in domains, such as automotive control, avionics mission computing, shipboard computing, space mission computing, among others. Request Brokers are also found in systems that require management and scheduling of storage resources, or in large, event-based or content-management systems.

Future Directions

As applications become more complex, heterogeneous, and require multiple different and simultaneous quality of service properties, such as real-time, fault tolerance and security, the responsibilities of the Request Broker increase substantially. Brokering capabilities themselves will need to be distributed requiring coordination among the distributed brokers. Supporting multiple QoS properties will require design-time tradeoffs due to the mutually conflicting objectives of each QoS property. Run-time resource management will be a key in supporting the QoS properties since applications are increasingly demanding autonomic capabilities.

Experimental Results

Experimental research on Request Brokers is proceeding along the discussion articulated in the future trends. Service oriented computing is requiring Request Brokers to move beyond simple client-server or peer-to-peer computing to more advanced scenarios where the brokering capabilities are required across entire application workflows.

URL to Code

The following URLs provide more information on different Request Broker technologies and sample code.

CORBA is standardized by the Object Management group (http://www.omg.org).

Java RMI is a technology of Sun Microsystems (http://java.sun.com/javase/technologies/core/basic/rmi/index.jsp).

DCOM and .NET Remoting are technologies from Microsoft (http://msdn2.microsoft.com/en-us/library/ms809340.aspx and http://msdn2.microsoft.com/en-us/library/2e7z38xb.aspx, respectively).

DCE is a technology standardized by the Open Group (http://www.opengroup.org/dce/).

Structure of truth values

Definition

The residuated lattice is a basic algebraic structure accepted as a structure of *truth values* for fuzzy logic and fuzzy set theory. In general, it is an algebra

$$\langle L, \vee, \wedge, \otimes, \rightarrow, 0, 1\rangle$$

where L is a support, $\vee$ and $\wedge$ are binary lattice operations of join and meet, 0 is the smallest and 1 is the greatest element. The $\otimes$ is additional binary operation of *product* that is associative and commutative, and $a \otimes 1 = a$ holds for every $a \in L$. The $\rightarrow$ is a binary *residuation* operation that is adjoined with $\otimes$ as follows:

$$a \otimes b \le c \quad \text{if and only if} \quad a \le b \rightarrow c$$

for arbitrary elements $a, b, c \in L$. The residuation operation is a generalization of the classical implication.

Key Points

The residuated lattice is naturally ordered by the classical lattice ordering relation defined by

$$a \le b \quad \text{if and only if} \quad a \wedge b = a.$$

In general, of course, there can exist incomparable elements in L. A typical property of the residuation operation is $a \rightarrow b = 1$ iff $a \le b$. In words: $a \le b$ iff the degree of implication $a \rightarrow b$ is equal to 1.

A typical example of residuated lattice is the *standard Łukasiewicz MV-algebra*

$$\langle [0, 1], \max, \min, \otimes, \rightarrow, 0, 1\rangle$$

where $a \otimes b = \max\{0, a+b-1\}$ is Łukasiewicz product (conjunction) and $a \rightarrow b = \min\{1, 1-a+b\}$ is Łukasiewicz implication.

Another widely used residuated lattice is an MTL-algebra, where $L = [0,1]$, $\otimes$ as some left continuous *t-norm* (see TRIANGULAR NORMS) and $\rightarrow$ is the corresponding residuation.

Every boolean algebra is a residuated lattice. Thus, a special case of residuated lattice is also the boolean algebra for classical logic

$$\langle \{0, 1\}, \vee, \wedge, \otimes, \rightarrow, 0, 1\rangle$$

where $\otimes = \wedge$ (i.e., $\otimes$ coincides with minimum) and $\rightarrow$ is the classical boolean (material) implication.

Both $\wedge$ as well as $\otimes$ are natural interpretations of logical conjunction. This means that there are two, in general different, conjunctions in fuzzy logic. In classical logic they coincide, though. The residuation $\rightarrow$ is natural interpretation of implication.

Negation is defined by

$$\neg a = a \rightarrow 0.$$

This operation coincides with classical negation in boolean algebra for classical logic, i.e., $\neg 0 = 1$ and $\neg 1 = 0$. In the standard Łukasiewicz MV-algebra (based on $[0,1]$) this operation reduces to $\neg a = 1 - a$.

The *biresiduation* operation is defined by

$$a \leftrightarrow b = (a \rightarrow b) \wedge (b \rightarrow a).$$

This operation coincides with with classical equivalence in boolean algebra for classical logic. In fuzzy logic, it is used as a natural interpretation of logical equivalence. In standard Łukasiewicz MV-algebra it gives $a \leftrightarrow b = 1 - |a - b|$, $a, b \in [0,1]$.

There are many more special kinds of residuated lattices. Except for boolean algebra, the most important are BL-algebra, Gödel algebra, product algebra and MV-algebra.

Resource Allocation Problems in Spatial Databases

Facility-location problem

Definition

Assume that a franchise plans to open one or more branches in a state. How shall the locations of the new branches be allocated to maximally benefit the customers? Depending on whether some branches already exist and how to quantify the benefits to the customers, there are multiple forms of such resource allocation problems. In spatial databases, distance plays an important role. A customer is assumed to always visit the closest branch. Therefore it is beneficial to a customer if a new branch is opened at a location closer than her closest existing branch. The *max-inf optimal-location query* assumes the existence of a set of sites (already opened franchise branches), and aims to find a new location within a given area which benefits the largest number of customers. The *min-dist optimal-location query* also assumes the existence of a set of sites and aims to find a location for a new site which is optimal; but here the optimality is defined as minimization of the average distance from each customer to the nearest site. Compared with its max-inf counterpart, the min-dist optimal-location query takes into account the saved distance for each customer. The *k-medoid query* assumes that there does not exist any p as residential blocks) that minimize the average distance from every customer to the nearest picked location.

Historical Background

There exists an extensive literature in operations research on resource allocation problems, named the *facility location problems*. The most widely studied version is the *uncapacitated facility location (UFL)* problem.

Given a set of customers, a set of potential sites, a non-negative cost for opening each site, and a non-negative service cost between each site and a customer, the *UFL* problem is to find a subset of the potential sites so that the total cost (opening cost plus service cost) is minimum. Here, the term "uncapacitated" refers to the assumption that there is no limit on the number of customers that each site can serve.

The k-medoid problem is a variation of the UFL problem, where the set of customers and sites are identical, the opening cost of each site is zero, the service cost between a site and a customer is the distance between them, and there is an additional constraint that exactly *k* sites will be opened. The k-means problem is a related problem, where the potential sites can be anywhere.

Facility location problems are (typically) NP-hard. Therefore research has focused on approximate algorithms with low computational complexity and small approximation errors. A recent survey of approximate algorithms for facility location problems appeared in [5]. Unlike spatial database research, the operations research assumes that all objects fit in memory and existing approaches typically scan through the dataset multiple times.

Foundations

When considering resource allocation problems in a large spatial database, the data usually reside in secondary storage and are indexed by spatial index structures so that scanning through all objects is avoided. The research goal is not to derive good asymptotic complexities, but to design efficient algorithms which, when applied to real datasets, incur a small number of I/O operations.

For both the max-inf and min-dist optimal-location queries under L_1 distance, there exist straightforward $O(n^2)$ solutions which find *exact* answers. Note that this differentiates the optimal-location queries from the NP-hard facility-location problem. However, such $O(n^2)$ algorithms are prohibitively slow in large spatial databases. Exploiting spatial index structures, [1] and [6] proposed solutions which are much faster (sub-linear in practice).

Similarly, the k-medoid query was examined in the context of spatial databases by utilizing spatial index structures. In particular, [2] relies on the clustering of higher-level index entries in an R-tree to avoid scanning through all objects.
