In other words, $\Psi(i)$ refers to the position in the suffix array of the text suffix that follows $SA[i]$ in T, namely, the text suffix which is one-symbol shorter. The compact storage of SA proposed by Grossi and Vitter is based on a hierarchical decomposition that deploys Ψ. To represent $SA_0 = SA$ they use three vectors: B_0, Ψ_0 and SA_1. The binary vector $B_0[1,n]$ marks the entries of SA_0 which are even (suffixes). The vector $\Psi_0[1,\lceil n/2 \rceil]$ stores the values Ψ(i) for which $SA[i]$ is odd (hence $B_0[i] = 0$). The vector $SA_1[1,\lceil \mathrm{n}/2 \rfloor]$ is a "halved" version of SA_0, in that it contains the even elements of SA_0 divided by 2. Surprisingly enough, these three vectors suffice to retrieve any entry SA[i]. Of course, it is easy to determine whether $SA[i]$ is even or odd by simply looking at $B_0[i]$. If $SA[i]$ is odd, the following suffix $SA[i] + 1 = SA[\Psi(i)]$ is even, and its suffix-array position can be determined as $\Psi(i) = \Psi_0(\mathtt{rank}_0(B_0,i))$. If $SA[i]$ is even, it is enough to look at its *halved* value stored at $SA_1[\mathtt{rank}_1(B_0,\mathrm{i})]$. The three vectors Ψ_0, B_0 and SA_1 form the first level of the hierarchical decomposition of SA. This idea is applied recursively on SA_1 which is replaced by three other vectors: Ψ_1, B_1 and SA_2. This goes on until SA_h can be represented within O(n) bits, namely when $h = \lceil \log \log n \rceil$. Accessing $SA[i]$ takes h time. By storing the text T, in additional $n\lceil \log \sigma \rceil$ bits, one can search for a pattern P via the classic binary-search, now on the compacted SA. Grossi and Vitter proposed to store vectors B in compressed form via proper `rank`-data structures (see [14] and references therein), and deployed the *piecewise increasing property* for Ψ – namely, if $T[SA[i]] = T[SA[i + 1]]$, then $\Psi(i) < \Psi(i + 1)$ – to store each level of Ψ within $\frac{1}{2} n \log \sigma$ bits, still preserving constant time lookup to any level of Ψ. Other time/space tradeoffs are possible by using different numbers of levels. Essentially, not all the levels are represented and the function Ψ is used to jump from one represented level to the next represented one.

Recently, Csa has been the subject of two main improvements. The first one, due to Sadakane [16], showed that the original text T can be replaced with a binary vector F such that $F[i] = 1$ iff the first symbol of the suffixes $SA[\mathrm{i} - 1]$ and $SA[i]$ differs. Since the suffixes in SA are lexicographically sorted, one can determine the first symbol of any suffix in constant time by just executing *a rank*$_1$ query on F. This fact, combined with the retrieval of Ψ's values in constant time, allows comparing any suffix with the searched pattern $P[1,p]$ in time $O(p)$. Sadakane also provided an improved representation for Ψ achieving $nH_0(T)$ bits. Theoretically, the best variant of Csa is due to Grossi, Gupta and Vitter [12] who devised some further structural properties of Ψ that allow to come close to $nH_k(T)$ bits, still preserving the previous time complexities for all full-text queries (see Table 1). Practically, the best implementation of the Csa is the one proposed by Sadakane that actually does not use the hierarchical decomposition above, but orchestrates a compact representation of the function Ψ together with the backward search and the sampling strategy of the Fmi family. This *hybrid* index is among the fastest compressed indexes to count and locate pattern occurrences over highly-compressible data.

Other Compressed Indexes

Previous families of compressed indexes based their search on the implicit or explicit availability of the suffix array data structure. Recent years have seen the design of several other approaches, the two most notable ones are the *LZ-index*, proposed by Navarro, and the *Compressed Suffix Tree*, devised by Sadakane and then improved by many other authors. The former index bases its design on the parsing of the text T via the LZ78-compression scheme, and then enriches its output by additional data structures that support efficient searches over the parsed phrases. By properly orchestrating LZ78-parsing with compressed dictionary data structures, [1] achieved interesting search and entropy-based space bounds which are not competitive theoretically with the ones obtained by Fmi and Csa indexes (see Table 1) but are, nonetheless, fast in practice. As far as the compressed suffix-tree is concerned, it is worth noticing that the compression of this data structure is obtained by properly orchestrating succinct tree and succinct array encodings [15]. The total space is the one required by the Csa built on T plus no more than $6n + o(n)$ bits; all known suffix-tree operations are supported with a maximum slowdown of $O(\log\ n)$ time with respect to the uncompressed suffix tree.

Key Applications

Compressed full-text indexes might be used at the core of modern web search, IR, data base and data mining applications because, as Knuth observed in the Art of Computer Programming (vol. 3): "*space optimization is closely related to time optimization in a disk memory*". Data compression can not only squeeze the space overhead of an index, but also improve its speed, as remarked earlier. Several authors [3,5,11,17,18] have recently addressed these issues in various settings but, nonetheless, there is much more room for theoretical and practical improvements.

Future Directions

An open challenge concerning compressed indexes is to fasten their `locate` queries in order to achieve the optimal $O(occ)$ time bound. The best known result is due to Ferragina and Manzini [9]: each occurrence is located in constant time, and the index takes $O(nH_k(S) \log^{\in} n) + o(n \log \sigma \log^{\in} n)$ bits, where $\in$ is any positive constant. This bound has the extra log-factor in front of the entropy term! Therefore, it is natural to ask: Is there a full-text index achieving $O(p + occ)$ query time and $O(nH_k(S)) + o(n \log \sigma)$ bits of space occupancy in the worst case? This result would be *provably better* than any known uncompressed full-text index.

Another interesting open problem consists of designing a compressed full-text index which is disk-aware or, better, memory-oblivious in that it scales optimally over all memory levels available in a modern PC. The above data structures are compressed, but their overall size may span many memory levels so that issues pertaining to proper *arrangement of data* and properly *structured algorithmic computations* come into play. The most attractive disk-aware index is the String B-tree [7]; whereas the best cache-oblivious index is the COSB-tree [3,8]. Unfortunately the former is uncompressed, whereas the latter uses a compression heuristic which does not guarantee entropy-bounds in the worst case. It would be therefore valuable, also in practice, to devise a compressed index that combines the I/O-efficiency of the (cache oblivious) String B-tree with the space efficiency of the compressed full-text indexes discussed in this entry. Some preliminary results have been devised in [8], but the ultimate goal has yet to be achieved.

Experimental Results

Site Pizza&Chili [6] provides a full experimental comparison among the major implementations of compressed indexes. The experiments mainly show that these indexes can compress a text within 40–80% of its original size, and support searches for 20,000–50,000 patterns of 20 chars each within a second, locate about 100,000 pattern occurrences per second, and decompress text symbols at a rate of about 1MB/s. The compressed indexes are from one (`count`) to three (`locate`) orders of magnitudes slower than what one can achieve with a plain suffix array, at the benefit of using up to 18 times less space. This slowdown is due to the fact that search operations in compressed indexes access the memory in a non-local way thus eliciting many cache/IO misses, with a consequent degradation of the overall time performance. Nonetheless compressed indexes achieve a (search/extract) throughput which is significant and may match the efficiency specifications of most software tools running on commodity PCs. Recently, Ferragina and Venturini [11] provided a comparison among classic and compressed indexes for the Dictionary Indexing Problem showing that, in this case, compressed indexes may be faster than classic IR approaches.

Synonyms

Indexing the past; Historical spatio-temporal access methods; Trajectory indexing

Definition

Consider an object O that reports to a database server two consecutive locations $P_0 = (x_0,y_0)$ and $P_1 = (x_1,y_1)$ at times t_0 and t_1, respectively. The database server has no idea about the exact locations of object O between t_0 and t_1. To be able to answer queries regarding the user location at any time, the database server interpolates the two accurate locations through a trajectory that connects P_0 and P_1 through a straight line. While object O keeps sending location samples, the database server keeps accumulating set of consecutive trajectory lines that represent the historical movement of object O. Indexing historical spatio-temporal data includes dealing with such large numbers of trajectories. The main idea is to organize past trajectories in a way that supports historical spatial, temporal, and spatio-temporal queries.

Historical Background

The rapid increase in spatio-temporal applications calls for new auxiliary indexing structures. A typical spatio-temporal application is one that tracks the behavior of moving objects through location-aware devices (e.g., GPS). Through the last two decades, many spatio-temporal access methods were developed.

Spatio-temporal access methods focus on two orthogonal directions: (i) Indexing the past i.e., historical location data, (ii) Indexing the current and predicted future positions. This entry focuses on the former direction. A first approach to support spatio-temporal data is to extend existing spatial data (e.g., R-tree [4]) to support the temporal dimension. However, as the temporal dimension has distinct properties from other spatial dimensions, these approaches are later modified to give special attention to the temporal dimension.

Foundations

The main challenge in indexing historical spatio-temporal data is that the size of the history is continuously increasing over time. Consider moving objects that continuously send their positions. Keeping track of all updates is almost infeasible. Two approaches are used to minimize the history size: (i) *Sampling*. The stream of data is sampled at certain time positions. Linear interpolation may be used between sample points to form trajectory lines. (ii) *Update on change only*. Moving objects send information only when their data is changed (e.g., change in speed or direction). In general, spatio-temporal indexing methods for historical data can be categorized into the following three categories:

1. Three-Dimensional Structures

This category augments existing spatial access methods (e.g., the R-tree [4]) to support the newly introduced temporal dimension. Examples of this category include:

- *RT-tree* [15]: The RT-tree combines the foundation of the R-tree as a spatial access method and the TSB-tree [7] as a temporal access method. In the RT-tree, a new entry is added to the regular R-tree that indicates the start and end times of the current object. An RT-tree entry has the form (id, MBR, t_s, t_e), where id is the object identifier, MBR is the objects minimum bounding rectangle, and t_s and t_e give the time interval in which this object is valid. The RT-tree supports spatial queries as efficient as the regular R-tree. However time slice queries and interval queries may span the whole tree.
- *3D R-tree* [13]: The 3D R-tree treats time as yet another dimension in addition to the spatial dimensions. The main idea is to avoid discrimination between spatial and temporal queries. The 3D R-Tree supports both the temporal and spatial queries, although with performance drawbacks. A main drawback is that timeslice queries are no longer dependent on the live entries at the query time, but on the total number of entries in the history.
- *STR-tree* [9]: The STR-Tree is an extension of the R-Tree, with a different insert/split algorithm. Leaf nodes has the form (id, t_{id}, MBR, o) where t_{id} is the trajectory identifier and o is the orientation of this trajectory in the MBR. The main idea is to keep spatial closeness and partial trajectory preservation by trying to keep line segments belonging to the same trajectory together while keeping spatial closeness as the R-Tree. A parameter p is introduced to balance between spatial properties and trajectory preservation. p indicates the number of levels reserved for trajectory preservation. When inserting a new line segment the goal is to insert it as close as possible to its predecessor in the trajectory within p levels. A smaller p decreases the trajectory preservation, while increasing the spatial closeness.

2. Overlapping Two-Dimensional Structures

This category separates between the spatial and temporal dimensions. The main idea is to use a separate spatial index for each time instance. Then, a temporal index is used to index the spatial indexes. To reduce the storage overhead, consecutive spatial indexes may overlap to avoid storing multiple instances of objects that are not frequently changed over time. Examples of this category include:

- *MR-tree* [15]: The MR-tree employs the idea of overlapping B-trees [2] in the context of the R-tree. The main idea is to avoid the storage overhead of having separate R-trees for each timestamp. The saving in storage is achieved by not storing the common objects among consecutive R-trees. Instead, links from different roots point to the same nodes where all the node entries keep their values over the different timestamps. This idea is perfect in the case of a time slice query. The search is directed to the appropriate root, and then a spatial search is performed using the R-tree. However, the performance of time window queries is not efficient. Also, one major drawback is that many entries can be replicated. Consider the case that only one node entry is changed over two consecutive timestamps, then all other node entries need to be replicated in two consecutive R-trees.

- *HR-tree* [8]: The Historical R-tree (HR-tree) is very similar to the MR-tree. The HR-tree has a concrete algorithm and implementation details of using the overlapping B-tree [2] in the context of the R-tree. The same idea of overlapping trees is applied in the context of quadtrees, where it results in *overlapping quadtrees* [14].
- *HR+-tree* [11]: The HR+-tree is designed mainly to avoid the replication of some entries in the HR-tree. The main reason for having duplicate entries in the HR-tree is that the HR-tree has a condition that any node can contain only entries that belong to the same root, i.e., ones that have the same timestamp. The HR+-tree relaxes this condition by allowing entries from different timestamps to reside in the same node. However, the parent of this node in each R-tree has only access to the entries that belong to the parent's timestamp. In other words, a node may have multiple parents, where each parent has access only to a different part of the node.
- *MV3R-tree* [12]: The MV3R-tree is based mainly on the multi-version B-tree (MVB-tree) [11]. The main idea is to build two trees, an MVR-tree to process timestamp queries, and a 3D R-tree to process long interval queries. Short interval queries are optimized to check which tree is to be used based on a threshold value.

3. Trajectory Indexing

This category is radically different from other categories where the main concern is to support trajectory-oriented queries. On the other side, spatial queries are not well supported. Examples of this category include:

- *TB-tree* [9]: The Trajectory-bundle tree (TB-tree) is an R-tree-like structure that strictly preserves trajectories. A leaf node can only contain segments belonging to the same trajectory. As a drawback, line segments of different trajectories that lie spatially close will be stored in different nodes. The TB-tree grows from left to right. The left-most leaf node is the first inserted node and the right-most leaf node is the last inserted one. The TB-tree is an extension of the STR-tree to handle only trajectories.
- *SETI* [3]: The Scalable and Efficient Trajectory Index (SETI) partitions the spatial dimension into static, non-overlapping partitions. The main observation is that the change of the spatial dimension is limited while the temporal dimension is continuously evolving. Thus, the spatial dimensions are partitioned statically. Within each partition the trajectory segments are indexed using an R-tree. Using a good partitioning function results in having line segments of the same trajectory stored in the same partition. Thus, trajectory preservation is achieved by minimizing the effect of the spatial dimensions in the R-tree. A segment that crosses the boundary of two spatial partitions is clipped and is stored twice in both partitions. This may lead to duplicates in the query result.
- *The SEB-tree* [10]: The Start/End timestamp B-tree (SEB-tree) has an idea similar to SETI, where the space is partitioned into zones that may be overlapped. Each zone is indexed using the SEB-tree that considers only the start and end timestamps of the moving objects. Each moving object is hashed to its zone. A key difference over SETI is that there are no trajectories. Instead only two-dimensional points are indexed. By having the spatial zoning partitioning, two-dimensional points that belong to similar trajectories are kept together.

Key Applications

Moving Object Databases

The wide spread of location-detection devices (e.g., GPS-like devices and cellular phones) along with the recent advances in mobile computing enable the so-called location-based environments. In such environments, a large number of moving objects continuously send their location information to a location-based database server. Storing and indexing past location information enable new types of queries that include: "*What are the vehicles near my shop yesterday between 7:00 and 8:00* A.M. *yesterday*" and "*At what time yesterday, my car was within one mile of a fast food restaurant.*" Indexing historical spatio-temporal data is a major module for efficient query retrieval for moving object databases.

Indexing Metric Spaces

Pavel Zezula, Michal Batko, Vlastislav Dohnal
Masaryk University, Brno, Czech Republic

Synonyms

Distance indexing

Definition

Metric space indexing is closely related to the recent digitization revolution where almost everything that one can see, hear, read, write or measure is available in digital form. Unlike traditional attribute-like data types such as numbers and strings of sortable domains, instances of these new data types are complex, and the only measure of comparison to apply is a sort of *similarity*. Such a situation implies an application of the *query-by-example* search paradigm where the database is searched for objects that are *near* the example object, also called the *query object*. A useful abstraction of this similarity is to see it as mathematical *metric space* [7]. The problem of organizing and searching large datasets of complex objects can then be considered from the perspective of generic or arbitrary metric spaces, sometimes labeled *distance spaces*. In general, the search problem can be described as follows:

- *Let D be a domain, d a distance measure on D, and (D,d) a metric space. Given a set $X \subseteq D$ of n elements, preprocess or structure the data so that similarity queries are answered efficiently.*

From a practical point of view, *X* can be seen as a file (a dataset or a collection) of objects that takes values from domain *D*, with *d* as the proximity measure, i.e., the distance function defined for an arbitrary pair of objects from *D*. Though several types of similarity queries exist and others are expected to appear in the future, the basic types are known as the *similarity range* query whose results are constrained by a maximum distance expressed as the query radius, and the *nearest neighbor(s)* query bounding the query response size by the maximal number of closest objects $k \leq n$.

The metric space indexing approach significantly extends the scope of traditional search approaches. It supports the execution of similarity queries without obviating the traditional attribute-like searching. The distance-searching approach to indexing is thereby highly *extensible*.

Historical Background

The need for similarity searching in collections of metric objects was recognized quite early and the history documented by numerous citations is nicely summarized in recent surveys such as [2, 6, 8, 10]. The first known proposal was the *Burhard-Keller tree* from 1973, which was later extended into the *Fixed queries tree* and the *Fixed queries array* techniques, all of which specialize in discrete distance functions only. By recursive applications of the basic *ball* and *generalized-hyperplane* partitioning principles, the *Vantage point tree* and the *Generalized-hyperplane tree* were defined. The advantage of exploiting pre-computed distances to speed up retrieval was first recognized in the 1980's and formalized as the *Approximating and Eliminating Search Algorithm*, AESA. However, all of these early attempts were only considering small data collections stored in the main memory.

The importance of processing large datasets stored on disk memory was reflected for the first time in the M-tree [3]. It is a balanced metric tree supporting a disk-oriented storage, trying to optimize the I/O as well as the CPU costs of query processing by means of a synergistic combination of several elementary strategies. It can be considered as a generalization of the R-tree and the B-tree. The M-tree's success has been demonstrated by numerous modifications and extensions concerning mainly insertion algorithms, mechanisms of splitting, and strategies for query execution. The most significant extension is the Slim-Tree [9]. As an orthogonal approach to tree partitioning, the D-index [4] is constructed as a multi-tier hashing structure consisting of search-separable sets of objects on each tier organized in directly-accessible buckets. The structure supports easy insertion and its search costs are bounded because no more than one bucket needs to be accessed at each level for range queries up to a pre-defined value of the search radius. Other important hybrid approaches are known as the *Multi vantage point tree*, the *Geometric near-neighbor access tree*, and the *Spatial approximation tree*.

The similarity search in metric spaces is generally expensive and state-of-the-art access methods designed for a single computer do not provide sufficient performance for highly interactive applications that access large collections of data. The *approximate similarity search* techniques offer greatly improved efficiency vis à vis precise similarity searching at the expense of some imprecision in the results. The use of the approximate similarity search is mainly justified by the following two observations: (i) the similarity between objects is often subjective, thus very difficult to express as a unique rigorous function; (ii) similarity search processes are intrinsically iterative – users typically issue several similarity queries to the search system, possibly reusing the previous query results to express new ones. Practical experiments with approximate similarity search techniques register performance improvements up to two orders of magnitude compared to the precise evaluation of the same queries. Other techniques overcome the *scalability* problem by distributing partitions of data and by executing similarity queries in parallel using structured peer-to-peer networks. Four such peer-to-peer techniques are compared in [1].

Foundations

In the last decade, metric space indexing for similarity search has prompted major research efforts resulting in a number of specific theories, techniques, implementation paradigms and analytic tools aimed at making the distance-based approach viable. There are basically two ways to solve the indexing problem: (i) to transform the metric space so that a working solution from another domain can be applied; or (ii) exploit the general properties of metric functions directly. This entry focuses on native indexing.

Due to the lack of a global ordering or a fixed position as in coordinate spaces, elementary *partitioning* in generic metric spaces is defined with respect to either one or two fixed reference objects taken from *D*. The first principle, known as the *ball partitioning*, uses one given object as a center and a specific radius as a boundary to form a sphere (ball). The set of data is then divided into two disjoint subsets: objects inside the ball and those outside the ball. The other principle partitions the space using two given reference objects where the distance establishes the borderline of the *generalized hyperplane partitioning* – objects that are closer to the first reference object than to the second form one partition, while the rest of the objects belong to the second partition.

In addition to the partitioning principles, strategies for query execution play another important role in search structures because they can significantly influence the efficiency of answering queries. Efficient search algorithms for similarity range and nearest neighbor queries have been defined for metric indexes, based on the *branch and bound* strategy in principle. There are even algorithms for evaluating *incremental nearest neighbor* queries, as well as *similarity joins*. Approximate similarity searches have also been studied thoroughly in order to improve performance. The general idea of approximation algorithms is to relax some constraints of the "precise" similarity search to reduce search costs, as measured in disk accesses and/or the number of distance computations. This inevitably means that *false hits* or *false dismissals* may occur.

Since the computational complexity of some metric distance functions can be quite high, it is very important for metric indexes to limit the number of distance computations as much as possible. The rationale behind such strategies is to exploit already-evaluated distances between some objects while properly applying the metric space postulates – namely the *triangle inequality*, *symmetry*, and *non-negativity* – to determine bounds on distances between other objects. The most elementary case can be explained on three objects a,b, and $c \in D$. Provided the distances $d(a, b)$ and $d(b, c)$ are known, it is clear that the distance between a and c cannot be longer than their sum, i.e., $d(a, c) \leq d(a, b) + d(b, c)$. Alternatively, if the known distances are $d(a, c)$ and $d(b, c)$, the distance $d(a,b)$ must be at least as long as their difference, that is $d(a, b) \geq |d(a, c) - d(b, c)|$. Several *bounding strategies* originally proposed in [5] are summarized in [6]. These techniques represent the foundations of the general pruning rules that are employed, in a specific form, in practically all index structures for metric spaces. They can be considered as the basic formal background of metric indexes.

Key Applications

Treating data collections as metric objects is advantageous in that many data classes and information-seeking strategies conform to the metric view. Accordingly, a single metric indexing technique can be applied to many specific search problems quite different in nature. In this way, the important *extensibility* property of indexing structures is satisfied by default. An indexing scheme that allows various forms of queries, or which can be modified to provide additional functionality, is of more value than an indexing scheme otherwise equivalent in power or even better in certain respects, but which cannot be extended.

Distance functions of metric spaces represent a way of quantifying the closeness of objects in a given domain. The distance functions are often tailored to specific applications or a class of possible applications. In practice, the distance functions are specified by domain experts, however, no distance function restricts the range of query types that can be asked with this metric. The distance functions can be *discrete* or *continuous*. Another classification is possible according to the type of domain of compared objects. For example, the *Minkowski distance* functions form a whole family of metric functions, designated as the L_p metrics, because the individual cases depend on the numeric parameter p. These functions are defined on n-dimensional vectors, where the L_1 metric is known as the *Manhattan distance* (also the *City-Block distance*), the L_2 distance denotes the well-known *Euclidean distance*, and the L_∞ is called the *maximum distance*, the *infinite distance* or the *chessboard distance*. The closeness of sequences of symbols (strings) can be effectively measured by the *edit distance*, also called the *Levenshtein distance*. In order to identify common molecular subsequences, the Smith-Waterman algorithm has been proposed. In case the processed objects are sets, the *Jaccard's coefficient* or the *Hausdorff distance* can be applied. More details about metric functions can be found in [5], but the set of metric distance functions is still growing, as evidenced by the recent *Earth Mover's Distance*, for example.

Experiments show that metric indexing techniques are very competitive even in specific data domains traditionally supported by specialized index structures, the R-tree for *multi-dimensional data* and the B-tree for one-dimensional *attribute-like data* being two such examples. The number and variety of metric distance functions determine the range of applications which can apply the metric indexing approach. It has proved useful for *multimedia data features* since most of the standard MPEG7 image descriptors are metrics. But the application of metric indexing involves a lot of diverse fields such as *spatial databases*, *computer graphics and vision*, *game programming*, *geographic information systems*, *computational geometry*, *computer-aided design*, *robotics*, *computational biology* and many others.

Future Directions

The biggest challenge of a perspective search paradigm is to find self-organized solutions that evolve in time and still scale into the expected data volumes. In general, the self-organizing systems build and maintain an internal knowledgebase in response to the flow of data and queries. Such initiative must be based on solid theoretical backgrounds to avoid possible quick but ad-hoc solutions which will sooner or later fail due to the absence of rigorous definitions and unpredictable behavior. The research needs to go beyond the capabilities of traditional computer science and should try to find an inspiration in other scientific areas. The social sciences offer a promising alternative, especially advances in online social networking.

Experimental Results

Experimental results demonstrate the extensibility of the metric space approach since most of the proposed indexing tools work for any metric distance function. The performance is primarily influenced by the distribution of distances, the smaller the variation of distances, the more expensive the search becomes. At the same time, the scalability of expensive queries is practically linear [8]. In order to deal with the huge volumes of data required by current applications, distributed architectures with P2P navigation [9] seem to offer a solution. Given enough resources, P2P networks maintain almost constant response-time while scaling to data volumes larger by several orders of magnitude.

Data Sets

Several influential research groups are currently collecting large repositories to test the scalability of their indexing tools. One of the most significant and publicly available web pages is the UCI Machine Learning Repository http://mlearn.ics.uci.edu/MLRepository.html with nearly 200 various datasets.

Data warehouse indexing

Definition

Indices are data structures especially designed to allow rapid access to data in large databases. Data warehouses are typically used to perform intensive analyses of very large data sets. Several indices, such as projection indices, bitmap indices, bitslice indices, and summary indices, have been developed to address the special needs of data warehousing, and are presented in this entry.

Historical Background

Data warehouses were developed to capture operational information, store it over a long period, and provide support for intensive analysis of historical data. The special needs of data warehouses – very large data sets, high dimensional data, and the extensive use of categorical data – has led to the development of specialized indices intended for use in data warehouses. The use of these indices was pioneered in such systems as Model 204 and Sybase IQ.

Foundations

Indices, such as *B-trees*, *R-trees*, *quad-trees*, *hash tables*, and *inverted indices*, are integral parts of any database system. Query processing in data warehouses place special demands on the indices: very large data sets, high dimensional data, large materialized aggregate views, and categorical data. Several special techniques have been developed in response.

Projection Indices: Data warehouses are often used to store one or more high dimensional *fact tables*, which contain historical records of past events. For example, a SALES fact table might have fields which describe the customer (CustomerID, FirstName, LastName), the product sold (ProductLine, Brand, Size, Color), the method of sale (Store, Referrer, SalesPerson), and values (i.e., *measures*) which quantify the sale (Price, Discount, Quantity).

The large number of dimensions, especially those involving categorical values with a small to moderate range (e.g., Store), or with redundant information (e.g., CustomerID determines FirstName and LastName) can cause an unnormalized fact table to require an excessive amount of storage. *Star schemas* and *snowflake schemas* are common techniques to reduce fact table storage costs. Another useful technique is *vertical partitioning*. Groups of columns, or even individual columns, are stored independently but related via their record ID, or *rid*. Columns with a low cardinality and/or many null values can use special encoding schemes. Sybase IQ made prominent use of this technique.

An advantage of vertical partitioning is that many queries reference only a few of the fields of the fact table. For example, a query might be, "What is the volume of sales which involve a Discount larger than 50%, broken down by Store." If SALES is vertically partitioned, an efficient query plan is to scan the Discount and Store fields. Whenever the Discount field is 50% or larger, retrieve the linked Store field and increment a corresponding counter.

In the above example, the Discount field acts as a *projection index* [9]. Access to the field is fast because of the compact vertically partitioned storage. The set of records which satisfy the "Discount $\geq$ 50%" might be dense (more than 1 in 100), making random access indices inefficient. Furthermore, complex predicates involving several fields can be processed in the same way, providing highly efficient multi-dimensional indices.

Bitmap Indices: Bitmap indices are a logical extension of projection indices [9]. Suppose that the predicate of the query is, "Store = 'Foo' and Brand = 'Bar''. Suppose that both individual predicates is true for about 1 in 100 records – dense enough that linear scanning is effective. However their conjunct is likely to be true for about 1 in 10,000 records – sparse enough that random access is preferable. Therefore an efficient query plan is to:

- Scan the Store vertical partition for values of Foo, and record the corresponding rids
- Scan the Brand vertical partition for values of Bar, and record the corresponding rids
- Compute the intersection of the two rid lists, and fetch the corresponding records

An efficient way to store the rids and then compute their intersection is to use a *bitmap*. Each bit corresponds to a record – the bit at position 0 refers to record 0, the bit at position 1215 refers to record 1215, and so on. A bitmap can be stored as a packed array of bits, e.g., 64 bits per word. Given two bitmaps, Boolean functions can be computed by taking the corresponding Boolean function of the corresponding packed bit array, which are typically very fast CPU register operations.

Store = 'Foo Brand = 'Bar'

$$\boxed{\begin{array}{c}1\\0\\0\\1\\1\\0\\0\\0\\0\\0\\1\\1\\0\\1\end{array}}\ \text{AND}\ \boxed{\begin{array}{c}1\\0\\1\\0\\1\\1\\1\\0\\1\\0\\0\\1\\0\\0\end{array}} = \boxed{\begin{array}{c}1\\0\\0\\0\\1\\0\\0\\0\\0\\0\\0\\1\\0\\0\end{array}}$$

Given a set of bitmaps, complex Boolean predicates can be evaluated very efficiently. Therefore, a natural extension of projection indices are *bitmap indices*: for each value of a field, create and store a bitmap. When a predicate is to be evaluated, the bitmaps can be fetched directly, bypassing the cost of computing them. Bitmap indices are very effective for fields with low cardinality, or for representing pre-computed predicates. However, bitmap indices require a large amount of storage if the field has more than a few distinct values.

Compressed Bitmap Indices: If a field has a large number of distinct values, the bitmaps for most of the values must be sparse, and therefore compressible. A variety of techniques based on *run-length encoding* were developed in the context of image compression, but are also usable for bitmap index compression. While the RLE-based techniques can achieve near-optimal compression, the compression and decompression can be slow because compression is achieved by compressing run length codes and packing them into a bit array.

A bitmap compression technique better suited for compressing bitmap indices are the *Byte-aligned Bitmap Codes*, or BBC codes [1]. Each code word consists of one or mote bytes, eliminating the need for bit extraction. Furthermore, Boolean operations can be performed on the BBC codes directly, creating BBC code output. However, modern processors operate on multi-byte words, and data elements such as integers must be word-aligned before they can be operated upon. *Word-aligned* codes [11] extend the BBC code idea, and achieve even greater performance by avoiding word alignment costs.

The penalty for using byte-aligned or word-aligned compression codes is that they are less space efficient than the best RLE codes. A bitmap index might therefore be stored using a variety of codecs, depending on the individual bitmap properties. Furthermore, evaluating a complex predicate requires an evaluation plan, and there are a very large number of evaluation plans for a large and complex predicate. Fortunately, there is a linear-time dynamic programming optimization algorithm for choosing an optimal evaluation plan. By using BBC codes, word-aligned codes, and optimized evaluation, a bitmap index can be stored in space similar to that of a conventional index, and yet evaluate complex predicates, including large range queries, very efficiently [1,11].

Hybrid B-tree/Bitmap Indices: If a bitmap index is used for a high cardinality field, the field will have a large number of bitmap indices, and finding the correct bitmaps to use in evaluating a predicate becomes a search problem. Conversely, a B-tree index for a non-key field will in general need to store a set of records for each indexed value. A natural solution to both issues is to record the rid set of a value using a compressed bitmap. Oracle uses this technique, with BBC codes used to compress the bitmap [9].

Bitslice Indices: If the indexed field has a very high cardinality (e.g., ranges over the integers), bitmap indices lose their value. However, one can still make use of bitmap indices by using bitmaps to index value ranges. For example, one can partition the range of an integer or floating point field into, say, 1,000 ranges, then create a bitmap for each range. Range queries are likely to be efficient, but point queries might not be as selective as desired. By a judicious choice of overlapping value ranges, one can obtain more value from each bitmap. For example, a *bitslice index* [8] applied on an integer value creates a bitmap for each bit position of the value. So, for example, the value 13 has set bits in the bit-0, bit-2, and bit-3 bitmaps, reset bits in the bit-1, bit-4, bit-5, etc. bitmaps. Point queries are efficiently supported with a bitslice index; but perhaps surprisingly, one can write range queries into compact predicates on bitslice indices (see below an example of bitslice indices on an integer field).

(193)	1	1	0	0	0	0	0	0
(87)	0	1	0	1	0	0	0	0
(225)	1	1	1	0	0	0	0	1
(7)	0	0	0	0	0	1	1	1

Aggregate-Storing Indices: Data warehouses very often support aggregation queries to summarize the mass of data in the fact tables. A common type of query is to ask for the value of an aggregate within a particular range of field value(s). A hierarchical index structure, such as a B-tree, summarizes the data at every level of its hierarchy. For example, a B-tree node has a field value range, and points (directly or indirectly) to the collection of records which have a value in that range for the indexed field.

One can change the definition of "summarize" to mean storing an aggregate value. In a leaf node entry for a value *v*, instead of pointing to the records which have value *v* for the indexed field, the entry contains an aggregate value, e.g., the sum of a measure field, over all records with value *v* in their indexed field. An entry in an interior node (above the leaf level) contains the sum of the aggregates in the child, as well as a pointer to the child and its indexed value range. Finding the aggregate value of the range can be done by walking the tree, once down to the minimum value of the range, and once to its maximum value.

The principle of the aggregate-summarizing B-tree can be extended to handle more useful situations, including aggregate-summarization of multiple dimensions [4,6], and summarization of intervals (useful for temporal database systems) [5].

Summary Indices: A common technique for managing a very large data warehouse is *horizontal partitioning* – partitioning records by one or more predicates. A data warehouse often receives regular updates of new data into its fact table(s), and stores a window (e.g., 1 year) of the most recent data. Fact tables may also be partitioned by other attributes, to narrow search spaces, help ensure that partitions are dense, etc.

If a fact table is sliced into a large number of vertical partitions, the partition predicates act as another type of index. This idea can be extended to recording properties of the data in a partition. For example, a summary index might record aggregates of the data, such as minimum and maximum timestamps [7]. Alternatively, a summary index can record whether or not particular field values exist in the partition [3]. For example, the index can record a list of all customer IDs that appear in a partition (or conversely in which partitions a customer identifier appears). If the average customer ID appears in only a few partition, this type of index minimized the number of partition indices to be searched.

Join and Star Indices

A *join index* is a collection of pairs $\{(r,s)\}$ such that the record in table R with record ID (RID) r joins with the record in table S with RID s, according to the join predicate which defines the index. A join index accelerates the processing of joins, a common activity in a data warehouse with a star or snowflake schema. A *star index* is a join index between a fact table and each of its dimension tables.

Key Applications

The most commonly implemented of these indices is the bitmap index, which has been implemented in most of the major commercial databases used for data warehousing. Bitmap indices are also commonly used in scientific database applications, such as High Energy Physics. In HEP applications, bitmaps indices are often used to record "interest sets" – collections of events found to satisfy some complex property – to accelerate their retrieval for later processing [10].

Indexing of the Current and Near-Future Positions of Moving Objects

Simonas Šaltenis, Christian S. Jensen
Aalborg University, Aalborg, Denmark

Definition

A scenario is assumed where a large population of objects capable of reporting positional data to a central server exists. Specifically, an object may report its current position, but may also report its current velocity vector.

A key challenge is to be able to accommodate the very frequent updates inherent to this scenario. Another important challenge is to contend with, and indeed exploit, all the available positional data so that better query results to near-future queries are enabled.

To address these challenges, the position of an object is typically modeled as a linear function from time to space (typically the two- or three-dimensional Euclidean spaces are assumed). Such functions are readily available, and the positions they return get outdated less frequently than do constant functions, thus reducing the update rate. Further, they enable the computation of more accurate results for near-future queries.

The fundamental types of queries to be supported by an index include ones that retrieve the objects with a position within a specified, rectangular spatial region: *timeslice* and *window* queries consider a stationary region for a single time point or a time interval; and so-called *moving queries* attach a rectangle to a moving object and consider a time interval. The times supported range from the current time to some near-future time.

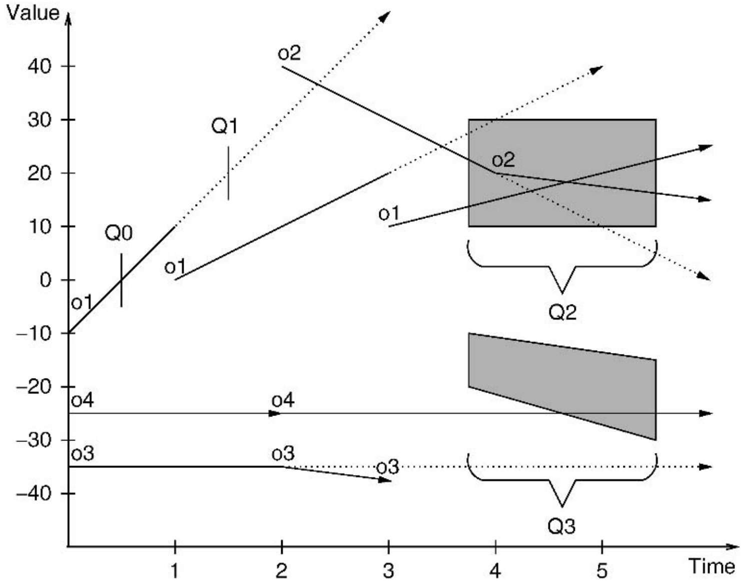
Figure 1 shows a set of trajectories in (x, t)-space of objects and illustrates the three types of queries: $Q0$ and $Q1$ are timeslice queries, $Q2$ is a window query, and $Q3$ is a moving query.

Other types of queries such as nearest neighbor queries or reverse nearest neighbor queries may also be supported. In addition, an index should also support updates, i.e., insertions and deletions.

For its illustration of key concepts, this entry uses primarily R-tree-based techniques; specifically, the TPR-tree [12] is covered in some detail, as it is the ancestor of a sizable family of indices.

Historical Background

The first proposal for the indexing of moving object positions as linear functions is due to Tayeb et al. [14] who propose to use PMR-quadtrees for indexing the future linear trajectories of one-dimensional moving point objects as line segments in (x, t)-space. Kollios et al. [6] also focus mostly on one-dimensional data



Indexing of the Current and Near-Future Positions of Moving Objects. Figure 1. Query examples for one-dimensional data [12].

and employ the so-called *duality* data transformation where a line $x = x(t_{ref}) + v(t - t_{ref})$ is transformed to the point $(x(t_{ref}),v)$, enabling the use of regular spatial indices.

Later research focuses on two-dimensional and, in some cases, three-dimensional data. In general, the proposed indexing methods can be classified according to the space that they index, i.e., what view is taken on the indexed data. Assume the objects move in d-dimensional space (d = 1,2,3). The first approach is to index future trajectories as lines in $(d + 1)$-dimensional space. This is the approach taken by Tayeb et al. [14], but the approach is difficult to extend to higher dimensions, and the index has to be rebuilt periodically.

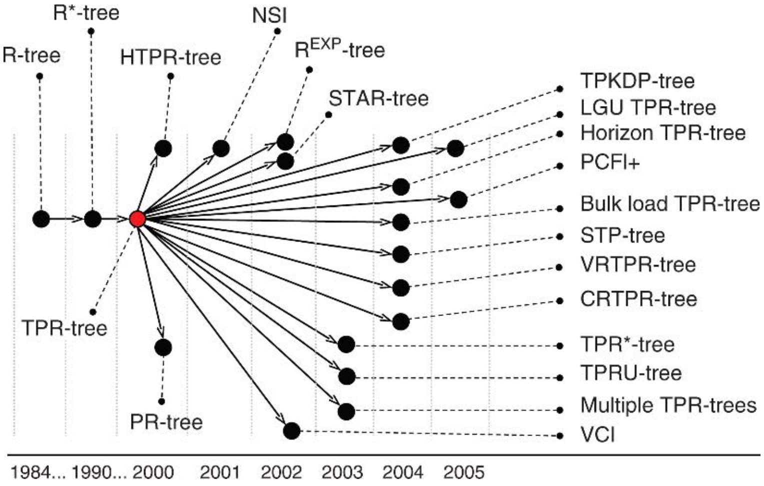
The second approach is to transform the trajectories to points in a higher-dimensional space which are then indexed. Queries are then also transformed to counter the data transformation. The transformation of Kollios et al. [6] maps linear functions in d-dimensional space into static points in $2d$-dimensional space.

In STRIPES [8], PR quadtrees are used to index these $2d$-dimensional points. Yiu et al. [15] instead propose to use space filling curves to further transform $2d$-dimensional points into one-dimensional points that are then indexed by the B^+-tree. Agarwal et al. [1] combine the duality transformation with kinetic data structures [2]. The main idea of kinetic data structures is to schedule future events that update a data structure so that necessary invariants hold.

The third approach, sometimes referred to as indexing in the *primal* space, is to index the data in their native, d-dimensional space, which is possible by parameterizing the index structure using velocity vectors and thus enabling the index to be "viewed" as of any future time. This absence of transformations yields quite intuitive indexing techniques.

The Time-Parameterized R-tree (TPR-tree) [12] exemplifies this approach. Proposed by Šaltenis et al. in 2000, the TPR-tree gave rise to a number of other access methods, as illustrated in Fig. 2. For example, the R^{EXP}-tree [11] extends the TPR-tree to index data with expiration times, so that the positions of the objects that do not update their positions are automatically removed from the index. The TPR*-tree [13] introduces new heuristics with the objective of improving the query performance of the TPR-tree and to optimize it for workloads of queries that differ slightly from those targeted by the TPR-tree. The STAR-tree [10] modifies the TPR-tree by introducing more complex time-parameterized bounding rectangles and making the index self-adjustable. The Velocity Constrained Indexing (VCI) [9] technique uses the regular R-tree with an additional field of v_{max} in each node. The v_{max} is used to expand the bounding rectangles of the R-tree when future queries are processed.

The fourth approach is to index the objects' positions as of some specific time points, so-called label timestamps, and to extend the spatial extents of queries according to the maximum speeds of objects



Indexing of the Current and Near-Future Positions of Moving Objects. Figure 2. TPR-tree origins and follow-up research.

and the difference between the time specified in the query and the label timestamps. The B^x-tree [4,5] uses a combination of space-filling curves and B$^+$-trees to index the (static) positions of objects as of label timestamps.

Foundations

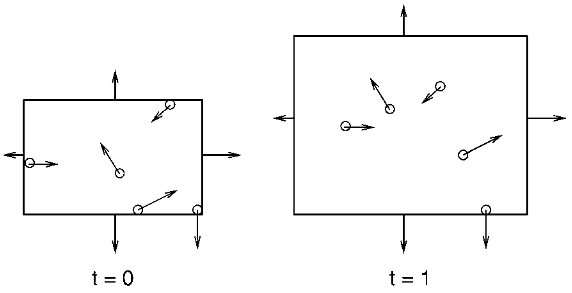
Data and Queries

For an object moving in d-dimensional space, the object's position at some time t is given by $\bar{x}(t) = (x_1(t), x_2(t),\ldots, x_d(t))$, where it is assumed that the times t are not before the current time. This position is modeled as a linear function of time, which is specified by two parameters. The first is a position for the object at some specified time t_{ref}, $\bar{x}(t_{ref})$, which is called the reference position. The second parameter is a velocity vector for the object, $\bar{v} = (v_1, v_2,\ldots, v_d)$. Thus, $\bar{x}(t) = \bar{x}(t_{ref}) + \bar{v}(t - t_{ref})$.

Then, as shown in Fig. 1, a *timeslice* query, $Q = (R, t)$, retrieves points that will be inside the d-dimensional hyper-rectangle R at time t. A *window* query, $Q = (R, t^{\vdash}, t^{\dashv})$, retrieves points that will be inside the hyper-rectangle R sometime during time-interval $[t^{\vdash}, t^{\dashv}]$. A *moving* query, $Q = (R_1, R_2, t^{\vdash}, t^{\dashv})$, retrieves points with trajectories in $(\bar{x}, t)$-space crossing the $(d + 1)$-dimensional trapezoid obtained by connecting R_1 at time $t^{\vdash}$ to R_2 at time $t^{\dashv}$.

The Structure of the TPR-Tree

A large number of indices utilize the structure of the TPR-tree, which indexes moving points in one, two, or three dimensions. It employs the basic structure of the R-tree, which stores data in the leaves of a balanced index tree, and each non-leaf index entry contains a minimum bounding rectangle (MBR) of all the data in the subtree pointed to by the entry. In contrast to the R-tree, the indexed points as well as the bounding rectangles are augmented with velocity vectors. This way, bounding rectangles are time parameterized – they can be computed for different time points. Velocities are associated with the edges of bounding rectangles so that the enclosed moving objects (points or other rectangles) remain inside the bounding rectangles at all times in the future. More specifically, if a number of points p_i are bounded at time t, the spatial and velocity extents of a bounding rectangle along the x axis are computed as follows:



Indexing of the Current and Near-Future Positions of Moving Objects. Figure 3. Example time-parameterized bounding rectangle [3].

$$x^{\vdash}(t) = \min_i\{p_i.x(t)\}; \quad x^{\dashv}(t) = \max_i\{p_i.x(t)\};$$
$$v_x^{\vdash} = \min_i\{p_i.v_x\}; \quad v_x^{\dashv} = \max_i\{p_i.v_x\}.$$

Figure 3 shows an example of the evolution of a bounding rectangle in the TPR-tree computed at $t = 0$. Note that, in contrast to R-trees, bounding rectangles in the TPR-tree are not minimum at all times. In most cases, they are minimum only at the time when they are computed. A process called *tightening*, performed whenever an index node is modified during an insertion or a deletion, recomputes a node's time-parameterized bounding rectangle, rendering it minimum at that time.

Querying the TPR-Tree

The TPR-tree can be interpreted as an R-tree for any specific time, t_q. This suggests that algorithms that are based on the R-tree are easily "portable" to the TPR-tree. For example, answering a timeslice query proceeds as for the R-tree, the only difference being that all bounding rectangles are computed for the time t_q specified in the query before intersection is checked.

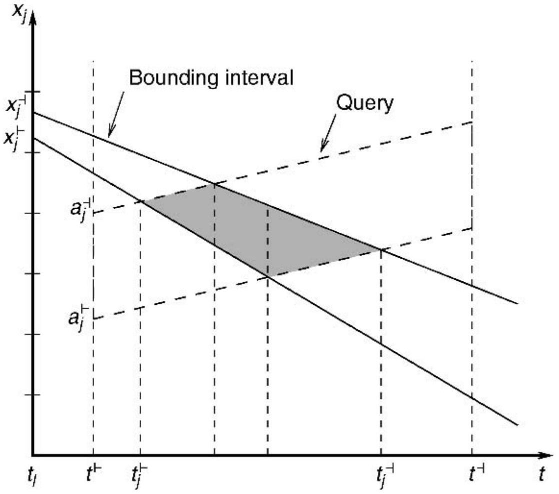
To answer window queries and moving queries, the algorithm has to check if, in $(\bar{x}, t)$-space, the trapezoid of a query intersects with the trapezoid formed by the part of the trajectory of a bounding rectangle that is between the start and end times of the query. This can be checked using a simple algorithm [12]. Figure 4 illustrates the intersection between a one-dimensional time-parameterized bounding rectangle (interval) and a moving query.

Updating the TPR-Tree

An update of the moving object's position is modeled as a deletion of the old position followed by an insertion of the new position. The TPR-tree's update algorithms are based on the update algorithms of the R*-tree, which is an R-tree with improved update algorithms. The update algorithms of the TPR-tree differ from the corresponding algorithms of the R*-tree only in the heuristics that are used. The R*-tree uses heuristics that minimize certain functions, including the area of a bounding rectangle, the intersection of two bounding rectangles, the margin of a bounding rectangle, and the distance between the centers of two bounding rectangles. As the TPR-tree employs time-parameterized bounding rectangles, the above-mentioned functions are time dependent, and their evolution in time should be considered. Specifically, given an objective function $A(t)$, the following integral should be minimized:

$$\int_{t_c}^{t_c+H} A(t)\,dt,$$

where t_c is the time when the heuristics is being applied and H is a so-called *time horizon* parameter, the value of which reflects how far into the future queries are expected to "see" the effects of the application of this heuristics. If $A(t)$ is area (in d-dimensional space), the integral computes the area of the trapezoid that represents part of the trajectory of a bounding rectangle in $(\bar{x}, t)$-space (a d+1-dimensional volume, see also Fig. 4).



Indexing of the Current and Near-Future Positions of Moving Objects. Figure 4. Intersection of a bounding interval and a query [12].

Duality-Transformation Approach

The general approach of indexing moving points in their native space using a time-parameterized index structure such as the TPR-tree is closely related to the duality transformation approach [6, 8, 15].

Considering one-dimensional data, the duality transformation transforms the linear trajectory of a moving point $x = x(t_{ref}) + v(t - t_{ref})$ in (x, t)-space into a point $(x(t_{ref}), v)$, where t_{ref} is a chosen reference time. Queries, then, are also transformed.

Bounding points $(x(t_{ref}), v)$ in the dual space with a minimum bounding rectangle is equivalent to bounding them (as moving points) with a time-parameterized bounding interval computed at t_{ref}. Figure 5 shows the same bounding rectangle and query in $(x(t_{ref}), v)$-space and in (x, t)-space.

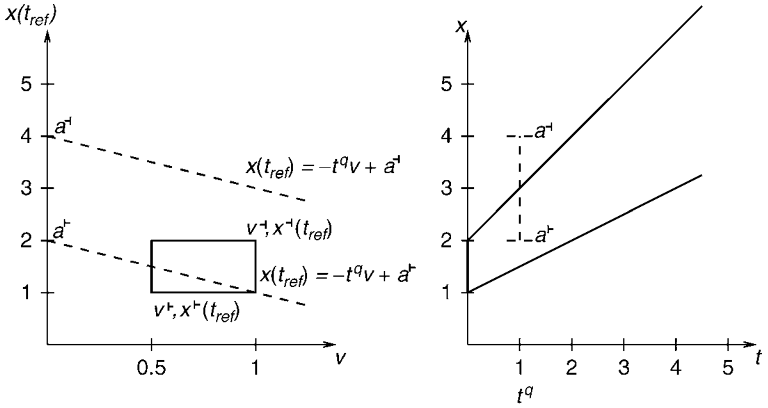
In spite of the equivalence among the bounding rectangles used in the two approaches, the algorithms used in different indexes may vary substantially. A duality-transformation index may not even explicitly use minimum bounding rectangles [15]. Furthermore, while the heuristics of time-parameterized indexes consider the objects' positions at the time the heuristics are applied, the algorithms of duality-transformation approaches always use a pre-chosen constant t_{ref}. For this reason, duality-transformation approaches usually use two (or more) indexes, such that updates are placed into the latest index; and when the earliest index becomes empty, a new index is created [6].

A sufficiently high update rate is crucial in order for both the time-parameterized indexes, such as the TPR-tree, and the indexes using the duality transformation to offer good query performance. The reasons for this are most obvious in the TPR-tree, where query performance degrades due to the uninterrupted expansion of time-parameterized bounding rectangles, which results in more queries intersecting with a given bounding rectangle.

Key Applications

Online, Position-Aware People, Vehicles, and Other Objects

The rapid and continued advances in positioning systems, e.g., GPS, wireless communication technologies, and electronics in general render it increasingly feasible to track and record the changing positions of objects capable of continuous movement. Indexing of such positions is necessary in some Location-Based Services



Indexing of the Current and Near-Future Positions of Moving Objects. Figure 5. Timeslice query (*dashed*) and bounding interval (*solid*) in dual ($x(t_{ref})$, v)-space and (x, t)-space.

(LBS), such as location-based games, tourist-related services, safety-related services, and transport-related services (e.g., fleet tracking).

Process Monitoring

Applications such as process monitoring do not depend on positioning technologies. In these, the position of a "moving point" could for example be a pair of temperature and pressure values at a specific sensor. A timeslice query then would retrieve all sensors with current measurements of temperature and pressure in given ranges.

Future Directions

Tracking continuous real-world phenomena inevitably involves high rates of updates that have to be processed by the index. Very recent research provides a number of interesting ideas for speeding up the processing of index updates. Further research is needed to fully explore trade-offs among update performance, query performance, and query accuracy. Finally, main-memory indexing of such data could be explored to dramatically boost the performance of index updates.

How to handle the always-present uncertainty about the positions of objects has not been sufficiently explored in connection with indexing and warrants further study.

Web indexing

Definition

The process of collecting, parsing, and storing data to provide fast and accurate retrieval of content available on the web. The result of this process is a structure called index that maps the collected data (for instance, words, phrases, concepts, or sound fragments) to the web location where it is possible to find content associated with the data (for instance, pages containing these words, phrases, concepts, or music with the sound fragments). Depending on the data collected, several indices may be created. The process can be manual or automatic. Manually generated indices include web directories, back-of-book-style indices, and metadata. Automatically generated indices are normally associated with the infra-structure of search engines.

Historical Background

One of the first efforts to index the web content was developed by a MIT student, Matthew Grey, who created a program to estimate the size of the Web. This program, called Word Wide Web Wanderer, was able to recursively traverse the web's hypertext structure, retrieving all the referenced documents [11,12,15]. It was the first crawler (also known as robot, bot, or spider). The URLs collected by this program formed the first database of web sites, the Wandex. It also caused quite a controversy due to the large amount of bandwidth it used. In response to this in October 1993, Martijn Koster created a program called ALIWEB (Archie-like Indexing of the Web). To avoid using crawlers, Koster asked webmasters to post their own index information for each page they wanted listed. ALIWEB, however, never reached a size large enough to compete with crawler-based indexers.

After its controversy start, crawlers became a standard component in most search engine indexers. By the end of 1993, search services such as JumpStation, World Wide Web Worm, the Repository-based Software Engineering (RBSE), and Excite used crawlers to gather information of Web pages. In general, these services indexed words extracted from URL, title, and text fragments of the pages.

The indices used by search engines were not designed towards human navigation. Thus, unlike book indices or yellow pages, they did not allow users to freely explore web contents by narrowing the field of interest. This observation motivated the University of Texas to create Elnet Galaxy in January 1994, the oldest web directory. In this index, contents were manually reviewed and organized into hierarchical categories. As in ALIWEB, only pages submitted to the service were listed. In April 1994, two students from Stanford University, David Filo and Jerry Yang, expanded a personal list of pages into a searchable directory, Yahoo!. Unlike Galaxy, Yahoo! automated aspects of the gathering and categorization process, blurring the distinction between search engine and directory.

Still in 1994, a student of the University of Washington, Brian Pinkerton, started another crawler-based search engine, the WebCrawler. It was the first one to index the full text of the pages. Soon after, in July, a project from Carnegie-Mellon University, headed by Michael Mauldin, Lycos, provided indices supporting prefix matching, word proximity, and a multimillion page catalog. In 1995, Altavista started indexing text associated with images, music, and videos. In the following years, several other services were stated, such as Inktomi (1996), Google (1997), and MSN Search (1998), improving image and video indexing, addressing spam issues related to indexing, targeting other document and media formats as well as other web elements. For instance, the increasing adoption of link analysis in ranking algorithms motivated the maintenance of citation indices. Also in 1998, the Open Directory was started to create a human-reviewed directory constructed and maintained by a community of volunteers.

Foundations

Introduction

The web is a space for mass publication at an unprecedented scale. The earliest strategies to make all the information in this space discoverable by the users consisted of applying traditional information retrieval techniques to the new content [8,10]. As a consequence, the first search engines adopted approaches based on manually or automatically built indices.

When performing manual indexing, experts describe the web content by selecting terms which indicate what the content is about. These terms are normally selected from controlled vocabularies and are organized as flat or hierarchical lists. It is also common that the authors of the contents select keywords and metadata to describe them. The resulting indices may be oriented towards direct navigation by humans or to be retrieved by other programs.

An example of index oriented towards human navigation is the web directory. In such an index, links to sites are organized into hierarchical categories, according to the sites' contents. In web directories, normally the tasks of collecting and categorizing pages are carried out under supervision of human editors.

An example of index not oriented to humans is a hidden list of metadata. Metadata are data about data. As a mean of assisting a search engine to locate content or an information entity, they can be used to describe that content or entity. While not visible to humans, this information can provide contextual clues to automatic algorithms used by search engines.

Manual indexing presents two problems. First, it does not scale with the size of the web. This is an even more daunting problem considering the dynamic nature of web, where many documents have no persistent state and would require frequent revisions. Second, to be effective as a search tool, experts and users have to agree with respect to the taxonomy employed for classification, which is hard when using large taxonomies [8]. These problems contributed for the dominance of strategies based on automatic indexing.

In automatic indexing, a program (i.e., a web crawler) scans the web, collecting pages to extract data useful to describe them. The contents of the pages (text, media, links, etc.) are parsed, and decomposed into their components (tokens). Each token constitutes an atomic search criterion. For instance, in the case of textual content, the tokens are normally words and the most simple search query is composed of at least one word. They are normally converted to a standard form through some transformations and inserted into one or more data structures. These structures are the base for one or more indices.

The resulting indices are used by search engines to allow several search strategies, such as full-text search, and support different ranking algorithms, central components of systems with automatic indexing. Such algorithms increase the likelihood that the system will automatically order results according to their relevance to the users. Typically, the indexing is performed at a predetermined time interval due to the required time and processing costs.

While manually created indexes are commonly associated with natural language text, automatic indexers are likely to support additional kinds of media, such as images, sounds, and video. It is also common that indexers expand the textual content of a web page *p* with additional evidence such as the anchor text found in pages that link to *p*. The anchor text is the text highlighted by web browsers to indicate the presence of a link. Normally, it provides a useful description of the target page. Thus, pages with many incoming links can accumulate several descriptions emphasizing what the page is about. In fact, the use of different evidence is a common way to assist ranking algorithms to order results.

Data Structures to Support Automatic Indexing A typical data structure used to map tokens to their associated contents is the inverted file or inverted index [2,10]. The inverted file stores a list of occurrences of each token, normally in the form of a hash table or binary tree. In larger indices it normally assumes a form of a distributed hash table. The list associated with each token is called an inverted list.

By using an inverted file, the search engine can find content (for instance, a document) through direct access. In its simplest design, this structure can only determine if a token exists in a document, since the inverted lists store only occurrence information. Further, they can only determine which documents match a query. They do not rank them.

In real indexers, however, the inverted list stores additional information to support searching and ranking. Further, the list can be sorted in such way that some documents are more likely to be retrieved than others, which enables several ranking speedup optimizations.

Additional information typically stored in inverted lists include the frequency and position of a token. In the case of textual content, the frequency information can be used to assist ranking algorithms to judge the relevance of a document to a search query whereas the position information enables search algorithms to support word proximity and phrase search.

To ensure that more promising documents will be retrieved earlier, the inverted list is normally sorted according to a query-independent document score. This score is calculated by combining query-independent factors associated with the document, such as the frequency that users click on it, its link popularity, URL size, and spam score.

Other data structures are used to support automatic web indexing. They are generally adopted to speedup retrieval or provide additional information for ranking algorithms. For instance, by using only the previously described inverted file, a search engine can correctly answer phrase queries. For this, it has to retrieve the inverted lists for all words in the phrase and intersect them. In practice, this is a very slow process and other strategies are employed. A simple alternative strategy is to extend the inverted file to support phrases along with words, as tokens. In such a case, only common phrases are included in the data structure. Another strategy consists in using a structure that facilitates the processing of pairs of words. For instance, the inverted list associated with a word *w* can be divided into sublists, according to the words that follow *w*. For instance, for retrieving the list associated with the phrase “web indexing”, one can retrieve the inverted list of “web” and then the inverted sublist of “indexing.”

Additional data structures used to support automatic web indexing are citation indices, n-gram indices, term document matrices, and tries, to cite a few. A citation index stores hyperlinks between documents to assist citation analysis, a set of bibliometric techniques used by ranking algorithms. N-gram indices store sequences of length of data to support some types of retrieval, such as phrase retrieval. Term document matrices are sparse matrices that store the occurrence of the words in the documents, needed for a technique called latent semantic analysis [4]. Tries are ordered tree data structures used to store an associative array where the keys are usually strings. A particular kind of trie is a suffix tree, used to store the suffixes of data strings in order to carry out fast full text searches.

Challenges and Design Factors in Automatic Indexing

By using automatic methods, search engines are able to index a significant part of the web while sustaining very low response times, when compared to manual indexing. Given the huge size and diversity of the web, many challenges were faced to reach such a performance.

From an engineering point of view, it was necessary to deal with several design factors, such as the amount of computer storage necessary to support the index, how the index should be filtered, compressed, and distributed [14]. Other key design factors are the update policy, reliability, and required electric power.

Regarding distribution, for instance, indices are normally partitioned by documents, that is, each node contains the index for a subset of all documents [8]. To answer a query, such query has to be submitted to each subset of documents and the results merged before being shown to the user.

A strategy to reduce the use of disk, network, and memory resources is to compress the key data structures. These compressed structures enable fewer disk and network accesses leading to faster processing, in spite of the processing costs associated with compression and decompression algorithms.

From a computer science point of view, it was necessary to find properly data structures to support the desired search and ranking operations in the required time and space. Examples of aspects considered included the processing of strings and n-grams, the possibility of approximated searching, document position, and the type of media to be indexed.

It was also necessary to deal with several algorithmic challenges. For instance, the adoption of distributed architectures required parallel algorithms for building the indices and synchronize the crawlers. Space, time, and accuracy requirements motivated researches on data selection with minimum impact on ranking, compression, subject categorization, and clustering. Robustness and completeness requirements motivated research on format analysis in order to design methods able to handle malformed documents, documents whose content is dynamically generated, proprietary formats, and multiple character sets.

Given the importance of ranking results for search engines, indices include much evidence which require the development of new ranking algorithms to take advantage of them. For instance, by storing hyperlinks between pages it is possible to infer the importance of the pages. A page pointed to by many other pages, specially by important ones, is probably an important page. This is the central idea of a very popular ranking strategy called PageRank [3]. This idea can be refined by characterizing the importance of a page according to its role, in particular, as a hub or an authority. The hubness of a page is the quality associated with its capability to point to other interesting pages in the web, whereas its authority is related to how good is considered its own informative content. HITS is a very well known ranking algorithm that infers page importance by taking into consideration these roles [6]. In particular, HITS explores a recursive definition of hub and authority pages, that is, a good hub is the page that points to many good authorities and a good authority is the page that is pointed to by many good hubs.

From a linguistic point of view, it was necessary to deal with the complexity inherent to the processing of natural language [13]. This is particularly difficult due to the necessity to handle multiple languages [8]. In a multilingual indexer, even apparently simple tasks as recognizing the word boundaries represent a challenge, since words are not clearly separated by white spaces in some languages such as Chinese, Japanese, and Arabic. Further, to deal with issues such as ambiguity, compression, and properly match of sentences, many search engines use additional information such as the lexical category of the words and their roots. All of this information requires language-dependent techniques and, by extent, automated language recognition, a subject of ongoing research in natural language processing.

Key Applications

Web indexing is essential for making the wealth of information in the web discoverable by the users.

Future Directions

The web continues growing uncoordinatedly, at large scale and with great diversity of interests [8]. These aspects of the web raise several problems that affect indexing, motivating many studies to address them. For instance, since the number of pages in the web grows beyond the capabilities of search engines collecting them, research has been and will likely continue to be focused on improving the ability of recognizing as early as possible not so useful pages in order to avoid indexing them [1].

On the other hand, most of the information in the web is stored in databases and is only available through systems that generate pages dynamically in response to user interactions. These dynamic pages comprise which is called *the hidden web* (also referred to as *deep web*). As a consequence, much digital content is inaccessible to typical crawlers. Research is under way to make it possible to index the hidden web, for instance, by exploring search query syntax, standard formats of online resources, and application programming interfaces [9].

There is an increasingly interest on indexing rich media formats. Current indexing approaches for such media take advantage of text clues such as image legends, video subtitles or music lyrics. New research has focused on describing them by means of their content [7] in order to make possible, for instance, the retrieval of an image by its description or of music by a sound fragment. The main challenge regarding media indexing is how to represent it such that it can be efficiently stored, retrieved, and compared. For instance, a music retrieval system should be able to map pitches to notes by analyzing waveforms, to store these notes into an index structure, and to match note strings allowing a certain amount of noise [9].

Another research focus is fighting spam [5]. The diversity of interests in the Web along with a growing audience led to the adoption of several strategies to ensure top positions on search engine results lists. Many of these strategies consisted of manipulating the content of the pages to deceive the indexer by using misleading terms or abusing of metatags. In response, movements to standardize metatag content has emerged. Also, research has lead to the design of robust crawling algorithms able to deal with several spam traps and new methods to infer content quality and reliability.

Indexing granularity

Definition

Indexing units refers to the granularity of information in the retrieval system's index, which can be in principle any document part of a structured text, and as a consequence determines the possible units of retrieval. There are three basic approaches. The first approach is to index every potentially retrievable unit as a whole – the so-called element-based approach [13]. The second approach is to index disjoint nodes – and relying on aggregation or score propagation methods for scoring higher-level nodes [e.g., 1,12]. The third approach is to index only selected elements, for example by indexing particular element types in separate indexes [10]. Various mixtures of these approaches have also been applied.

All approaches make implicit or explicit assumptions on the (most likely) *unit of retrieval*. Although there may be no designated retrieval unit (such as the document or root node of the structured document), this also does not mean that every document part (such as a sub-tree of the structured document) is an equally desirable retrieval unit. Such assumptions may be relatively generic (such as paragraphs and sections being more informative than very short excerpts in bold or italics) or may depend on the query at hand (such as a structured query requesting elements with a particular tag). In all cases these assumptions depend on the sort of structured documents (which may range from strict XML databases to loosely structured textual documents with mark-up), and on the sort of information need (which may range from a strict database query with well defined semantics to a vague information retrieval topic of request). Structured text retrieval typically deals with loosely structured textual documents and vague information retrieval queries.

Historical Background

Structured text retrieval has a long pre-history in text retrieval. The first test collections consisted of short document surrogates such as bibliographic descriptions (in various forms) or abstracts. Since the 1990s, test collections consisted predominantly of full text newspaper and newswire data. Interestingly, the bibliographic descriptions were highly structured catalogue records, and the newspaper data were typically structured in SGML, yet no particular use was made of the internal document structure. In fact, the use of the internal structure was usually explicitly outlawed, the main motivation for this being the desire to develop retrieval techniques that would work on all (flat) texts.

The use of document structure derived from SGML mark-up was pioneered by Wilkinson [15], studying ad hoc SGML element retrieval, and by Myaeng et al. [11], exploring structured queries that contain references to the SGML document structure. Similar early work on HTML is in [4]. There are also many similarities with the early work on multimedia retrieval, such as the DOLORES system [5] and the FERMI model [3], which are addressing the problem of retrieving information from structured documents. Ad hoc XML element retrieval and best entry point retrieval was studied in the Focus project [9]. In recent years, the main thrust of research in structured text retrieval is the annual initiative for the evaluation of XML retrieval [7].

Foundations

Structured text retrieval typically deals with loosely structured textual documents and vague information retrieval queries, and the discussion is focused exclusively on this case. Indexing structured texts presents a number of challenges since such documents can be decomposed according to their internal structure. XML documents have a hierarchical structure of nested elements (or subtrees). That is, for example, an entire article consisting of front matter, body, and back matter. The body, in turn, consists of sections. The sections, again, consist of subsections. The subsections of paragraphs, and so on. Since there is no fixed unit of retrieval it is an open question what should be put in the index.

A prototypical structured text retrieval task is XML element retrieval. In text retrieval, evaluation is based on a "frozen" set of search requests (or "topics") with a set of known relevant results – XML elements regarded as relevant by the topic author. In XML retrieval, topics consist of a short keyword (or content-only) title; a structured (or content-and-structure) query in NEXI [14]; a single sentence description; and a long narrative statement of the search request. The retrieval system takes as *input* the standard keyword query, or the structured NEXI query. To give a concrete example, the ⟨title⟩ field of the INEX 2004 topic number 104 is

► *Toy Story*

The requested *output* is a ranked list of document components (in this case XML elements in the INEX IEEE collection containing full-text articles). There is no fixed *unit of retrieval*: if a whole article is relevant, return the ⟨article⟩ element, but if only a section is relevant, return the ⟨sec⟩ element. Retrieval systems will, of course, rank the XML elements based on the occurrences of query terms (or possibly phrases, stems, or synonyms based on these terms). However, whether a result is indeed relevant for the query is determined by a human judgment on whether the information in the element satisfies the topic author's information need. For the above mentioned INEX 2004 topic 104, the ⟨narrative⟩ field reads

► *To be relevant, a document/component must discuss some detail of the techniques or computer infrastructure used in the creation of the first entirely computer-animated feature-length movie, "Toy Story."*

A human judge (usually the topic author) will assess the relevance of the retrieved results, where relevant means that the element is both *exhaustive* (it provides useful information on the topic of request) and *specific* (there is a minimal amount of off-topic material) (There have been different measures developed over the years).

Although, in principle, any document part or XML element can be retrieved, some document parts tend to be more likely to be relevant. Table 1 shows the distribution of relevant elements over tag-names (Here relevant is according to the strict quantization function). In this case, most frequently paragraphs (⟨p⟩), sections (⟨sec⟩), and subsections (⟨ss1⟩, ⟨ss2⟩) are judged relevant, but also entire articles (⟨article⟩). The precise tags are a direct result of the particular mark-up structure of the IEEE collection, which is mostly based on the logical structure of the articles. Generalizing over the particular tag-names, there is also a suggestion on the granularity of information that is most likely to be a relevant result. The following two observations present themselves. First, the most frequent elements such as paragraphs and (sub)sections are of relatively short-length.

Indexing Units. Table 1. Distribution of relevant elements over tag names (reproduced from [8])

Second, there is great variety of elements regarded as relevant. Even for a single topic there is a very similar variety of elements, making clear that relevancy is both depending on the topic of request, and on the precise structure of the document at hand.

Recall the question of what to put in the index. The most obvious approach is to index all information in the structured text. But already here different options present themselves, as is illustrated in Table 2. On the left-hand side of Table 2 is a very simple example document, an article with title, abstract and two sections. The first approach, shown in the middle of Table 2, is to index every retrievable unit, in this case every XML element. In a "bag of words" approach all six XML elements of the document are indexed separately, but each with all the content or text contained inside the element. That is, an element is indexed with both the text nodes directly contained in it, and all text nodes of its descendants. The indexing of subtrees of the XML hierarchy is known as the element-based approach [13]. Indexing subtrees is closest to traditional information retrieval since each XML node is a *bag of words* of itself and its descendants, and can be scored as ordinary plain text document. This directly relates structured text retrieval to the more general and well-understood problem of document retrieval. The indexing scheme is only using the structure to decompose the document into all retrievable units, and hence is applicable to any structured text. The main disadvantage is that it leads to a highly redundant index: text occurring at depth *n* of the XML tree is indexed *n* times.

On the right-hand side of Table 2, an alternative approach is shown, in which the text is only indexed once at the node where it occurs. The ⟨article⟩ and ⟨body⟩ elements are missing since they have no textual content. Since there are only four elements with content, the index is much smaller, and there is no redundancy of information. But the main advantage of indexing disjoint nodes is also creating a new problem of scoring higher level nodes. For example, as shown above, the whole article is a reasonably attractive XML element type, but it may not even occur in the index. This creates both a practical and a fundamental problem. The practical problem is that articles may contain thousands of XML elements, and hence may require considerable propagation of scores over the navigational axis. The fundamental problem is that it is not evident how to aggregate scores to ancestor elements, and various approaches exist in the literature. One of the earliest proposals is the augmentation approach of Abolhassini et al. [1], a straightforward propagation of scores to ancestor elements. The following simplified example illustrates the main idea behind augmentation. Assume the following document.

```
⟨body⟩
  ⟨sec⟩cat...⟨/sec⟩
  ⟨sec⟩dog...⟨/sec⟩
⟨/body⟩
```

and a query consisting of the two terms "cat dog." Furthermore assume that: /body/sec[1] scores 0.7 for cat; /body/sec[2] scores 0.4 for dog; and the rest 0 (that is, dog does not occur in the first section, and cat not in the second section). The problem is to determine the score of the body, which is not indexed itself. The *augmentation* approach propagates scores up with a certain weight (the augmentation factor) which is set to 0.3 based on experiments. The motivation for the augmentation factor is to avoid larger elements accumulating scores, and thus (almost) always get higher rankings than elements deep in the hierarchy. So in this case, the /body[1] will score $0.3 * 0.7 = 0.21$ for cat; and $0.3 * 0.4 = 0.12$ for dog. So the element /body[1], although not in the index, will be returned. In fact, it will be the highest ranked result for "andish" query evaluation where only results containing all query terms are returned. A very similar approach is taken by the GPX model and its decay factor [6]. The element specific language models of Ogilvie and Callan [12] provide an elegant alternative approach within the language modeling framework. Here, every XML element forms a particular language model, and the ancestor elements are modeled as mixture language models of their direct children. A final alternative is to just propagate term frequencies and effective reconstructing the element-based index discussed above, e.g., using the region models of Burkowski [2].

A third indexing approach is to index only selected elements in their entirety. This is essentially the approach taken in the FERMI model of Chiaramella [3]. The selection is tailored to the collection at hand, usually based on the human interpretation of the tags in the collection. An example of this approach is to index particular types of elements separately [10]. Mass and Mandelbrod [10] create separate indexes for articles (⟨article⟩, abstracts ⟨abs⟩, sections ⟨sec⟩, subsections ⟨ss1⟩, sub-subsections ⟨ss2⟩, and paragraphs ⟨p⟩ and ⟨ip1⟩). Each index provides statistics tailored to particular components, which may be an advantage if language statistics deviate significantly between element types. This is essentially a distributed approach where queries are issued to all indexes, and the results of each of the indexes are combined after score normalization. The selective indexing approach turned out to be effective for the IEEE collection used at INEX. The requirement to select particular element-types makes it strongly collection-dependent, and it is less straightforward to apply this indexing approach to arbitrary structured text.

Three prototypical indexing approaches for structured text have been discussed above. Some observations present themselves. First, there is a trade-off between exploiting the document structure, and being generically applicable to all structured text. The element-based approach uses the document structure for decomposing documents by focusing on the hierarchical structure only. This ignores (potentially) useful structure like the tag-names, their attributes, the schema or DTD, etc. However, to phrase it positively, since it is completely schema-ignorant the approach can handle data with any type of tag-structure, even mixed-schema XML. The selective indexing approach is on the opposite side of the spectrum. Here, the specific tags and their semantics and importance have to be taken into account when selecting the element types to index. In cases where it is known what the more important elements are, this gives powerful handles to exploit this information. The downside is, of course, that the particular choice of element to index, and thereby the effectiveness of the approach, is completely dependent on the collection at hand. Second, there is a trade-off between indexing and query time complexity. The element based approach seems unattractive since its index is highly redundant: text appearing in a given element, will also appear in all the index entry for all the ancestors of this element. This may not be as undesirable as it may appear at first glance, since it can be viewed as a trade-off between query time and storage space complexity. The redundant index has essentially "precomputed" term frequencies per element, that otherwise need to be computed at query run time, and hence has relatively low query time complexity. The indexing complexity of the disjoint nodes approach requires much less storage space. However, an article may contain thousands of XML elements, and hence will require considerable propagation of scores over the navigational axes of the document at query time. Third, the indexing methods and retrieval models are standard information retrieval approaches or straightforward extensions of them.

Individually Identifiable Data

Chris Clifton
Purdue University, West Lafayette, IN, USA

Synonyms

Personally identifiable data; Personal data

Definition

Individually Identifiable Data is data that identifies the person that the data is about, or that can be used to identify that individual. This generally refers to data that contains either an identification number, or factors relating to physical, mental, economic, cultural, or social identity that could be used to link the data to an individual. Regulatory requirements for privacy generally apply (only) to individually identifiable data.

Key Points

Individually Identifiable Data is a legal term (e.g., personal data in the EU Privacy Directive [1], or Individually identifiable health information in U.S. Healthcare Laws [2]); in general privacy laws only protect individually identifiable data. Unfortunately, it is not clearly defined in technical terms. Anonymous data is presumably not individually identifiable, but what about *k-anonymous* data? (Presumably data is individually identifiable if $K = 1$, but at what level of K is data no longer individually identifiable?) This leads to considerable difficulty in developing data management technology that balances privacy with the utility of disclosing anonymous data.

Regulatory frameworks do give some guidance; for example the U.S. Healthcare Privacy rules allow data to be considered not individually identifiable if names, geographic units of less than 20,000 people, dates of finer granularity than a year (or that can indicate age for those over 89), biometric identifiers (fingerprint, full-face images), or any identifying numbers (telephone, account, vehicle license, IP address, etc.) other than numbers generated specifically for the particular dataset.

Inference Control in Statistical Databases

Josep Domingo-Ferrer
Universitat Rovira i Virgili, Tarragona, Catalonia

Synonyms

Statistical disclosure control (SDC); Statistical disclosure limitation (SDL)

Definition

Inference control in databases, also known as Statistical Disclosure Control (SDC), is a discipline that seeks to protect data so they can be published without revealing confidential information that can be linked to specific individuals among those to which the data correspond. SDC is applied to protect *respondent privacy* in areas such as official statistics, health statistics, e-commerce (sharing of consumer data), etc. Since data protection ultimately means data modification, the challenge for SDC is to achieve protection with minimum loss of the accuracy sought by database users.

Historical Background

The literature on inference control started in the 1970s, with the seminal contribution by Dalenius [4] in the statistical community and the works by Schlörer [12] and others in the database community. The 1980s saw moderate activity in this field. An excellent survey of the state of the art at the end of the 1980s is [1]. In the 1990s, there was renewed interest in the statistical community and the discipline was further developed under the names of statistical disclosure control in Europe and statistical disclosure limitation in America. Subsequent evolution has resulted in at least three clearly differentiated subdisciplines:

- *Tabular data protection.* This is the oldest and best established part of SDC, because tabular data have been the traditional output of national statistical offices. The goal here is to publish *static* aggregate information, i.e., tables, in such a way that no confidential information on specific individuals among those to which the table refers can be inferred. See [13] for a conceptual survey and [7] for a software survey.
- *Queryable databases.* The scenario here is a database to which the user can submit statistical queries

(sums, averages, etc.). The aggregate information obtained by a user as a result of successive queries should not allow him to infer information on specific individuals. Since the 1980s, this has been known to be a difficult problem, subject to the tracker attack [11]. SDC strategies here include perturbation, query restriction and camouflage (providing interval answers rather than exact answers).

- *Microdata protection.* This subdiscipline is about protecting static individual data, also called microdata. It is only recently that data collectors (statistical agencies and the like) have been persuaded to publish microdata. Therefore, microdata protection is the youngest subdiscipline and is experiencing continuous evolution in the last years.

Good general works on SDC are [13,9].

Foundations

Statistical disclosure control will be first reviewed for tabular data, then for queryable databases and finally for microdata.

In spite of tables displaying aggregate information, there is risk of disclosure in tabular data release. Several attacks are conceivable:

- *External attack.* For example, let a frequency table "Job" × "Town" be released where there is a single respondent for job J_i and town T_j. Then if a magnitude table is released with the average salary for each job type and each town, the exact salary of the only respondent with job J_i working in town T_j is publicly disclosed.
- *Internal attack.* Even if there are two respondents for job J_i and town T_j, the salary of each of them is disclosed to each other.
- *Dominance attack.* If one (or a few) respondents dominate in the contribution to a cell of a magnitude table, the dominant respondent(s) can upper-bound the contributions of the rest (e.g., if the table displays the total salary for each job type and town and one individual contributes 90% of that salary, he knows that his colleagues in the town are not doing very well).

SDC methods for tables fall into two classes: non-perturbative and perturbative. Non-perturbative methods do not modify the values in the tables; the best known method in this class is *cell suppression* (CS). Perturbative methods output a table with some modified values; well-known methods in this class include *controlled rounding* (CR) and the recent *controlled tabular adjustment* (CTA).

The idea of CS is to suppress those cells (primary suppressions) that are identified as sensitive by the so-called sensitivity rules. The two most common sensitivity rules are:

- *Dominance rule (n, k).* The cell is deemed sensitive if n or less respondents contribute at least k% of the cell value.
- *p%-rule.* The cell is deemed sensitive if some respondent can estimate the contribution by another respondent within p% accuracy.

After primary suppressions, additional suppressions (secondary suppressions) are performed to prevent primary suppressions from being computed or even inferred within a prescribed protection interval using the row and column constraints (marginal row and column totals). Usually, one attempts to minimize either the number of secondary suppressions or their pooled magnitude, which results in complex optimization problems. Most optimization methods used are heuristic, based on mixed integer linear programming or network flows (e.g., [6]), most of them implemented in the τ-Argus free software package [10]. CR rounds values in the table to multiples of a rounding base. This may entail rounding the marginal totals as well. On its side, CTA modifies the values in the table to prevent the inference of values of sensitive cells within a prescribed protection interval. The idea of CTA is to find the *closest* table to the original one that ensures such a protection for all sensitive cells. This requires optimization methods, which are typically based on mixed linear integer programming. Usually CTA causes less information loss than CS.

Regarding SDC of queryable databases, there are three main approaches to protect a confidential vector of numerical data from disclosure through answers to user queries:

- *Data perturbation.* Perturbing the data is a simple and effective approach whenever the users do not require deterministically correct answers to queries that are functions of the confidential vector. Perturbation can be applied to the records on which queries are computed (input perturbation) or to the query result after computing it on the original data (output perturbation). An example of perturbation methods can be found in [5].

- *Query restriction*. This is the right approach if the user does require deterministically correct answers and these answers have to be exact (i.e., a number). Since exact answers to queries provide the user with a very powerful information, it may become necessary to refuse to answer certain queries at some stage to avoid disclosure of a confidential datum. There are several criteria to decide whether a query can be answered; one of them is query set size control, that is, to refuse answers to queries which affect a set of records which is too small. An examples of the query restriction approach can be found in [3].
- *Camouflage*. If deterministically correct non-exact answers (i.e., small interval answers) suffice, confidentiality via camouflage (CVC [8]) is a good option. With this approach, unlimited answers to any conceivable query types are allowed. The idea of CVC is to "camouflage" the confidential vector a by making it part of the relative interior of a compact set Π of vectors. Then each query $q = f(a)$ is answered with an inverval $[q^-, q^+]$ containing $[f^-, f^+]$, where f^- and f^+ are, respectively, the minimum and the maximum of f over Π.

Regarding microdata SDC, given an original microdata set V, its goal is to release a protected microdata set V' in such a way that:

1. Disclosure risk (i.e., the risk that a user or an intruder can use $\mathbf{V}'$ to determine confidential attributes on a specific individual among those in $\mathbf{V}$) is low.
2. User analyses (regressions, means, etc.) on $\mathbf{V}'$ and on $\mathbf{V}$ yield the same or at least similar results.

Microdata protection methods can generate the protected microdata set $\mathbf{V}'$ either by

- *Masking original data*, i.e., generating $\mathbf{V}'$ a modified version of the original microdata set $\mathbf{V}$ or
- *Generating synthetic data* $\mathbf{V}'$ that preserve some statistical properties of the original data $\mathbf{V}$.

Masking methods can in turn be divided in two categories depending on their effect on the original data [13]:

- *Perturbative*. The microdata set is distorted before publication. In this way, unique combinations of scores in the original dataset may disappear and new unique combinations may appear in the perturbed dataset; such confusion is beneficial for preserving statistical confidentiality. The perturbation method used should be such that statistics computed on the perturbed dataset do not differ significantly from the statistics that would be obtained on the original dataset. *Noise addition, microaggregation, data/rank swapping, microdata rounding and PRAM* are examples of perturbative masking methods.
- *Non-perturbative. Non-perturbative masking methods* do not alter data; rather, they produce partial suppressions or reductions of detail in the original dataset. Sampling, global recoding, top and bottom coding and local suppression are examples of non-perturbative masking methods.

Microdata SDC faces an inherent trade-off between loss of information (i.e., analytical utility) and disclosure risk. Given a particular dataset, the microdata SDC method optimizing that trade-off is the best choice. Approaches to modeling such a trade-off include *SDC scores*, *k-anonymity* and R-U maps (plots of disclosure risk against data utility for a certain parameterization of an SDC method).

Key Applications

There are several areas of application of SDC techniques, which include but are not limited to the following:

- *Official statistics*. Most countries have legislation which compels national statistical agencies to guarantee statistical confidentiality when they release data collected from citizens or companies. This justifies the research on SDC undertaken by several countries, among them the European Union (e.g., the CASC project [2]) and the United States.
- *Health information*. This is one of the most sensitive areas regarding privacy. For example, in the U.S., the Privacy Rule of the Health Insurance Portability and Accountability Act (HIPAA) requires the strict regulation of protected health information for use in medical research. In most western countries, the situation is similar.
- *E-commerce*. Electronic commerce results in the automated collection of large amounts of consumer data. This wealth of information is very useful to companies, which are often interested in sharing it with their subsidiaries or partners. Such consumer information transfer should not result in public

profiling of individuals and is subject to strict regulation, especially in the European Union and the United States.

Future Directions

There are many open issues in SDC, some of which can be hopefully solved with further research and some which are likely to stay open due to the inherent nature of SDC. First some of the issues that probably could and should be settled in the near future are listed:

- Identifying a comprehensive listing of data uses (e.g., regression models, association rules, etc.) that would allow the definition of data use-specific information loss measures broadly accepted by the community; those new measures could complement and/or replace the generic measures currently used. Work in this line has been started in Europe in 2006 under the CENEX SDC project sponsored by Eurostat.
- Devising disclosure risk assessment procedures which are as universally applicable as record linkage while being less greedy in computational terms.
- Identifying, for each domain of application, which are the external data sources that intruders can typically access in order to attempt re-identification. This would help data protectors figuring out in more realistic terms which are the disclosure scenarios they should protect data against.
- Creating one or several benchmarks to assess the performance of SDC methods. Benchmark creation is currently hampered by the confidentiality of the original datasets to be protected. Data protectors should agree on a collection of non-confidential original-looking data sets (financial datasets, population datasets, etc.) which can be used by anybody to compare the performance of SDC methods. The benchmark should also incorporate state-of-the-art disclosure risk assessment methods, which requires continuous update and maintenance.

There are other issues whose solution seems less likely in the near future, due to the very nature of SDC methods. If an intruder knows the SDC algorithm used to create a protected data set, he can mount algorithm-specific re-identification attacks which can disclose more confidential information than conventional data mining attacks. Keeping the SDC algorithm secret used would seem a solution, but in many cases the protected dataset itself gives some clues on the SDC algorithm used to produce it. Such is the case for a rounded, microaggregated or partially suppressed microdata set. Thus, it is unclear to what extent the SDC algorithm used can be kept secret.

Information Extraction

Heng Ji
New York University, New York, NY, USA

Definition

Information Extraction (IE) is a task of extracting prespecified types of facts from written texts or speech transcripts, and converting them into structured representations (e.g., databases).

IE terminologies are explained via an example as follows.

- Input Sentence:

Media tycoon Barry Diller on Wednesday quit as chief of Vivendi Universal Entertainment, the entertainment unit of French giant Vivendi Universal whose future appears up for grabs.

- IE output:
  - Entities:
    Person Entity: {Media tycoon, Barry Diller}
    Organization Entity: {Vivendi Universal Entertainment, the entertainment unit}
    Organization Entity: {French giant, Vivendi Universal}
  - "Part-Whole" relation:
    {Vivendi Universal Entertainment, the entertainment unit} is part of {French giant, Vivendi Universal}.
  - "End-Position" event.

The above sentence includes a "Personnel_End-Position" event mention, with the trigger word which most clearly expresses the event occurrence, the position, the person who quit the position, the organization, and the time during which the event happened (Table 1).

Historical Background

The earliest IE system was directed by Naomi Sager of the Linguistic String Project group [11] in the medical domain. However, the specific task of information extraction was formally evaluated through the U.S. Defense Advanced Research Projects Agency (DARPA) sponsored Message Understanding Conferences (MUC) program from 1987 to 1998 [4].

There were four specific evaluations: Named entity, coreference and template element reflected in the evaluation tasks introduced for MUC-6, and template relation introduced in MUC-7.

The MUC tasks have been inherited by the U.S. National Institute of Standards and Technology (NIST) Automatic Content Extraction (ACE) program (The ACE task description can be found at http://www.nist.gov/speech/tests/ace/and the ACE guidelines at

Information Extraction. Table 1. Event extraction example

Trigger	Quit	
Person	Barry Diller	Media tycoon
Organization	Vivendi universal entertainment	The entertainment unit of french giant vivendi universal
Position	Chief	
Time-within	Wednesday	

http://www.ldc.upenn.edu/Projects/ACE/), with more general types of entities/relations/events defined. ACE includes the following tasks.

Entity Detection and Recognition

ACE defines the following terminologies for the entity detection and recognition task:

entity: an object or a set of objects in one of the semantic categories of interest

mention: a reference to an entity (typically, a noun phrase)

name mention: a reference by name to an entity

nominal mention: a reference by a common noun or noun phrase to an entity

Seven types of entities were defined: PER (persons), ORG (organizations), GPE ("geo-political entities" – locations which are also political units, such as countries, counties, and cities), LOC (other locations without governments, such as bodies of water and mountains), FAC (facility), WEA (Weapon) and VEH (Vehicle) mentioned in an input document. This task was proposed in 2000 and evaluated in English, and then expanded to include Chinese and Arabic in 2003, Spanish in 2007.

Relation Detection and Recognition

The relation detection task was proposed in 2002, aiming to find specified types of semantic relations between pairs of entities. ACE 2007 had 7 types of relations, with 19 subtypes. The following table lists some examples (Table 2).

Event Detection and Recognition

ACE defined 8 types of events, with 33 subtypes. Some examples are presented in Table 3.

Entity Translation

Entity Translation is a cross-lingual IE track at ACE 2007 to take in a document in a foreign language (e.g., Chinese or Arabic) and extract the English catalog of the entities.

Foundations

There are two main approaches to develop IE systems, described separately as follows.

Pattern Matching Based IE

Many IE systems during MUC evaluation use high-accuracy rules, dictionaries and patterns for each specific domain. For example, for the end-position event in Table 1, an IE system generates patterns such as

- [Person] quit as [Position] of [Organization]

Manually writing and editing patterns requires some skill and considerable time. So some systems have moved on to learning these patterns automatically based on an annotated corpus pre-processed by syntactic and semantic analyzers. A more comprehensive survey of pattern matching based IE approaches can be found in [8].

The above pattern acquisition is still quite costly because for particular domain a separate annotated corpus is needed. Therefore some systems have used unsupervised learning approach [10,12,13]. The general idea is to obtain a pattern if a pair of arguments (mostly names) (Arg_1, Arg_2) and their context C_{12} appear frequently in other instances of the event.

The idea of using bootstrapping to obtain patterns was first proposed by Riloff [10]. Riloff [10] manually pre-classified the documents into relevant and irrelevant, then collect and score patterns around each noun

Information Extraction. Table 2. Examples of the ACE relation types

Relation Type	Example
Agent-Artifact (User-Owner-Inventor-Manufacturer)	*Rubin Military Design, the makers of the Kursk*
ORG-Affliation (Employment)	Mr. Smith, *the CEO of Microsoft*
Gen-Affiliation (Citizen-Resident-Religion-Ethnicity)	*Salzburg Red Cross officials*
Physical (Near)	*A town some 50 miles south of Salzburg*

Information Extraction. Table 3. Examples of the ACE event types

Event Type	Example
Movement (Transport)	*Homeless people* have been *moved to schools*
Business (Start-ORG)	*Schweitzer founded a hospital* in *1913*
Conflict (Attack)	The *attack* on *Gaza* killed *13 people*
Personnel (Start-Position)	*Cornell Medical Center recruited 12 nursing students*
Justice (Arrest)	*Zawahiri was arrested* in *Iran*

phrase. Yangarber et al. [13] used seed patterns to address the limitation of manual document classification. They started with a few initial seed patterns, and then applied an incremental discovery procedure to identify new set of patterns. Both of [10,13] are based on predicate-argument or subject-verb-object structures. Sudo et al. [12] presented a new Subtree model based on dependency parsing, and proved the Subtree model can obtain higher recall while preserve high precision.

Machine Learning Based IE

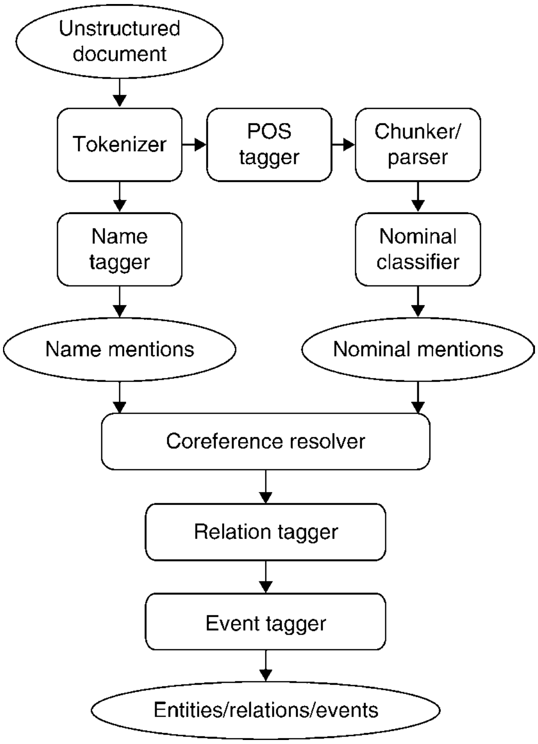
The IE systems relying entirely on pattern matching have attempted some success in MUC domains. However these patterns cannot be easily adapted into new domains. Therefore, IE research has grown by splitting the task into several components and then applying machine learning methods to address each component separately.

Machine learning based IE systems typically include name identification and classification, parsing (or partial parsing), semantic classification of nominal mentions, coreference resolution, relation extraction and event extraction. A typical IE system pipeline is presented in Fig. 1. For instance, state-of-the-art IE systems such as BBN system [2], IBM system [3] and NYU system [5] were developed in this pipeline style. This "pipeline" design provides great opportunity to applying a wide range of learning models and incorporating diverse levels of linguistic features to improve each component. Large progress has been achieved on some of these components. In the following some typical learning methods are described for the important components.

Trainable Name Tagging

The problem of name recognition and classification has been intensively studied since 1995, when it was introduced as part of the MUC-6 Evaluation. A wide variety of unified learning algorithms have been applied to the name tagging task, including Hidden Markov Models (HMMs), Maximum Entropy Models, Decision Trees, Conditional Random Fields and Support Vector Machines.

The most well-known BBN's Nymble name tagger [1] used several methods to improve performance over a simple HMM. Within each of the name class states, a statistical bigram model is employed, with the usual one-word-per-state emission. The various probabilities involve word co-occurrence, word features, and class probabilities. Since these probabilities are estimated based on observations seen in a corpus, several levels of "back-off models" are used to reflect the strength of support for a given statistic, including a back-off from words to word features.



Information Extraction. Figure 1. A minimal machine learning based IE system pipeline.

Trainable Coreference Resolution

Coreference Resolution is the task of determining whether two mentions refer to the same entity. For example in the sentence in Table 1, the name mention "Barry Diller" and the nominal mention "media tycoon" refer to the same person entity.

In a corpus-trained system, coreference resolution is usually converted into a supervised binary classification problem of determining whether a candidate mention is referring to an antecedent or not. Here an "antecedent" can be another single mention, or a cluster of mentions which the system has generated. Each pair is assigned probability value by a supervised learning based classifier. If the sampling is constructed on each mention pair, then a separate clustering algorithm is applied to group coreferring mentions.

Most coreference resolution systems use representations built out of the lexical and syntactic attributes of the mentions for which reference is to be established [9]. A typical feature set includes:

1. Representing agreement of various kinds between mentions (number, gender)
2. Degree of string similarity
3. Synonymy between mention heads
4. Measures of distance between mentions (such as the Hobbs distance)
5. The presence or absence of determiners or quantifiers

Though gains have been made with such methods, there are clearly cases where this sort of local information will not be sufficient to resolve coreference correctly. Coreference is by definition a semantic relationship, therefore a successful coreference system should exploit world knowledge, inference, and other forms of semantic relations in order to resolve hard cases. Since 2005, researchers have returned to the once-popular semantic-knowledge-rich approach, investigating a variety of semantic knowledge sources. For example, [7] incorporated the feedback from semantic relation detection to infer and correct coreference analysis. If, for example, two library mentions which are located in two different cities, then these mentions are less likely to corefer.

Trainable Relation Detection

For ACE-type relations, various machine learning methods have been used such as K-Nearest-Neighbor [9] and Support Vector Machines [14]. The typical features used to classify relations include:

1. The heads of the mentions and their context words
2. Entity and mention type of the heads of the mentions
3. The sequence of the heads of the constituents, chunks between the two mentions
4. The syntactic relation path between the two mentions
5. Dependent words of the mentions

Trainable Event Detection

A typical event extraction pipeline includes three main steps:

1. Trigger Identification
   Identify the trigger word in a given sentence and assign event type using the probability computed from the training corpora.
2. Argument Identification
   For a given trigger and a mention, determine whether the mention is an argument of the trigger or not.
3. Argument Classification
   For an identified argument, classify the argument as a specific event role.

Event detection heavily relies high-quality deep parsing [2,5] have further shown that the predicate-argument structures can provide deeper linguistic analysis and therefore effectively enhance the performance of event detection.

Key Applications

An enormous amount of information is now available through the Web. Much of this information is encoded in natural language, which makes it accessible to some people (those who can read the particular language), but much less amenable to computer processing (beyond simple keyword search). If computers can be enabled to extract and utilize the knowledge embedded in these texts, a powerful knowledge resource for many fields will be unleashed. Some typical applications of IE are presented as follows.

1. IE for Daily News
   IE can be applied to identify the events in the daily news articles. If an informative database can be returned based on the facts extracted by IE from multiple sources of news, it can be a very valuable result and save the time a user has to spend in browsing. For example, for the news articles about Olympic sport games, an IE engine can automatically provide a table of the player's person names, the team names they come from and the game results.
2. IE for Financial Reports
   Every year the U.S. government releases the annual reports from millions of industrial agencies. The financial analysis companies then gather all these reports and analyze the most up-to-date information such as the company start-up and merge events, the competition and cooperation relations among banks or companies. It will be very helpful if an automatic IE system is applied to compress these articles into data bases. Recently such IE systems are widely applied in the financial domain to assist human analysts.
3. IE for Biology Literatures
   In the biology domain, thousands of new papers and data sets are published in natural language on a daily basis. It has become impractical for scientists to manually track all these new results and observations, and manually mine the data sets to construct

a knowledge base. IE can play a significant role by automatically generating an accurate summary of facts (e.g., gene named entities) and predicting new results (e.g., Bio-nano structures of different peptide sequences), and thus assist scientists in decision making.

4. IE for Medical Reports
   Since the early work by Sager et al. [11], IE has obtained successful applications in processing the narrative clinical documents including patient discharge summaries and radiology reports. Some of these systems have shown positive impact on providing information to assist clinical decision, result analysis, error detection, etc.

Future Directions

For each IE component there are different aspects to improve. This section proposes some high-level directions in which IE can be further explored.

1. Cross-document Information Extraction
   One of the initial goals for IE was to create a database of relations and events from the entire input corpus, and allow further logical reasoning on the database. The artificial constraint that extraction should be done independently for each document was introduced in part to simplify the task and its evaluation.

   However, almost all the current event extraction systems focus on processing single documents and, except for coreference resolution, operate a sentence at a time. Therefore, one interesting area worth exploring would be to gather together IE results from a set of related documents, and then apply inference and constraints to propagate correct results and fix the wrong information generated from the within-document IE system [6].
2. IE for Noisy Input
   Recently there has been rapid progress in applying text processing techniques on "noisy" texts such as the output of automatic speech recognition (ASR) and machine translation (MT). The potential ASR transcription and machine translation errors, in particular name recognition errors, make IE more difficult. However, it is possible to optimize the parameters in the ASR or MT systems for IE purpose. Another interesting direction would be using IE results to provide feedback to ASR and MT in a joint inference framework.
3. Cross-lingual IE
   A shrinking fraction of the world's web pages are written in a language different from the user's own, and so the ability to access information from foreign languages is becoming increasingly important. This need can be addressed in part by the research on cross-lingual IE (CLIE).
4. Active Learning for Domain Adaptation
   Since about one decade ago in MUC program, the "portability" problem has become a noticeable bottleneck for IE techniques. Until today this problem has not yet been solved. There is an urgent need to develop effective adaptation algorithms to apply IE systems to a new domain with low cost. Active learning and semi-supervised learning techniques, which have achieved success on name tagging, may be worth expanding to all stages in the IE pipeline.

Experimental Results

The state-of-the-art IE results can refer to the ACE evaluation results on NIST website (http://www.nist.gov/speech/tests/ace/). All IE results are given in terms of the entity/relation/event value scores, as produced by the official ACE scorer. These value scores include weighted penalties for missing extractions, spurious extractions, and for type errors in corresponding extractions (Scoring details can be found in the ACE07 evaluation plan: http://www.nist.gov/speech/tests/ace/ace07/doc/ace07-evalplan.v1.3a.pdf). The top systems obtained mention values in the range of 70–85, entity values in the range of 60–70, relation values in the range of 35–45, event values in the range of 15–30.

Information Filtering

Christian Fluhr

Synonyms

SDI, Selective dissemination of information; push transactions; IF

Definition

Information retrieval (IR) and information filtering (IF) are strongly related [3,5]. Information retrieval indexes a large set of documents and when a user asks a query, answers are extracted out of this set. Information filtering processes a stream of documents and for each document arriving in the system a comparison is made with one or more filtering profiles provided by users and in case of a match the document is sent to the user who created the profile. Applications of information filtering are found in competitive intelligence or technology watch. Another way of filtering is to send the document to the user only if the match is negative. This is useful for applications such as child protection or anti-spam.

Another difference is that IR queries are short, for immediate use, with answers expected as if in a conversational mode (in less than few seconds). For Information filtering, queries are permanent, can be elaborated using a long process, are often quite lengthy sometimes including relevant example documents and must be refined using feedback over time.

Historical Background

The first systems of information filtering, then called selective dissemination of information (SDI), appeared in the early 1960s [4]. For a long time they were used principally by librarians to route journal articles, using fixed profiles, to users interested in a particular domain. Because of the time lag then existing between publication, manual indexing, and bibliographic database updating, this kind of service gave delayed access to sometimes stale information.

Newswires about current events was then and remains a good source of fresh information. Companies, eager for information about their competitors, and financiers, interested in having early information about interesting companies, are large consumers of newswire.

The internet has enlarged the use of information filtering because both the number of users and the quantity of information has increased as more information becomes accessible. News filtering remains a major activity, but new activities (such as the filtering of spam and child protection in accessing internet sites) have appeared.

Another new filtering activity brought by the internet is the possibility to advertise new product availability according to user interest, even if this interest is only implicitly observed on by their browsing behavior or search engine queries. This is called *push advertising*.

Foundations

Organization of a filtering system

A filtering system (Fig. 1) processes a stream of documents. Each entering document is compared to a stored expression of user need constructed using key words, possibly limited to relevant structural parts of the input documents. If the document is considered relevant for this profile, the document is sent to the user. The following figure illustrates this process:

One might say that Information Retrieval compares a unique query with several documents whereas Information Filtering compares a unique document to several queries.

In Information Retrieval, a user generates a spontaneous, simple query and desires a rapid response. On the contrary, in Information Filtering, because the subject of the search is permanent, the user has time to elaborate and refine the query, called rather a *profile* here. The search process is continuous. It is not a conversational process though the user still wants to be notified as early as possible about relevant incoming information.

In practice, search engines providers propose a filtering service which is not based on a real filtering system but they use their search engine by periodically submitting the profile query to the database limiting the answers to documents that have arrived since the last run. Of course this is a simulation that does not guarantee the fastest access time to information but this is sufficient for many users.

Profile building and evolution

For Boolean systems, a profile can be a very long and complex equation of keywords that can have hundreds of keywords and logical operators. Generally the elaboration of such queries is performed by professional librarians.

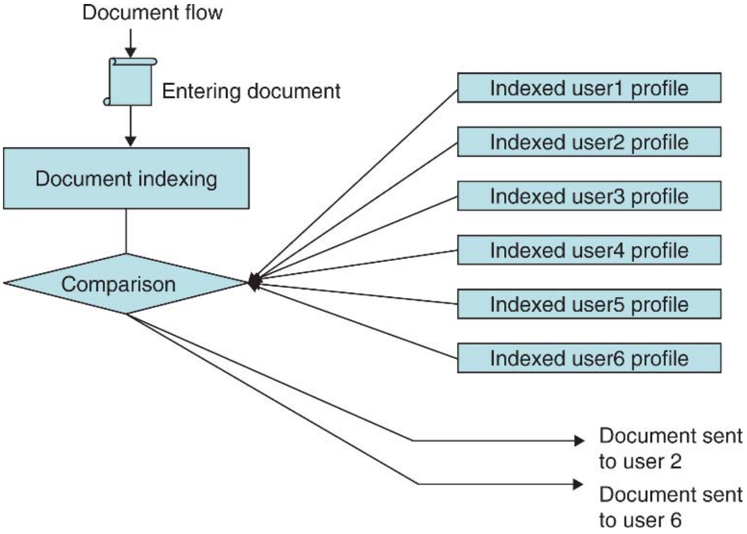
The best way to define a profile is to give a list of keywords along with some document passages relevant for the profile. Such profiles must be processed by systems that can compute a semantic proximity between the profile and the incoming document to decide relevance.

Even if the user's long term information need is stable, the profile expressing this need varies over time. At first, the initial description of user need is often incomplete. Verifying the filtering behavior of an initial set of filtered documents, the user can fine-tune, adding additional keywords, and try to refine ambiguities that he had not foreseen. This process can be simplified for the user by supervised relevance feedback. In this setup, the user need only provide positive or negative reactions to a limited number of proposed documents. According to this positive or negative judgment, the profile can be adjusted by addition or deletion of words, or by modification of their weights in the comparison.

A second reason for profile evolution over time is due to a clearer understanding of the problem on the part of the user, after viewing of retrieved documents. This learning on the part of the user can lead him to rebuild a modified profile.

Comparison procedure

Most filtering systems use the standard information retrieval approach of comparing the vector representing the document with the vector representing the profile. Because the filtering result must be a



Information Filtering. Figure 1. Organization of a filtering system

yes-or-no choice, it is necessary to create a threshold of relevance. A first difficulty is choosing a good threshold. In a filtering system, there is no database as documents arrive in a stream, so document frequency for a term is not known. This can be overcome by computing document frequencies on the fly without producing a database.

The process of attribution of a document to a profile can also be assimilated to a categorization process which assigns documents to one of a set of classes. Key words and document samples car be considered as representative of a category, addition of new relevant documents increase data that can be used to learn the difference between the two classes "good for this profile" and "bad for this profile". Popular categorization methods like Rocchio [6], KNN (K Nearest Neighbors) [9] and SVM (Support Vector Machine) [2] can be used to perform this learning.

As users are interested in a precise domain, the document as an information unit can be too large as a response. Technologies for passage retrieval can be usefully applied to solve this problem. Documents are then cut into parts that are semantically homogeneous. These separate parts are compared to profiles instead of the full document.

Relevance feedback

Because at the beginning for filtering, little information is provided for the profile, it is necessary to improve the profile through relevance feedback. The reaction of the user accepting or rejecting proposed documents gives implicit information about positive or negative influence of the words contained in these documents (Weights of terms in the original query are adjusted and new words are also added to provide a new vector representing the adjusted profile) [1].

Named entities in filtering

Named entities are proper nouns representing names of persons, of organizations, of places, of products, or numerical information like dates, measures, and percentages. They are particularly important for filtering, especially in the case of competitive intelligence.

Thematic filtering versus event filtering

According to the user need, some profiles are more domain oriented and comparison between words vectors are a good solution. Other needs are more event-oriented and necessitate more language processing to identify events that are characterized by a particular action with a particular class of actors. Examples of such event-oriented filtering can be nomination or resigning of company managers, terrorist acts, purchase of a company by another, etc.

Evaluation of filtering systems

Since the beginning of the TREC (Text REtrieval Conference) in 1992, Information Filtering was considered for evaluation. A training corpus was given to participants with queries to train their system. Afterward a new corpus was given to participants and the previously supplied queries were then applied on this new corpus. Participants had to give an ordered list of relevant documents (1000) according to the computed relevance between documents and each query.

This was far from real usage of filtering systems. For this reason, from 1998 to 2002, a new evaluation paradigm was established to evaluate filtering systems [7]. The first difference was that only very few documents are used for training. The participants then had to make a binary decision (document relevant or not) rather than perform a ranking. In addition, documents had to be treated one after the other and for each document proposed as relevant a simulated feedback could be performed. This simulated feedback enabled the tested system to increase their effectiveness. Such process is called adaptive filtering.

Since then, new measures have been established. These measures attempt to take into consideration the different types of users. Some users are interested in having only relevant documents even if they miss many other relevant ones. Other users want to be sure to get all relevant documents but will also accept noise in the form of non relevant documents.

Because of the binary decision about relevance, it is not possible to apply measures developed for answers consisting of ranked list of ordered documents according a level of relevance such as used in the ad hoc track of TREC.

Linear utility: This measure assigns a positive or negative cost to elements in the following contingency table.

	Relevant	Not relevant
Retrieved	R+/A	N+/B
Not retrieved	R–/C	N–/D

R+, R−, N+, N− are the number of document in each category

A, B, C, D give the relative cost for each category.

For example, in TREC 11, the linear utility measure uses the following values $A = 2, B = -1, C = 0, D = 0$

F-beta: This is a modification of the classical F-measure [8]. It combines recall and precision with a parameter beta b which gives a relative weighting between recall and precision.

$0 <= \beta <= 1$

F-measure = $((1 + \beta) * \text{precision} * \text{recall}) / ((\beta * \text{precision}) + \text{recall})$

$\beta = 1$ is neutral, in TREC 2001 $\beta = 0{,}50$ which is an advantage given to precision

Key Applications

Information Filtering is a tool which is used for technology watch and competitive intelligence. It is used both in the security domain and in the civil economy. Companies need to know as early as possible what the activity of their competitors and their potential partners is, in order to decide their future on the technical level and also on the commercial and strategic level.

The other growing need for Information Filtering is the elimination of unsolicited information by filtering spam in the incoming mails. It is also applied to prevent access to some sites (pornographic, pedophile, racist; . . .) for child users of internet.

Information Foraging

Peter Pirolli
Palo Alto Research Center, Palo Alto, CA, USA

Synonyms

Information seeking; Browsing

Definition

Information foraging theory [9] provides scientific predictions and explanations of information-seeking behavior in human-computer interaction (HCI). It also provides engineering models for designing and evaluating information systems and their user interfaces. Information foraging theory assumes that people adapt their information-seeking behavior to maximize their rate of gaining useful information to meet their ongoing goals. Specific models of human-information interaction are developed through (i) rational analysis of the structure and constraints of the task environment and information environment that constitute the ultimate forces driving information-seeking behavior and (ii) specification of cognitive models (user knowledge and cognitive processes) that constitute the psychological machinery behind the observed information-seeking behavior of users. Rational analysis draws upon theories and mathematical approaches developed to address rational choice under uncertainty, and specifically draws upon many models developed to address food-foraging strategies in optimal foraging theory (a branch of behavioral ecology in biology). Cognitive models are developed as programs in computational cognitive architectures that simulate human perception, action, thinking, memory, and other aspects of human information processing.

Historical Background

Information Foraging Theory arose during the 1990s, coinciding with an explosion in the amount of information that became available to the average computer user, and with the development of new technologies for accessing and interacting with information. The late 1980s witnessed several strands of HCI research that were devoted to ameliorating problems of exploring and finding electronically stored information. The confluence of increased computing power, storage, networking, and information access and hypermedia research in the late 1980s set the stage for the widespread deployment of hypermedia in the form of the World Wide Web in 1993. The emergence of the Web in the 1990s provided new challenges and opportunities for HCI. The increased wealth of accessible content, and the use of the Web as a place to do business, exacerbated the need to improve the user experience on the Web and other large-scale collections of content.

Models of information foraging were initially developed by analogy to optimal foraging theory. A typical optimal foraging model characterizes an agent's interaction with the environment as an optimal solution to the tradeoff of costs of finding, choosing, and consuming food against the energetic benefit gained from that food. Information foraging theory, however, assumes that costs of interaction are weighed against the benefits gained from gathering information and knowledge. These models attempt to understand the design of an agent's behavior by assuming that it is well engineered (adapted) for the problems posed by the environment. The two optimal foraging models that were initially applied to information seeking and browsing were the diet model (prediction of the food types that an animal selects to eat or not) and the patch model (prediction of when an animal chooses to give up food seeking in a food patch to go to another). The information diet model was applied to the prediction of how users would select some information collections and ignore others in order to maximize the benefits gained in information browsing. The information patch model was used to predict when users would give up on search in an information collection (e.g., a Web site). The first detailed application of the information diet and patch models was used to evaluate a novel document clustering browser called Scatter/Gather [10,11]. Detailed predictions of individual user behavior with Scatter/Gather were derived from computer simulations (cognitive models) of user perceptions, cognition, and action. A novel cognitive modeling technique introduced by information foraging theory predicted how users assessed cues from the user interface to make information seeking and browsing choices. *Information scent* refers to these user interface cues that guide users to the information they seek. Information foraging theory has been used to develop models of information-seeking on the Web, and interaction with information visualizations. It has also been used as a foundation for design guidelines, novel user interfaces, and automated usability evaluation tools.

Foundations

It is assumed that a user's fitness is improved to the extent that the user can gain valuable information to solve problems faced in everyday life. Increasing the rate at which people can find, make sense of, and use valuable information improves the human capacity to behave intelligently. It is assumed that adaptive information systems evolve towards states that maximize gains of valuable information per unit cost.

Users engaged in information foraging will exhibit such adaptive tendencies, and they will prefer technologies that tend to maximize the value (utility) of knowledge gained per unit cost of interaction.

Information Foraging Theory has adopted the *rational analysis* program [1]. Rational analysis addresses the questions: (i) *what* environmental problem is solved, (ii) *why* is a given behavioral strategy a good solution to the problem, and (iii) *how* is that solution realized by cognitive mechanism. The products of this approach include (i) characterizations of the relevant goals and environment, (ii) mathematical rational choice models (e.g., optimization models) of idealized behavioral strategies for achieving those goals in that environment, and (iii) computational cognitive models. Rational analysis in information foraging theory focuses on the task environment that is the aim of performance, the information environment that structures access to valuable knowledge, and the adaptive fit of the human-information interaction system to the demands of these environments. The following recipe has been proposed for rational analysis [1].

1. Precisely specify the goals of the agent.
2. Develop a formal model of the environment to which the agents is adapted.
3. Make minimal assumptions about the computational costs.
4. Derive the optimal behavior of the agent considering (1–3).
5. Test the optimality predictions against data.
6. Iterate.

The recipe focuses on optimal behavior under given goals and environmental constraints with minimal assumptions about the mechanisms that might produce such behavior.

To illustrate, rational analyses of information foraging on the Web have focused on the (i) the choice of the most cost-effective and useful browsing actions to take based on the relation of a user's information need to the perceived cues (information scent) associated with Web links and (ii) the decision of whether to continue at a Web site or leave based on ongoing assessments of the site's potential usefulness and costs. The rational analysis of information scent assumes that the goal of the information forager is to use perceived information scent cues (e.g., a Web link) to predict the utility of desired sources of content (i.e., a Web page that provides a needed answer), and to choose to navigate the links having the maximum expected utility. It is minimally assumed that the user's cognitive system represents information scent cues and information goals in cognitive structures called *chunks*. A Bayesian analysis leads to a specification of *strengths* of association, S_{ji}, among chunks that reflects the log likelihood odds of an information source associated with information cue *j* being relevant to a goal chunk *i*:

$$S_{ji} = \log\left(\frac{\Pr(i|j)}{\Pr(i)}\right), \tag{1}$$

where $\Pr(i|j)$ is the probability (based on past experience) that chunk *i* has occurred when chunk *j* has occurred in the environment, and $\Pr(i)$ is the base rate probability of chunk *i* occurring in the environment. Equation (1) is also known as *Pointwise Mutual Information.* Each chunk *i* in the user's goal is assumed to receive *activation.* A_i, from all associated information scent chunks *j*,

$$A_i = \sum_j S_{ji}, \tag{2}$$

and the total amount of activation received by all goal chunks is,

$$V = \sum_i A_i. \tag{3}$$

It is assumed that the utility of choosing a particular link is just the sum of activation it receives plus random noise drawn from independently and identically distributed (IID) Gumbel distributions. The probability that a user will choose link *L*, having a summed activation V_L, from a set of links *C* on a Web page, given an information goal, *G* is,

$$\Pr(L|G, C) = \frac{e^{\mu V_L}}{\sum_{k \in C} e^{\mu V_k}}. \tag{4}$$

where μ is a scaling parameter. Another choice facing a Web user is whether to continue navigating a particular Web site or leave. The rational analysis of this problem employs a modified patch model from optimal foraging theory. It is assumed that the user employs learning mechanisms to develop an assessment of the potential yield of a Web site, based on the user's current experiential state *x*. This *potential function h*(x) is

$$h(x) = U(x) - C(t). \tag{5}$$

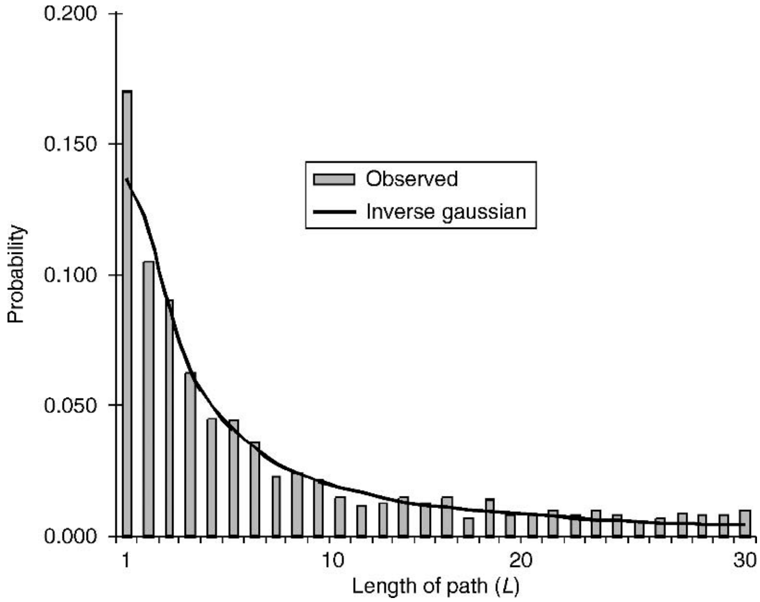
where *U*(x) is the utility of continued foraging in the current Web site and *C*(*t*) is the *opportunity cost* of foraging for the *t* amount of time that is expected to be spent in the information patch. So long as the potential of the Web site is positive (the utility of continuing is greater than the opportunity cost) then the user will continue foraging.

Individual information foraging behavior can be related to the behavior of aggregates of users. For instance, the *Law of Surfing* [6] relates the rational analysis of individual Web surfing to aggregate Web user behavior. Such aggregate distributions are of practical interest because content providers on the Web often want to know how long people will remain at their Web sites. The Law of Surfing characterizes the distribution of the length, *L*, of sequences of page visits by Web users. Figure 1 presents a typical empirical distribution of the length of paths taken by visitors to a Web site. The distribution is skewed with the bulk of path lengths being short, and a long positive tail. The skewness of the distribution, and the long positive tail, imply that the mean of the distribution will typically be larger than the mode.

The Law of Surfing assumes that the expected utility from continuing on to the next state, X_t, is stochastically related to the expected utility of the current state $X_{t\text{-}1}$,

$$U(X_t) = U(X_{t-1}) + \varepsilon_t, \tag{6}$$

where the ε_t are IID Gaussian distributions with mean *m* and variance s^2. This is known as a *Wiener process* (a Brownian motion process) with a random drift parameter *m* and noise s^2. It is assumed that the process continues until a threshold expected utility is reached. That is, from an initial starting page in a Web foraging episode, the expectation is that users continue browsing (surfing) according to the Wiener process specified in (6) until some threshold θ is reached. It is assumed that an individual will continue to surf until the expected cost of continuing is perceived to be larger than the discounted expected value of the information to be found in the future. In the limit, this analysis of Web surfing is the same as the analysis of *first passage times* in Brownian motion. First passage times are distributed as an Inverse Gaussian



Information Foraging. Figure 1. The Law of Surfing: The probability distribution of the length of paths surfed by users prior to leaving a web site are approximated by an inverse Gaussian distribution.

distribution: the probability density function of L, the length of sequences of Web page visits, is distributed is

$$f(L) = \sqrt{\frac{\lambda}{2\pi} L^{-3/2} e^{\frac{\lambda}{2v^2 L}(L-v)^2}}, \quad L > 0, \qquad (7)$$

where the parameter v is the expected value, and λ is related to the expected value and variance as

$$\frac{\lambda = v^3}{Var[L]}.$$

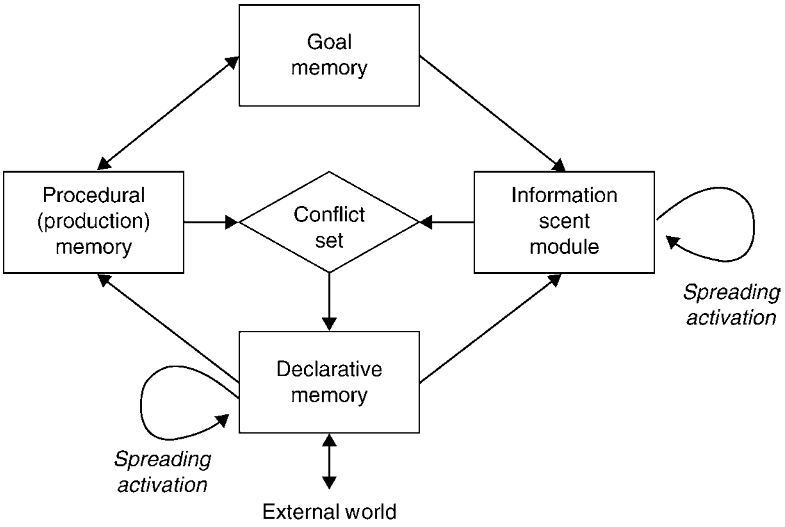
Computational cognitive models developed in information foraging theory simulate the psychological mechanisms that yield adaptive behavior. Typically, these are implemented in a simulation system that embodies a theory of *cognitive architecture* developed in psychology [2]. Theories of cognitive architecture attempt to provide a deeper account of the mechanisms underlying cognition, learning, and performance. The ACT family of *production system* theories has the longest history (since 1976) of these kinds of cognitive architectures.

Figure 2 presents the ACT-Scent cognitive architecture developed in the ACT family. It includes a module that computes *information scent*. The architecture includes a *declarative memory* containing declarative knowledge represented as chunks, which correspond to things that the user's mind is aware it knows and that can be easily described to others, such as the content of Web links, or the functionality of browser buttons, and the current user's goal (e.g., evaluating a link, choosing a link, etc.). The architecture also includes a *procedural memory*. Procedural knowledge is represented as *production rules*. For instance, the following is an English gloss of a production rule, Click-link, that is used to simulate the choice of a Web link,

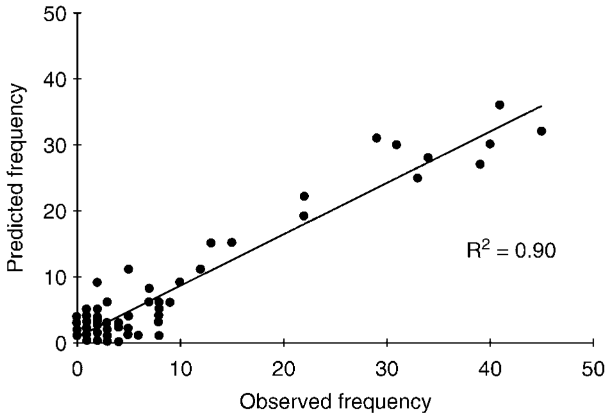
```
Click-link:
IF the goal is to process a link
& there is a information-seeking task
& there is a browser
& there is a link that has been read
& the link has a link description
THEN
Click on the link
```

If selected, the rule will execute the action of clicking on the link. A production rule has a *condition* side and an *action* side. When the all the conditions on the condition side (the "IF" portion) are *matched* to goal information and declarative memory, the production may be *fired* and when it does, the actions (the "THEN" portion) of the production will be *executed* to possibly update goals and memory, or initiate behavior. At any point in time, only a single production can fire. When there is more than one match, the matching productions form a *conflict set*. One production is then selected from the conflict set based on its utility based on information scent. The *goal memory* contains representations of intentions driving behavior. The information scent module computes the utility of actions.

Information perceived from the external world is encoded into chunks in declarative memory. Goals



Information Foraging. Figure 2. The ACT-Scent cognitive architecture used in simulating web foraging.



Information Foraging. Figure 3. The scatter plot for the observed and theoretically predicted frequency that users select links at the Yahoo! web site assessed over eight information-seeking tasks. Predictions were generated by Monte Carlo simulations using an ACT-Scent model.

and subgoals controlling the flow of cognitive behavior are stored in goal memory. The system matches production rules in production memory against goals and activated information in declarative memory and those that match form a conflict set. The matched rule instantiations in the conflict set are evaluated by utility computations in the information scent module. Based on the utility evaluation, a single production rule instantiation is executed, updates are made to goal memory and declarative memory, if necessary, and the cycle begins again. Simulations models generate predicted user behavior. Figure 3 presents the predicted frequencies for links being chosen at a popular Web site generated by Monte Carlo simulations of users working on pre-specified tasks.

Key Applications

Engineering Models of Browser Use

Graph-based algorithms based on information foraging models have been used to predict the flow of user at a Web site and identify Web site navigation problems, and this was implemented in a automated usability analysis tools available through a Web interface [5]. Dynamic programming models based on information foraging theory have been used to identify trade-offs in the design of the Scatter/Gather document cluster browser that varied over task conditions. The CogTool-Explorer [8] tool supports the rapid prototyping of user interfaces and then automatically simulates user interaction with specified designs to make performance time predictions.

Novel Search and Browsing Interfaces

Novel user interface techniques have been developed to automatically render improved information scent cues that yield more efficient user browser [7,14].

Usability Guidelines

Concepts and metaphors from information foraging theory have been influential in the development of Web usability guidelines. The concept of information scent has been used to develop Web page design guidelines aimed at producing efficient matches between user goals and Web link cues [13].

Future Directions

Information foraging theory has been extended to predictions of user interaction with highly interactive information visualizations [12,4], programming environments, and skimming and reading time allocation under varying deadline conditions. Recent work is also extending the research to social information foraging (information seeking and production by collections of users) in systems such as social bookmarking sites [9,4].

Synonyms

Data integration; Enterprise information integration

Definition

Information integration systems offer uniform access to a set of autonomous and heterogeneous data sources. Sources can range from database systems and legacy systems to forms on the Web, web services and flat files. The data in the sources need not be completely structured as in relational databases. The number of sources in an information integration application can range from a handful to thousands.

Historical Background

Database applications are typically heavily designed and tuned for a specific context. But as data management needs in enterprises change and the information economy evolves, the need to combine information from multiple sources arises frequently. Examples of such scenarios include mergers and acquisitions, internal restructuring, the need to interoperate with third parties and to expose data on the web. Since the early 1980s the need to combine multiple heterogeneous data sources has become a research topic for the database research community. In the 1990s, as the web emerged and the many data sources came on line, the need to integrate data and for companies to work with third-parties grew, and these trends fueled the information integration research and industry.

Foundations

Information integration is a challenging problem for three different classes of reasons: systems-level, logical-level and social challenges.

The systems challenges arise fundamentally because enterprises need to enable multiple systems to talk seamlessly to each other. This is hard even when they are all running ODBC/JDBC compliant databases, let alone radically different systems. For example, while SQL is a standard query language for relational databases, there are some differences in the way different vendors implement it. Executing queries efficiently over multiple systems is even more challenging. In addition to the difficulties that arise in distributed databases, information integration systems cannot assume that data is A priori distributed to the different nodes by one entity and in an organized and known fashion. Furthermore, the query processing capabilities of each source can be very different. For example, while one source may be a full SQL engine and therefore may be able to accept very complex queries, another source may be a web-form and therefore only accepts a very small number of query templates.

The second set of challenges has to do with the way data is logically organized in the data sources. At the core, the problem is that when schemas are designed by different people and for different applications, there will be significant differences between them, even when they model the same domain. Differences include (i) naming of tables and attributes, (ii) tabular organization of the data (or hierarchical structure in XML), (iii) domain coverage and level of detail modeled, and (iv) differences in data-level representation of objects.

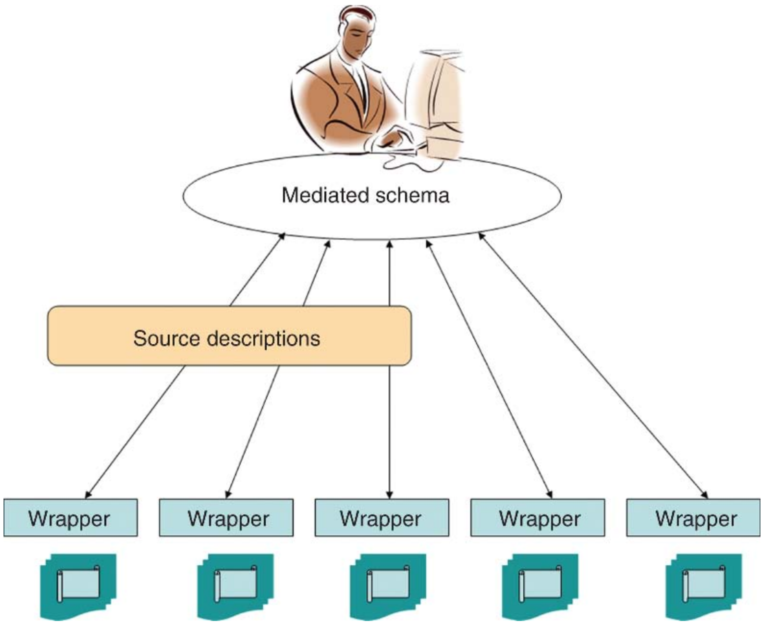
The social challenges in building an information integration application, while not technical, are often very significant in practice. The first challenge may be to *find* a particular set of data. It may be hard to find a particular piece of data within a large enterprise, and in some cases, the data needed is not captured in the proper form. Even when the location of the data is known, owners of the data may not want to cooperate with an integration effort. In some cases this may happen for competitive reasons, and in others it may be because systems are carefully tuned for performance and the owners are afraid that participating in an information integration effort may adversely affect their system. Of course, privacy and security concerns are rampant.

For all these reasons, the goal of information integration is to build tools that make it *easier* to build integration applications, rather than completely automating the process.

Information Integration Architecture

Figure 1 shows a prototypical architecture of an information integration system, often referred to as *virtual information integration*. The *data sources* are shown on the bottom of the figure. As explained earlier, data sources can vary on many dimensions, such as the data model underlying them, their schema, and their ability to process queries.

The *wrappers* are (hopefully small) programs whose role is to send queries to a data source, receive



Information Integration. Figure 1. Logical components of a virtual information integration system.

answers and possibly apply some basic transformations on the answer. For example, a wrapper to a web form source would accept a query and translate into the appropriate HTTP request with a URL that poses the query on the source. When the answer comes back in the form of an HTML file, the wrapper would extract the tuples from the HTML file. There are two main approaches to creating wrappers. The first approach is to explicitly write a set of rules for extracting the structure from the answer returned from the source. The second approach is to train the wrapper on a set of examples, and use Machine Learning techniques to learn the rules.

The top of the figure depicts the *mediated schema*. This is the schema in which users (or applications) pose queries. The mediated schema is built for the information integration application and contains *only* the aspects of the domain that are relevant to the application. Therefore, it does not necessarily contain all the attributes present in the sources, but only a subset of them. The mediated schema is not meant to store any data, but is purely a logical schema.

The key to building an information integration application are the *source descriptions*. These descriptions specify the properties of the sources that the system needs to know in order to use their data. The main component of source descriptions are the *semantic mappings*, that relate the schemata of the data sources to the mediated schema. The semantic mappings specify how attributes in the sources correspond to attributes in the mediated schema (when such correspondences exist), and how the different groupings of attributes into tables are resolved. In addition, the semantic mappings specify how to resolve differences in how data values are specified in different sources. It is important to emphasize that the virtual information integration architecture only requires specifying mappings between the data sources and the mediated schema and not between every pair of data sources. Hence, the number of mappings that need to be specified is the same as the number of sources and not the square of that number.

Schema Mediation Languages

There has been quite a bit of research on developing appropriate languages for specifying schema mappings. The common theme to these languages is that they use query expressions for the mappings, and they differ in how they use these expressions.

The Global-as-View (GAV) language describes the mediated schema as a set of view definitions over the source relations. In contrast, the Local-as-View language (LAV) describes the data sources as views over the mediated schema. The GLAV language combines the expressive power of GAV and LAV. The following example illustrates these differences.

Example: Consider a mediated schema with the following three relations: `Movie(title, director, year, genre), Actors(title, name) Plays (movie, location, startTime)` *and the sources shown in* Figure 2.

The mappings shown in Figure 3 are GAV schema mappings. Note how Movie is defined to be the union of two conjunctive queries.

The $\subseteq$ *symbol in the mapping denotes the* open-world assumption*: that is, the data sources may not contain all the data in the domain.*

The mappings shown in Figure 4 are LAV schema mappings. The first description states that S5 *contains a subset of the projection on a relation in the mediated*

S1:
Movie(MID, title)
Actor(AID, firstName, lastName, nationality, yearOfBirth)
ActorPlays(AID, MID)
MovieDetail(MID, director, genre, year)
S4: ActDir(actor, director)
S5: MovieGenres(title, genre)
S6: MovieDirectors(title, dir)
S7: MovieYears(title, year)

Information Integration. Figure 2.

Movie(title, director, year, genre) $\subseteq$ S1.Movie(MID, title),
S1.MovieDetail(MID, director, genre, year)
Movie(title, director, year, genre) $\subseteq$ S5.MovieGenres(title, genre),
S6.MovieDirectors(title, director),
S7.MovieYears(title, year)

Information Integration. Figure 3.

S5.MovieGenres(title, genre) $\subseteq$ Movie(title, director, year, genre)
S4.ActDir(actor, dir) $\subseteq$ Movie(title, director, year, genre),
Actors(title, actor)

Information Integration. Figure 4.

schema, and the second description states that S4 *is a subset of the join of two relations in the mediated schema. Neither of these sources can be described in GAV.*

As shown, the main advantage of GAV is that query processing is conceptually easier. The main benefit of LAV over GAV is that describing a data source does not require knowing which other data sources exist in the system. Hence, it is easier to add more sources to the system. Furthermore, since the source descriptions in LAV can leverage the expressive power of the view definition language, it was easier to describe precise constraints on the contents of the sources and describe sources that have different relational structures than the mediated schema. Describing such constraints is crucial because it enables the system to select a minimal number of data sources relevant to a particular query.

User queries are posed in terms of the relations in the mediated schema. Hence, the first step the system must do is *reformulate* the query into queries that refer to the schemas of the data sources. To do so, the system uses the source descriptions. The result of the reformulation is a set of queries that refer to the schemata of the data sources and whose combination will yield the answer to the original query. The result of reformulation is referred to as a *logical query plan.*

Hence, an important aspect of schema mapping languages is developing algorithms for (and understanding the complexity of) query reformulation. For GAV, since the mediated schema is defined as a set of views over the sources, query reformulation amounts to query unfolding. In the case of LAV, since sources are described as views, query reformulation amounts to rewriting queries using views. While, in general, the complexity of answering queries using views is exponential, there are several algorithms that work efficiently in practice. Query reformulation in GLAV is a combination of answering queries using views followed by a query unfolding step.

In addition to schema mappings, source descriptions also need to consider (i) access-pattern limitations to sources: for example, a database served behind a web form or web service typically requires a set of inputs to serve tuples, and (ii) completeness (or partial completeness) of data sources: when a data source is known to be complete on a particular slice of the domain, the system can eliminate the need to access other data sources. The differences between complete and incomplete sources are formulated in terms of the open-world (closed-world) assumption.

Generating Schema Mappings

A major bottleneck in setting up an information integration application is the effort requires to create the source descriptions, and more specifically, writing the semantic mappings between the sources and the mediated schema. Writing such mappings (and maintaining them) required database expertise (to express them in a formal language) and business knowledge (to understand the meaning of the schemas being mapped).

To address this problem, several techniques for semi-automatic schema mapping have been developed with the goal of reducing the time it takes a human to create mappings. These techniques rely on several principles. First, the techniques explore methods to map between schemas based on clues that can be obtained from the schemas themselves, such as linguistic similarities between schema elements and overlaps in data values or data types of columns. Second, based on the observation that none of the above techniques is foolproof, the next development involved systems that combined a set of individual techniques to create mappings. Finally, based on the observation that schema mapping tasks are often repetitive, novel schema mapping methods incorporate Machine Learning techniques that enable the system to leverage past work. It should also be noted that the process of generating schema mappings is typically divided into two steps. In the first step, referred to as *schema matching*, the system generate *correspondences* between attributes (or other schema elements) in the two schemas. In the second step, the system builds on the correspondences and creates expressions in the mapping language.

In addition to the schema level, an information integration system also needs to reconcile references at the data level. There are often cases where the same object in the world is referenced in different ways in data sets (e.g., people, addresses, company names, genes). The problem of reference reconciliation is to automatically detect references to the same object and to collapse them. Unlike reconciling schema heterogeneity, the amounts of data are typically much bigger, and therefore these techniques need to put more emphasis on being mostly automatic. These techniques typically rely on some sophisticated forms of string matching, augmented by looking at neighboring values in the same row of a table to gather additional match clues.

Information integration is one of several contexts in which mappings between data sources need to be created, manipulated, composed and inverted. The area of Model Management was developed to provide a formal framework for supporting generic operations on schemas and mappings between them. Knowledge Representation languages, and in particular, Description Logics, have also been shown to offer benefits in modeling data sources in a flexible fashion. In a sense, Description Logics offer a schema and query language that can also express very rich constraints, but still support effective reasoning. More generally, information integration has been an active topic also in the field of Artificial Intelligence, leveraging techniques from Knowledge Representation, Machine Learning and Automated Planning.

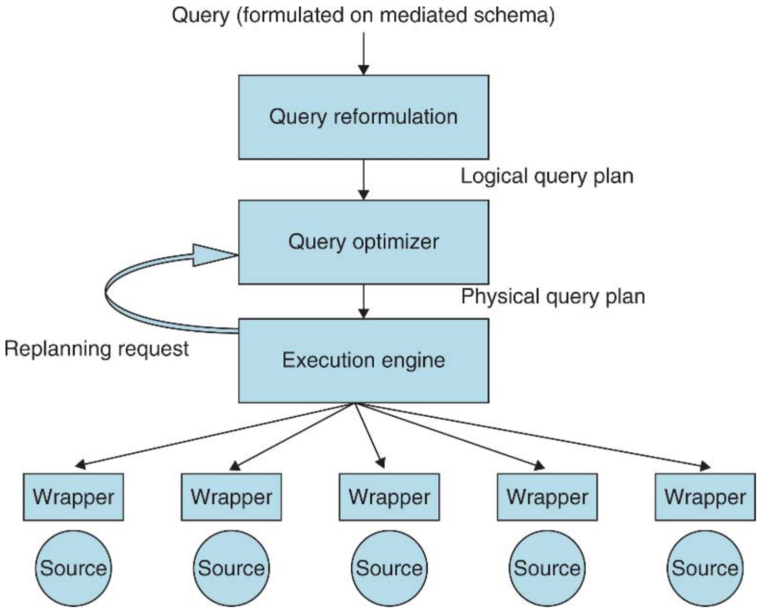
Query Processing

Given a logical query plan, it needs to be optimized and executed by the system (see Fig. 5). Herein lies the second main difference between database systems and information integration systems. Unlike the conventional database setting, an information integration system cannot neatly divide its processing into a query optimization step followed by a query execution step. The contexts in which an information integration system operate are very dynamic and the optimizer has much less information (e.g., statistics) than the traditional setting. As a result, two things happen: (i) the optimizer may not have enough information to decide on a good plan, and (ii) a plan that looks good at optimization time may be arbitrarily bad if the sources do not respond exactly as expected. To address these challenges, researchers developed techniques for *adaptive query processing*. (Adaptive query processing was already investigated in traditional database systems because even there, the estimates of the optimizer may be wrong, leading to bad plans).

The key idea of adaptive query processing is that the engine may decide to change the query plan *during* execution. The variations on the techniques developed have to do with how and when the plan can be changed. For example, one strategy may consider changing the plan only at materialization points, or the system may put conditionals into the plan that examine the intermediate results and decide what to do next. More aggressive techniques consider a different plan for every single tuple, while others continuously monitor the execution and change plans when it appears as if there is a better global plan. One of the challenges that each of these techniques needs to keep in mind is to minimize wasted computation (i.e., intermediate results that are computed and then discarded).

Related Data Management Architectures

Virtual information integration is one of several architectures for sharing and integrating data. Before the development of virtual information integration, data



Information Integration. Figure 5. Components of an information integration system.

warehousing was the common method for integrating data from multiple sources. However, data warehousing suffered from the fact that the data is loaded only periodically into the warehouse and therefore may be stale. Furthermore, data warehousing requires a single physical store thereby limiting the range of contexts in which data can be shared.

The emergence of peer-to-peer file sharing systems inspired the data management research community to consider P2P architectures for data sharing. The advantage of peer-data management systems is that it is no longer necessary to create a single mediated schema in cases where such a schema is hard to build or agree upon.

Finally, data exchange refers to an architecture that includes source and target databases, and the semantic mappings specify how to populate the target from data in the source. Many of the same issues encountered with GLAV mappings also occur here.

The Information Integration Industry

Beginning in the middle 1990s, information integration moved from the lab into the commercial arena. Today, this industry is known as Enterprise Information Integration (EII). The vision underlying this industry is to provide tools for integrating data from multiple sources *without* having to first load all the data into a central warehouse as required by previous solutions. Broadly speaking, the architectures underlying the products were based on the principles investigated in the research arena.

Some of the first applications in which these systems were fielded successfully were customer-relationship management, where the challenge was to provide the customer-facing worker a *global view* of a customer whose data is residing in multiple sources, and digital dashboards that required tracking information from multiple sources in real time. Of the many challenges faced by the industry, perhaps the greatest one was the business question of whether to build a horizontal platform that can be used in any application or to build special tools for a particular vertical. The argument for the vertical approach was that customers care about solving their *entire* problem, rather than paying for yet another piece of the solution and having to worry about how it integrates with other pieces. In addition, there are challenges in integrating with other middleware tools, such as Enterprise Application Integration tools.

In addition to the enterprise market, information integration has also played an important role in internet search. For example, the *vertical search* market focuses on creating specialized search engines that integrate data from multiple deep web sources in specific domains (e.g., travel, jobs). These engines also embed complex source descriptions.

Finally, information integration has also been a significant focus in the life sciences, where diverse data is being produced at increasing rates, and progress depends on researchers' ability to synthesize data from multiple sources. Personal Information Management is also an application where information integration is taking a significant role.

Key Applications

Some of the key applications of information integration are:

1. Enterprise data management, querying across several enterprise data repositories,
2. Accessing multiple data sources on the web (and in particular, the deep web),
3. Large scientific projects where multiple scientists are independently producing data sets,
4. Coordination accross mulitple government agencies.

Future Directions

With all the progress to date, the set-up time for information integration systems is still too long. To set up an information integration application, one still needs to create a mediated schema, and create semantic mappings to obtain any visibility into the data sources. An important research challenge is to provide as many services as possible with as little set up time as possible. The management of *dataspaces* emphasizes the idea of pay-as-you-go data management: offer some services immediately without any setup time, and improve the services as more investment is made into creating semantic relationships.

To support pay-as-you-go data management, the information integration system needs to model and reason about uncertainty. Uncertainty can appear in several forms: in the underlying data, the imprecise nature of semantic mappings and vaguely specified queries (i.e., keyword queries). Hence, incorporating uncertainty into data management and in particular, to information integration systems, is an important challenge going forward.

Information Integration Techniques for Scientific Data

Amarnath Gupta

Synonyms

Graph theory; Graph data structure; Graph database

Definition

Information integration refers to the field of study of techniques attempting to combine information from disparate sources despite differing conceptual, contextual and lexical representations. One goal of information integration, commonly held by the data management community, is to combine the information in such a way that the user gets a unified view of the data. In other words, the user should see and query the data as though it is present in a common, unified schema.

In the domain of scientific applications, the problems and expectations are different. In this domain the semantics of data play a very strong role in data integration, and semantic compatibility need to be ensured as part of the data integration process. Further, straightforward view-based data integration, which works well for commercial applications, does not always suit the needs of the scientific users. Finally, scientists need to ensure that the result of any query on integrated data is scientifically valid.

Historical Background

Database applications are typically heavily designed and tuned for a specific context. But as data management needs in enterprises change and the information economy evolves, the need to combine information from multiple sources arises frequently. Examples of such scenarios include mergers and acquisitions, internal restructuring, the need to interoperate with third parties and to expose data on the web. Hence, from the early 1980s the need to combine multiple heterogeneous data sources has become a research topic for the database research community. In the 1990s, as the web emerged and the many data sources came on line, the need to integrate data and for companies to work with third-parties grew, and these trends fueled the information integration research and industry.

Foundations

There are several technical challenges in information integration in science.

Semantic Heterogeneity

Semantic heterogeneity [6] refers to a problem that occurs in both scientific and commercial applications and arises when the data to be integrated have been developed by different groups for different purposes. An aspect of semantic heterogeneity is schema heterogeneity (one schema uses two attributes “firstName” and “lastName,” and another uses a single attribute “fullName”); another aspect is data heterogeneity (“IBM” in one database versus “International Business Machines” in another). A more complex kind of semantic heterogeneity involves generalization, where one database has a value like “thoracic surgeon” and another has a value “surgeon.” This difference can be reconciled if the system uses the additional knowledge that a "thoracic surgeon is a surgeon," and have an integration rule that a narrower term can be mapped to the more general term. In scientific databases, the reconciliation between schema and data heterogeneities becomes more complex. The term "Purkinje cell" can be mapped to the more general term "neuron" if the anatomical location of the Purkinje cell is known to be the brain, it should map to "muscle cell" if the location is known to be the heart, otherwise it will map to the even more general term "cell." Similar mapping rules can be defined at the schema level. Thus, one needs a more extensive, yet easily computable, mapping logic, and an integration framework that uses this extra mapping layer. Hakimpour and Geppert [5] and Ludäscher et al. [7] make use of ontologies or other semantic structures to specify these semantic mappings.

Role of Metadata in Managing Semantic Heterogeneity

Metadata refers to additional information about data that cover the scope, the creation, the coverage and so forth that is not directly represented in the data. In science, the norm is to call the experimental output as the "data" and other related information like the experimental protocol, the people conducting the experiment and recording the data etc. as metadata. Metadata can play a partial role in resolving some forms of semantic heterogeneity in both commercial and scientific applications. Suppose there are two tables in two sources where each contains a variable called "oxygen-saturation." Is it possible to create integrated views that would perform unions of the tables, or a join operation with "oxygen-saturation" as the joining column? Since they both have the same data types and notionally represent the same physical quantity, it might seem that combining the relations using this variable is a valid operation. However, if it is known that one database has a daily value of this variable, while the other database has monthly averages, then the answer does not remain so obvious any more. One role of metadata is to capture this kind of information such that the information integration rules can use additional guard conditions based on metadata.

Functional Relationships

Functions play a significant role in scientific applications. The data exposed to a user is often the result of a computation. For example, in many geospatial applications, the value of a variable at a specific location is not directly stored and needs to be provided through interpolation. This is one of the many typical cases where the user can get access to the data only through functions [2]. In an integration scenario, the mapping between two data elements coming from two different data sources may also be established through functions. Suppose there are two sources S1 and S2, and both provide a variable Y when a parameter X is supplied to them. When an integration system accesses S1, it has to use the function f1, and for S2 it has to use the function f2. Suppose, the integration system takes a value x1 and sends it to both sources by executing f1(x1) and f2(x1), and gets back values y1 and y2 respectively. The relationship between y1 and y2 may need to be determined by mapping functions g1 and g2 to be applied to the two sources respectively. Thus if the values returned are equivalent then g1(f1(x1)) will be equivalent to g2(f2(x1)). If the sources need to be integrated through a view that requires a semijoin, transformation functions are needed to convert the output of one source to input of another source. In actual scientific applications that involve wider variety of data types, these functions can be complicated and specialized and need a separate service. While information integration products like DB2 DiscoveryLink from IBM allow sources to export functions, optimized techniques for data integration with functions is still an area of research.

Non-schematic Integration

Not all scientific data integration can be done by schema integration, or even schema integration extended by semantic mapping structures. This is especially true if the task of the "integration" is to compute a cascade of functions whose parameters come from different sources. This form of information integration is covered in detail in the entry *Scientific Workflow Management*. A different class of non-schematic information integration occurs through statistical tools. Critchlow et al. [3] reviews a number of "data integration" tools in the domain of drug discovery. All these two use multiple data sources from domain specific data types like microarrays and protein interaction graphs, and use statistical structures like decision trees and Bayesian networks to achieve data combination. How data management techniques can be effectively used for this class of data integration remains an open issue.

New Issues

Interactive Information Integration The ability to visualize information is common to many scientific disciplines. Scientists often find the fully automated schema mapping and integration techniques developed by computer scientists to be less useful because they would like the data integration process to be more interactive and exploratory. In this mode of integration, the user needs a system's guidance to discover sources that may potentially be integrated, would use exploratory tools to investigate which subset of data from different sources might scientifically qualify for integration, and provide additional semantic input at query time to ensure compatibility of data that need to match each other. Research projects are currently underway to explore how interactivity can be introduced in information integration and querying.

Quality of Integration

A common goal in any science task is to develop a better understanding of a phenomenon by observing, modeling and computation. In the case of information integration, the desired goal is to ensure that when two previously unconnected pieces of information are combined, the resulting product of integration will provide a better or more accurate or novel understanding that the unconnected data pieces could not have provided by themselves. A real impediment in achieving this is that scientific data often has uncertainties and suffers from obsolescence due to the progressive nature of scientific information. Further, data from different sources can be contradictory or incompatible and combining them may need additional techniques that a data integration system needs to support. A formal framework is therefore needed to assess the "goodness" of the integration. Qi et al. [8] has taken an initial step for integrating conflicting data in an archeological application.

Key Applications

A number of scientific information integration systems have developed over the last decade. A few of them are listed below.

BIRN

The Biomedical Informatics Research Network (http://www.nbirn.net) has developed a semantic information integration system for Neuroscience applications. It uses a relational Global-As-View Mediator [4] extended with a semantic network of inter-term relationships to achieve scientific information integration.

Data Foundry

The Data Foundry system (https://computation.llnl.gov/casc/datafoundry) [3] uses a mediator based system for integration of Bioinformatics data. The system contains a modeling language to represent metadata which is used to generate a specific mediator for an information integration task.

GEON

In the domain of geological sciences, the Geosciences Network (http://www.geongrid.org/) [1] uses all information resources including maps and spatial information to be explicitly registered to an OWL (Web Ontology Language – see http://www.w3.org/TR/owl-features/) ontology. The ontology-registered data sources are then queried using an SQL called SOQL.

Information Lifecycle Management

Hiroshi Yoshida
Fujitsu Limited, Yokohama, Japan

Synonyms

ILM

Definition

Information lifecycle management is the activity of storing data in the most appropriate storage infrastructure, according to the business value of that data as it changes over time. The Storage Networking Industry Association (SNIA) defines Information Lifecycle management as follows:

The policies, processes, practices, services and tools used to align the business value of information with the most appropriate and cost-effective infrastructure from the time when information is created through its final disposition. Information is aligned with business requirements through management policies and service levels associated with applications, metadata and data.

Key Points

The business value of information varies during its lifecycle, e.g., from the time when information is created through to its final disposition. Considering the varying business value of information, it is necessary to provide cost-effective storage infrastructure which meets the requirements corresponding to the business value. For example, information related to current transactions is most valuable from the viewpoint of current business operations and is usually stored in online disk arrays with high performance and high availability. Information on transactions during the past year has value as statistics and is stored in less expensive hard disk drives. Finally, information on transactions over several years has value only in meeting regulatory compliance and is stored in offline tape libraries.

Information lifecycle management is the generalization of such practices. In a typical example of ILM process, information is classified based on business values first, referring to its metadata or content. Then appropriate service level requirements are defined for information based on its classification. On the other hand, storage infrastructure resources are also classified based on service level attributes such as performance and availability. Finally the most cost-effective storage infrastructure resources, which meet the classified information requirements, are chosen. When information value changes, the information is migrated between multiple storage infrastructure classes according to predefined policies.

A simple example of information lifecycle management is hierarchical storage management (HSM). In HSM, files are migrated between multiple storage tiers such as high performance disk arrays, low performance hard disks, and tape libraries based on access frequency or latest access date. Instead of such simplistic policies, supporting policies which reflect the change of business value of information is the key to implementing ILM.

Information Loss Measures

Josep Domingo-Ferrer
Universitat Rovira i Virgili, Tarragona, Catalonia

Synonyms

Data utility measures

Definition

Defining what a generic information loss measure is can be a tricky issue. Roughly speaking, it should capture the amount of information loss for a reasonable range of data uses. It will be said that there is little information loss if the protected dataset is analytically valid and interesting according to the following definitions by Winkler [4]:

A protected microdata set is *analytically valid* if it approximately preserves the following with respect to the original data (some conditions apply only to continuous attributes):

1. Means and covariances on a small set of subdomains (subsets of records and/or attributes)
2. Marginal values for a few tabulations of the data
3. At least one distributional characteristic

A microdata set is *analytically interesting* if six attributes on important subdomains are provided that can be validly analyzed.

More precise conditions of analytical validity and analytical interest cannot be stated without taking specific data uses into account. As imprecise as they may be, the above definitions suggest some possible measures:

- Compare raw records in the original and the protected dataset. The more similar the SDC method to the identity function, the less the impact (but the higher the disclosure risk!). This requires pairing records in the original dataset and records in the protected dataset. For masking methods, each record in the protected dataset is naturally paired to the record in the original dataset it originates from. For synthetic protected datasets, pairing is less obvious.
- Compare some statistics computed on the original and the protected datasets. The above definitions list some statistics which should be preserved as much as possible by an SDC method.

Key Points

A strict evaluation of information loss must be based on the data uses to be supported by the protected data. The greater the differences between the results obtained on original and protected data for those uses, the higher the loss of information. However, very often microdata protection cannot be performed in a data use specific manner, for the following reasons:

- Potential data uses are very diverse and it may be even hard to identify them all at the moment of data release by the data protector.
- Even if all data uses could be identified, releasing several versions of the same original dataset so that the *i*-th version has an information loss optimized for the *i*-th data use may result in unexpected disclosure.

Since datasets must often be protected with no specific data use in mind, generic information loss measures are desirable to guide the data protector in assessing how much harm is being inflicted to the data by a particular SDC technique.

Information loss measures for numerical data. Assume a microdata set with n individuals (records) $I_1, I_2,...,I_n$ and p continuous attributes $Z_1, Z_2,...,Z_p$. Let X be the matrix representing the original microdata set (rows are records and columns are attributes). Let X' be the matrix representing the protected microdata set. The following tools are useful to characterize the information contained in the dataset:

- Covariance matrices V (on X) and V' (on X').
- Correlation matrices R and R'.
- Correlation matrices RF and RF' between the p attributes and the p factors $PC_1,...,PC_p$ obtained through principal components analysis.
- Communality between each of the p attributes and the first principal component PC_1 (or other principal components PCi's). Communality is the percentage of each attribute that is explained by PC_1 (or PC_i). Let C be the vector of communalities for X and C' the corresponding vector for X.
- Factor score coefficient matrices F and F'. Matrix F contains the factors that should multiply each attribute in X to obtain its projection on each principal component. F' is the corresponding matrix for X'.

There does not seem to be a single quantitative measure which completely reflects those structural differences. Therefore, it was proposed in Domingo-Ferrer, Mateo-Sanz and Torra [1] and Domingo-Ferrer and Torra [2] to measure information loss through the discrepancies between matrices X, V, R, RF, C and F obtained on the original data and the corresponding X', V', R', RF', C' and F' obtained on the protected dataset. In particular, discrepancy between correlations is related to the information loss for data uses such as regressions and cross tabulations.

Matrix discrepancy can be measured in at least three ways:

- *Mean square error.* Sum of squared component wise differences between pairs of matrices, divided by the number of cells in either matrix.
- *Mean absolute error.* Sum of absolute component wise differences between pairs of matrices, divided by the number of cells in either matrix.

- *Mean variation.* Sum of absolute percent variation of components in the matrix computed on protected data with respect to components in the matrix computed on original data, divided by the number of cells in either matrix. This approach has the advantage of not being affected by scale changes of attributes.

For alternative [0,1]-bounded information loss measures for numerical data, see Mateo-Sanz et al. [3].

Information loss measures for categorical data. These can be based on direct comparison of categorical values, comparison of contingency tables, on Shannon's entropy. See Domingo-Ferrer and Torra [2] for more details.

Information Navigation

Thomas Rist
University of Applied Sciences, Augsburg, Germany

Synonyms

Information foraging; Information browsing; Interactive information exploration

Definition

The word "navigate" has its roots in the two Latin words "navis" (ship) and "agere" (to "move"/"direct") and has been used for centuries in the domain of nautics for activities necessary to find one's way, and to control the movement of a vessel while traveling from one location to another. Different scientific discoveries, technical inventions, and cultural backgrounds, have brought about a wide variety of navigation techniques and navigation devices, all of them have in common that they assume a certain structuring of the underlying geographical space. With the advent of electronically stored volumes of information, and electronically networked information sources in particular, the concept of geographical navigation has been generalized and adopted as a metaphor for accessing chunks of digitalized information in a goal-directed way. In this metaphorical view perceivable presentations of meaningful information chunks of an overall information space with form the counterparts of physical locations in a geographical space, and information navigation capitalizes on the fact that structural relations between physical locations, such as neighborhood, proximity, distance, connectedness, reachability, or crossway can be mapped onto meaningful relations between information chunks as well. Depending on nature of an application, a user is confronted with different navigation tasks. A typical task in a database application is to find the shortest access path from an entry point to a certain data record, in an e-Learning system, the navigation task may manifest itself in accessing the learning units in a didactically meaningful sequential order, while in an online bookstore, a user may navigate through the assortment of books following the traces of other customers with a similar interest profile. In any case, goal-directedness and exploration of structure distinguishes navigation activities from arbitrary, disoriented movements, be it in a geographical space, an information space or a combination of both in which an information space is superimposed on a geographical space.

Key Points

With the increasing amount of accessible electronic data, information navigation has become a central issue in many application domains and a challenge for architects and developers of user interfaces as aids to assist users in accomplishing various navigation tasks. Navigation tasks are often described relative to an navigation space that is characterized by the set of potentially accessible information units, and the structural relationships that hold between these units. The structure of an navigation space determines in which order information units can be accessed and thus the effort it takes to navigate from an entry point to a particular unit. The spectrum of commonly used principles includes linear, hierarchical/tree-like, radial, and graph-like structuring of navigation spaces. The structuring of a navigation space should, however, comply with a reasonable, semantically-motivated structuring of the information units of the application domain.

An effective navigation aide supports a user in at least two basic navigation tasks: *orientation* – "where am I," and *path continuation* – "where to go from here to get (closer) to the target?" Techniques to support keeping orientation include: sitemaps and distorted views – such as "*fisheye views*" – both designed to show a user's location in a broader context, or navigation histories, such as "*bread-crump navigation*" as today used by many web-sites to show a user her trail from a chosen entry-point to her current location. Supporting users in the decision making of how to continue a navigation path from a current location/information unit comprises the disclosure of available and relevant options, as well as de-emphasizing or even hiding of options that should not be taken with regard of achieving the underlying navigation objective.

Among the supporting techniques are techniques that aim to provide environmental cues about where to find further interesting information – the "*information scent*" approach is an exemplar of such a technique. Also, the concept of "adaptive menus" falls into this category of techniques. It has been introduced with the aim to facilitate a user's navigation through a menu-based interface by hiding options which are regarded less relevant in a certain context. In practice, however, it is often too hard a task for a computer system to make appropriate assumptions about the user's current tasks and aims and therefore inadequate suggestions for the continuation of a navigation may be given. Also, accessibility, comprehensibility and effectiveness of navigation structures of web-sites have become major criteria in most web-usability evaluations.

Earlier work on information navigation has mainly focused on graphical user interfaces (GUIs) and hypermedia-style information access with view-based navigation aids, assuming a user navigates through an information space by traversing interlinked visual presentations. Research includes the development of visual navigation aids as well as the understanding of the cognitive processes involved in conducting navigation tasks (e.g., [1]).

More recently, navigation issues are being researched in other areas too, including voice-dialogue systems, virtual reality applications, and computer games. In the emerging fields of ubiquitous and mobile computing the mutual interplay of geo-spatial navigation with information navigation provides interesting potential for new services that benefit mobile users. The advent of large-scale internet shops and forums has shed light on yet another aspect of navigation – social navigation, a term that has been coined for a model of navigation support that capitalizes on observed navigation patterns of others [2].

Information Quality: Managing Information as a Product

DIANE M. STRONG
Worcester Polytechnic Institute, Worcester, MA, USA

Definition

Traditionally, information has been viewed as a by-product of a computer system or an event. From this viewpoint, the focus is on designing and delivering computer systems, rather than designing and delivering information. To increase the quality of information available to information consumers, organizations need to treat information as a product being intentionally produced for those who will use that information. This means actively managing information and its quality. Such an information product (IP) approach focuses attention on information quality, i.e., delivering high-quality information that is fit for use by information consumers, rather than solely on data quality, i.e., maintaining the quality of the data stored in databases or data warehouses. While the terms "data" and "information" are often used interchangeably in the information and data quality literature, the term information quality is more often used in studies that take an IP approach and explicitly acknowledge the needs of information consumers, whereas data quality is more often used when the quality of data is assessed separately from the needs of users.

Historical Background

While there are some early seminal papers, information quality (IQ) only emerged as a recognized field of information technology (IT) research in the mid-1990s. For example, the first International Conference on Information Quality was held in 1996 at MIT [8]. In 1998, Wang et al. [14] published "Manage your Information as a Product", which argued for the concept of treating information as a product that is intentionally managed and produced for consumers who have expectations about its quality. This concept provided researchers with a useful lens for framing their information quality research ideas and led to many studies developing methods, measures, techniques, and recommendations for managing information as a product. Together, these methods, measures, techniques, and recommendations for managing information as a product are referred to as the information product (IP) approach.

Foundations

Managing information as a product, i.e., taking an information product (IP) approach, means actively managing organizational information in order to deliver high-quality information that is fit for use by information consumers [14]. The IP approach involves four principles for managing information as a product, with four corresponding areas of information quality research. These four areas of research, which are described below, are (i) the needs of information consumers, (ii) processes for producing high-quality information products, (iii) the life cycle of information products, and (iv) organizational governance structures and recommendations for actively managing information as a product.

The Needs of Information Consumers

Like other products, the quality of information is judged by those who purchase and use information products, referred to as information consumers. Thus, information is of high-quality to the extent that it is fit for use by information consumers. This means that information quality includes both objective dimensions (those dimensions that can be defined independently of a user or a task), such as accuracy, and subjective or contextual dimensions (those dimensions that are defined relative to the context of a user performing some task that requires that information), such as timeliness. For example, whether information is sufficiently timely depends on the task being performed, e.g., stock prices for a historical analysis or for day trading. Even those dimensions that can be objectively defined may still have a subjective or contextual aspect, e.g., whether the information is sufficiently accurate for the task versus whether it is completely accurate.

Research on the needs of information consumers has used marketing research techniques to understand the dimensions or characteristics of information products that consumers assess when considering an IP for their use. The result is sixteen dimensions that information consumers consider when assessing the quality of information, which are grouped into four categories, see Table 1 [15]. The intrinsic dimensions are those that capture the quality of the information itself. The contextual dimensions are those that capture quality in the context of the task and the users. The accessibility dimensions capture the quality of the process of obtaining and manipulating the information. The representational dimensions capture quality related to how the information is represented

Information Quality: Managing Information as a Product. Table 1. Information quality categories and dimensions

IQ category	IQ dimensions
Intrinsic IQ	Free-of-error, Objectivity, Believability, Reputation
Accessibility IQ	Accessibility, Ease of Manipulation, Security
Contextual IQ	Relevancy, Value-Added, Timeliness, Completeness, Amount of information
Representational IQ	Interpretability, Ease of understanding, Concise representation, Consistent representation

to users. These dimensions have been verified in organizational contexts [11,12] and by numerous studies that have used these dimensions or some subset of them in IQ studies.

The Information Quality Assessment (IQA) questionnaire measures information quality along these sixteen IQ dimensions [6]. Each dimension is represented by several questions for which questionnaire respondents rate the quality of their information on a scale of zero (not at all) to ten (completely). For example, two questions for the free-of-error dimension are “This information is correct” and “This information is accurate.” This questionnaire has demonstrated reliability and validity and has been used in research studies and in organizations seeking to improve their IQ. One interesting result from baseline IQ measures at several companies is that IT professionals responsible for storing and maintaining the information consistently assess information quality higher than do the information consumers who use that information.

While the IQA provides a comprehensive IQ assessment instrument, it is not the only method for assessing IQ [7]. For some dimensions, it is possible to develop objective measures that do not require data and time from information consumers for assessment. The typical approach is to define a metric on a 0–1 scale such as the following metric for timeliness [1]:

$$\text{Timeliness} = \left\{ \text{Max}\left[\left(\frac{1 - \text{currency}}{\text{shelf-life}} \right), 0 \right] \right\}^{s}$$

The parameter *s* adjusts the sensitivity of the timeliness measure to the ratio of the currency of the information relative to the shelf-life or volatility of that information. When such metrics can be defined, IQ can be assessed independently of users.

The Product and Service Performance Model for Information Quality (PSP/IQ model) groups the sixteen IQ dimensions into four IQ quadrants, sound, dependable, useful, and usable, as shown in Table 2 [3]. These quadrants are derived from the total quality management literature. Specifically, on one dimension, the PSP/IQ model captures aspects of IQ that are related to product quality and those related to service quality. On the other dimension, it distinguishes between conforming to specifications and meeting or exceeding information consumer expectations. These quadrants serve as a better foundation for analyzing and improving quality than the original four categories of IQ in Table 1. Several studies have used the PSP/IQ model, in combination with the IQA instrument, to consolidate the 16 dimensional measures into four overall measures, e.g., [6].

The PSP/IQ model and the IQA instrument are useful tools for benchmarking and analyzing IQ. The resulting measures of IQ provide the foundation for gap analyses [6]. One gap is the difference between an

Information Quality: Managing Information as a Product. Table 2. The PSP/IQ model

	Conforms to specifications	Meets or exceeds consumer expectations
Product quality	*Sound Information*	*Useful Information*
	Dimensions of Sound Information:	Dimensions of Useful Information:
	• Free-of-Error	• Appropriate Amount
	• Concise Representation	• Relevancy
	• Completeness	• Understandability
	• Consistent Representation	• Interpretability
		• Objectivity
Service quality	*Dependable Information*	*Usable Information*
	Dimensions of Dependable Information:	Dimensions of Usable Information:
	• Timeliness	• Believability
	• Security	• Accessibility
		• Ease of Manipulation
		• Reputation
		• Value-added

organization and a benchmark organization, which indicates the possibilities for improvement in that organization. Another gap is the difference between the assessments of IT professionals responsible for the information and the users of that information. When IT professionals rate IQ much higher, there are opportunities for better communication about IQ between information consumers and IT professionals.

The needs of information consumers, the first area of research in the IP approach to IQ, address the principle that the needs of information consumers are the primary purpose of improving information quality. Research in this first area addresses the information product itself and its quality as assessed by those who use the product.

Processes for Producing High-Quality Information

Like physical products, information products are produced by production/manufacturing processes. Like manufacturing processes for physical products, information manufacturing processes will only produce high-quality information if they are designed to do so. Thus, research on processes for producing high-quality information products, the second area of IP research, draws on parallels with manufacturing processes for physical products.

This area of research introduces two IQ roles beyond the information consumer described in the last section. Information collectors (also called information suppliers or providers) collect and provide the raw data for the information manufacturing process. The second role consists of those who perform the tasks of manufacturing the IP, which has been referred to as information custodians (also called information manufacturers or IT professionals).

One useful parallel with manufacturing is to apply the Total Quality Management (TQM) recommendations from quality gurus such as Deming, Crosby, and Juran that have resulted in major improvements in the quality of the products produced from manufacturing processes. For information processes, an IQ improvement cycle, similar to Deming's cycle, has been proposed. Called the Total Data Quality Management (TDQM) cycle, it involves the continuous and repeated application of four steps, define, measure, analyze, and improve IQ [13]. The previous section discussed research results that *defined* the dimensions of IQ, developed *measures* for them, and *analyzed* the gaps between an organization's IQ and benchmark IQ measures.

To *improve* the quality of information products, the processes that produce those information products must be defined, measured, analyzed, and improved. Research efforts in this area have focused on modeling information manufacturing processes in a way that permits analysis of process design alternatives and measurement of the IQ of the information products produced. One such research effort is the Information Manufacturing System (IMS), which is a method for developing a network model of information flow [1]. The model consists of five types of components that capture the steps in an information manufacturing system. These five are (i) the data vendor block represents a source of data, (ii) the processing block represents a step that adds value to the information, (iii) the data storage block represents a database, (iv) the quality block represents a step that enhances the quality of the information for information consumers, and (v) the customer block represents the delivery of an information product to an information consumer. At each step in the network of components, various dimensions of IQ are computed given the quality of data from the data vendor block and the quality effects of each of the processing and quality blocks.

Modeling information manufacturing processes in a way that captures the details needed to compute IQ metrics and to analyze process design alternatives is an active area of current research. One extension to the IMS modeling approach adds new modeling components, e.g., an information system boundary block and an organizational boundary block which capture handoff points at which the quality of information may be affected [10]. It also elaborates, and more formally defines, the data needed to specify each block so that IQ metrics can be computed. A variety of other extensions are also under development, e.g., [9], including software tools that assist with the modeling and metric computation tasks.

The Life Cycle of Information Products

The third principle of managing information as a product is to explicitly manage the life cycle of the IP, similar to how the life cycle of a physical product is managed. For physical products, the product is continually improved and extended, so that the product gradually becomes more useful to customers, more reliable, and less costly to produce, which in turn extends the life of the product. Few organizations treat their information as though it had a life cycle.

Instead they view information as a by-product of a computer system or event, and assume the life cycle of the information is the same as the life-cycle of that computer system or event. Information typically is upgraded or its characteristics changed as information consumers make requests, rather than the proactive management of upgrades typical for physical products.

While IQ researchers and practitioners acknowledge the need for managing an IP's life-cycle, there is only a little research addressing this issue. For example, there is some research addressing the optimal or recommended frequency for updating data. The lack of research on managing the life cycle of an IP may be related to the state of research on the governance structures needed for actively managing information as a product.

Governance Structures for Managing Information as a Product

The fourth area of research for managing information as a product focuses on the appropriate management and governance structures needed to support the IP approach. Wang et al.'s paper on managing information as a product [14] recommended appointing an Information Product Manager (IPM), a position similar to the Brand Manager role that organizations employ to manage products across the multiple functional areas of product development, manufacturing, marketing, and service that must all be coordinated to deliver high-quality products and manage their life cycle. Similarly an IPM would manage one or more IPs across information suppliers, information manufacturers, and information consumers. Thus, this is introducing a fourth information role, that of an information product manager. This role differs from that of a CIO, who typically is only responsible for the information manufacturing role and does not have responsibilities for information suppliers or information consumers. The CIO also must typically focus more on the hardware and software architecture and infrastructure than on the architecture and infrastructure of information. Thus, there is a need for a role that provides the cross-functional management structure needed to deliver high-quality information to information consumers.

The IPM role, however, is only one piece of the broader research area of information governance, management structures and best practices needed to adequately provide an IP approach in organizations. Such best practices also need to include the financial side of the IP approach [4], e.g., cost/benefit analysis of IQ improvements, the value and pricing of information, and the auditing of information manufacturing processes. There are still many opportunities for research and the exploration of best practices in the area of IQ governance.

Key Applications

Organizations are at varying stages of attempting to apply an IP approach to managing their information. Examples from several organizations including both for-profit and not-for-profit organizations illustrate the value of the four principles of the IP approach.

Principle 1: Understand the IP Needs of Information Consumers

As an investment bank examined the needs of its information consumers, it realized that it had both external customers who needed information as well as internal information consumers. For its external customers, it was providing adequate information for single requests, but was failing to consider that these customers interacted with multiple divisions, and thus it was failing to provide coordinated and aggregate information. For internal information consumers, it was treating their information needs as by-products of its events with external customers, and largely failed to consider or meet their needs.

A retail chain that sells eyewear had not examined the information needs of its grinders and thus was not treating the information sent from its opticians in retail outlets to the centralized lens grinders as an information product. Its investigation into the information needs of grinders revealed that many of its external customers' complaints about the quality of their eye products were not due to poor quality grinding but to the quality of the information products sent from the opticians to the grinders. When the opticians understood the grinders' needs as an information product, many of the problems with the quality of the eye products were eliminated.

A company that resells data to retailers worked to understand the information needs of its customers and then developed internal information production processes that could tailor its IPs to individual customers. By its attention to its internal and external information customers, it was able to deliver superior information products. A hospital tailored the IQA instrument to its needs and used it to better understand when it was meeting or failing to meet its information consumers' needs.

Principle 2: Manage Information as a Product of a Well-Defined Production Process

To provide information about customers' accounts across their activities with several divisions, the investment bank maintains a centralized customer account database. The production process for this information, however, was flawed, so that the IP's produced did not meet the needs of information consumers. As a result, information consumers in the various divisions created their own customer account databases with information production processes tailored to their needs. While these individual databases met local needs, the global needs for account information across divisions were not being met. The investment bank redesigned its information production processes to produce higher quality information and information tailored to the divisions, so that local needs were better met using information from the global customer account database.

The hospital that used the IQA instrument has also attended to improving its information production processes. It has used a modified version of the IMS modeling technique to model its information processes [2].

Principle 3: Manage Information as a Product with a Life Cycle

A petrochemical company produced a material safety data sheet (MSDS), an IP, for each of its chemicals. While the process for producing the initial MSDS was excellent, it was not managed as an IP with its own life cycle, but rather was updated as a by-product of making changes to the chemical. New hazards, however, were discovered as the chemical was used, and the company was exposed to legal risks when it did not issue a revised MSDS for newly discovered hazards. Because it treated the MSDS as a by-product of chemical development, it did not have an information production process for tracking new hazards and revising the MSDS. To address this problem, it started to treat the MSDS as an IP with its own life cycle, production process, and governance structure. The investment bank was required to maintain risk profiles for its customers. Like the petrochemical company, it did not treat these risk profiles as an IP, and thus did not have a well-defined process for updating them, exposing it to legal risks.

Principle 4: Develop a Governance Structure to Manage Information Production Processes and the Resulting Information Products

Although it is nearly 10 years since the publication of "Manage Your Information as a Product" [14], organizations are still struggling with finding governance structures appropriate for ensuring that information consumers receive information that is fit for their use. Individuals have been assigned roles similar to an IPM, but comprehensive governance structures are not yet common. For example, the petrochemical company appointed someone to develop and manage a process for keeping each MSDS up-to-date with emerging information about hazards. At the company that resells data, the CIO's role was changed to focus more on information processes and products. The hospital mentioned in principles 1 and 2 not only uses the IQA instrument and develops models of its information production processes, but also has an IQ group whose responsibility is to monitor IQ and develop solutions to IQ problems including developing governance structures. At another hospital, there is an information quality analyst role whose responsibilities include uncovering and investigating IQ problems.

Future Directions

The four research areas and principles of the IP approach were presented in approximate order of research maturity. The needs of information consumers in terms of the dimensions of information quality are well-defined; reliable measures of these dimensions have been developed; and methods for analyzing and improving information quality along these dimensions are available. These dimensions continue to be used in research studies and organizational practices. They provide a complete set from which most information quality research studies and practical IQ improvement projects select a subset that is most relevant for the particular IQ effort being undertaken.

Methods for modeling and improving information manufacturing processes are currently an active area of research. These studies borrow heavily from the manufacturing and TQM literature, but also tailor the application of manufacturing research results to address the different characteristics of information as a product. While this is an active area of current research, there is still much to be done to provide methods and techniques that can easily be used in organizations to improve the quality of IP as delivered to information consumers by improving the information production processes producing those IP.

Both the IP life cycle and the governance of IQ are areas with limited current research, but much potential for research. While organizations know how to manage the development and improvement of physical products, the same is not yet true for information products.

More research is also needed that integrates across two or more of these four research areas. For example, more research is needed that integrates the well-defined IQ measures of the IQ dimensions into studies of information production process improvements, e.g., see [5] as an early example of integrating process measures with the IQ outcome measures. Similarly, IP life cycles should be integrated into information production process models. IQ governance studies are needed that includes regular outcome measures to be used to direct efforts at process analysis and improvement. Governance studies are also needed that will develop methods for costing and justifying investments in IQ improvements. The purpose of these research efforts is to develop theories, methods, tools, and recommendations that will help organizations actively manage their information and thus ensure the delivery of high quality information to information consumers.

Information Quality and Decision Making

INDUSHOBHA N. CHENGALUR-SMITH

Data Quality

Definition

Decision-making is an inexact science, and one of the reasons is the utilization of data of imperfect quality in the decision process. If the user is aware of the caliber of the data and incorporates this information in the decision process, the effectiveness of the process is expected to increase.

Historical Background

A decision can be thought of as a set of actions related to and including the choice of one alternative rather than another. A rational model of decision-making is one in which decision-makers consider all aspects of all alternatives before making a decision. However actual decision-making often falls short of this ideal model because knowledge and experience of the consequence is incomplete, there is limited amount of time to explore all alternatives, and humans do not calculate perfectly. Hansson [8] stated that all decisions are made under uncertainty and he presented four components of great uncertainty: uncertainty of options, uncertainty of the consequences of the options, uncertainty of reliability of information and uncertainty of values. The third category, uncertainty of reliability of information, is the focus of this entry.

The decision process is sensitive to task complexity, time pressure and other contextual factors. Task complexity itself is a function of several variables such as the number of alternatives, the number of attributes, and time pressure. If humans have a processing limit of 7±2 items, as believed, the decision process quickly runs into information overload, even without the addition of data quality information. However, increases in decision complexity are often compensated for by a selective use of information or by shifting to more simplistic strategies. Exactly how this plays out, given the additional data quality information that needs to be evaluated, has not yet been conclusively determined. Thus, there could be plausible arguments for and against the use of data quality information in decision making.

Payne et al. [12] proposed that people adopt a decision strategy on the basis of a cost benefit framework, i.e., individuals compromise between making the best possible decision and minimizing their cognitive effort in making that decision. Decision making strategies could be (1) alternative-based or attribute-based, (2) compensatory or non-compensatory, and (3) consistent or selective. Consider, for instance, a satisficing strategy, where alternatives are considered one at a time, in the order in which they are presented. Each attribute is compared to a pre-determined cut-off level and the first alternative whose attributes all meet the cutoffs is selected and the process is stopped. Such a strategy is alternative-based (multiple attributes about an alternative are considered before the next alternative is processed), non-compensatory (no trade-offs are made among alternatives), selective (all the alternatives are not evaluated using the same amount of information). On the other hand, consider a "weighted additive" strategy that assigns relative importances (or weights) to each attribute and evaluates every alternative by multiplying the value of the attribute by its weight and summing up these weighted values for all attributes. Although it is another alternative based strategy, this is a compensatory strategy because tradeoffs are made among alternatives. It is also a consistent strategy because all the alternatives are evaluated using the same amount of information and the alternative with the highest overall evaluation is chosen.

It has been hypothesized that providing information about the quality of the data attributes used by the decision maker could be beneficial. It could also be argued that such data simply creates an additional burden, both on the data provider and the decision maker, without significant payback in improved decision making. The current research in this arena is focused on trying to determine the conditions under which providing data quality information may be useful to decision makers.

Foundations

Data quality is widely considered to be multi dimensional. Wang and Strong [15] identified 15 dimensions of data quality that they factored into 4 distinct groups: intrinsic, contextual, usability and accessibility and determined that accuracy (used interchangeably with reliability) was the most important attribute. It is expected that not only the type of data quality attribute provided but also the format in which the data quality information is recorded and presented would play a role in the decision process.

Data regarding the quality of stored data can be thought of as one type of metadata. In fact, some database systems already do this indirectly through the inclusion of a date field. The record of the time when the data was collected reflects one component of the quality of the data, namely currency. It is also possible to have information regarding data quality (e.g., accuracy) at the level of the individual data item. In certain situations this is warranted and can be achieved via the use of data tags [14]. Although this would be complex and costly, it may be necessary if the processes generating the data items were erratic and highly volatile. At the other extreme one could have data regarding the quality of an entire file or relational table. This approach would be most appropriate where the entire file was generated by a single, rather stable, process. An intermediate approach would be to record data quality information at the level of each data field. This approach is most appropriate where the data being utilized originated from a number of processes which may have substantially different data quality capabilities. Such an approach is neither as storage-intensive as item-level data nor as generic as file-level data. If it is assumed that the quality of data items in a particular domain is the same, although different domains may have different quality, creating such metadata may not be very labor intensive. Although at this time typical databases do not include the kind of data quality information envisioned, since data about data quality are metadata, it would be logical to include such information in the data dictionary.

Even though the inclusion of data quality information has become technologically feasible, the collection of such information is still a challenging undertaking. Quality characteristics of data may be declared through qualitative means such as a "data source" field or through a quantitative system such as a reliability rating. Clearly, providing data quality information on a two-point ordinal scale is more manageable than providing it on a 100-point continuum. But if the latter option leads to more effective decision-making, then the considerable effort required may be worth it. Thus the availability of information is not enough. It needs to be presented in a form that will promote effective decision making. The type of information regarding the data's quality that would be most helpful to users may depend on the sophistication of the users, but is more likely to be a function of the decision process or strategy.

Empirical evidence on the effective use of information during the decision making process has been mixed. Ben Zur and Breznitz [1] found that people under time pressure place more emphasis on negative information about alternatives. The way information is displayed (i.e., on a verbal or numerical scale) has also been found to affect decision behavior [13]. Even within a numerical format, decision making is sensitive to different displays [9]. Thus both content and style of the metadata could have an impact on the decision process. In the public policy arena, Grether et al. [7] found that consumers ignore less relevant information in complex information environments. On the other hand, Gaeth and Shanteau [6] indicated that expert decisions were adversely affected by irrelevant factors, although this could be overcome by training. Several other studies, including [10], found that increasing the amount of attribute information about alternatives increases subjects' confidence in their decisions but also increases the variability of responses. Anecdotal evidence showed that higher information loads lead to simpler processing strategies and hence more consistent decisions.

Having unequivocal measures of the effectiveness of the decision making process is imperative because of the difficulty of identifying what constitutes a good decision. Ideally a decision aid (such as the inclusion of data quality information) should lead to more accurate results. When there are no correct answers, consistency is a desirable outcome of the decision process. MacGregor et al. [11] define two forms of consistency. One is the tendency to produce the same results when applied by the same user under identical circumstances, and the other is the tendency to produce similar results in the hands of different users. MacGregor et al. [11] found that the more structured the decision aid, the greater the improvement in accuracy and consistency of the resulting decision.

Chengalur-Smith et al. [4] expanded on this concept to measure the impact of providing data quality information on decision processes and defined three key measures of the outcome of the decision:

1. Decision Complacency: Complacency refers to the degree to which data quality information is ignored. If the decision-maker does not change the originally preferred alternative after viewing data quality information, he/she has exhibited decision complacency. Complacency can be regarded as a measure of futility, for it implies that providing data quality information has not impacted the final decision. Obviously low levels of decision complacency are the most desirable outcome.
2. Decision Consensus: Consensus examines the degree to which decision-makers can converge on a decision in the presence of data quality information. Often a number of decision-makers will be involved in the same decision process. Consensus explores the impact of data quality information upon the ability of such groups to maintain the prior degree of agreement concerning the preferred course of action. It is a measure of group response to this new incremental information.
3. Decision Consistency: Consistency is designed to capture agreement across all alternatives, when data quality information is provided. Note that the previous two measures, complacency and consensus, focused on only the top-ranked or preferred alternative. In a sense, consistency is an extension of complacency to the entire set of alternatives. Once again a high value for this measure would indicate that major re-orderings in the ranks did not occur.

Note that complacency (not changing the originally preferred alternative in the presence of data quality information) and consensus (ability to converge on an alternative using data quality) deal only with the issue of the top-ranked alternative. Although decision-makers would most often be interested in the top ranked alternative, there are numerous decision contexts where the interest is in the ranking of all alternatives (e.g., the allocation of merit raises across an entire department). In general, complacency and consensus should be considered hierarchically, i.e., consensus should only be evaluated after non-complacency is established.

Key Applications

The widespread use of data warehouses has highlighted the necessity of data hygiene. However, it is infeasible to thoroughly cleanse the data, particularly when the ways in which the data may be used is in flux. A viable alternative may be to tag the fields in the warehouse with data quality information. Some of the issues that need to be considered when designing such a warehouse have been discussed earlier. The results from preliminary experimental studies described below indicate that it would be beneficial to include data quality tags when the data warehouse is used by managers on an ad hoc basis.

Future Directions

Although some experimental research has established that data quality information is used by decision makers, more work is required to determine exactly how such information is used. This would help in identifying the best format in which data quality information should be presented to users. The results of such investigations would also provide guidelines for designers of data warehouses and those that implement warehouse applications.

Experimental Results

Several experiments have been conducted to provide insight into the type of data quality information that would be most effective to support decision processes. A preliminary question that needed to be addressed was the proposition that the type of data quality information that is appropriate may be a function of individual preferences. If individuals processed data quality information in substantially different ways, incorporating data quality information may be counter-productive. A study that used learning styles as a surrogate for individual differences in the mindsets of professionals in an organization found no significant differences that were attributable to learning styles using the three key measures outlined above [4]. This makes for simpler implementation since this implies that the data quality information for a database does not necessarily have to be tailored to individuals.

A series of controlled experiments [2–4] investigating the impact of providing data quality information to decision makers found that the impact depended on factors such as the complexity of the task, the decision strategy and the format in which the information was provided. Preliminary results suggested that when decision makers are confronted with clearly differentiated alternatives, the inclusion of data quality information impacted the selection of a preferred alternative while maintaining group consensus. A follow-up study examined these factors while also taking experience and time pressure into account [5]. The findings suggested that managers with little to no domain-specific experience were more likely to use the data quality information provided. In addition, the results indicated that those who felt time pressure during the decision making process were more likely to use the data quality information provided. Finally, older decision makers were more likely to use data quality information than younger ones. However the level of consensus among the decision makers declined, indicating that improvements gained in individual decision processes through the inclusion of data quality information may be at the expense of group consensus.

Information Quality Assessment

Leo L. Pipino
University of Massachusetts, Lowell, MA, USA

Synonyms

Information; Data

Definition

This entry uses the terms data and information interchangeably. The classical distinction is that data are raw facts whereas information is data in context or data that have been processed. Nevertheless, other than at an abstract level, it is a distinction that is often not made and one finds that the terms are used interchangeably. It is important to note that one individual's information can be data to another individual. This entry will also use the terms information quality dimension and information quality variable interchangeably.

Further, this chapter defines information of quality as information that is fit for use (or data of quality as data that is fit for use). This means that context and use plays an important role in evaluating information quality. For example, the instantaneous changes in a stock's price may be of importance to the stock trader who may trade stocks on a minute by minute basis. This instantaneous information, however, will be of minor importance to a long term investor whose strategy is "buy and hold" in which long term price trends are of more interest and use.

The process of measuring data quality must confront two major questions: (i) Exactly what should be measured? and (ii) What is the metric that will be used to measure the variable? Often, answering the first question is much more difficult than answering the second.

This entry does not address the area of software quality or the quality of information systems. The former has been examined extensively in the Computer Science literature and the latter has received a great deal of attention in the Management Information Systems literature.

Historical Background

Historically, prescriptions for the measurement of information quality have focused on specific variables. The often cited variables of accuracy, timeliness, completeness, and consistency are examples. Indeed, what dimensions to measure and the definition of what metrics to use are still debated today. This entry will not present a detailed recapitulation of the history and literature of information quality measurement. Rather, it will present one approach – broader in scope than simply measuring specific variables – that can be an effective way to measure data and information quality.

Foundations

As alluded to in the above paragraph, the typical approach to measurement is to measure specific variables or dimensions of information quality. This chapter advocates a broader approach that views the assessment of information quality in an organization to include assessment of the management of the process of insuring information quality. Within this framework, the chapter also widens the scope of what is to be measured.

An assessment of management involvement and management practices is essential. These would include, but are not limited to, examining whether policy and procedures are in place, if learning is proactively fostered in the organization, if proper configuration and control is in place, and whether or not audits are periodically conducted.

Measurement of the information product includes evaluations of fitness for use, such as the existence and maintenance of metadata, whether or not data integrity constraints are in place, and assessments of many of the traditional quality dimensions. These evaluations would be more qualitative than quantitative in nature. An example of an instrument that has been used by a major healthcare facility to help in performing this assessment is the Data Quality Practice & Product Assessment Instrument described in [8].

One must, however, also measure the quality of information along specific dimensions at a more detailed level than described above. Again, the approach suggested here to measure specific information quality dimensions has a wider perspective than is typical. It is based on previous work [8,9]. A variant of this approach, for example, has been used in practice by a major teaching hospital.

The basic approach is to assess (i) subjective perceptions of information quality, that is, the perceived quality of information along some specific quality dimensions and (ii) objective quantitative measures of the same dimensions, when measurable.

The subjective assessments measure the perception of different stakeholders. Specifically three stakeholders are identified:

1. The collector – the individual (or group) that obtains and/or enters the data.
2. The custodian – the individual (or group) that is responsible for storing, retrieving, and providing the data.
3. The consumer – the user of the data.

Each may (and most likely) will have different perceptions of the quality of specific data and information. These subjective measures can provide comparisons across stakeholders and, as a consequence, provide valuable information regarding the disconnects among the different stakeholders with respect to specific data.

For many variables, these perceptions can also be compared to quantitative measures of the same variable. Here, the comparison may show, for example, that stakeholders think data is of good quality along a certain dimension when, in fact, the data is actually poor. Of course, the comparison can also show agreement between the quantitative measure and the subjective perception.

What should be measured? As mentioned earlier, what to measure can be more difficult to decide than how to measure it. The decision will be context dependent and must be determined by the organization and what variables (data quality dimensions) are important to it and its goals, objectives, and environment. The variables accuracy, timeliness, and completeness rank high among those mentioned often. Exactly how these are defined is important and the granularity of the definition and, consequently the measurement, must be carefully considered. For example, accuracy is always mentioned in the same breadth as data quality. Exactly how can one define accuracy. Assume that the unit of measurement is the record. Further assume that records have missing values, that is, they are incomplete. Will the record be considered inaccurate or will this type of problem be defined as incompleteness and accuracy defined more as "free from error," that is that fields in the record with values (those that are not missing) are correct. This chapter will not answer this question. These are questions that the organization and its analysts must answer in the specific context of the organization. Different organizations will answer the question somewhat differently. This simple example points out the issue and helps focus on the importance of the definitions in determining what is to be measured.

The metric itself may be easier to define. For illustration purposes, if the incompleteness definition given above is used, then a simple ratio of complete to total records can be used. Assuming that in most databases the number of complete records far outweigh the records with missing data, the formulation of one minus the above ratio could be used.

Although not an exhaustive nor a completely independent set, a comprehensive set of dimensions from which one can choose has been provided in [13]. The list is not meant to exclude other possible variables. A subset from this list or other variants can be used. The important point is to clearly define what is to be measure.

The subjective perceptions can be measured using questionnaires whose questions are rated numerically using a Likert type scale. One example that has been used in practice is the Information Quality Assessment instrument (IQA) [8] or a subset of the IQA. For example, such statements as shown below are evaluated in the context of a specific organization and data set or database:

1. The information is incomplete.
2. The information is believable.
3. The information is correct.

In the case of the IQA, the respondent (any of the stakeholders) would provide an evaluation on a scale from 0 to 10 with 0 representing complete disagreement with the statement and 10 representing complete agreement. Of course, one could use a different numerical range for the evaluations. It is important to reemphasize that with the IQA the respondents are subjectively assessing the pool of information or database(s) which the organizations has chosen to evaluate. It is not an evaluation of one item or piece of solitary information.

For those variables that can be quantified, metrics can be defined and quantitative measurements can be performed. For example, one might physically measure the number of incomplete records and use a metric similar to the following:

Degree of Completeness = 1 – Number of Incomplete Records/Total Number of Records

For other dimensions, such as the believability of information, it may be decided that only the subjective perceptions will be used. Alternatively, if a reasonable definition of, for example, believability can be specified as a function of other quantitatively measured variable, and this is a big if, then some type of aggregation function can be used. An example might be a weighted average of the numerical values of the quantitative variables where the weights indicate relative importance, range from zero to one, and sum to one. Such aggregation, if done at all, must be performed with care since one must always be attentive to inappropriately combining scales of different types (ratio, interval, ordinal, and nominal [7]). This can lead to inappropriate use. Accepting the resulting precise numerical values as ratio or interval data could lead to poor decisions on the part of the decision maker.

In sum, at the detailed measurement level, the approach recommended here is a comparative approach wherein after what to be measured has been determined:

1. Subjective perceptions are measured.
2. Objective/quantitative measurements are performed. This would then lead to:
3. Comparison of results.
4. The taking of action where necessary to improve the data quality.

Of course, either step (1) or (2) can be used independently, that is, as the sole measure.

Recent work merits mention in a chapter on the measurement of data quality. It has been suggested [5] that the construct of utility be incorporated into the information quality measurement. Here utilities would indicate the relative value or importance of certain records within the set. These would be taken into account in generating quantitative assessments for a specific dimension. Note that, as modeled in [5] utility is not a measure of the relative importance or value of different variables (dimensions) but rather the relative importance of the records within a set measured along one dimension. This is ongoing research but can easily be incorporated into the metrics used in step 2 above.

Key Applications

The key application is the assessment of the quality of information that an organization uses.

Information Quality Policy and Strategy

Data Quality

Definition

Information quality policy and strategy is an emerging area of study and practice. Information quality policy and strategy involve managing both information product and information practice. A recent piece of literature structured information quality policy around ten key guidelines and provided a questionnaire on four key areas of information product: source data, metadata, system-based data integrity, and data quality, all of which were assessed by all stakeholders. The questionnaire also included the assessment of strategic, managerial, and operational level of information practice [3].

Conventionally, managing information quality means ensuring data integrity of stored data in a database and managing authoritative access and security. Increasingly, organizations manage and use heterogamous databases in dispersed strategic business units. With globalization trends, mergers and acquisitions, and virtual collaboration, managing information entails much more beyond managing data in a stored database within a single organization. Managing information in today's organization, therefore, means managing the comprehensive information process: data collection, storage and utilization processes [3]. High-quality information is used to compete in the market place and is a new strategically competitive asset [5]. To improve the quality of information available to information consumers, organizations need to manage information with an established policy and strategy.

Historical Background

While there are some early seminal papers, information quality (IQ) only emerged as a recognized field of information technology (IT) research in the mid-1990s. For example, the first International Conference on Information Quality was held in 1996 at MIT. In 1998, Wang et al. [6] published "Manage Your Information as a Product," which argued for the concept of treating information as a product which is intentionally managed and produced for consumers who have expectations of its quality. In 2006, Lee et al. [3] published "Journey to Data Quality," which included the first set of generic information quality policies, arguing for the principles of managing information with an institutionalized set of policies that structures decisions on information.

Foundations

This section provides ten policy guidelines that should form the basis of an organizational data quality policy and strategy [3].

Treat Information as a Product, Not By-Product

Treating information as a product, not by-product, is the overarching principle that informs the other guidelines [6]. This principle must be continually communicated throughout the organization. It must be a part of the organization's ethos. More details on the approach are available in Wang et al. [6].

Establish and Maintain Information Quality as a Part of the Business Agenda

An effective policy requires that an organization maintain information quality as part of its business agenda. The organization must understand and document the role of data in its business strategy and operations. This requires recognition of the data needed by the firm's business functions to complete its operational, tactical, and strategic tasks. It should be clearly understood that this data is fundamental to the competitive positions of the firm.

The responsibility for ensuring that data quality is an integral part of the business agenda falls on senior executives. Senior executives should understand their leadership is critical to success and that they must be proactive in fulfilling the leadership role. They must take an active part in ensuring data quality in the organization so as to utilize quality information as a strategically competitive advantage.

Ensure that Information Quality Policy and Procedures are Aligned with Business Strategy, Business Policy, and Business Processes

The primary function of data is to support the business. To do so, a data quality policy must be in place and consistent with an organization's business policy. This implies that a broad view of what constitutes data policy is necessary. An integrated, cross-functional viewpoint is a prerequisite to achieving an aligned data quality data quality policy. Proper alignment will also foster the seamless institutionalization of data quality policy and procedures into the fabric of the organization's business processes.

Improper alignment or too narrow of a focus can cause data quality problems and prove disruptive to the organization. It can lead to conflict which could otherwise be avoided. For example, a view that restricts data quality policy to technical details of data storage and ignores the uses of the data at different levels of decision making would result in misalignment and subsequent problems. In short, data quality policy should reflect and support business policy. It should not be independent or isolated from business activities.

Establish Clearly Defined Information Quality Roles and Responsibilities as Part of Organizational Structure

Clear roles and responsibilities for data quality must be established. There should be specific data quality positions within the organization, not ad hoc assignments to functional areas in times of crisis. Additionally, one of the fundamental goals of data quality function should be to identify data collectors, data custodians, and data consumers as well as make these members of the organization aware of which of these roles that they and others play.

Roles and responsibilities specific to the data quality function range from the senior executive level to the analyst and programmer level. Current examples of titles in practice include chief Data Officer, Senior VP of Information Quality, Data Quality Manager, and Data Quality Analyst.

Ensure Data Architecture is Aligned with Enterprise Architecture

The organization should develop an overall data architecture that is aligned with and supports its enterprise architecture. Enterprise architecture means the blueprint of the organization-wide information and work infrastructure. The data architecture helps promote a view of the information product which is consistent across the enterprise. This promotes accessibility of information across the organization.

The data architecture reflects how the organization defines each data item, how data items are related, and how the organization represents this data in its systems. It also establishes rules and constraints for populating individual data items. All of theses are essential elements of any product – a definition of the item, statements indicating how it is related to other entities in the business, and what constraints exist for populating it in various databases.

To ensure that the data architecture is and remains aligned with the enterprise architecture entails a number of specific and detailed tasks. For example, establishing a data repository is critical to the development and maintenance of viable data architecture. The organization should generate a set of metadata that clearly defines data elements and provides a common understanding of the data. This enables efficient data sharing across the organization.

Be Proactive in Managing Changing Data Needs

The data needs of consumers change over time. The term *consumers* means any individuals and enterprises internal or external to the organization who use the data of their organization. To maintain a high degree of data quality, the organization must be sensitive to ever-evolving environments and changing needs. This entails continual scanning of the external environment and markets along with the changing needs of internal data consumers.

It is also critical to the maintenance of high data quality that the rationale for changes in policy and procedures is clearly and promptly communicated throughout the organization. Steering committees and forums can play a crucial role in the dissemination of this information.

The organization must also be cognizant of local variances as they relate to global data needs. In today's multinational and global firms, long-standing local culture and customs exist. These local differences must be clearly identified and policy adapted to incorporate these local variances accordingly.

Have Practical Data Standards in Place

It is easy to get people to agree that standards should be in place. It is much more difficult to reach agreement on what should be standardized and the prescription of the standard. At times, it is difficult to obtain agreement on the definitions of the most basic data elements. Data standards entail many areas of data practice. Addressing the following questions will help inform the process for instituting practical data standards internally. If external standards are to be used, which ones should be chosen? Does the standard apply locally or globally? In either case, how and when will it be deployed? What processes are appropriate to monitor and adopt changing standards over time? How should they be documented and communicated?

The process an organization uses to determine whether to choose external or internal standards, and under what conditions, should be continually developed. The preferred solution would be to use a standard which has been created and maintained by an organization other than the organization using the standard. If this is possible and acceptable, then existing standards to adopt must be determined. This may be a choice between international, national, or industry standards or between two national standards. For example, the International Standards Organization (ISO) has a standard set of country codes. One's first choice would be to choose the international standard. Other things being equal, this provides the greatest degree of flexibility and lowest costs to the firm.

Plan for and Implement Pragmatic Methods to Identify and Solve Data Quality Problems, and Have in Place a Means to Periodically Review Data Quality Practice and the Data Product

Pragmatic methods based on diagnostic methods and measures should be promoted as standards across the organization. Example methods include system-based data integrity, data quality assessment, and data product and practice assessment methods.

Periodic reviews of the data quality environment and the overall data quality of the organization is a must. One method to achieve this is to assess the data quality practice and the firm's data quality using a standard assessment survey. Multiple assessments over time with a standard survey will provide a series of assessments against which the firm can measure its progress. Further, if an evaluation of an exemplary organization is available, the firm can use this exemplar's results as a benchmark and evaluate its performance against it.

A practice related to the auditing task involves certification of data. Data of both transaction systems and data warehouses must be included in the certification process. A robust process of data certification will ensure that data practice and data product will be of high quality. As a consequence, a data certification policy must be put in place. The policy should stipulate that sources for the information be clearly identified; including definitions, valid values, and any special considerations about the data.

Foster an Environment Conducive to Learning and Innovating with Respect to Data Quality Activities

Initiatives that contribute to a learning culture would include the use of a high-level data quality steering committee, the installation of forums across the organization, the stress on continuous education and training. All should be strongly supported and conveyed by senior management.

The organization should put in place a policy of rewards, and if necessary, sanctions, that are consistent with achieving a high level of data quality and maintaining this high level. What should not be discouraged is the identification and reporting of data quality problems, even if these prove embarrassing to management. Employees should feel free and safe to report data quality problems openly. A formal mechanism for reporting such problems can help in this regard. Establishing a forum for data collectors, data custodians, and data consumers to voice and share data quality problems and discuss data quality issues will be of great value. This will also aid in the dissemination of the experiences of the collectors, custodians, and consumers and foster an appreciation for each other's perspectives and roles.

It is especially important for data collectors to understand why and how consumers use the data. Data collectors also must adhere to the data quality principles as they enter data even though they are not the prime beneficiaries of such activity and do not usually get measured on this portion of the data entry task. Data consumers are critical to providing appropriate feedback on the quality of the data they receive, including whether it is needed data. The function would include apprising the data collectors of changes in data needs. Data custodians must recognize that although they are not directly responsible for the data, they must understand its purpose and use. As with data collectors, data custodians should be aware of how and why data consumers use the data.

Establish a Mechanism to Resolve Disputes and Conflicts Among Different Stakeholders

Data policy and jurisdictional disputes, data definition disagreements, and data use debates will occur. An organization must have in place a mechanism to resolve theses differences and conflicts. These could be a set of hierarchically related mechanisms corresponding to different levels of the firm. Their form is not as important as their existence and that they have a clear charter specifying their responsibilities and authority.

Any of a number of conflict resolution techniques and mechanisms can be used. The specifics must be consistent with an organization's business strategy and culture. Examples are the use of steering committees, data quality boards, data quality work groups, and data quality councils. The scope of responsibilities, the degree of authority, and clearly defined lines of reporting and communications must be specified. Ambiguity in the specifications will render theses resolution mechanism ineffective.

It is most important that a historical record maintains disputes and their resolutions. This institutional memory will serve the organization well as it adapts to changing future environments.

Key Applications

Early adaptors are applying information policy and strategy in their organizations to great avail. Public sector agencies are advanced in their adoption of the policy and strategy since most public agencies approach information quality policy for their planning and implementation of information management that is guided by the mandated Information Quality Act. The public agencies such as the Intelligence Community, Environmental Protection Agency, Department of the Interior, and Department of Housing and Urban Development also align information quality policy with their Enterprise Architecture and Governance policy. In the private sector, most organizations approach information quality policy initially from their data warehouse or customer data management point of view that they need a policy to share the information at the enterprise level. Software vendors align some of the pragmatic policy issues as the underlying methodology which frames their tools; such as data integration, business intelligence, data migration, ETL, and data profiling tools.

Future Directions

The importance of data quality polices and strategies, good data practices and principles, effective data quality training, and communication within the organization cannot be overemphasized. This often overlooked aspect of data quality practice can mean the difference between those that are successful in this "journey to data quality" and those that are not [3].

The ten policy guidelines presented can serve as potential areas for future research. The needs of information consumers are well-defined; reliable measures of data quality assessment have been developed; and methods for analyzing, diagnosing, and improving information quality are readily available. The data products are studied and used in organizational practices. However, the data practice area including policy and strategy is in an early stage and will mature in the future as more firms demand policy and strategy for improving and aligning their information quality agenda with their business agenda.

More research is also needed to integrate the perspective of data product and data practice. To integrate both perspectives effectively, researchers will need to apply multi-disciplinary methods and theories. For example, "context-reflective data quality problem-solving" [2] uses various disciplinary areas and integrates data product and data practice. Another example [4] is seen with "process-embedded data integrity" which integrates data product and data practice. Studies focused on IQ policy and strategy studies are also needed which include organizational outcome measures to be used for directing efforts at policy analysis and strategy forming level. Strategy studies are also needed to develop methods for costing and justifying investments in IQ improvements and assessing competition in the market. The purpose of these research efforts is to develop theories, methods, tools, and policies to help organizations proactively manage their information. Thus, ensuring the delivery of quality information to information consumers and the provision of quality information as a strategic asset; not only to its own organization, but to partner organizations and the extended enterprise of the globalized economy as well.

Definition

Information Retrieval (IR) deals with the construction of automatic systems that allow users to inquire about textual data of any kind through natural language queries. The retrieved information of IR systems may vary from a ranked list of relevant textual items of any kind, such as full documents or their excerpts, or can be distilled into more elaborated forms, such as document summaries or answers to questions. Information Retrieval is an empirical science studying the representation, storage and access to information, and covers a large number of interdisciplinary topics of theoretical computer science including information theory, machine learning, coding theory, probability theory, programming theory, computational semantics, natural language processing, logics and algebra. From a practical perspective research investigation in IR includes: data representation, storage and retrieval, such as indexing, data encoding and text compression, document and term classification and clustering, systems architecture, distributed systems, document-query matching functions (IR models); user-oriented studies and aspects of behavioral science, such as data visualization, browsing, user interfaces, system evaluation, user relevance feedback and automatic query-expansion. With the advent and diffusion of the Web and the dramatic increase of public available information sources IR research also focuses on efficiency in terms of query response time and storage space of indexes in a distributed setting, as well as on personalized search where results can be filtered and adapted to user's area of interest taking into account, for example, geographical knowledge and user's historical data.

Historical Background

Information Retrieval has its origins in the 1950s to support the librarians activities of indexing and accessing textual collections. Hans Peter Luhn is one of the pioneers of IR [5] with his studies on automatic indexing, which concerns the assignment of significant keywords to documents. In the early stage of IR due to the limitations of computer capabilities document retrieval was restricted to satisfy the boolean exact match between the query-terms and document surrogates (title, subject headings or abstract). Luhn thought that the automation of indexing and abstracting was less prone to errors than human indexers. Before Luhn's original ideas, Shanny, the founder of the mathematical theory of communication, was the first to consider text generation as a "sequence of words" and processed as a discrete information source by a stochastic process (a discrete Markov process) [10]. Following Shanny's idea, Mandelbrot derived theoretically the empirical model by Eustop on word distribution and further studied by Zipf [14]. Mandelbrot showed that text generation is finding the least costly method of coding as obtained in the classical problem in communication theory [6]. The law of Estoup-Zipf-Mandelbrot establishes that the logarithm of rank of words by decreasing frequency is in linear relation with this frequency. An important milestone in the history of Information Retrieval is the introduction of evaluation measures for IR by Cleverdon. in 1953 Cleverdon led a project of Librarian of Cranfield College of Aeronautics to assess retrieval with a "document source – question" method, that consists in collecting questions and their relevance judgments from individuals; the Cranfield test collection is still publicly available for experimentation in IR [3]. In 1960 Maron and Kuhns used the term "probabilistic indexing" in the theory of IR to model the concept of relevance explicated in terms of the theory of probability [7]. Nevertheless, it was the vector space model, a model not based on probability theory, that influenced most of the research for some decades. The SMART project, dedicated to the realization of one of the first IR systems, the SMART system, was initiated at Harvard University in 1961 by Gerard Salton, but actually most of the research was conducted at the Cornell University [9]. The SMART system used the cosine of the index vectors derived from documents and search requests to obtain for each document a coefficient of similarity with each search request. After Maron and Kuhns, a probabilistic model of relevance was introduced by Stephen Robertson and Karen Spärck Jones [8] that has led to the development of the OKAPI system. The probabilistic model is based on Spärck Jones' observation that the significance of a term in a document is due to its rareness in the collection, and it can be measured by the logarithm of the inverse of the relative frequency of the term in the collection (document frequency) [11]. In the early 1970s the "cluster hypothesis" was stated by Jardine and van Rijsbergen [4]. According to the cluster hypothesis both efficiency and effectiveness of search could benefit from clustering similar documents because such clusters are easily retrieved by the same search requests, while Salton thought that clustering would have reduced effectiveness in favor of a better response time.

The first main international conference on IR, ACM SIGIR, was held in 1978 [1]. The first commercial search engines appeared in the 1980s, while the 1990s saw the birth of the first web search engines. Since the beginning of the TREC (Text REtrieval Conference) conference series in 1992, a conference organized by the US government's National Institute of Standards and Technology and dedicated to large-scale evaluation of text retrieval methodologies, very large test collections of full-text documents and standards for retrieval evaluation are available. Evaluation is an important issue in IR, therefore TREC has a significant impact in research because provides an objective evaluation of fresh techniques and approaches, and because promotes new specialized retrieval tasks, as well as, the transfer of emerging new ideas into commercial systems and Web search engines.

Foundations

Information Retrieval systems have four main components: query representation and document indexing, term and document retrieval, query-document matching, relevance feedback processing (see Figure 1). Typically, a user submits a query made up of a few words and phrases, or several sentences. The internal representation of the original query and the text extracted from a document are both processed by the same tokenizer: a *parser* extracts the words taking into account specific properties of the language, then most frequent words and other words that have a functional role in the text (*stop-words*) are removed, and finally the constituents of the lexicon of the system (*tokens*) are created by removing linguistic suffixes or prefixes (*stemmer*), their multiplicity of occurrence in the text is recorded. The text of each document is indexed into two files: the *inverted* and the *direct* file. Both files contain the set of *pointers* of the collection, also knows as *postings*, that is the matrix containing all possible term-document pairs of the collection. With the inverted file one can access the set of pointers, e.g., (term, document, frequency), and thus the set of documents containing a given term together with some extra information about these pointers, that is the frequency of that term in these documents and possibly the positions occupied by that given term in each document. With the direct file, one can instead access the set pointers, e.g., (document, term, frequency), that is the set of terms contained in a given document together with the frequency of each term in that document. Positions of terms within documents are used to restrict search with the use of proximity operators. For example, one can submit the query "information retrieval" wishing to find and rank by relevance all and only all documents containing the word "information" followed by the word "retrieval." While *information AND retrieval* is the query to find and rank all and only all relevant documents containing both the words "information" and "retrieval" irrespective of the positions occupied by these words in the text. Frequencies are instead essential to obtain a ranked list of documents.

Document ranking
Query expansion
User's relevance feedback

Information Retrieval. Figure 1. A conceptual architecture for an Information Retrieval system.

The direct file is used to perform other post-processing activities, such as *automatic query expansion*, or to *cluster* the retrieved documents into homogeneous or similar classes of documents, or to present results in different output formats (e.g., into an XML form).

Both inverted and direct file are stored in a compressed form, and it is possible to achieve a very good rate of compression with respect to the size of the original textual data. For example the inverted file of the TREC corpus WT10g containing 1,692,096 documents of 10 GB of text and 280,571,311 pointers, can be compressed in about 385.5 MB, each pointer (term-document, term frequency) requiring an average of 11.5 bits of information only. In general, the most frequent words are declared in a special list of words, the *stoplist*, and are not indexed because they require the storage of too many pointers (the size of the collection in the worst case). A comprehensive study of compression algorithms for text retrieval can be found in the book *Managing Gigabytes* [13].

The kernel of an information retrieval system is the query-document matching model, producing the document-scores for the given query, also known as the *retrieval status value* (RSV) of the documents for that query. The matching model is the theoretical component responsible of the effectiveness and the quality of the retrieval.

Similarly to any other empirical science, Information Retrieval makes inferences by analysis of the empirical data consisting of three phases: *model specification*, *parameter estimation* and *model evaluation*. However, unlike other empirical sciences, IR has two types of data: the postings, that is the elements of the term-document matrix, and the user relevance data set, that are in general provided by a set of document-query relevance assessment pairs. The relevance data set can be used to accomplish two different tasks: query re-formulation for improving document retrieval or the evaluation of system performance.

Due to the existence of relevance feedback data, IR has two different kinds of models: the *query-language model* and the *term-document model*. The query models aim at providing the weights of the query terms irrespective of the observed document. The term-document model instead compares and weights the frequency of the term within a document with respect to its frequency in the collection.

For example, the query "What is a prime factor?", which is transformed into the query "prime factor" after stop-words removal and stemming, can be simply represented as the vector (prime = 1, factor = 1). After a first pass retrieval in absence of user's feedback, one may deem the first retrieved documents as relevant and assume that the terms contained in this small portion of retrieved documents as a sample of the term population relative to the topic "prime factor." Then, the query-language model will assign new weights to the original query-terms and add new terms to the query. For example, retrieving just the first three documents the new query might be (prime = 1.3581, factor = 1.2327, integ = 0.2154, number = 0.1778, primal = 0.0941,...). The term-document weights assigned by the term-document model will be resized according to query-term weights, that is as the inner product of these two weight vectors.

A theory on evaluation of IR systems is mainly developed in van Rijsbergen's book [12]. The effectiveness of an IR system is evaluated by two standard mea sures: *recall* and *precision*, that are defined as follows:

$$Recall = \frac{\mu(Rel \cap Ret)}{\mu(Rel)}$$

$$Precision = \frac{\mu(Rel \cap Ret)}{\mu(Ret)}$$

where $Ret = \{d|d \text{ is retrieved}\}$ and $Rel = \{d|d \text{ is relevant}\}$, and $\mu = |\cdot|$ is the counting measure. Then, $|Rel \cap Ret|$ is the number of relevant and retrieved documents, $|Ret|$ is the number of retrieved documents, and $|Rel|$ is the number of relevant documents.

Key Applications

Main applications of Information Retrieval concern the construction of search engines either for specific domains, like biomedicine and genomics, law, web, blogs, or adapted to particular types of document structure (e.g., XML or hypertext documents) search engines, or dedicated to multimedia and digital libraries.

Future Directions

Notwithstanding the increase of computer processing power, most of IR applications deal with very large collections that cannot be in general processed by only one server. Both efficient implementation and distributed versions of IR systems are required. The design of efficient partitions of very large indexes that need to be distributed over a cluster of machines is an important research topic. Also, large community of users may wish to share their information and knowledge, but not local indexes, and therefore merging local search results to obtain one effective global document ranking is a challenging research issue (*data fusion*). Most of the new technology for information retrieval is becoming more and more an asset of the most popular web search engines, and therefore it is mainly the market that influences new academic research directions. Although social network analysis has achieved a quite mature technology based on variations of Markov chain models with stationary probability distributions, a new social phenomenon is now emerging in the web, the *social tagging*; systems also provide collaborative tools to Internet users to store and search structured comments of web pages. Query search on movies, music or books will be in the very next future conditioned, for example, by opinions or by recommendation. More generally, search will be more and more personalized and tailored to one's own profile or to all other profiles similar one's own. The major techniques to discover statistical relationships for hypertext documents and hyperlinks can be found in Chakrabarti's book [2].

Data Sets

Most of data sets and test collections can be found at the TREC (NIST) web site http://trec.nist.gov/data.

html. There are several types of test collections concerning different range of IR applications. To cite few of them, there are the *ad hoc* collections, that are dedicated to the standard document retrieval based on a primitive notion of user's relevance, *web* test collections, that are dedicated to web retrieval, *Blog Track* test collections, that contains a large collection of permalinks from the blogosphere.

URL to Code

There are several open source IR systems on the web. In the following there is a list of the most popular and advanced academic IR research systems.

1. Indri and Lemur search engines developed by the Carnegie Mellon University and the University of Massachusetts, Amherst, United States: http://www.lemurproject.org/
2. Terrier developed by University of Glasgow, United Kingdom: http://ir.dcs.gla.ac.uk/terrier/.
3. Wumpus developed by University of Waterloo, Canada: http://www.wumpus-search.org/
4. Zettair by the RMIT Univerisity of Melbourne in Australia: http://www.seg.rmit.edu.au/zettair/

Other IR systems are the open source Apache Lucene (http://lucene.apache.org/) and the SMART system (ftp://ftp.cs.cornell.edu/pub/smart/).

Information Retrieval Models

GIAMBATTISTA AMATI
Ugo Bordoni Foundation, Rome, Italy

Synonyms

Document term weighting; Ad hoc retrieval models; Term-document matching function

Definition

An Information Retrieval (IR) model selects or ranks the set of documents with respect to a user query. Text in documents and queries is represented in the same way, so that document selection and ranking can be formalized by a matching function that returns a Retrieval Status Value (RSV) for each document of the collection. Most IR systems represent document contents by a set of descriptors, called terms, belonging to a vocabulary **V**.

Main IR models define the query-document matching function that weights the query terms occurring in a document according to four main approaches:

- The estimation of the probability of user's relevance *rel* for each document **d** and query **q** with respect to a set $R_{\mathbf{q}}$ of training documents

$$\mathrm{Prob}(rel|\mathbf{d}, \mathbf{q}, R_{\mathbf{q}})$$

- The computation of a similarity function between queries and documents in a vector space

$$SIM(\mathbf{d}, \mathbf{q})$$

- The estimation of the probability of generating the document **d** given a query **q**,

$$\mathbf{p}(\mathbf{d}|\mathbf{q})$$

- The information carried by the query terms in the document, that is that is the number of bits necessary to code X_i occurrences of the query terms $\mathbf{t}_i \in \mathbf{q}$ in the document:

$$-\log_2 \mathrm{Prob}(\mathbf{d}|X_1,\ldots,X_{\mathbf{q}})$$

Historical Background

The history of Information Retrieval goes in parallel to the development of IR models. In general, an IR system is mainly identified with retrieval function employed to rank documents, because it is the retrieval *effectiveness* that matters in IR systems. In the early days, research focused on methods for automatic indexing in contraposition to the manual activities made by librarians. Early works concerned the construction of effective methods for keywords selection to represent succinctly the documents, and document-query matching thus was performed by Boolean search of the query terms in the index of such surrogates of the documents. A full exploitation of a probabilistic model was achieved in the 1990s with the birth of the BM25 ranking formula [7]. Before BM25, most of the theoretical investigation was devoted to the vector space model, the first parameter free model for ranking documents [8]. It was only in the late 1990s that other new models appeared on the scene, such as the language models [6] and the information theoretic models that include the Divergence From Randomness models [1]. Boolean model remains attractive because it requires less computational cost both in terms of size of the indices and response time, and quite a few models tried to extend the Boolean model with fuzzy or logical operators, yet the potentialities of such algebraic and logical models have not been fully exploited.

Foundations

IR models can be classified into four types: probabilistic models, algebraic and logical models, information theoretic models and Bayesian models.

Probabilistic models require a training set of data consisting of set of documents which are assessed relevant to a set of queries by users. Algebraic models assume that both queries and terms are represented by vectors, and that the similarity between queries and documents is obtained through a specific normalization of the inner product of these two vectors. In logical models queries and terms are represented by propositions, and the dependency between queries and documents is given by an entailment operator. Information theoretic models are based on the notion of coding cost of terms in the documents, the most informative documents being those generated by the least probable configurations of terms. Bayesian models process two sources of evidence for terms, the term frequencies in the document and in the collection, that are combined to produce an estimate of the probability of the term in the document.

Binary independence model (BIR) and BM25 are probabilistic models. Vector space, Boolean, fuzzy and logical models belong to the algebraic and logical models. The 2-Poisson model [5], and Divergence From Randomness models (DFR) belong to the class of information theoretic models. Language models are instead derived by Bayesian methods.

Probabilistic Indexing

As first IR models, it is interesting to consider the automatic indexing techniques used in the origins of IR. In statistics, observations of empirical data are predicted by stochastic models, that is a probabilistic model which takes into account the presence of some randomness in its variables. In particular, the IR model predicts a probability distribution of possible estimates for term frequencies. An hypothesis that describes the distribution of frequencies is formulated, and the values of inherent parameters of the distribution are estimated by fitting the empirical data to the specified model. Finally, the hypothesis on the distribution form (e.g., Poisson, gaussian, etc.) is accepted or rejected according to an error associated to the fit.

A stochastic model of Information Retrieval models aims to predict a frequency **tf** of a term **t** in a document **d**, that is

$$\mathbf{p}(X_{\mathbf{t}} = \mathbf{tf}, \theta_1, \ldots, \theta_k)$$

where $\mathbf{p}$ is the distribution in the parameters $\theta_1,\ldots,\theta_k$. Both the distribution form and the parameters depend on the observed word.

Once the probability of the frequency **tf** of a term **t** in a document **d** is obtained, then it is also possible to obtain the *probability of relevance of a document* **d** given the term frequency $X_{\mathbf{t}}$:

$$\mathbf{p}(\mathbf{d}|X_{\mathbf{t}} = \mathbf{tf}, \theta_1, \ldots, \theta_k)$$

For example, the Two-Poisson assumes that the distribution of a significant word is a mixture of two Poisson models with mean frequencies $\lambda_{\mathbf{t}} \ll \mu_{\mathbf{t}}$, and the estimate of the probability of the document given the term frequency **tf** is:

$$\mathbf{p}(\mathbf{d}|X_{\mathbf{t}} = \mathbf{tf}, \beta_{\mathbf{t}}, \lambda_{\mathbf{t}}, \mu_{\mathbf{t}}) = \frac{1}{1 + \beta_{\mathbf{t}} \cdot e^{\mu_{\mathbf{t}} - \lambda_{\mathbf{t}}} \left(\frac{\lambda_{\mathbf{t}}}{\mu_{\mathbf{t}}}\right)^{\mathbf{tf}}} \quad (1)$$

with $\lambda_{\mathbf{t}} \ll \mu_{\mathbf{t}}$, and where the values of the parameters $\beta_{\mathbf{t}}$, $\lambda_{\mathbf{t}}$ and $\mu_{\mathbf{t}}$ are learned from data and depend on the observed term **t**.

Information Theoretic Models

The probability estimated by information theoretic models is based on the generation of a document as an unordered partition of terms. Each term $\mathbf{t}_i$ of a vocabulary **V** has a prior probability p_i of occurrence in an arbitrary document of the collection, and a document **d** of length k is conceived as a partition satisfying the constraint $\mathbf{tf}_1 + \ldots + \mathbf{tf}_{\mathbf{V}} = k$ over **V** cells, where $\mathbf{tf}_i$ is the term frequency in the document.

Similarly to the Two-Poisson model the probability of generating a document satisfy the condition

$$\sum_{\mathbf{tf}_i \geq 0} p(X_1 = \mathbf{tf}_1, \ldots, X_{\mathbf{V}} = \mathbf{tf}_{\mathbf{V}}) = 1$$

The connection with Shannon's theory of information is obtained by regarding *a document as a message to transmit.* Shannon explains the notion of information in terms of cost of transmission of a message, which is $-\log_2 p(X_1 = \mathbf{tf}_1, \ldots, X_{\mathbf{V}} = \mathbf{tf}_{\mathbf{V}})$, that is inversely related to the number of choices one has to generate the message with respect to the universe of possible messages: the larger the uncertainty, the larger the information.

If the term independence is assumed, according to which only term frequency counts and positions of terms in documents are irrelevant, a document is treated as an ensemble and is said to be a *bag of words.* In such a case, the probability of generating a document **d** is given by the multinomial distribution:

$$p(X_1 = \mathbf{tf}_1, \ldots, X_{\mathbf{V}} = \mathbf{tf}_{\mathbf{V}}) = \binom{k}{\mathbf{tf}_1 \mathbf{tf}_2 \ldots \mathbf{tf}_{\mathbf{V}}} p_1^{\mathbf{tf}_1} p_2^{\mathbf{tf}_2} \ldots p_{\mathbf{V}}^{\mathbf{tf}_{\mathbf{V}}}$$

It can be shown that

$$\lim_{k \to \infty} \frac{-\log_2 p(X_1 = \mathbf{tf}_1, \ldots, X_{\mathbf{V}} = \mathbf{tf}_{\mathbf{V}})}{k} = D(p_{ML}||p) \quad (2)$$

where $p^i_{ML} = \frac{\mathbf{tf}_i}{k}$ and $D(p_{ML}||p) = \sum_{\mathbf{t}_i \in \mathbf{V}} p^i_{ML} \log_2 \frac{p^i_{ML}}{p_i}$ is the *Kullback-Leibler divergence.*

Exploiting the additivity of the divergence, one can computes the contribution of the query terms to the document:

$$-\log_2 p(X_1 = \mathbf{tf}_1, \ldots, X_{\mathbf{V}} = \mathbf{tf}_{\mathbf{V}}|\mathbf{q}) = \sum_{\mathbf{t}_i \in \mathbf{q}} \mathbf{tf}_i \log_2 \frac{\mathbf{tf}_i}{k \cdot p_i} \quad (3)$$

Similarly to TF-IDF used in the vector space model, also (3) can be used for retrieval.

Different ways to compute the probability $-\log_2 p(X_1 = \mathbf{tf}_1, \ldots, X_{\mathbf{V}} = \mathbf{tf}_{\mathbf{V}}|\mathbf{q})$ and normalize this information with respect the length of the documents is provided by the Divergence From Randomness models.

Vector Space Models

In the vector space model terms and documents are treated as vectors and relevance document scores are obtained by the similarity function

$$SIM(\vec{\mathbf{q}}, \vec{\mathbf{d}}) = \frac{\vec{\mathbf{q}} \cdot \vec{\mathbf{d}}}{||\vec{\mathbf{q}}|| \cdot ||\vec{\mathbf{d}}||}$$

which is the *cosine* function of the angle between the query-document vectors, where the numerator is the inner product of the two vectors and $||\vec{x}|| = \sqrt{\sum_i x_i^2}$ is the norm of a vector. Any term-document weighting model can be employed in the vector space model, differences depend on the ways queries and documents are represented. The vector space model thus is a way to normalize the term-document weight with respect to the length of the document and this normalization is achieved by the cosine function, that is by dividing the inner product by the norms of the vectors.

Assuming each term weight w_i is the number of the bits necessary to encode the $\mathbf{tf}_i$ occurrences of the term in the document, that is $w_i = -\log_2 p(X_i = \mathbf{tf}_i)$, it is easy to show that the inner product can be rewritten as inversely related to the probability of occurrence of the query-terms in the document. According to the *term independence assumption*, the inner product is inversely related to the product of the probabilities of occurrence of each query-term in the document:

$$\sum_i q_i \cdot w_i = -\log_2 \prod_i p(X_i = \mathbf{tf}_i)^{q_i}$$

If $\lambda_i = \frac{\mathbf{n_i}}{\mathbf{N}}$ is the relative document frequency of a term, that is the ratio of the number $\mathbf{n_t}$ of documents in which the term occurs and the number $\mathbf{N}$ of documents of the collection, then the probability $p(X_i = \mathbf{tf}_i)$ can be given by the *geometric distribution*:

$$p(X_i = \mathbf{tf}_i) = \left(\frac{\lambda_i}{\lambda_i + 1}\right)^{\mathbf{tf}_i}$$

that leads to the representation of a document provided by the the first IR vector space model:

$$\vec{\mathbf{d}} = \left(\mathbf{tf}_1 \cdot \log_2\left(1 + \frac{\mathbf{N}}{\mathbf{n}_{\mathbf{t}1}}\right), \ldots, \mathbf{tf}_n \cdot \log_2\left(1 + \frac{\mathbf{N}}{\mathbf{n}_{\mathbf{t}n}}\right)\right)$$

The TF-IDF model weighting of the vector space model is probabilistic, or information theoretic, in its nature, and the *term independence* is an implicit assumption of the model. An estimate of the value of the document relevance is then obtained by dividing the information by the norms of the two vectors $\vec{\mathbf{d}}$ and $\vec{\mathbf{q}}$.

The drawback of this model is the cost of computing document norms. If norms are computed in batch, then a dedicated index must be maintained and updated when documents are added or deleted. On the other hand, if norms are computed online, then one needs to access the direct file to retrieve all the term frequencies $\mathbf{tf}$ of the document.

Bayesian Models

The application of Bayes' theorem to IR concerns the combination of two term frequencies coming from two sources of evidence: the *relative term frequency p_C in the collection*, that is regarded as an estimate of the *prior probability* of occurrence of the term in an arbitrary document of the collection, and *term frequency $p_{ML} = \frac{\mathbf{tf}}{\mathbf{l(d)}}$ in the document*, that is the *maximum likelihood estimate* of the term in the document.

Bayesian models estimate the probability θ_i of a term $\mathbf{t}$ in a document $\mathbf{d}$, considering the θ_i as parameters of the posterior probability

$$\mathrm{Prob}(\theta_1,\ldots,\theta_n|\mathbf{d}) = \frac{L(\mathbf{d}|\theta_1,\ldots,\theta_n) \cdot \pi(\theta_1,\ldots,\theta_n)}{\mathrm{Prob}(\mathbf{d})}$$

where $L(\mathbf{d}|\theta_1,\ldots,\theta_n)$ is the likelihood, $\pi(\theta_1,\ldots,\theta_n)$ is a prior distribution for the parameters θ_i and $\mathrm{Prob}(\mathbf{d}) = \int_0^1 \ldots \int_0^1 L(\mathbf{d}|\theta_1,\ldots,\theta_n) \cdot \pi(\theta_1,\ldots,\theta_n) d\theta_1 \ldots \theta_n$.

If a document is regarded as a set of words, so that permutations of sequences of terms from the vocabulary $\mathbf{V}$ have the same probability distribution (*exchangeable sequences*), then the posterior probability has the form of the product of the multinomial distribution and of a unique prior distribution π:

$$\mathrm{Prob}_{\mathbf{d}}(\theta_1,\ldots,\theta_n|\mathbf{d}) = \frac{\binom{\mathbf{l(d)}}{\mathbf{tf}_1\mathbf{tf}_2\ldots\mathbf{tf}_n} \theta_1^{\mathbf{tf}_1}\theta_2^{\mathbf{tf}_2} \ldots \theta_n^{\mathbf{tf}_n} \cdot \pi(\theta_1,\ldots,\theta_n)}{\mathrm{Prob}(\mathbf{d})}$$

In Bayesian methodology, the prior is chosen in order to have both prior and posterior distribution with the same functional form (*conjugate prior*). The conjugate form to the multinomial distribution is given by the *Dirichlet's distribution*, that is the posterior probability is:

$$\mathrm{Prob}_{\mathbf{d}}(\theta_1,\ldots,\theta_n|\mathbf{d}) \propto \theta_1^{\mathbf{tf}_1+A_1-1}\theta_2^{\mathbf{tf}_2+A_2-1} \ldots \theta_n^{\mathbf{tf}_n+A_n-1} \tag{4}$$

where $\sum_i A_i = A$ are the parameters. The *expectations* $\hat{\theta}_i$ of variables θ_i comes to be:

$$\hat{\theta}_i = \frac{\mathbf{tf}_i + A_i}{\sum_i(\mathbf{tf}_i + A_i)} = \frac{\mathbf{tf}_i + A_i}{\mathbf{l(d)} + A}$$

The Bayesian method constitutes the bulk of the language modeling approach to IR [2,4] (see *language modeling*). However, the values for the parameters A_i need to be learned. The parameters A_i can be further reduced to a single parameter μ by setting the values of A_i to the expected term frequency of $\mathbf{t}_i$ in a document of a fixed length μ, that is $A_i = \mu \cdot p_i$, where p_i is $\frac{\mathbf{TF}}{\mathbf{TFC}}$ is the frequency in the collection (and thus $\mu = \sum_i A_i$). The expectation of (4) thus smoothes the maximum likelihood estimate (MLE) $p_{ML} = \frac{\mathbf{tf}}{\mathbf{l(d)}}$ with the term frequency in the collection, p_i, that is:

$$\hat{\theta}_i = \frac{\mathbf{tf}_i + \mu \cdot p_i}{\mathbf{l(d)} + \mu}$$

The value of the parameter μ depends on several factors, but mainly on the collection and the query length. Another way of smoothing the raw MLE $p_{ML} = \frac{\mathbf{tf}}{\mathbf{l(d)}}$ of the likelihood is the Mercer-Jelinek smoothing technique for IR, that mixes linearly the two frequencies p_{ML} and p_i:

$$\lambda \cdot p_{ML} + (1 - \lambda) \cdot p_i$$

with $0 \leq \lambda \leq 1$.

Probabilistic and Binary Retrieval Models

The independence binary retrieval model (BIR) is based on the assumption that relevance is an event *rel* of the probabilistic space and that relevance can be learned directly from user's feedback. The data containing relevance information are initially gathered by sampling or by assessment on a first pass retrieval, then relevance information is processed to set the values of certain parameters associated with the BIR matching function. The BM25 model also derives from the BIR model.

The BIR model is built upon four probabilities $p_{\mathbf{q}}(\mathbf{t} = a | rel = b)$, where the subscript $\mathbf{q}$ denotes that relevance depends on a specific query, and $a, b \in \{0, 1\}$ are the boolean values *false* and *true* for the variables $\mathbf{t}$ (the term occurs in the documents or not) and for the variable *relevance* (the document is relevant or not) respectively. For the estimation of probability of document relevance BIR uses Bayes' Theorem, which relates the posterior probability of relevance $(p_{\mathbf{q}}(rel = b| \mathbf{t} = a))$ to the prior probability of relevance $(p_{\mathbf{q}}(rel = b))$ and the likelihood of relevance after observing a document $(p_{\mathbf{q}}(\mathbf{t} = a | rel = b))$.

Logical and Algebraic Models

Other approaches to IR modeling include those based on logics, fuzzysets, Bayesian inference networks and the Dempster-Shafer theory of evidence. All these models share the view that (stochastic and/or logical) dependency between sets of words can be captured by a probability defined on top of a (graphical or logical) link between boolean propositional sentences.

A Bayesian inference network is a directed, acyclic dependency graph (DAG) in which nodes represent propositions andedges represent dependence relations between these propositions [10].

Fuzzy models are based on fuzzy-set theory, whichdefines partial membership of elements to a set. Fuzzy models extend logical operators with partial set membership, and processes user queries in a similar way to the conventional Booleanmodel.

A common generalization of both Boolean and fuzzy model is Salton, Fox and Wu's Extended Boolean Information Retrieval Model [9], where the query-document similarity is defined in the L_p-spaces (p-norms).

The logical approach to IR is motivated by modelling retrieval as an inference process. The foundational assumption of logical models is that the semantics of the content of a document is related to a query through a conditional connective, which consists of a type of logical implication set out by Van Rijsbergen in 1986 [11]. One of the IR models based on probabilities on conditionals is obtained by a probability revision method called *imaging* [3].

Key Applications

IR models are applied to a wide range of fields and domains: digital libraries, biomedicine, web search engines, enterprise search, desktop search, search engines for blogs, for legal and other vertical domains, recommendation systems for content providers, information filtering and routing for the selective delivery of news or for detecting spamming and junk mails.

Future Directions

With the dramatic growth of document sources information needs to be retrieved in a distilled manner. The most popular search algorithms for WEB, like PageRank or HITS, clearly indicate that document quality and authoritative content depend on social and collaborative aspects of the community of the users. Users will more and more cite their favorite information sources, express and share their opinions with other in the same network of interests or for entertainment reasons.

Information Retrieval Models will thus naturally evolve along to dynamic search dimensions such as analysis of the social networks, time and context. Contexts include background knowledge about the domain, group of interests, relevant information sources and specific ontologies, as well as profiles with users background, interests, and preferences.

One of the most important research direction is the development of systems that integrates database and IR technology. Such an integration requires new query language, new indexing techniques but more importantly models that combines exact matching, proper of the database systems processing queries for structured information, with partial matching, proper of the IR systems.

Experimental Results

The performance measures of the IR models are based on precision and recall. Significance tests on a set of queries must be conducted to assess the relative performance of models.

Data Sets

Most of data sets and test collections can be found from the TREC (NIST) web site (http://trec.nist.gov/data.html).

Information retrieval processing

Definition

An information retrieval system for collections of unstructured text can be viewed as a set of processing modules, beginning with lexical analysis of documents and leading ultimately to a retrieval process in which user queries are matched against documents. The processes which make up an information retrieval system are referred to as information retrieval operations. In some cases, the end goal is not the retrieval of matching documents from a collection but an auxiliary application, such as document categorization, summarization, or filtering of information from an information stream. While the basic operations in information retrieval systems are similar, there can be considerable variability in the model or details of implementation, making evaluation of information retrieval system effectiveness an important step.

Historical Background

Early work in information retrieval began in the 1950s with the recognition that words in documents could be used as indicators of the content or meaning of the document. Hans Peter Luhn, in early work on automatic abstracting and Keyword-in-Context indexing, recognized that words had differential value in representing the document's meaning [4,5], a concept that is fundamental to modern information retrieval systems. In the 1960s, Salton [7] and his research group developed the SMART system based on the vector space model, combining the basic operations for information retrieval in an information retrieval system. This allowed them to experiment with a variety of information retrieval operations, including stemming, term weighting, similarity functions, and relevance feedback.

Subsequent research has developed and refined information retrieval operations, and there has been increased emphasis on modular implementations which allow specific operations to be isolated. In 1992, Frakes and Baeza-Yates edited Information Retrieval: Data Structures and Algorithms [3], with the goal of making information retrieval more widely known, and making available pseudo-code and code for the basic information retrieval operations. More recently, open-source software such as the Lemur Toolkit has provided easy access to information retrieval systems which allow the isolation and modification of information retrieval operations [1].

Foundations

The basic operations in the building of an information retrieval system are the pre-processing of text, creation of index files, and processing of queries to provide a (usually) ranked list of potentially relevant documents.

Pre-processing of text involves parsing the text to create a list of index terms (lexicon) which will be stored for retrieval. In identifying the index terms, some words may be identified as Stopwords, i.e., common words that are not considered meaningful, and which are not indexed. Words with common suffixes may be identified through an operation called Stemming, and concatenated under a single index entry. While it is possible to select a subset of the words in a text as index terms, usually all words (except words identified as stopwords) in the text are used, so that this is sometimes referred to as a "bag of words" approach.

Early research demonstrated the value of using differential weights for the index terms associated with a document, and testing different models for assigning term weights continues to be an active research area. A long-standing approach was the tf*idf, or term frequency-inverse document frequency weighting scheme, in which every term in a document was assigned a weight proportional to its frequency in that document, and inversely proportional to its frequency in the collection as a whole. More recent weighting schemes include BM25 and weights derived from language models [6].

The resultant document-term matrix is sparse and it is not efficient for storage and processing, so the next set of operations involves building the index to store the terms and associated term weights. The inverted index, in which a postings list of document numbers and associated weights is given for each term, is commonly used. For large data collections, some form of index compression may also be applied [6,10].

Finally, a set of operations on the query results in delivery of the output to the user of the system. A query is presented to the system through a user interface, and it undergoes the same processing as the document collection to identify the index terms which it contains. The order in which query terms are processed may be considered to achieve efficiencies in processing. The query is matched against the documents in the collection using some similarity function, and the documents are ranked in order of similarity. A variety of similarity functions have been proposed and tested; the choice may depend on the underlying information retrieval model. For example, in the vector space model, the similarity function was usually the cosine function which measures the angle between the document and query vector.

Further operations may be carried out on the query in an attempt to improve it. In relevance feedback, information about documents in the ranked list which are either known to be relevant (from user input) or assumed to be relevant, is used to reweight the query terms and potentially offers performance improvement. In query expansion, terms are added to the query, automatically or with the assistance of the searcher, in an attempt to improve retrieval performance.

The retrieval process described above performs what is sometimes referred to as the ad hoc retrieval task, in which the query is matched against a relatively static collection of documents. In some situations it is the query which is (relatively) static, and the documents which are changing. Matching a query against a document stream is referred to as information filtering, and is useful in situations where information which is continually being created must be monitored (for example, from a newswire).

In some instances the end goal is not to produce documents in response to a query, but to perform some other task through specialized processing of the indexed document collection, often in support of information retrieval. An example is document categorization, whereby documents being added to a collection are automatically assigned to what is predicted to be the most appropriate category for them, based on characteristics which have been observed for that category (such as patterns of term occurrence). In document clustering, document-document similarity based on term occurrence and term weights is used to divide a document collection into clusters or groupings of like objects. (Clustering differs from categorization in that the clusters are not a priori known.) Clusters may be created from retrieval output, in order to provide the user with documents which are organized by topic. Similarly, in document summarization, information about the document is used to identify the most important words, sentences or concepts it contains in order to build a summary of it, for instance, to use as a document surrogate to present to the searcher. Another post-retrieval operation is information visualization [11], in which a visual display is generated rather than, or in addition to, a ranked list. In some cases the visual display can be manipulated to provide further interpretation of the retrieval results.

Experimental Results

Almost as soon as computerized information retrieval systems were conceived, evaluation was seen as an important component. The best known of the early tests were the Cranfield experiments [8], so-called because they were conducted by Cyril Cleverdon and a group of researchers at the Cranfield College of Aeronautics, primarily as a test of indexing techniques. The first set of experiments, conducted in 1958–1962, provided controversial results, and in response to criticism of the methodology, a second set of experiments was devised by Cleverdon, with emphasis on rigor and a laboratory model. These second experiments, known as Cranfield II, led to the basic model for information retrieval experimentation in common use today: a document collection, a set of queries and associated relevance judgments, and measurement based on precision and recall. In terms of findings, the Cranfield experiments and a series of experiments on the SMART system [8] showed that the interest of the time in complex indexing systems was misguided, and that in general simpler indexing systems worked as well as more complex techniques. The laboratory model as exemplified by the Cranfield experiments made it possible to isolate individual information retrieval operations and evaluate performance with, for instance, different values or functions.

Through the 1970s and 1980s, the laboratory for information retrieval research expanded, with new test collections, query sets and relevance judgments. The collections grew steadily larger, though still falling far short of those found in operational systems. After 30 years of IR experimentation in the Cranfield model, there was confidence within the IR community that the basic information retrieval operations had been refined to achieve real performance improvements, although the transfer of the technology to the commercial section was extremely limited.

One of the strongest arguments for the lack of commercial success was skepticism about the scalability of performance improvements from the laboratory to large scale systems. Partly in response to this criticism, in 1992 the National Institute of Standards and Technology (NIST) hosted the first Text REtrieval Conference (TREC) [9]. TREC provided the infrastructure for large-scale IR evaluation, and resulted in the improvement and dissemination of many information retrieval operations, notably term weighting, as reports of the success of the BM25 model for term weighting were widely disseminated. TREC also supported the development of standard routines to analyze the results of query runs, minimizing the variance in analysis of data that existed, and making it easier to compare variations in information retrieval operations.

INitiative for the Evaluation of XML Retrieval

Gabriella Kazai
Microsoft Research Cambridge, Cambridge, UK

Synonyms

INEX; XML information retrieval; Evaluation forum

Definition

The INitiative for the Evaluation of XML retrieval (INEX), launched in 2002, is an established evaluation forum for XML Information Retrieval (IR) with over 90 participating organizations worldwide. The initiative is sponsored by the DELOS Network of Excellence for Digital Libraries and supported by the IEEE Computer Society.

INEX encourages research in XML IR by providing an infrastructure to evaluate the effectiveness of XML IR systems. The infrastructure takes the form of a large XML test collection, appropriate scoring methods, and a forum for participating organizations to compare their results. The construction of the test collection is a collaborative effort, where participating organizations contribute by providing test queries and relevance judgments on the collection of XML documents. The constructed test collection provides participants a means for comparative and quantitative experiments.

Historical Background

The motivation for INEX stems from the increasingly important role of XML IR in many information access systems (e.g., in digital libraries and on the Web) where content is a mixture of text, multimedia, and metadata, formatted according to the adopted W3C standard of the eXtensible Markup Language (XML).

XML offers the opportunity to exploit the internal structure of documents in order to allow for more precise access, providing more focused answers to users' requests. XML IR thus breaks away from the traditional retrieval unit of a document as a single large (text) block and aims to implement more focused retrieval strategies that return document components, i.e., XML elements, instead of whole documents in response to a user query. This focused retrieval approach is seen of particular benefit for information repositories containing long documents, or documents covering a wide variety of topics (e.g., books, user manuals, legal documents), where the user's effort to locate relevant content can be reduced by directing them to the most relevant parts of the documents. Providing effective access to XML based content is therefore a key issue for the success of these systems.

INEX aims to provide the means necessary for the evaluation of XML IR systems. It follows the predominant approach in IR of evaluating retrieval effectiveness using a test collection constructed specifically for that purpose.

A test collection usually consists of a set of documents, user requests (topics), and relevance assessments which specify the set of "right answers" for the requests.

In the field of IR, there have been several large-scale evaluation projects, including the Text REtrieval Conference (TREC) (http://trec.nist.gov/), the Cross-Language Evaluation Forum (CLEF) (http://www.clef-campaign.org/), and the National Institute of Informatics Test Collection for IR Systems (NTCIR) (http://research.nii.ac.jp/ntcir/), which resulted in established test collections and evaluation methodologies. These traditional IR test collections and methodology, however, cannot be directly applied to the evaluation of content-oriented XML retrieval as they do not consider structural aspects and, for example, provide relevance judgments only at the unit of the document. Furthermore, the evaluation is based on assumptions that do not hold in XML IR. For example, the evaluation of IR systems treats documents as independent and well-distinguishable separate units of approximately equal size. XML IR, however, allows for varying sized document components to be retrieved. It is also possible that multiple elements from the same document are retrieved, which cannot be viewed as independent units.

The evaluation of XML retrieval systems thus makes it necessary to build test collections and develop appropriate metrics where the evaluation paradigms are provided according to criteria that take into account the imposed structural aspects. INEX aims to address these goals.

Foundations

Since its launch in 2002, INEX has grown both in terms of number of participants and with respect to its coverage of the investigated retrieval tasks. Throughout the years, INEX faced a range of challenges regarding the evaluation of XML IR approaches. These include the question of suitable relevance criteria, feasible assessment procedures, and appropriate evaluation measures. Different theories and methods for the evaluation of XML IR were developed and tested at INEX, leading to a now stable evaluation setup and a rich history of learned lessons.

In 2002, INEX started with 36 active participating organizations and a small collection of XML documents donated by the IEEE Computer Society, totaling 494 MB in size and containing over eight million XML elements [3, pp. 1–17]. INEX 2002 run a single track, investigating ad hoc retrieval applied to XML documents based on the focused retrieval approach. In IR literature, ad hoc retrieval is described as a simulation of how a library might be used, and it involves the searching of a static set of documents using a new set of topics [15]. While the principle is the same, the difference for INEX is that the library consists of XML documents, the queries may contain both content and structural conditions and, in response to a query, arbitrary XML elements may be retrieved from the library.

Two subtasks were defined within the Ad hoc track based on the query types of Content-Only (CO) and Content-And-Structure (CAS). In the CO task, it was left entirely to the retrieval system to identify the most appropriate relevant XML elements to return to the user, while in the CAS task, systems could make use of the structural clues specified by the user in the query.

The queries were created by the participating groups, contributing 30 CO and 30 CAS topics to the test collection. For each topic, a title, a description and a narrative were specified, where the syntax of the title allowed the definition of target elements and so-called containment conditions (content word and containment element pairs).

The relevance criteria was defined along two dimensions, each with four possible grades for assessors to choose from. Assessors were asked to assign scores for both dimensions to all XML elements of the collection that contained relevant information.

Based on the collected relevance judgments, effectiveness scores were calculated by adopting Raghavan's

Precall measure [3, pp. 1–17]. Table 1 shows summary information on INEX 2002.

In 2003, the CAS subtask was separated into the Strict CAS (SCAS) and the Vague CAS (VCAS) strands so that the effect of interpreting a query's structural clues strictly or vaguely could be studied. The CO subtask remained unchanged, and so did the document collection.

The syntax of the topic title was modified based on the XPath standard (http://www.w3.org/TR/xpath), where a new *about()* function was introduced [4, pp. 192–199].

Due to the fact that the coverage dimension of the relevance criterion was found to be susceptible to misinterpretation, INEX 2003 renamed and redefined the relevance dimensions to Exhaustivity and Specificity.

A new measure, inex_eval_ng [10], was also introduced, allowing to take into account the possible overlap (e.g., paragraph and its container section) and the varying size of the XML elements. Table 2 shows summary information on INEX 2003.

By 2004, INEX had 43 active participating groups and four additional tracks: Relevance feedback, Heterogeneous collection, Natural language processing (NLP) and Interactive tracks. The ad hoc track ran only two of the subtasks defined in 2003: CO and VCAS. The format of a topic's title field was formally defined using the Narrowed Extended XPath I (NEXI) language. The purpose of the Relevance feedback track was to explore issues related to the use of relevance feedback in a structured environment [1]. The Heterogeneous track aimed to address challenges where collections of XML documents from different sources and with different DTDs or Schemas were to be searched. The NLP track investigated whether it was practical to use a natural language query in place of the formal NEXI topic title used in the Ad hoc track [9]. The Interactive track focused on studying the behavior of searchers when presented with components of XML documents that have a high probability of being relevant (as estimated by an XML IR system) [12].

Both the document collection and the relevance dimensions remained unchanged from 2003. The measure of Precall was used as in previous years to report the retrieval effectiveness scores of the participating search systems. Table 3 shows summary information on INEX 2004.

The ad hoc track at INEX 2005 continued studying the role of structure in user queries, and defined four separate strands of the VCAS subtask based on the strict

INitiative for the Evaluation of XML Retrieval. Table 1. Summary information on INEX 2002

INEX 2002	
Organizers:	N. Fuhr, N. Gövert, G. Kazai, M. Lalmas
Participants:	36 active (49 from 21 countries signed up)
Tracks:	Ad hoc retrieval with two subtasks
Ad hoc tasks:	Ad hoc retrieval based on CO (content-only) and CAS (content-and-structure) topics
Document corpus:	12,107 articles from IEEE Computer Society, 1995–2002
	Totaling 494 MB and over eight million XML elements
Topics:	30 CO and 30 CAS topics
Relevance:	Topical relevance (Irrelevant, Marginal, Fairly, Highly relevant),
	Component coverage (No coverage, Tool large, Too small, Exact)
Metrics:	Precall (inex_eval) [3, pp. 1–17]
Proceedings:	[6]

	Metrics: G. Kazai, A.P. de Vries
Participants:	43 active (55 from 20 countries signed up)
Tracks:	Ad hoc retrieval with two subtasks
	Relevance feedback track (C. Crouch, M. Lalmas)
	Heterogeneous collection track (T. Rölleke, Z. Szlávik)
	Natural language processing track (S. Geva, T. Sahama)
	Interactive track (A. Tombros, B. Larsen, S. Malik)
Ad hoc tasks:	CO (content-only) and VCAS (vague content-and-structure)
Document corpus:	Same as in 2002 and 2003
Topics:	40 CO and 35 CAS topics
Relevance:	Same as in 2003
Metrics:	Precall (inex_eval) [3, pp. 1–17]
Proceedings:	[6]

or vague interpretations of the structural conditions of a query [13]. The CO subtask has also diversified into six strands based on a combination of three subtasks (Focused, Thorough and FetchBrowse) and the use of the CO or CO+S (CO+Structure) type topics. The latter type expands the CO topic format with an additional CAS title field, where structural hints for the CO title can be expressed. The Focused task asked systems to return a ranked list of the most focused (specific and exhaustive) document parts, without returning overlapping elements. The Thorough task required systems to estimate the relevance of all XML elements in the searched collection and return a ranked list of the top 1,500 elements. The FetchBrowse task asked systems to return to the user the most focused, relevant XML elements clustered by the unit of the document containing the elements. Put another way, the task was to return documents with the most focused relevant elements highlighted within them.

All additional tracks started in 2004 run again in 2005, together with the new Document mining and Multimedia tracks. The Document mining track focused on the tasks of classification and clustering by developing methods that are able to exploit the XML markup for this purpose [2]. The Multimedia track was set up aiming at the evaluation of structured document retrieval approaches which are able to combine the relevance of the different media types into a single (meaningful) ranking that is presented to the user [14].

INEX 2005 obtained additional resources in the form of additional XML articles from the IEEE Computer Society, increasing the total size of the collection to 764 MB. In addition, the Multimedia track made use of an XML version of the Lonely Planet collection.

Other changes to the evaluation framework included new assessment procedures and new metrics. The assessment process was simplified to asking assessors to first highlight relevant passages and then assess the elements overlapping these passages. As a consequence, the Specificity dimension could be automatically measured on a continuous scale [0,1] by calculating the ratio (in characters) of the highlighted text (i.e., relevant information) and the total length of the element.

To report effectiveness scores, INEX 2005 adopted the eXtended Cumulated Gain (XCG) measures [5, pp. 16–29], which were developed specifically for graded (non-binary) relevance values and with the aim to allow XML IR systems to be credited according to the retrieved elements' degree of relevance. Table 4 shows summary information on INEX 2005.

In 2006, INEX finished with 50 active participating organizations and expanded to a total of nine tracks: Ad hoc, Relevance feedback, Heterogeneous collection, Natural language processing, Interactive, Multimedia, Document mining, Use case, and Entity ranking tracks. The Ad hoc track consisted of four subtasks: Focused, Thorough, Relevant in Context (FetchBrowse in 2005), and Best in Context tasks. The new Best in Context task asked systems to return a single best entry point (BEP) to the user per relevant document. Rather than dealing with information access to XML elements, the new Entity ranking track set as its task the retrieval of a list of entities of specific types (e.g., people, products, artifacts). The Use case track attempted to identify examples of how XML IR systems can be exploited by end-users for various purposes [11].

A major change in 2006 was the departure from the use of the IEEE document collection, which has been replaced by a collection of XML articles from the Wikipedia project.

INEX 2006 has also further simplified the assessment procedure by dropping the exhaustivity dimension of the relevance criteria.

INitiative for the Evaluation of XML Retrieval. Table 4.
Summary information on INEX 2005

INEX 2005	
Organizers:	Overall: N. Fuhr, M. Lalmas
	Topic format: B. Sigurbjörnsson, A. Trotman
	Relevance assessment tool: B. Piwowarski
	Metrics: G. Kazai, A.P. de Vries, P. Ogilvie, B. Piwowarski
Participants:	41 active (47 signed up)
Tracks:	Ad hoc retrieval with ten subtasks
	Relevance feedback track (Y. Mass, C. Crouch)
	Heterogeneous collection track (R. Larson)
	Natural language processing track (S. Geva, T. Sahama)
	Interactive track (B. Larsen, A. Tombros, S. Malik)
	Multimedia track (R. van Zwol, G. Kazai, M. Lalmas)
	Document mining track (L. Denoyer, A-M. Vercoustre, P. Gallinari)
Ad hoc tasks:	CO.Focused, CO.Thorough, CO. FetchBrowse,
	COS.Focused, COS.Thorough, and COS.FetchBrowse,
	VVCAS (vague target and vague containment CAS),
	SVCAS (strict target and vague containment CAS),
	VSCAS (vague target and strict containment CAS), and
	SSCAS (strict target and strict containment CAS)
Document corpus:	16,819 articles from IEEE Computer Society, 1995–2004
	Totaling 764 MB, and over 11 million XML elements
	Includes an additional 4,712 new articles
Topics:	40 CO+S and 47 CAS topics
Relevance:	Exhaustivity (Not, Somewhat, Highly exh., Too small),
	Specificity (Continuous scale)
Metrics:	XCG metrics [6, pp. 16–29]
Proceedings:	[6]

A new passage-based recall and precision was adopted to report effectiveness scores for the Relevant in Context task, while XCG was employed for the Focused and Thorough tasks [7, pp. 20–34]. Two further measures, BEP-distance and EPRUM [7, pp. 20–34], provided the performance results for the Best in Context task. Table 5 shows summary information on INEX 2006.

Participants:	50 active (68 signed up)
Tracks:	Ad hoc retrieval with four subtasks
	Relevance feedback track (Y. Mass, R. Schenkel)
	Heterogeneous collection track (I. Frommholz, R. Larson)
	Natural language processing track (S. Geva, X. Tannier)
	Interactive track (B. Larsen, A. Tombros, S. Malik)
	Multimedia track (R. van Zwol, T. Westerveld)
	Document mining track (L. Denoyer, A-M. Vercoustre, P. Gallinari)
	Use case track (A. Trotman, N. Pharo)
	Entity ranking track (A.P. de Vries, N. Craswell)
Ad hoc tasks:	Focused, Thorough, Relevant in Context, and
	Best in Context
Document corpus:	659,388 articles of the Wikipedia project, covering a hierarchy of 113,483 categories, totaling over 60 GB (4.6 GB without images) and 30 million XML elements
Topics:	125 CO+S topics
Relevance:	Specificity (Continuous scale)
Metrics:	XCG metrics [6, pp. 16–29], passage-based recall and precision,
	BEP-distance and EPRUM [7, pp. 20–34]
Proceedings:	[7]

For INEX 2007, 100 groups registered to participate. A total of six track were run in 2007: The Ad hoc, Document mining, Multimedia, and Entity ranking tracks were continued, and two new tracks were started: Link the Wiki, and Book search. The Ad hoc track pitted XML element retrieval approaches against passage retrieval methods on three tasks: Focused, Relevant in Context and Best in Context. The Link the Wiki track aims at evaluating the state of the art in automated discovery of document hyperlinks. The Book search track builds on a collection of over 40,000 digitized books, marked up in XML. It aims to investigate book-specific relevance ranking strategies, user interface issues and user behavior, exploiting special features, such as back of book indexes provided by authors, and linking to associated metadata like catalogue information from libraries.

There were no changes in the document collection, which remained the Wikipedia XML corpus, and the relevance assessment criteria and procedures. The metrics from 2006 have been refined to allow for the evaluation of arbitrary passages as retrieval results and a new measure generalized precision and recall has also been introduced to measure retrieval effectiveness for the Relevant in Context task [8, INEX 2007 Evaluation Measures]. Table 6 shows summary information on INEX 2007.

INEX 2008 is to set to start in the Spring of 2008.

Relevance:	Same as in 2006
Metrics:	Passage-based recall and precision, generalized precision and recall, and BEP-distance [8, INEX 2007 Evaluation Measures]
Proceedings:	[8]

Key Applications

Evaluation is a key component of any system development as it allows to quantify improvement in performance. INEX provides an important resource to facilitate the evaluation of XML IR systems.

XML IR is a form of semi-structured text retrieval, which aims to exploit the inherent structure of documents to improve their retrieval, where the structure is given by the XML markup.

Some of the issues and proposed solutions within INEX are applicable to other areas of IR, such as passage, video and Web retrieval, where there is no fixed unit of retrieval and where the evaluation needs to handle overlapping fragments and users' post query browsing behavior.

Data Sets

Until 2004, the document collection consisted of 12,107 articles, marked-up in XML, from 12 magazines and 6 transactions of the IEEE Computer Society's publications, covering the period of 1995–2002, and totaling 494 MB in size, consisting of over eight million XML elements. On average, an article contains 1,532 XML nodes, where the average depth of the node is 6.9.

In 2005, the collection was extended with further publications from the IEEE Computer Society. A total of 4,712 new articles from the period of 2002–2004 were added, giving a total of 16,819 articles, and totaling 764 MB in size and over 11 million XML elements.

The overall structure of a typical article in the IEEE collection consists of a front matter, a body, and a back matter. The front matter contains an article's metadata, such as title, author, publication information, and abstract. The article's body contains the actual content of the article. The body is structured into sections, subsections, and sub-subsections. These logical units start with a section title, followed by a number of paragraphs. In addition, the content has markup for references (citations, tables, figures), item lists, and layout (such as emphasized and bold faced text), etc. The back matter contains a bibliography and further information about the authors.

INEX 2006 and 2007 switched to a different document collection, consisting of 659,388 English articles, marked-up in XML, from the Wikipedia (http://en.wikipedia.org) project, totaling over 60 GB (4.6 GB without images) and 30 million XML elements. The collection's structure is similar to that of the IEEE collection's. On average, a Wikipedia article contains 161.35 XML nodes, where the average depth of an element is 6.72.

In addition to these, the different tracks worked with additional document collections. For example, the Multimedia track in 2005 made use of an XML version of the Lonely Planet collection and the Book Search track in 2007 provided a collection of 42,000 digitized books marked up in XML.

Initiator

Kaladhar Voruganti
Network Appliance, Sunnyvale, CA, USA

Synonym

SCSI initiator

Definition

In SCSI protocol, the client which requests data is known as the initiator. The initiator typically resides on the host server that is accessing the storage. Initiators can also reside in storage virtualization boxes which can act as both initiators and targets.

Key Points

The SCSI initiator can reside in software or in a hardware adapter card. SCSI protocol provides commands that allow initiators to reserve LUNs and prevent them from being accessed by other initiators. SCSI initiators communicate with SCSI targets using SCSI block level protocol. The block level protocol data is transported via other transport protocols such as parallel SCSI, Fiber Channel, Serial SCSI or Infiniband.

In-Network Query Processing

Samuel Madden
Massachussetts Institute of Technology, Cambridge, MA, USA

Synonyms

Tiny aggregation (TAG); TinyDB

Definition

In-Network query processing refers to the complete or partial evaluation of database queries at the edges of a network, rather than in a centralized database server. Though this phrase may also apply to the general process of distributed or parallel query evaluation, it is most commonly applied to environments like sensor networks, where the network edges consist of small, wireless devices with power and CPU constraints. Typically these devices produce the data to be processed via local sensors, so processing in the edges of the network can be beneficial because it can reduce bandwidth usage, which in turn can conserve energy.

Historical Background

Sensor networks are collections of small, inexpensive battery-powered, wirelessly networked devices equipped with sensors (microphones, temperature sensors, etc.) that offer the potential to monitor the world with unprecedented fidelity. To capture data from these networks, researchers have proposed several sensor network database systems, including TinyDB [11], Cougar [15], and SwissQM [12] have been proposed. These systems provide a high level SQL-like query language that allows users to specify what data they would like to capture from the network.

The canonical sensor network platform is the Berkeley Mote hardware running the TinyOS operating system [8]. Initial versions of the motes used Atmel 8-bit microprocessors and 40 kbit/s radios; newer generations, developed by companies like Crossbow Technologies (http://www.xbow.com) and Moteiv Technologies (http://www.moteiv.com) use Zigbee (802.15.4) radios running at 250 kbits/s and Atmel or Texas Instruments 8 or 16 bit microprocessors running at 4–8 MHz. Nodes typically are very memory constrained (with 4–10 KB of RAM and 48–128 KB of non-volatile flash-based program memory.) Most varieties can be interfaced to sensors that can capture a variety of readings, including light, temperature, humidity, vibration, acceleration, sounds, or images. The limited processing power and radio bandwidth of these devices constrains sample rates to at most a few kilo-samples per second. The dominant power cost of operating these nodes is often cited as network transmissions [9,10]. Table 1 summarizes the major operations in a sensor network, and illustrates the reason why communication costs are considered dominant: the time spent sending messages is huge compared to the time spent computing or sampling. Therefore, the total energy consumption is dominated by message transmissions (in this example, communication cost is 50 times the combined cost to sample a sensor and evaluate a predicate).

Given these high per-message energy costs, one primary goal of sensor network database systems is to reduce message transmissions; in network processing is key to do this, as explained in the next section.

Foundations

Before describing the various in-network processing techniques that have been proposed, it is important

In-Network Query Processing. Table 1. Major activities in a data collection network, with time, power, and energy for each. Computation is assumed to be one sample, one message transmission, and one predicate evaluation per second (with no reception.) The sensor is assumed to be attached directly to the on-chip ADC. The sensor node is a MicaZ-class [4] mote with Atmel Atmega 128L microprocessor at 4 MHz and a TI/ChipCon CC 2420 250 kbps ZigBee radio running at 0 dBm. Predicate evaluation is assumed to take 400 cycles; sensor sampling is assumed to take 40 cycles

Activity	Time per action	Power	Energy
Send a message	3 ms	60 mW	180 μJ
Sample a sensor	10 μs	24 mW	0.24 μJ
Evaluate a predicate	100 μs	24 mW	2.4 μJ
Idle	899 ms	45 μW	40 μJ

to understand the basics of sensor network query languages and the usage model for the systems.

Network Formation and Communication

Typically, a user deploys one of these systems by placing a collection of static sensor nodes around an area to be monitored. These nodes contain a pre-compiled binary image of the sensor network database, but are not yet running any queries. When powered up, the nodes immediately begin to organize themselves into an ad-hoc network which typically takes the form a *spanning tree* rooted at a *root node* connected to a *basestation*. The basestation is usually a more powerful machine, such as a laptop PC, which issues queries to nodes and collects, processes, and visualizes query results.

Tree formation is accomplished by have the basestation periodically broadcast a beacon message. Nodes that hear this beacon re-broadcast it, indicating that they are one hop from the basestation. Nodes that hear those messages in turn re-broadcast them, indicating that they are two hops from the basestation, and so on. This process of (re)broadcasting beacons occurs continuously, such that (as long as the network is connected) all nodes will eventually hear a beacon message. When a node hears a beacon message, it chooses a node from which it heard the message to be its *parent*, sending messages through that parent when it needs to transmit data to the basestation. (In general, parent selection is quite complicated, as a node may hear beacons from several candidate parents. Early papers by Woo et al. [14] and DeCouto et al. [5] provide details.)

Users interact with the system by issuing queries at the basestation, which in turn broadcasts queries out into the network. Queries are typically disseminated via flooding down the routing tree. As nodes receive the query, they begin processing it. The basic programming model is data-parallel: each node runs the same query over data that it locally produces or receives from its neighbors. As nodes produce query results, they apply in-network processing to reduce query results, and then send those reduced result up the routing tree, towards the basestation, which receives the results and possibly merges them together to form a final query answer.

Query Language and Data Model

Most sensor network databases systems provide a SQL-like query interface. For example, the a TinySQL query (used in TinyDB) that requests the temperature from every node in a sensor network whose value is greater than 25°C once per second would look like:

```
SELECT nodeid, temperature
FROM sensors
WHERE temperature > 25°C
SAMPLE PERIOD 1s
```

This query is essentially standard SQL, with a few small additions. First, the `SAMPLE PERIOD` clause requests that a data reading be produced once every second. This means that each query produces a continuous stream of results rather than a single result set. Second, the `nodeid` attribute is a unique identifier assigned to each sensor node and available in every query. Third, the table `sensors` is *virtual table* of sensor readings. Here, *virtual* means that it conceptually contains one row for every sensor type (light, temperature, etc.) from every sensor node at every possible instant, but all of those rows and columns are not actually materialized. Instead, only the sensor readings needed to answer a particular query are actually generated.

Note also that although this table appears to be a single logical table its rows are actually produced by different, physically disjoint sensors. This is the key to in-network processing: when a sensor receives a query, it begins sampling its sensors at the appropriate rate, applying predicates and aggregating data locally and forwarding on only those readings that will eventually be a part of the final query answer.

It should be clear that selection predicates over a single attribute of the sensors table can always be evaluated locally, inside of the network, before any network transmission is done. The remainded of this section discusses techniques that have been developed for in-network processing for aggregate and join queries.

In-Network Processing of Aggregates

Aggregate queries are particularly common in sensor networks, since users are often more interested in what is happening in general geographic regions rather than at a specific sensor. A common environmental monitoring query might ask for the temperature in a building grouped by room number:

```
SELECT roomNo, AVG(temp)
FROM sensors
GROUP BY roomNo
SAMPLE PERIOD 1 s
```

A naive implementation of sensor network aggregation would be to use a centralized, *server-based* approach where all sensor readings are sent to the base station, which then computes the aggregates. In the TAG system [10], however, the authors proposed computing aggregates in-network, and showed that this approach requires fewer message transmissions, is lower latency, and uses less power than the server-based approach.

Consider first the case of an aggregation query without group. Once the query has been disseminated into the network, the TAG data processing phase begins. In this phase, aggregate values are continually routed up from children to parents. The goal of the TAG algorithm is to produce a single aggregate value (or a single value per group) that combines the readings of all devices in the network once per sample period.

The basic insight of the TAG protocol is that it is possible to *partially aggregate* sensor values together at intermediate points inside the network. TAG accomplishes this by having each parent node collect readings from its children before doing its own transmission. Rather than simply forwarding all of the raw data, each parent node combines its data with data from its children to produce a compact *partial state record* (PSR). For example, suppose the user wants to compute the average temperature in the network. In TAG, the PSR representation for an average is a <*sum*, *count*> pair. Each node transmits exactly one PSR per sample period. Suppose a node receives a set P of n PSRs from its children, such that $P = p_1,\ldots,p_n$. If the node has the local sensor value v; then it can compute its own partial state record as:

$$sum = v + \sum_{i=1}^{n} p_i \cdot sum$$

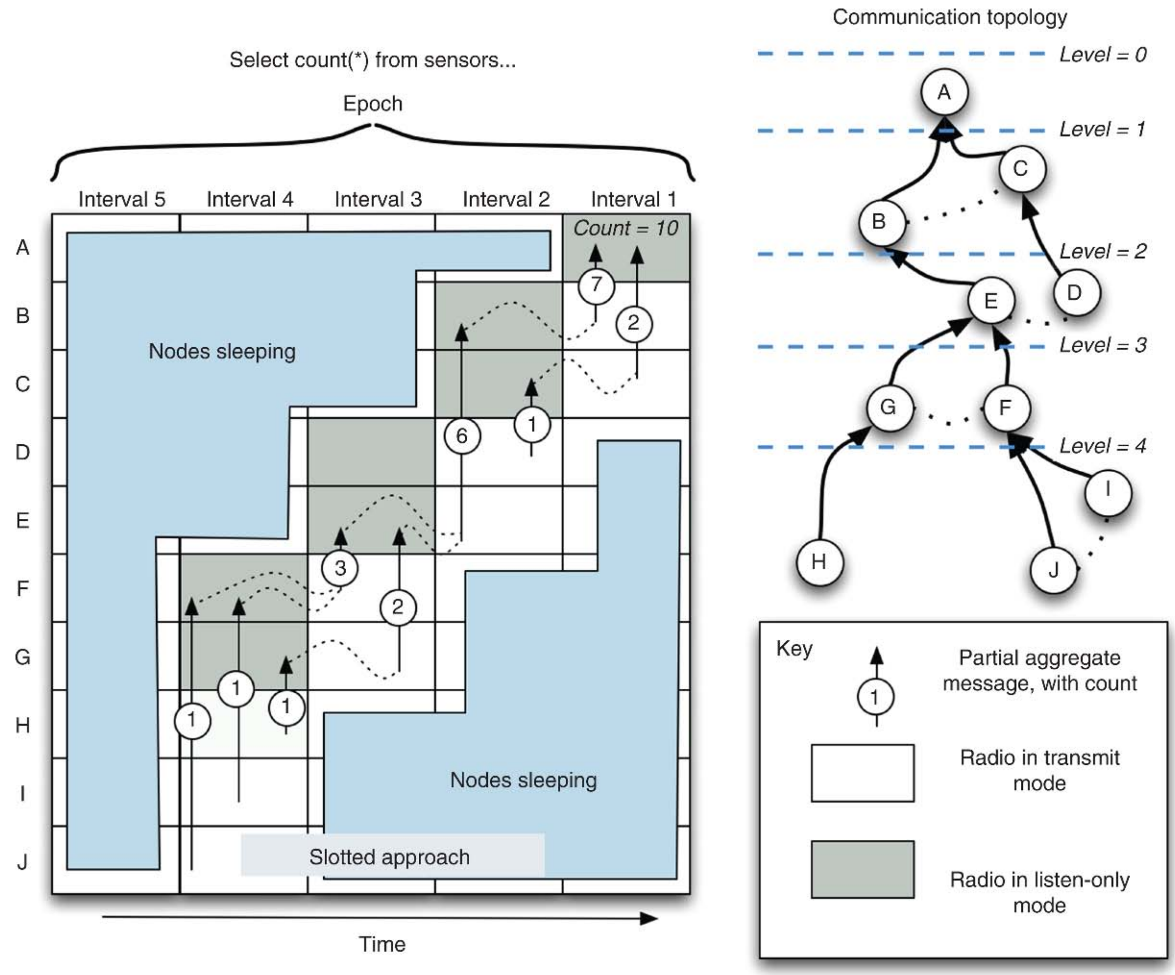
$$count = n + 1$$

By this definition, if a node has no children, it transmits the PSR <v, 1>. Finally, at the root of the network, the final average can be computed from the root's PSR as *PSR.sum/PSR.count*. To support the addition of new aggregation functions to the system, TAG includes a facility that allows programmers to define functions that initialize, merge, and compute the final value of partial state records for different aggregation functions.

Clearly, this technique reduces both the number of messages and total number of bytes that must be sent in networks of even modest size, as a parent with k nodes below it must transmit k readings without the TAG technique but only two values with the TAG approach.

For tag TAG-like protocols to work, nodes must nodes wait to receive readings from children. TAG does this by sub-dividing each sample period up into a series of time intervals corresponding to transmission slots, and assign nodes deeper in the routing tree to an earlier interval. This approach will work as long as sample periods are relatively long (on the order of half a second or so for Mica motes) and as long as it is possible to time synchronize nodes (using a technique like RBS [6]). The TinyDB system demonstrated a proof-of-concept implementation of this technique.

Figure 1 illustrates this in-network aggregation scheme for a simple `COUNT` query that reports the number of nodes in the network. In the figure, time advances from left to right, and different nodes in the communication topology are shown along the Y axis. Nodes transmit during the interval corresponding to their depth in the tree, so `H, I,` and `J` transmit first, during interval 4, because they are at level 4. Transmissions are indicated by arrows from sender to receiver, and the numbers in circles on the arrows represent `COUNT`s contained within each partial state record (which consists simply of a running count.) Readings from these three sensors are combined, by summing the running counts in the PSRs, at nodes `G` and `F`, both of



In-Network Query Processing. Figure 1. Partial state records flowing up the tree during and interval-based aggregation approach.

which transmit new partial state records during interval 3. Readings flow up the tree in this manner until they reach node A, which then computes the final count of 10. Notice that motes are idle for a significant portion of each sample period, during which time they can enter a low power sleeping state.

Supporting grouping in this setting can be done simply by tagging each partial state record with a group number (which can be derived by local evaluation of the grouping predicate at each sensor), and then treating each group as a separate aggregation operation that is independently merged and forwarded through the network.

For queries involving a HAVING clause, the TAG system proposes several optimizations for early in-network rejection of aggregates that do not satisfy the clause. The main observation is that in MIN/MAX queries it may be possible to determine that a particular group will definitely not satisfy the HAVING clause before the group reaches the root of the network.

Classes of Aggregates

One observation is that some aggregates will show more or less benefit from the TAG in-network processing techniques. In particular, if the partial state record is very compact (as in a COUNT or AVERAGE) query, there is a tremendous win to in-network aggregation. However, for aggregate functions that require access to all or most of the sensor readings before that final aggregate can be computed, the benefit is much less. For example, computing the exact median of a collection of readings requires all of the readings to be present. Hence, the TAG implementation of median offers no reduction in data transmission over a naive, centralized approach. (Greenwald and Khanna [7] propose techniques for approximate and efficient computation of order statistics like medians in sensor networks.)

There are other important semantic properties of aggregates. One that is of particular interest relates to the sensitivity of the aggregation function to duplicates. Some functions, like MAX and MIN, are insensitive to duplicates: even if a particular reading is merged together with a partial state record many times, the final value of the aggregate will not be affected. Other aggregates, like SUM, COUNT, and AVERAGE are obviously sensitive to duplicates. The TAG system exploits this property by using a directed acyclic graph that terminates at the network root rather than a simple spanning tree when computing duplicate insensitive aggregates. This substantially improves the reliability of the algorithms (using little additional energy since radios generally operate in a broadcast mode that allows multiple receivers to hear a message at no additional cost). Several researchers [3,13] have proposed methods that accurately approximate the value of duplicate sensitive aggregates using a duplicate insensitive synopsis data structure, allowing the same DAG-based network topologies to be used with a broader range of aggregates.

In-Network Processing of Joins

There have been several join algorithms proposed for specific classes of join queries in sensor networks.

Bonfils and Bonnet [2] view joins as a way to correlate or compare data between several sensors in a network. They propose a setting in which two sensors each produce a data stream, and the user wishes to apply a temporal join operation over these streams that combines readings from approximately the same time together when a predicate is satisfied. Clearly, such an operation can be done at the root of the network. They observe, however, that it can also be done at the root of any subtree in the network that has both producer nodes as a subchild. If the join is data-reducing (e.g., it filters out some readings or produces tuples that are smaller than the combined size of the tuples from both producers) then this should result in an overall reduction in network bandwidth. Rather than trying to compute the best location for such operators centrally (using global network topology information), they propose a distributed algorithm where the join operator slowly moves towards the nodes, tending to move closer to the node that is producing a larger fraction of the join data, since that will result in the greatest overall reduction in network bandwidth.

Abadi and Madden [1] propose a method called REED for in-network execution of joins that involve a static table of data from outside of the sensor network with a stream of sensor data. Such situations arise, for example, where there is a table of thresholds that dictate what data should be sent out of the network at different times of the day. The observation here is that if the table is static and the join is cardinality reducing, then paying the cost of disseminating the table once will save energy in the long run. When there is sufficient memory on each of the nodes to store the complete table, such joins can be evaluated purely locally at each node. The REED system proposes several techniques that can be used to execute queries in-network when the static table exceeds the memory available on any one node. The most effective techniques involve sending just a portion of the table to each node (e.g., the thresholds for 8 A.M. to 8 P.M.) and then sending the raw data out of the network when the needed portion is unavailable (e.g., when it is between 8 P.M. and 8 A.M.)

Key Applications

In-network processing of queries can be used in any setting where declarative queries over sensor networks are needed. In network processing techniques make selection, join, and aggregation queries substantially cheaper to run – often saving an order of magnitude in totally energy cost to process a given query. These savings mean that sensor network deployments can last longer, or provide higher sample rates for the same longevity when compared to solutions that do not use in-network processing.

Integrated DB&IR Semi-Structured Text Retrieval

Ralf Schenkel[1], Martin Theobald[2]
[1]Max-Planck Institute for Informatics, Saarbrücken, Germany
[2]Stanford University, Stanford, CA, USA

Synonyms

Using efficient database technology (DB) for effective information retrieval (IR) of semi-structured text

Definition

Integrated DB&IR semi-structured text retrieval combines IR-style scoring and ranking methods for effective search with indexing techniques and processing algorithms from the database world for efficient query evaluation.

Historical Background

Database research has traditionally focused on semi-structured documents that represent structured data with a well-defined schema and only little unstructured, textual content (aka. "data-centric" XML). Typical examples for such documents are invoices, purchase orders, or even complete bibliographies.

Early work in the field concentrated on "classical" data management problems for XML: storing XML data in relational or native XML systems, defining query languages that integrate conditions on the structure and the content of results (like SQL for relational data), efficiently processing these queries on huge collections of documents, and auxiliary structures (like structural summaries and path indexes) to support processing. The focus of this work was on space and runtime efficiency.

Foundations

When semi-structured data formats, especially XML, became popular for storing and exchanging information throughout the 1990s, an abundance of different schemas for such data was developed independently. This created a challenge for existing database query languages like the Structured Query Language (SQL), focusing on exactly matching conditions on the content and structure of results. Now, similar structured and textual information was present in different, heterogeneous formats and schemas, which was often the case when information from different sources was integrated in a single application. In reaction to this, the strict, SQL-style querying paradigm prevalent at that time evolved towards a more relaxed IR-style vague search with partial and imprecise answers. This created three main scientific problems at the intersection of the DB and IR fields: (i) the definition of query languages to specify vague constraints on the structure and/or the content of results, (ii) the definition of relevance scores to rank results by their degree of matching with the query, and (iii) efficient algorithms and auxiliary structures to quickly compute the best results to a vague query, according to the relevance score. Solutions to these problems were developed mainly with data-centric documents in mind, and with a strong focus on query languages and algorithms (thus addressing problems i and iii).

One of the first systems to retrieve semi-structured data using a relaxed query language was the *Lore* [1] system developed at Stanford University. Its object-oriented, OQL-style, query language, coined *Lorel*, provided regular path expressions and tag wildcards to express structural vagueness, as well as keyword conditions over the content of subtrees matching the path condition. However, it was still more of a database query language as it did not yet foresee any ranking for the results.

Querying Semi-Structured Data with IR Support

A large body of proposals have been made for query languages over semi-structured data that support IR-style vague conditions on structure and content. The simplest of them merely aim to extend keyword search as known from text retrieval to semi-structured data by enhancing the keyword conditions with tag names of elements that should be matched (like in the query "`author:widom`" which restricts occurrences of the keyword "`widom`" to elements with tag name "`author`"). Matches to such a query are subtrees of the document that contain matches to all (for conjunctive evaluation) or at least one (for disjunctive evaluation) keyword. An important aspect here is the selection of subtrees of the right granularity, as large subtrees (such as the complete document) would often not be specific enough. The proposed solutions usually consider some variant of lowest common ancestor (LCA) search to identify suitable root nodes of the result trees, sometimes allowing for additional path conditions from elements containing the keywords towards the root element. Hardly any of the early proposed systems consider ranking of results; instead, they focus on efficient methods to retrieve all possible matches. Note that these techniques were primarily developed for data-centric XML (such as bibliographies) and cannot easily be applied for true full-text search over semi-structured documents.

Among the most prominent approaches for keyword-based ranked retrieval of XML data is XRank [7]. It generalizes traditional link analysis algorithms such as PageRank for authority ranking of linked XML collections and conceptually treats each XML element as an interlinked node in a large element graph. Then the *element rank* of an XML element corresponds to the PageRank value computed over a mixture of containment edges, obtained from the XML tree structure, and hyperlink edges, obtained from the inter-document link structure.

Full-fledged XML query languages with rich IR models for ranked retrieval were proposed by [6,13]. *XIRQL* [6], a pioneer in the area of ranked XML retrieval, presents a path algebra based on XQL, an early ancestor of W3C's XQuery, for processing and optimizing structured queries. It combines Boolean query operators with probabilistically derived weights for ranked result output, thus transferring the probabilistic IR paradigm to the XML case. It defines data-type-specific vague predicates for similarity search over differently typed XML elements such as person names or numbers, and it introduces a notion of *index objects* that serve as anchors from which the probabilistic weights are derived (in the classic IR notion of a document). Using index objects follows the idea that only nodes of specific type and granularity in the document hierarchy should be presented as results to the end-user. Defining these index objects, however, may be strongly schema-dependent and assumes substantial knowledge about the general document structure and user intent, which typically requires their manual pre-selection from a – preferably compact – document type definition (DTD).

The *XXL* search engine [13] specifies a full-fledged, SQL-oriented query language for ranked XML IR with a high semantic expressiveness that made it stand way apart from the predominant XQL and XPath language standards at its time. For ranked result output, XXL leverages both a standard IR vector space model and an ontology-oriented similarity search for the dynamic relaxation of structure and term conditions. The principal structure of the query, however, is evaluated in a strictly Boolean manner.

More recently, various groups from both the DB and IR fields have started adding IR-style keyword conditions and full-text search to existing XML query languages. The NEXI (for Narrowed Extended XPath I) query language used in the INEX (INitiative for the Evaluation of XML Retrieval (INEX), see http://inex.is.informatik.uni-duisburg.de) benchmark series aims at a simplified and easy-to-comprehend subset of XPath, the W3C standard language for path matches within a document, with extended IR functionality. Here the `about` operator already anticipates the role of the `ftcontains` operator in the later W3C Full-Text extensions of XPath 2.0 and XQuery 1.0. TeXQuery [2], on the other hand, has been the foundation for the W3C's official Full-Text extension to XPath and XQuery, which extends these languages with the option to express actual full-text queries over XML documents. It provides many retrieval options known from text retrieval, such as phrases, weighting terms, and expanding terms using ontologies, but leaves details of the scoring model used to rank results up to the implementation.

Pioneering work in the area of vague structural matches was done by [3,11] (and refined later by [4]), who proposed relaxing queries with structural constraints to find matches in structurally similar, but not exactly matching documents. The *FlexPath* [4] algorithm integrates structure and keyword queries and regards the query structure as templates for the context of a full-text keyword search. The query structure (as well as the content conditions) can be dynamically relaxed for ranked result output according to predefined tree editing operations when matched against the structure of the XML input documents.

Query Processing for Semi-Structured Text Retrieval

Efficient evaluation and ranking of conditions on content and structure of semi-structured data has been a very fruitful and popular research area in recent years. The majority of the proposed algorithms for efficient query evaluation combine some form of precomputed auxiliary indexes (like inverted files) with top-k aware processing algorithms, most notably Fagin's family of threshold algorithms (TA), which provide threshold-based candidate pruning and early termination.

XRank uses inverted lists containing – for each term – the elements that contain the term, sorted in descending order of element rank, along with a threshold algorithm for pruning the search space. The *FlexPath* query processor uses separate index structures for storing and retrieving the structure- and content-related conditions of a path query. The *Whirlpool* system introduced by Marian et al. [10] provides a flexible architecture for processing top-k queries on XML documents *adaptively*. Whirlpool allows partial matches to the same query to follow different execution plans, and takes advantage of the top-k query model to make dynamic choices during query processing. The key features of Whirlpool are: (i) a partial match that is highly likely to end up in the top-k set is processed in a prioritized manner, and (ii) a partial match unlikely to be in the top-k set follows the cheapest plan that enables its early pruning. Whirlpool provides several adaptivity policies and also supports parallel evaluations.

TopX [12], the actual successor of XXL, focuses on a small, XPath-like subset of the XXL query language which allows for a radically different query processing architecture that outperforms XXL in terms of efficiency by a large margin. As a native top-k engine for XML, TopX also uses sorted index lists, but keeps a candidate queue in-memory and therefore is able to focus on sequential disk access and on minimizing random disk access through sophisticated index structures and judiciously scheduled index access decisions.

A large effort has been made on mapping XML to relational schemas with highly specialized index structures for efficient support of approximate query processing, including support for IR-style retrieval functionality. *PF/Tijah* [8], which is now a part of *MonetDB/XQuery*, is an example for such an XQuery engine.

Support for XML-IR in Commercial Database Systems

Meanwhile, all commercially available databases with XML support, relational or native, provide some support for IR-style content search in combination to structural queries. As the full-text extensions of XPath and XQuery have not yet been finalized, systems typically come with their own extensions of their query language that are incompatible with – and sometimes less powerful than – the W3C proposals. Frequently, existing text search components are extended for XML support and provide the standard text search features (like phrase search, proximity conditions, stemming, etc.) for searching XML elements, usually with some scoring function to rank results.

Key Applications

The techniques presented before can be applied for efficiently retrieving information from large, possibly heterogeneous collections of semi-structured data. This includes more data-centric collections like bibliographies, collections of textual documents (like abstracts or full-text of publications or books), heterogeneous data exported from different sources, and eventually documents on the Web.

Integration of Rules and Ontologies

Jan Małuszyński
Linköping University, Linköping, Sweden

Definition

The layered structure of the Semantic Web (see http://www.w3.org/2007/03/layerCake.png) adopted by the World Wide Web Consortium W3C includes, among others, the Ontology layer with the web ontology language OWL and the rule layer with the emerging Rule Interchange Format (RIF) http://www.w3.org/TR/rif-fld/ which allows rules to be translated between rule languages. The integration of rules and ontologies aims at developing techniques for interoperability between rules and ontologies in the Semantic Web. This is necessary for rule-based applications to access existing domain ontologies. In most of the proposals the integration is achieved by defining and implementing a new language which is a common extension of a given rule language and a given ontology language, enhancing the expressive power of each of the components. Alternatively, the integration of rules and ontologies may be achieved by designing from scratch one language sufficiently expressive to define both rules and ontologies as well as their combinations.

Historical Background

In the initial phase of the Semantic Web research a significant effort was devoted to defining a language for ontology modeling. In 2004, it resulted in OWL, a family of three ontology languages OWL Lite, OWL DL, and OWL Full, based on Description Logics(DL). Each of them is a subset of the next one. The first two are syntactic variants of expressive description logics with semantics given by translation to formulae of first-order logic with equality. OWL DL (hence also its subsets) is supported by several reasoners. The original intention was to define OWL as a layer on top of RDF Schema which itself can be seen as ontology language. OWL Full, designed to achieve this goal, has a non-standard semantics and is difficult to implement. On the other hand, OWL DL includes a substantial subset of RDF Schema, which is extensively used in ontology definitions.

The importance of rules for web applications is reflected by the rule layer in the Semantic Web architecture. The rules formalisms considered for this layer offer modeling primitives not expressible in OWL. Their integration with OWL would thus enhance the expressive power of the latter.

In contrast to the ontology layer, no standard has been proposed yet for the rule layer. The rule languages proposed for the Semantic Web originate mainly from *logic programming* (see e.g., [18]). In contrast to OWL DL, they usually adopt the *closed world assumption*. This means that if a fact cannot be derived from a knowledge base it is concluded to be false. In logic programming, the closed world assumption is implemented by the *negation-as-failure* rule which returns $\neg p$ on failure to prove a fact p. This is an example of *non-monotonic reasoning*, not allowed in FOL.

Designing rules languages for the Semantic Web is among the objectives of the RuleML initiative (http://www.ruleml.org/). The W3C RIF Working Group is developing a core rule language as a basis for rule interchange (for more details see http://www.w3.org/2005/rules/wiki/RIF_Working_Group).

Foundations

Shortcomings of OWL

The following examples show why OWL is not sufficient for some applications and motivate its extensions. OWL Ontologies include classes (e.g., *Person*, *Woman*, *Man*) which are unary predicates and properties (e.g., *ParentOf*, *SisterOf*) which are binary predicates, but predicates of arity larger than two are not allowed. In OWL it is not possible to formalize the statement "an aunt of a person is a sister of a parent of that person." Also, the semantics of OWL does not allow to conclude that Mary is not a sister of John if the assertion *SisterOf*(*john*,*mary*) is not a logical consequence of the ontology. This kind of reasoning based on closed world assumption is useful in some applications. Most of the rule languages proposed for the Semantic Web do not share these shortcomings.

Rule Languages for Integration

The rule languages considered in integration proposals are usually extensions of Datalog. Generally rules have a form of "if" statements, where the predecessor, called the *body* of the rule, is a Boolean condition and the successor, called the *head*, specifies a conclusion to be drawn if the condition is satisfied.

In Datalog the condition of a rule is a conjunction of zero or more atomic formulae of the form $p(t_1,...,t_n)$ where p is an n-ary predicate symbol and $t_1,...,t_n$ are constant symbols or variables. Hence they are a restricted kind of FOL *terms* (see First order logic: syntax).

The head of a rule is an atomic formula (atom). For example, the rule

$$auntOf(X, Y) \leftarrow parentOf(Z, Y), sisterOf(X, Z)$$

states that X is an aunt of Y if Z is a parent of Y and X is this parent's sister. The semantics of Datalog associates with every set of rules (rulebase) its least Herbrand model (see e.g., [18]), where each ground (i.e., variable-free) atom is associated with a truth value *true* or *false*. The least Herbrand model is represented as the set of all atoms assigned to true. These are all the ground atoms which follow from the rules interpreted as implications in FOL. For example, the least Herbrand model of the rulebase consisting of the rule above and of the facts *parentOf*(*tom*, *john*), *sister Of*(*mary*, *tom*) includes the formula *auntOf*(*mary*, *john*). On the other hand, *auntOf*(*mary*, *tom*) does not follow in this rulebase. Hence the closed world assumption, used in Datalog, will result in the conclusion $\neg auntOf(mary, tom)$. Datalog rulebases constitute a subclass of logic programs. The latter use FOL terms, not necessarily restricted to constants and variables. Proposals for the integration of rules and ontologies are mostly based on the following extensions of Datalog (which apply also to logic programs):

- *Datalog with negation*, where the body may additionally include negation-as-failure (NAF) literals of the form *not a* where *a* is an atom. Intuitively a NAF literal *not a* is considered true if it does not follow from the program that *a* is true. For example, *happy*(*john*) can be concluded from the rulebase:

  $$happy(X) \leftarrow healthy(X), \text{ } not \text{ } hungry(X)$$
  $$healthy(john) \leftarrow$$

  Two commonly accepted formalizations of this intuition are: the *well-founded semantics* and the *stable model semantics* (see the survey [2]). The well-founded semantics [22] associates with a rulebase a unique (three-valued) Herbrand model, where each ground atom is assigned one of three logical values *true*, *false* or *unknown*. The stable model semantics [9] (called also the *answer set semantics*) associates with each rulebase some (possibly zero) two-valued Herbrand models. For a large class of programs relevant in practice (so called *stratified programs*, see e.g., [2]) both semantics coincide.
- *Extended Datalog*. This extension (see e.g., *extended logic programs* in [2]) makes it possible to state explicitly negative knowledge. This is achieved by allowing negative literals of the form $\neg p$, where $\neg$ is called the *strong negation* connective, in the heads of rules as well as in the bodies. For example, the rule

  $$\neg healthy(X) \leftarrow hasFever(X)$$

  allows to draw an explicit negative conclusion. In addition, NAF literals are also allowed in the bodies.
- *Rulebases with priorities*. Datalog rulebases employing strong negation may be inconsistent, i.e., may allow to draw contradictory conclusions. For example, the rules

  $$fly(X) \leftarrow bird\ (X)$$
  $$bird(Y) \leftarrow penguin(Y)$$
  $$\neg fly(X) \leftarrow penguin(X)$$
  $$penguin(tweety) \leftarrow$$

  allow to conclude *fly*(*tweety*) and $\neg$*fly*(*tweety*). In Defeasible Logic [19] and in Courteous Logic Programs [10] a priority relation on rules can be specified for a rulebase. The contradictions in the derived conclusions are then resolved by means of the defined priorities.
- *Disjunctive Datalog* [5] (see also *disjunctive logic programs* in [2]) admits disjunction of atoms in the rule heads, and conjunction of atoms and NAF literals in the bodies, e.g.,

  $$male(X) \vee female(X) \leftarrow person(X).$$

  A commonly used semantics of Disjunctive Datalog rulebases is an extension of the answer set semantics.

The rule languages are supported by implementations which make it possible to query and/or to construct the models of rulebases.

Approaches to Integration

The integration of a given rule language with a given ontology language is usually achieved by defining a common extension of both, to be called the integrated language. Alternatively, one can adopt an existing knowledge representation language expressive enough to represent rules and ontologies. As OWL is a standard ontology language the ontology languages considered in integration proposals are usually its subsets. The approaches can be classified by the degree of the integration of rules and ontologies achieved in the integrated language.

- *Homogeneous Integration*. The integrated language makes no distinction between the rule predicates and the ontology predicates. It includes the original rule language and the original ontology language as sublanguages. The integration is to be *faithful* in the sense that the sublanguages should have the same semantics as the respective original languages. The homogeneous integration is difficult to achieve since ontology languages are usually based on FOL and rule languages have different kind of semantics. Examples of the homogeneous integration include:
  - *DLP (Description Logic Programs)* [12], which is a language obtained by intersection of a Description Logic with Datalog rules interpreted as FOL implications. DLP has a limited

  expressive power, but a DLP ontology can be compiled into rules and easily integrated into a rulebase of a more expressive rule language. For example *Sweet Rules* http://sweetrules.projects.semwebcentral.org/ combine DLP and Datalog with strong negation and priorities. The technique of compiling ontologies to rules is also used in DR-Prolog [1] based on Defeasible Logic.
  - *F-logic*, extending classical predicate calculus with the concepts of objects, classes, and types. It is expressive enough to represent ontologies, rules and their combinations [13].
  - *SWRL (Semantic Web Rule Language)* http://www.w3.org/Submission/SWRL/, extending OWL DL with rules interpreted as FOL implications. Thus, SWRL is based on FOL and does not offer non-monotonic features, such as negation-as-failure. A so-called DL-safe subset [17] of SWRL is supported by KAON2 system http://kaon2.semanticweb.org which also offers a support for a restricted subset of F-logic.
  - *Hybrid MKNF Knowledge Bases* [16], taking a modal logic as a basis of faithful integration of Description Logic with Disjunctive Datalog under the answer set semantics. A variant of this approach considering nondisjunctive hybrid MKNF knowledge bases under well-founded semantics is presented in [14].
  - *Quantified Equilibrium Logic*, considered in [3] as a unified framework which embraces classical logic as well as disjunctive logic programs, thus providing a foundation for the integration of rules and ontologies.
- *Heterogeneous Integration.* In this approach, the distinction between the rule predicates and the ontology predicates is preserved in the integrated language. The integration of rules and ontologies is achieved by allowing the ontology predicates in the rules of the integrated language. Assume, for example, that an ontology classifies courses as project courses and lecture courses.

$$\mathit{Project} \sqcup \mathit{Lecture} = \mathit{Course}$$

It also includes assertions like $\mathit{Lecture}(cs05)$, $\mathit{Project}(cs21)$ or $\mathit{Course}(cs32)$ (e.g., for courses including lectures and projects). The assertions indicate offered courses. A person is considered a student if he/she is enrolled in an offered lecture or project. This can be expressed by the following rules, using the ontology predicates

$$\begin{aligned} &\mathit{student}(X) \leftarrow \mathit{enrolled}(X,Y),\ \mathit{Lecture}(Y) \\ &\mathit{student}(X) \leftarrow \mathit{enrolled}(X,Y),\ \mathit{Project}(Y) \end{aligned}$$

In addition the rulebase includes enrollment facts, e.g., $\mathit{enrolled}(\mathit{joe}, cs32)$. The extended language allows thus to define ontologies using the constructs of the ontology language and the rulebases with rules referring to the ontologies. An extended rulebase together with an ontology is called a *hybrid knowledge base*. In the heterogeneous approaches implementations are often based on *hybrid reasoning principle*, where a reasoner of the ontology language is interfaced with a reasoner of the rule language to reason in the integrated language.

Two kinds of heterogeneous approaches can be distinguished:

1. *Loose coupling.* In this approach the semantics of hybrid knowledge bases is based on a transformation which eliminates ontology queries from ground extended rules by querying the underlying ontology. A ground set of extended rules is thus reduced to a set of rules without ontology predicates in the following way. If the answer to a ground ontology query in a rule body is positive, the query is removed from the rule, otherwise the rule is removed from the set. The loose coupling approach applied to the example above does not allow to conclude that Joe is a student. This is because neither $\mathit{Lecture}(cs32)$ nor $\mathit{Project}(cs32)$ can be derived from the ontology. Examples of loose coupling include:
   - *dl-programs* [6], combining (disjunctive) Datalog with negation under the answer set semantics with OWL DL. So called DL-queries, querying the ontology, are allowed in rule bodies. They may also refer to a variant of the ontology, where the set of its assertions is modified by the DL-query. This enables bi-directional flow of information between rules and ontologies. A variant of the language based on the well-founded semantics is presented in [7].
   - *TRIPLE* [21], a rule language with the syntax inspired by F-logic. It admits queries to the ontology in rule bodies.
   - *SWI Prolog* http://www.swi-prolog.org/, a logic programming system with a Semantic Web library

which makes it possible to invoke RDF Schema and OWL reasoners from Prolog programs.

2. *Tight integration.* In this approach the semantics of hybrid knowledge bases is defined by combining the model-theoretic semantics of the original rule language with the FOL semantics of the ontology language. For example, tight integration of Datalog (without negation) with a Description Logic can be achieved within FOL by interpreting Datalog rules as FOL implications. In this semantics $student(joe)$ is a logical consequence of the example hybrid knowledge base. As $Course(cs32)$ is an assertion of the ontology, it follows by the axiom $Project \sqcup Lecture = Course$ that in any FOL model of the ontology $Project(cs32)$ or $Lecture(cs32)$ is true. As $enrolled(joe, cs32)$ is true in every model, so the premises of at least one of the implications

$$student(joe) \leftarrow enrolled(joe, cs32), Lecture(cs32)$$
$$student(joe) \leftarrow enrolled(joe, cs32), Project(cs32)$$

   must be true in any model. Hence $student(joe)$ is concluded. Examples of tight integration include:
   - *CARIN* [15], a classical work on integrating Datalog with a family of Description Logics under the FOL semantics.
   - $\mathcal{DL}+log$ [20], integrating Disjunctive Datalog under the answer set semantics with OWL DL. For each FOL model of the ontology the rules of the knowledge base are reduced to rules of Disjunctive Datalog, with stable models defined by the answer set semantics.
   - *Hybrid Rules* [4], integrating logic programs under well-founded semantics with OWL. For each FOL model of the ontology the rules of the knowledge base are reduced to a logic program with the model defined by the well-founded semantics.

The theoretical foundations developed by studying integration of ontologies with variants of Datalog provide a basis for further extensions. This includes dealing with uncertain and inconsistent knowledge, and using integrated Datalog-based languages as condition languages for ECA-Rules.

Key Applications

The integration of rules and ontologies is a relatively new research topic, focused so far on developing tools and prototypes. Key applications include semantic data integration, ontology-based web search and semantic recommendation systems. Industrial applications of this kind are discussed in the video lecture [8]. The Ontobroker system referred therein is based on F-logic. Another field of potential key applications is e-business as discussed in the tutorial video [11], with focus on Sweet Rules.

URL to Code

The following systems integrating rules and ontologies can be downloaded:

Definition

The term Intelligent Storage System is a general term used to describe a storage system which has the capability of fully or partially realizing functions that used to be or are usually implemented on host computers.

Historical Background

The idea behind Intelligent Storage Systems may have its origin in the early researches on database machines. Similar ideas have continued to be studied in the academic communities to date, and they have recently been partially applied in commercial storage systems.

Foundations

The basic ideas of implementing full or partial application code on controller processors of disk drives may be traced back to the database machines which were actively studied in the 1970s and 1980s. The database machine was an approach of special hardware solutions. The early researchers focused on the development of filter processors, which could do selection operations closely to disk drives so as to obtain strong performance benefits. Several prototypes such as CASSM (University of Florida) [11] and RAP (Ohio University) [7] were implemented in the 1970s. Filter processors were at times coupled with a front-end database server. Such ideas called backend processors [3] were attempted in the industry. When it came to the 1980s, with new algorithms such as hash-based joins, researchers proposed new database machines that pursued intensive parallel processing such as GRACE (The University of Tokyo) [6] and GAMMA (University of Wisconsin) [4]. Parallel machines that were specially designed for database processing were released and then resulted in commercial success. However, the solution of utilizing dedicated hardware lost its unique advantage by the 1990s, since powerful general-purpose machines became easily available. Major database vendors shifted to software-level solutions which used generic hardware instead.

Intelligent Storage Systems were again brought under the spotlight in the late 1990s. Storage network technologies such as Fibre Channel launched in the market. Then enterprise systems began to deploy the storage-centric system architecture, where storage systems could be designed and managed independently from host computers at the infrastructure level. Naturally, sophisticated new functions such as virtualization were being incorporated into storage processors and such solutions were widely accepted. Around the same time, Active Storage [8], Intelligent Disks [5] and Active Disks [1] were published in the academia in 1998. These were trying to exploit the capability of disk processors for data intensive applications such as ad-hoc query processing and image processing. The attempt of active storage looked similar to the database machine, but they carefully discussed software frameworks for running application code on disk processors.

After the twenty-first century began, storage networking has been practiced in many systems and storage resources are being consolidated more. A variety of new functions are being implemented in commercial storage systems. Functions that used to be run on host computers such as volume copy, remote replication and snapshot generation are usually executed in storage processors. Although only limited types of low-level applications are currently implemented in storage systems, the application domain is gradually being widened by the active research and development.

The motivation behind database machines and active storage was mainly in significant performance improvement. By processing data more closely to disk platters, they tried to efficiently exploit the limited bandwidth between main memory and storage systems. This "storage wall" is seen even in recent enterprise systems and thus such solutions are still beneficial. At the same time, in the light of the complexity of recent enterprise systems, Intelligent Storage Systems may have another substantial benefit. That is, storage-level implementation could improve the function-level isolation between components. This would be very helpful for system administrators to design and manage the complicated system.

Discussion on interface standards is a crucial point for realizing Intelligent Storage Systems. OSD (Object Storage Device) [2] has evolved out of the NASD (Network-Attached Secure Disk) project which started in Carnegie Mellon University in 1995. In contrast to traditional storage devices, where the storage space is represented as an array of fixed-size blocks, OSD works as a container of objects, their attributes and their metadata. Specifically, OSD can be seen as a storage device in which lower layers of file systems are implemented. The interface protocol of OSD, designed as an extension of SCSI, has been standardized as ANSI T10 SCSI OSD. Several NAS products and distributed files systems have already supported OSDs as backend storage devices. SNIA, a leading industry association of storage networks, has also promoted standardization. SMI-S (Storage Management Initiative-Specification) [9] is the standard protocol for storage management, which improves the interoperability between different storage devices, switches and management applications of different manufacturers. SNIA has developed and maintained SMI-S and has provided vendors with certification programs. XAM (eXtensible Access Method) [10] is another task operated by SNIA. XAM, a new suite of APIs, would provide an abstraction layer between storage devices which store fixed contents and management applications which access those contents.

Key Applications

Recent commercial storage systems have deployed storage-side implementation of simple functions such as data conversion between main frames and open systems, third-party copy, remote replication and snapshot generation. These were so far implemented only in top-end storage systems, but they are also being implemented in mid-range products and sometimes even in entry-level products.

Interface

Patrick Eugster
Purdue University, West Lafayette, IN, USA

Definition

An interface describes the functionalities exported by an entity such as a software module. These functionalities typically consist in named operations with signatures describing potential arguments and return values, but interfaces may also include the definitions of data types, constants, exceptions, or even describe semantics.

Interfaces shield the internals of corresponding software modules from the outside, providing several benefits. Interfaces provide abstraction, in the sense that the internals of modules may evolve while other modules can still rely on the same functionalities (encapsulation). Safety and security are promoted by interfaces as these define single access points to respective software modules.

In object-oriented programming, software modules often coincide with classes, which also describe data types implicitly. In the case of such a class, an interface is thus roughly made up of the methods exported by the class. Mostly, interfaces are then defined implicitly by the classes as such sets of exported methods, but languages such as Java provide programmers the possibility of declaring interfaces as first class citizens which are then explicitly implemented by classes.

When objects are physically distributed, they can offer specific remote interfaces facilitating invocations potentially coming from remote hosts. Remote interfaces span typically only a subset of all the methods exported by objects.

A set of interfaces which describe an entire software component or framework is more commonly referred to as an application programming interface (API).

Historical Background

The concept of interface has partly evolved out of the *header files* used with the C programming language. In contrast to several more recent programming languages providing notions of interfaces integrated with the language semantics, those header files served mainly as preprocessing feature.

Interfaces were greatly popularized by programming languages based on *modules*, such as Pascal, Modula-2, or Ada. A first step towards a more rigorous underpinning of modules and measures for a good decomposition of software into such modules was provided by Parnas [8]. Parnas' work primarily aimed at achieving a clean separation of duties in software components and an effective decomposition into modules. As a dual of this problem, the design process for interfaces to modules has also been strongly guided by Parnas' seminal work, coining the term "well-defined interfaces." The main driving force behind the quest for clear-cut interfaces are safety/security concerns aiming at providing well-defined entry points to given modules in the form of interfaces.

The term *interface* itself thus emerged from the software engineering community. Ever since, programming languages have been strongly influenced by this notion, in particular because there is a strong overlapping between the notions of interface and *type* (*data type*). This culminates in object-oriented programming, where data types and modules are largely unified through classes representing the units for both data abstraction and behavior, and thus a type defines the interface to its instances, even if only implicitly (cf. [2]).

More recently, modeling languages such as the Unified Modeling Language (UML) have also introduced interfaces aside classes as purely descriptive means of capturing functionalities of objects.

Foundations

Interfaces describe the functionalities exported by an entity such as a software module. These functionalities typically consist in named operations with signatures describing potential arguments and return values, but interfaces may also include the definitions of data types, constants, exceptions, or even more information.

Interfaces and Classes

Most object-oriented programming languages are class-based, meaning that classes present the main unit of decomposition and as such can be viewed as modules. Interfaces of such classes encompass the functionalities exported by these classes – typically a set of methods which are accessible to other classes. In many integrated development environments (IDEs), there is the possibility to automatically "extract" such an interface view from a class, by only summarizing the names and signatures of its exported features.

Interfaces can be in that sense seen as abstract types, as opposed to classes which may *implicitly* describe interfaces, but primarily describe the implementation of those. Current programming languages such as Java provide interfaces as a first class construct aside classes. Declaring an `interface` leads to defining an abstract type. In this case, an object can provide several interfaces if its class implements several instances; the *conceptual* interface of the instance(s) is then made up of the union of these interfaces.

When collapsed with types, interfaces reap the benefits of the Liskov substitution principle [6], which states rules under which a type `T1` can be considered to be compliant with another type `T2`. Instances of `T1` can then be used whenever entities of type `T2` are expected. Transposed to interfaces this means in short that the interface of the latter type subsumes the interface of the former type: any module that builds on the former interface can be presented with an instance of the latter interface.

Protection

Conceptual interfaces are sometimes decomposed according to potential beholders of references to the corresponding entities. More precisely, different objects, or more generally different modules, can have access to the same entities through individual interfaces. By supporting different visibility rules (e.g., `private`, `public`, `protected`), possibly at the method level, programming languages provide the ability to restrict interfaces (or parts of such interfaces) to families of classes for example based on containment criteria (e.g., packages). In C++ for instance, a class `C1` can be explicitly declared to be a `friend` of another class `C2`, providing instances of `C1` access to certain methods of class `C2` which are otherwise unreachable. Introducing varied levels of protection yields different (accessible) interfaces for different parties.

For languages with weaker inherent support for interfaces and protection levels, design patterns can be used to enforce constraints. The *read-only interface* pattern for instance is used to explicitly define an interface through which entities can be manipulated without modifications to their state.

Remote Interfaces

In remote method invocations, *remote interfaces* are used to explicitly offer methods for invocation from remote hosts. Remote interfaces usually span only a subset of the methods provided by a class. The remaining methods however are limited to invocations within the same address space. In that sense, remote interfaces introduce a specific level of protection.

Remote interfaces commonly enjoy descriptions in a dedicated specification language, when interoperability is desired. Such specification languages allow the description of remote interfaces in an interoperable format, and subsequent generation of language-specific versions with corresponding compilers based on well-defined mappings to target languages. Examples are the *interface definition language* (IDL) used in the Common Object Request Broker Architecture (CORBA), or more recently the *web service description language* (WSDL). An earlier incarnation is the *external data representation* (XDR) introduced with the remote procedure call (RPC) protocol. Compilation of such interfaces commonly goes hand in hand with the generation of proxes or stubs which take care of transforming method invocation arguments and return values to and from an interoperable format such as XDR.

Contents

Besides methods, interfaces can also include constants, exceptions, and sometimes even fields, though exporting fields is sometimes viewed as going against the principle of encapsulation underlying object-oriented programming. In the Eiffel programming language, methods are unified with field (accesses), implicitly yielding access methods for fields. Eiffel is also the most popular language with further *semantic* descriptions in the interfaces, consisting in *contracts* in the form of pre- and postconditions for methods, as well as invariants at the class level. These were introduced as part of the original definition of *abstract data type* [6], and have given rise to a design paradigm called *design by contract* (DbC) [7].

In the case of Eiffel, its IDE also allows the programmer to view the interface of a given class, in this case including contracts. Contracts have a descriptive flavor in the sense that they augment interfaces and thus represent a specification feature, but also have an implementation flavor since they may refer to fields, and can be monitored at runtime as in Eiffel. Spec# follows the Eiffel approach by providing first class support, while the Java Modeling Language (JML) promotes annotations, which can be viewed as optional semantic interface descriptions, to which programmers only must adhere when making use of specific tools (e.g., for compilation).

Besides contracts, other types of information have been considered for augmenting interfaces. *Typestates* [9] capture abstract states associated with instances of a given type and their relationship with exported methods, thus adding state information to interfaces. *Interface automata* [4] focus directly on the *order* in which functionalities exposed by a given interface can be triggered. Such sequences are sometimes also colloquially referred to as *protocols*. *Resource interfaces* [3] are another example of augmented interfaces, describing namely the physical resources necessary for a given module to be able to function properly.

Components

In software engineering, in particular in the *component* view, interfaces may similarly contain far more information than types. A component usually refers to a subsystem of its own consisting in several modules, whose individual interfaces make up the conceptual interface. The interface of a component can for instance also define what kind of interface the component itself relies upon (while this is usually somewhat embedded in object-oriented code).

When several interfaces are bundled either in the context of a component, or a framework, the term *application programming interface* (API) is commonly employed. The different levels of technical protection for functionalities offered at the programming language level are in the case of APIs often complemented by simply limiting the disclosure of APIs to selected corporate players only.

Key Applications

There are various reasons for further studying the domain of interfaces:

- Complexity. With the increasing complexity of computer systems, the problem of "efficiently" decomposing/composing software is given more and more attention. Abstraction and encapsulation are key desired properties. In software engineering terms, one attempts to achieve decoupling and increase modularity (For a precise definition of modularity see [8]). The art of decomposing software is also partly captured by the study of *software architectures*. There is a clear dependency between the decomposition of software into modules and the discipline of designing interfaces between modules/components to respect modularity and achieve low coupling.
- Reuse and maintainability. These are also desired features of any software package. With good design and modularity reflected in rich interfaces, code namely also becomes easier to reuse and maintain.
- Safety. Safety has become a major driving force for programming language and software engineering research. Ensuring that interaction between (sub-)modules takes place in a safe manner helps avoiding runtime errors, and is supported by clear-cut and precise interfaces. In the predominant settings with static typing, the goal is to ensure that once successfully compiled, a module contains no calls violating interfaces.
- Security. Access rights and confinement can be expressed in interfaces as mentioned above. This becomes particularly visible in distributed settings, i.e., for achieving clean interfaces between entities running on distinct physical hosts.
- Interoperability. Not all software is written in the same programming language. With interfaces being described in "neutral" generic languages interoperability can be achieved. Examples are clearly provided by *interface definition languages* (IDLs) for second class distributed object packages such as DCE, CORBA, or DCOM. The idea of interoperability has more recently flown into **service-oriented architectures** (SOA) in general and **Web Services** in particular.

Future Directions

Motivated by the above, there is quite some incentive to further investigate interfaces. Various aspects offer themselves for additional efforts:

- *Evolution*. Low coupling and modularity definitely support evolution of components, but as mentioned above, only in terms of the internals of components. Evolution of components sometimes also necessitates evolution of their interfaces, which can however break any existing code relying on these. Evolution of interfaces is thus an important area to investigate. In programming language terms, this leads to the problem of extending and changing types, which can be partly addressed by introducing versioning, and by assisting the programmer in the adaptation of code after changes to interfaces it relies upon.
- *Information*. Interfaces describe contracts between modules, i.e., functionalities provided by a module and sometimes also requirements for providing these functionalities. So far, interfaces are mostly described through functional aspects of the modules which in programming language terms boils down to syntactic and typing information. Design by contract (DbC) augments these interfaces with semantics, but further information might be of relevance, which is not even directly materialized in the implementation of modules, as illustrated by resource interfaces [3].
- *Discovery*. Interfaces and extended interfaces can also be obtained by *mining* existing modules, e.g., [1]. This is particularly appealing when dealing with legacy code, which might have been described in a programming language with weak inherent support for interface descriptions. Discovery of interfaces has also gained more interest recently in the realm of *aspect-oriented programming* (AOP), whenever aspects advise code *obliviously*, i.e., without knowledge or consent from the main code. In the AOP philosophy aspects attempt to achieve a separation of duty by implementing *crosscutting concerns* in aspects alike modules, separately from the base code. Without clean interfaces for the interaction between base code and aspects however, reasoning about an entire software becomes hard (cf. [5]).

  Discovery can also be understood in the sense of discovering services at runtime. Especially SOAs provide strong support for finding services based on their functionalities, often described as some abstract interfaces. UDDI is an example of a lookup service that supports queries based on a specific notion of interface.

Interface Engines in Healthcare

Transformation engines; Mapping engines; Messaging engines; Service buses

Definition

A computer application that supports the transformation of the syntactic and semantic structures in communication content during transmission from a sending system to receiving system(s), ensuring reliable delivery of the communication and minimizing information loss and semantic shift during the communication.

Historical Background

Before the invention of application programming interfaces (API) and CORBA Interface Definition Language (IDL) files, "interface" was the term used to describe the electronic communication of information between two computers [1]. Today, the term "interface" also refers to communications between layers of software and even between software objects within a software layer. A modern example of an interface is a Web Service Definition Language (WSDL) file in XML format (www.w3.org).

Within early interfaces, the syntax of the communication content, i.e., linear arrangement of characters in the communication exported by the sending system, often could NOT be imported directly by the receiving system. Consequently, transformation procedures were employed to rearrange the characters in the communication into a linear structure that COULD be imported by the receiving system. In the same manner, if terms used by the sending systems could not be imported into the receiving system, a substitution of terms that could be imported by the receiving system was also applied to the communication content.

In order to reduce the burden of computing these transformations on the slower computers of the past, the execution of these transformation procedures was transferred to a separate computer that was placed in-between the sending and receiving computers. As time passed, the ability of these "interface systems" to support better and easier transformation authoring and high "transaction" or messaging volumes, these systems became known in the 1990s as "interface engines," a new kind of software application in themselves [4,5].

As the language of the industry evolved, the communications between computers became known as "messages"; the transformation of the syntactic and semantic content became known as "mapping" from sender to receiver; and techniques for ensuring reliable receipt of communications between a sending and receiving computer became known as "reliable delivery protocols" or "reliable messaging protocols."

However, despite the increasing sophistication of the transformation tools, the industry soon discovered that there was a limited ability to ensure that all the information sent by the sending system could be imported by the receiving system [7]. Information loss and shift in meaning of the communication content was observed when evaluating the information content of the sending and receiving systems after the communication occurred. In many ways, the result was similar to the garbling of sentences that occurs in the children's games that test the ability of children sitting in a ring to sequentially whisper a sentence into the ear of the next child. The child who initiates the sentence rarely gets the same sentence whispered back by the last child.

As a consequence, organizations that developed standards in support of many other industries began to support standardized messaging structures for the computer industry, including message standards in the healthcare industry. These standards included both the arrangement of "fields" and special characters in the messages and the sets of terms used to populate these fields. In healthcare, the messages most widely used internationally by the year 2000 were authored by a specialized healthcare standards organization, the Health Level 7 (HL7) standards development organization (www.hl7.org), which focused on ISO Level 7 transaction protocols [1].

These messaging standards reduced the cost of each messaging "interface" between computers by as much as tenfold from the 1980s to the turn of the century. However, the implementation cost of these messaging interfaces (HL7 version 2.x messages) continued to retail at over $20,000 per interface (in addition to the cost of the interface engine), and many hospitals required over one hundred messaging interfaces.

By the early 1990s, planners in HL7 began exploring model-based development methods and new message authoring techniques that would both improve the quality and reduce the cost of communications between computer systems in healthcare. The improvement in quality of communication refers to the preservation of information content and semantic meaning of the communication or what is known as "semantic interoperability." The reduction in cost comes from decreasing the number of choices allowed to developers who "interpret" the standards into actual application code. The result of this planning effort was the publication of the HL7 Reference Information Model (RIM) [6] and RIM-derived messages, electronic documents [2], and web services.

Parallel efforts in other industries as well as the growth of Internet communications between computer systems have caused rapid evolution in both the kinds of communications the healthcare industry wishes to utilize and the techniques for electronically communicating between computer systems.

As the result of many initiatives across industries, there have been great strides in communication methods that no longer utilize the traditional, preconfigured point-to-point HL7 interface engines. The concept of a "bus" was borrowed from the internal computer bus that supports the physical "plug & play" communication of multiple physical components (such as hard drives) within a computer. This concept of a "bus" was abstracted to a "service bus" located within a data center that allows dynamic selection of multiple web services in a service-oriented architecture. As a result, interface communication in a data center no longer needs to rely on a "point-to-point" pre-configured solution. Rather, in a service bus, a "service directory" may be used to dynamically select the method of communication and the endpoint(s) of communication desired. Increasingly, these new kinds of "messaging engines" or "enterprise service buses" are being utilized in healthcare data centers. Finally, "healthcare service bus" is a term used to describe a "virtual service bus" or a system of "federated enterprise service buses" where dynamic web services are supported between individual enterprises and enable healthcare communications across the wider community (www.openhealthtools.org).

Although many people believe that legacy computer systems and traditional, preconfigured point-to-point messaging methods will continue to be used for many years in healthcare, the consequence of new communication techniques used by many other industries is that communication methods in healthcare will also evolve. The role of the traditional data-center-based, HL7 2.x interface engine will gradually be reduced in favor of web-service-based communications that support transformation and routing across healthcare communities.

Foundations

The scientific study of messaging concepts begins with narrow, reductionist models, e.g., the physics of electrons and gravitational bonds communicating between atoms and within molecules. These concepts are studied within incrementally more complex systems in chemistry labs, organic chemistry labs, genetic and hormonal communications, electronic systems and neural communications, human communication, and finally, in computer systems that support human communication.

The study of messaging was enhanced by the development of communication models, many of which include the concept of state machines. Communication may be defined as "transferring awareness of a change of state in the model of the sending system to the receiving system(s)." This communication may be as simple as informing the receiver of the increase in the state of ionic attraction that occurs when an atom has gained or lost an electron or as complex as informing a second organization that the state of a hospital now includes a patient ready for placement in a nursing home.

The concept of a "state machine" was introduced in the mathematical modeling and electronics literature. A "state machine" was a systems model developed in the 1950s and 1960s to describe state transitions in sequential circuits [3]. Generally, finite state machines describe a model wherein a "state" describes the static "snapshot" or configuration of elements within a modeled system. The visual image generated by the use of the term "machine" is that of a machine moving while an observer takes sequential snapshots, each of which illustrates the machine in different configurations or states. A "process" is the change in configuration or transformation of elements in the state machine, i.e., "state transition." "Event-driven state machines" highlight the trigger events used in event driven programming and messaging models; one visualizes an operator pushing buttons on the machine. And communication can then be described as the transferring of awareness between two or more systems, specifically, the awareness of the state transition of the sending system. One visualizes sending a picture of the new state of the machine, or perhaps a picture of the new state and a picture of the former state, as soon as the operator pushes the button on the machine.

A trigger event in healthcare is often a clinical observation result on a patient, a clinical order, or other clinical event. Observation results by clinicians characterize the clinical state of a patient during a specific time period. Changes in the clinical state of the patient are tracked by obtaining sequential observation results. When a transition occurs in the clinical state of a patient, the change may trigger a message alerting a physician. A new clinical order by the physician may trigger a message to the lab requesting a new lab test.

In the same manner, changes in the clinical state of the patient may be recorded in an electronic medical record system. The resulting state transition in the electronic medical record system may trigger a message to another electronic system. As illustrated, state transitions in electronic medical record systems are closely related to the clinical state changes in the patient and the awareness of care providers about the clinical state of the patient.

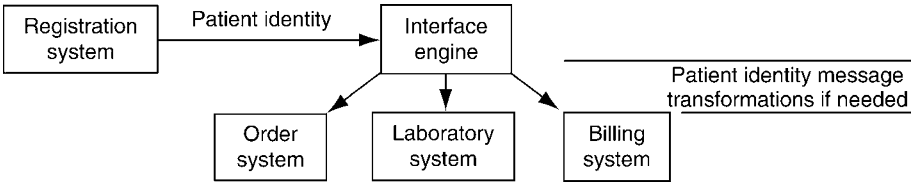
Finally, the study of the science of state changes, the communication of state changes, and the relationship of state changes to electronic communications in healthcare has been applied to more sophisticated techniques for dynamically orchestrating these communications into optimized process flows. Web service orchestrators have evolved as components of data integration engines such as service buses in healthcare. And optimized patient care processes are increasingly implemented with web service orchestrated electronic health record activities (www.infoway-inforoute.ca).

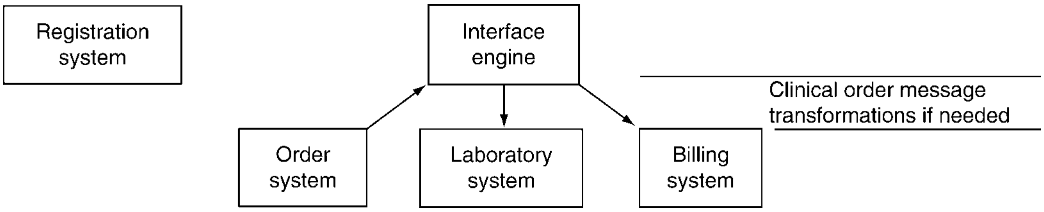
Key Applications

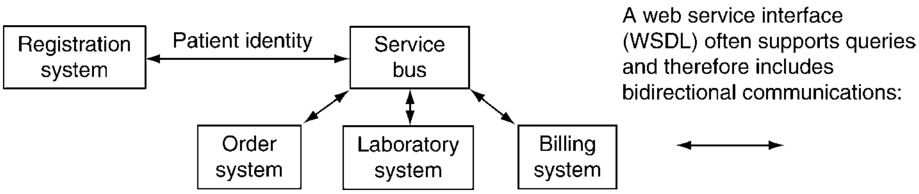
The most common first step in the installation of Hospital Information Systems (HIS) is to establish an identity system for enrolling patients as they enter the hospital, commonly referred to as a "registration system." When the registration system records a new patient identity or updates an older patient's demographic information, data about the patient is communicated via messages to other systems, such as order management systems, laboratory systems, and billing systems. This data includes a patient identifier and at least the first name, last name, date-of-birth, gender, and address. Traditionally, point-to-point interfaces are pre-configured within an interface engine from the registration system to the other systems, allowing broadcast of the identity of the new patient or updated demographic information to the other systems. If needed by any of the receiving systems, transformations may be applied to the syntax and semantics of the message that is outbound from the interface engine to each specific receiving system:

Later, if a clinical order is generated within the Order Management System for a patient, a subset of the fields in the Patient Identity message will be included in the clinical order and sent to the laboratory system and billing system via the interface engine. Again, transformations of the message may occur if needed by the receiving systems:

What is illustrated in the two figures above is that in a traditional interface engine scenario, the Registration System is never queried for additional Patient Identity information. Therefore, Patient Identity information is redundantly stored within the other systems. However, as populations managed by systems grow,







Registration system
Patient identity
Service bus
A web service interface (WSDL) often supports queries and therefore includes bidirectional communications:
Order system
Laboratory system
Billing system

the inefficiency of redundantly storing Patient Identity information grows as well. As a consequence, larger healthcare systems, such as regional or community-sized systems, are evolving towards a "just in time" communication of Patient Identity. A "service bus" replaces the Interface Engine, and the Registration System is dynamically queried as needed for additional Patient Identity information:

Interoperability in Data Warehouses

Riccardo Torlone
University of Rome, Rome, Italy

Synonyms

Data warehouse integration

Definition

The term refers to the ability of combining the content of two or more heterogeneous data warehouses, for the purpose of cross-analysis. This need emerges in a variety of practical situations. For instance, when different designers of a large company develop their data marts independently, or when different organizations involved in the same project need to integrate their data warehouses.

Data Warehouse interoperability is a special case of the general problem of database integration, but it can be tackled in a more systematic way because data warehouses are structured in a rather uniform way, along the widely accepted concepts of dimension and fact. As it happens in the general case, different degrees of interoperability can be pursued by adopting standards and/or by applying reconciliation techniques, likely specific for this context.

The problem is becoming increasingly relevant with the spreading of federated architectures. Nevertheless, it has been the focus of a few systematic works and numerous open problems remain to be solved.

Historical Background

In spite of its relevance, the problem of data warehouse integration has received little attention so far. Conversely, the general problem of databases integration has been studied in the literature extensively and several aspects, both at scheme and instance level, have been deeply investigated, such as the automatic matching of terms and the resolution of structural conflicts (see [8,12] for surveys on these topics).

In the specific context of data warehouses, Kimball [7] has identified the problem for the first time: he has investigated the integration of heterogeneous dimensions in a scenario of data warehouse design and has introduced the informal notions of dimension *conformity*. Intuitively, two dimensions are conformed if their share some information in a consistent way. This is an important requirement in *drill-across queries*, which are basically joins of different facts over common dimensions. The notion of conformity has been formalized and extended by Cabibbo and Torlone in the context of data mart integration [4] under the name of dimension *compatibility*: they have demonstrated that this property gives the ability to perform correct drill-across queries over heterogeneous data marts.

An issue related to the integration of data warehouses, which has been studied in the context of statistical databases, is the *derivability* of summary data. This notion has been defined by Sato [14] as the problem of deciding whether a summary data (which is, in a statistical database, the counterpart of a fact table) can be inferred from another summary data aggregated in a different way. The concept has been extended by Malvestuto [9], by considering the case in which the source is composed by several heterogeneous data sets: he proposes an algebraic approach to this problem and provides some necessary and sufficient conditions of derivability. Unfortunately, statistical databases have some similarity with multidimensional databases, but also some important diversities: this makes the application of these approaches to data warehouses not easy.

Some related work has been done on the problem of integrating a data warehouse with external data stored in XML [6] and in object-oriented [11] format, but just a few works have been devoted to the specific problem of the interoperability between heterogeneous data warehouses. They will be discussed in the following section.

While current commercial tools do not provide a complete support for data warehouse interoperability, they offer facilities that can be very useful in this framework, such as metadata import/export (using XML) and standardized ways to represent data (using a multidimensional model).

Foundations

Since data warehouse interoperability can be considered a special case of the problem of database integration, general data reconciliation techniques can be often used. For instance, methods for the automatic matching of terms or for the resolution of structural conflicts. In addition, it is possible to take advantage on the fact that, in this context, the data sources always have a multidimensional structure. Therefore, the problem can be addressed by focusing on the reconciliation of heterogeneous dimensions and facts. Following this observation, the section discusses: standards that can be adopted to support data warehouse interoperability, conflicts that can arise in this context, and methodologies that can be used to perform the integration.

Standards

An important support for interoperability can be provided by the adoption of standards. Initially, two industry standards have been proposed by multi-vendor organizations for data warehouses: the Open Information Model (OIM) developed by the Meta Data

Coalition (MDC), and the Common Warehouse Metamodel (CWM) developed by the Object Management Group (OMG) [16]. Later, MDC and OMG joined their efforts and proposed a new version of the CWM as the standard metadata model. The Common Warehouse Metamodel is a platform-independent specification for exchanging multidimensional data between different platforms and tools. It is based on the standards UML, XMI, and MOF, and provides a set of generic, external representations of metadata, called *metamodels*, that provide a comprehensive framework for data exchange. These metamodels can be used to describe the various components of the data warehouse architecture: data sources, ETL processes, multidimensional cubes, relational tables, and so on. However, it has been observed that their expressivity is not sufficient to capture all the complex semantics of conceptual multidimensional models, so they hardly can be used for effective integration of different data warehouses [13].

Conflicts

In the integration of different multidimensional data sources, a number of conflicts can arise, both at the schema and at the instance level.

- *Dimension conflicts*:
  - Schema: conflicts can arise on entity names (e.g., different names for the same dimensions and/or different names for similar levels of two dimensions) and on dimension hierarchies (similar dimensions organized over different levels of aggregation and/or inconsistencies on the roll-up relationships between levels).
  - Instance: conflicts can arise on member names (different names for the same members of different dimensions) and on the members of dimensions (similar dimensions populated by different members).
- *Fact conflicts*:
  - Schema: still, conflicts can arise on names (different names for the same measures) and on dimensions that differ in number and/or in the levels of aggregation.
  - Instance: conflicts can arise on measures (inconsistent values for the same measures and/or differences in scales).

As mentioned in the previous section, Cabibbo and Torlone [4] have identified a fundamental property that should be enforced while solving conflicts between heterogeneous data warehouses: dimension and fact *compatibility*. Two different dimensions d_1 and d_2 are compatible when their common information is consistent, that is, when aggregations computed over d_1 and d_2 and aggregations computed over the dimension obtained by merging d_1 and d_2 produce the same results. Having compatible dimensions and facts is important because it gives the ability to look consistently at data across data marts and to combine and correlate such data by means of drill across queries. Building on this notion, they have also identified a number of desirable properties that a *matching* between dimensions (that is, a correspondence between their levels) should satisfy: (i) the *coherence* of the hierarchies on levels, (ii) the *soundness* of the levels in correspondence, according to the members associated with them, and (iii) the *consistency* of the roll-up functions that relate members of different levels within the matched dimensions.

Integration Techniques

Two heterogeneous data warehouses can be combined if they share one or more dimensions and can be actually integrated if their facts can be joined, in a consistent way, over such common dimensions. It follows that a general methodology for achieving interoperability in data warehouses includes the following steps:

1. Identification of the facts that can be integrated and the dimensions of these facts that can be combined to perform the integration
2. Resolution of conflicts between common dimensions
3. Resolution of conflicts between facts to be integrated
4. Reconciliation and integration of dimensions and facts according to the desired level of interoperability

While this process can be supported by general reconciliation techniques based, for instance, on domain ontologies, it is possible to rely on specific techniques that take into account the rather standard structure of dimensions and facts. As usual, the level of interoperability can range from a scenario of loosely coupled integration, in which there is just the need to identify the common information between sources while preserving their autonomy, to a scenario of tightly coupled integration, in which the goal is rather merging the sources. In the former approach, queries are performed over a virtual view defined on the original sources, in the latter, queries are performed against a materialized view built from the sources.

Banek et al. [1] have addressed the problem of matching schema structures specific to data warehouses, the initial step of the above methodology. Their approach consists of two basic tasks. First, similarity matches between multidimensional structures are identified by comparing their names, data types and substructures (e.g., matches cannot violate the partial order in hierarchies). Then, heuristic rules, based on graph similarity, are used to choose the actual mappings, among the possible matches.

A methodology for the resolution of conflicts that guides the designers through the combination of independent data cubes has been proposed by Berger and Schrefl [2]. They also propose a specific language called SQL-MDi (SQL for multi-dimensional integration), supporting the methodology. In their approach, the goal is the generation of a tightly coupled architecture that combine heterogeneous multidimensional data sources into a materialized warehouse.

Cabibbo and Torlone [5] have proposed two practical approaches to the integration of autonomous data warehouses that try to enforce matchings satisfying the properties discussed in the previous section and refer to the scenarios of loosely and tightly coupled integration, respectively. As a preliminary tool, they introduce a powerful technique, the *chase of dimensions*, that can be used in both approaches to test for consistency and combine the content of the dimensions to integrate. This technique operates over a tableau populated by the members of the dimensions to be integrated, and makes use of the roll-up functions defined over such dimensions. Two integration algorithms are then proposed. The first algorithm provides the operations, expressed in an abstract algebra, that applied to the original dimensions, allow the specification of correct drill-across joins between the heterogeneous sources. The second algorithm generates new dimensions and facts, obtained by merging the original data sources, that constitute the reconciled data warehouse.

From a practical point of view, a general federated architecture supporting the interoperability of distributed and autonomous data warehouses has been proposed by Mangisengi et al. [10]. Tseng and Chen [15] have proposed a framework in which, after a resolution of conflicts, autonomous data cubes are first transformed into XML documents, then conflicts are solved by means of XQuery operations, and finally the access to integrated data is achieved through queries posed over an XML global view.

Key Applications

A common practice for building a data warehouse is to implement a series of data marts, each of which provides a dimensional view of a single business process [7]. These data marts should be based on common dimensions but what happens in practice is that, very often, different departments of the same company develop their data marts independently. It turns out that methods and tools for data warehouse reconciliation are very useful in such common situation.

Indeed, the need for combining autonomous data warehouse arises in other common scenarios. For instance, when different companies merge or get involved in a federated project or when there is the need to combine a proprietary data warehouse with data available elsewhere, for instance, in external and likely heterogeneous information sources, or in multidimensional data wrapped from the Web.

Furthermore, methods supporting data warehouse interoperability can be useful when there is the need to migrate a data mart from one implementation platform to another.

Future Directions

The area of data warehouse interoperability is largely unexplored and there is still a compelling need of systematic studies and effective tools. From a conceptual point of view, the problem needs a deeper investigation that takes into account, for instance, cases in which the structure of the data warehouses to be combined is non standard (e.g., for the presence of non-strict hierarchies or many-to-many relationships between facts and dimensions). In particular, the presence of irregular hierarchies makes the problem of dimension compatibility much harder since it requires complex tests at instance level. From a practical point of view, there is still a lack of effective tools specifically supporting the integration of autonomous and heterogeneous data warehouses.

Experimental Results

A preliminary tool supporting the interoperability of data warehouses has been recently proposed [3].

Interoperation of NLP-based Systems with Clinical Databases

Yves A. Lussier, Matthew G. Crowson
University of Chicago, Chicago, IL, USA

Synonyms

Semantic web

Definition

Natural language processing (NLP) is the automation of processes to interpret and understand meaning in human communications. In the life sciences, NLP assists in wide-scale storage and retrieval of specific "bundles" of clinical data embedded in patient charts which are commonly "free text". Both expert-system and statistical based NLPs have been in use in biomedicine for over three decades and some have shown an expert-like level of accuracy [1,3,6]. With the advent of electronic medical records, the sheer amount of data necessitates automated means for proper analysis to aid in patient care and research purposes.

Key Points

NLP commonly relies on indexing/tokenization, which is a process of breaking down text strings into data bundles. These bundles then need to be understood, which can be accomplished by mapping to clinical ontology. These clinical ontologies provide a means of disambiguating and organizing the mapped concepts to permit more efficient computation. See Fig. 1 below.

Once the tokenization process occurs, the data can be stored in a variety of methods. Fig. 2a demonstrates how a relational database requires an "unbundling process" to fit into its simplified, tabular storage structure. Although this is an efficient process for both storage and retrieval, data loss occurs as simplifying assumptions are made. As a consequence, during retrieval, queries can only be directed at the level of complexity that is stored. In contrast, Fig. 2b, post-tokenization, the data is not forced into a fixed structure, but rather is stored whole, i.e., in XML databases. XML format databases and ontology-anchoring [5] are important components of modern high-performance NLP systems. The retention of data complexity permits more nuanced and complex queries as the tokenized data can be retrieved in its entirety. This more rigorous model is more computationally intensive. However, recent advancements in processing power have made these arguments moot. The main upside of this model over the "lossy relational database model" is that it facilitates better storage and utilization of high-throughput generated biomedical data as researchers cannot always anticipate the clinical question posed *a priori*.

Inter-Operator Parallelism

Esther Pacitti
INRIA and LINA, University of Nantes, Nantes, France

Synonyms

Pipelined and independent parallelism

Definition

Inter-operator parallelism enables different operators of the query to be executed in parallel, i.e., by different nodes. Given an operator tree for a query, there are two forms of inter-query parallelism: pipelined and independent parallelism. With pipelined parallelism, an operator that consumes data produced by another operator can proceed in parallel to that operator, as soon as it receives some data. With independent parallelism, two operators with no data dependency can proceed in parallel.

Key Points

Inter-operator parallelism is very attractive when the query is complex, i.e., has many operators on different relations. Thus, the more complex the query, the more opportunities there are for inter-operator parallelism. With pipeline parallelism, operators with a producer-consumer dependency can be executed in parallel. For instance, a select operator can be executed in parallel with the subsequent join operator. The advantage of such execution is that the intermediate select result is not materialized, thus saving memory and disk accesses. Pipeline parallelism puts constraints on the way the data at the consuming operator node is stored, i.e., it should fit in main memory. Independent parallelism is easier since it applies when there is no dependency between the operators that are executed in parallel. For instance, the two select operators on two different relations can be executed in parallel. This form of parallelism is very attractive because there is no interference between the nodes.

Inter-Query Parallelism

Nikos Hardavellas, Ippokratis Pandis
Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

User-level parallelism

Definition

Inter-query parallelism is a form of parallelism in the evaluation of database queries, in which several different queries execute concurrently on multiple processors to improve the overall throughput of the system.

Key Points

When multiple non-conflicting requests are submitted to a database management system, then the system can execute them in parallel to improve the overall throughput [1]. This form of parallelism is called inter-query parallelism. Inter-query parallelism is a consequence of the concurrency of user requests. It is orthogonal to intra-query parallelism, in which several processors cooperate for the faster execution of a single query [2]. Both forms of parallelism can co-exist in a database management system. Inter-query parallelism is common in on-line transaction processing (OLTP), where multiple concurrent users submit requests to the system. It is a challenge for the database management system to achieve high performance and maintain the ACID properties in the presence of multiple concurrently executing requests or transactions.

Interval-based Temporal Models

▶ Period-Stamped Temporal Models

Intra-operator Parallelism

Esther Pacitti
INRIA and LINA, University of Nantes, Nantes, France

Synonyms

Single instruction multiple data (SIMD) parallelism

Definition

Intra-operator parallelism enables an operator which accesses some data to be executed by multiple nodes, each working on a different partition of the data. With intra-operator parallelism, the same operator is applied to multiple partitions, thereby dividing the response time by the number of nodes. Intra-operator parallelism exploits the various forms of data placement and dynamic partitioning using specific algorithms for the different relational operators.

Key Points

Intra-operator parallelism is based on the decomposition of a relational operator into a set of independent operator instances, each processing a different relation partition. This decomposition is done using static or dynamic partitioning of the relations. Static partitioning corresponds to the initial data placement and is typically exploited by the select or scan operators. Dynamic partitioning, i.e., repartitioning a relation a different way, is useful for binary operators that are costly. One main repartitioning solution is hashing on some important attribute, e.g., join attribute. Intra-operator parallelism is easier for unary operators such as scan or select and more difficult for binary operators such as join, in which case, more complex parallel execution algorithms are necessary.

Intra-Query Parallelism

Nikos Hardavellas, Ippokratis Pandis
Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

Query parallelism

Definition

Intra-query parallelism is a form of parallelism in the evaluation of database queries, in which a single query is decomposed into smaller tasks that execute concurrently on multiple processors.

Key Points

Intra-query parallelism is achieved when several processors cooperate in the execution of a single query to improve the query's response time. Intra-query parallelism is orthogonal to inter-query parallelism, in which multiple independent requests execute concurrently on several processors to improve the overall system throughput.

There exist two forms of intra-query parallelism: operator-level parallelism and intra-operator parallelism. Operator-level parallelism is obtained by executing concurrently several operators of the same query. For example, consider a simple query that consists of a scan operator and an aggregation. The scan operator uses a selection condition to filter tuples. The aggregation calculates some statistics over all qualifying tuples. Operator-level parallelism is obtained by executing concurrently the scan operation as a single task and the aggregation as another, pipelining tuples from the scan to the aggregation as soon as they are produced. To realize this form of parallelism, all participating operators must be pipelineable. Non-pipelineable operators cannot participate because they need their entire input before executing, thereby halting the pipeline.

Intra-operator parallelism is obtained by executing concurrently multiple instances of an operator, with each instance working on a subset of the data. Intra-operator parallelism is based primarily on partitioning the input relation into non-overlapping data segments. In the example above, intra-operator parallelism is achieved by dividing the input relation into non-overlapping data segments and executing the scan and the aggregation of the segments in parallel, followed by a final merge of the results. The interested reader is referred to [1] and [2] as more comprehensive readings.

Intrusion Detection Technology

Tyrone Grandison, Evimaria Terzi
IBM Almaden Research Center, San Jose, CA, USA

Definition

Intrusion Detection (ID) is the process of monitoring events occurring in a system and signalling responsible parties when interesting (suspicious) activity occurs.

Intrusion Detection Systems (IDSs) consist of (i) an agent that collects the information on the stream of monitored events, (ii) an analysis engine that detects signs of intrusion, and (iii) a response module that generates responses based on the outcome from the analysis engine.

Historical Background

The concept of ID has existed for decades in the domains of personal home security, defense and early-warning systems. However, automated IDSs emerged in the public domain in 1980 [2] and sought to identify possible violations of the system's security policy by a user or a set of users.

One of the basic elements of an IDS is the audit log that captures the system activity. The initial IDSs exposed to the academic community stored operating system actions, i.e., addressed the operating system layer. Over time, other IDSs have emerged that store different artifacts, and try to identify intrusive behaviors at different layers of operation. The following layers of operation can be easily identified:

Operating System: The logs in this layer contain information from the kernel and other operating system components and help determine if an attacker is trying to compromise the OS.

Network: At the network layer, communication data is analyzed to determine if an attacker is trying to access one's network.

Application: Application level IDSs examine the operations executed in an application to ascertain if the application is being manipulated to extract behavior that is prohibited. Database-specific IDSs form an important group of application-level IDSs. Examples of such systems include Discovery [14] and RIPPER [10]. Due to the sensitive information stored in database systems, issues related to database-specific IDSs were among the first to be addressed [3,9,15].

The above categorization is historical and mostly depends on the type of log data the IDS uses in order to identify abnormal patterns. Irrespective of the operational layer, the very basic detection techniques used by different IDSs have some common basis, which are described in the next section.

Foundations

A high-level categorization of IDSs is given along with an abstract idea of how they work. For a more complete discussion on IDSs see [1,8,13].

Traditionally, there are two basic approaches to intrusion detection; *anomaly detection* and *misuse detection*. In anomaly detection the goal is to define and characterize legitimate behaviors of the users, and then detect anomalous behaviors by quantifying deviations from the former. However, identifying the distance between anomalous and legitimate behaviors is a rather difficult notion to quantify.

Anomaly detection can be *static* or *dynamic*. A static anomaly detection system is based on the assumption that there is a static portion of the system being monitored. Static portions of the system can be represented as a binary string or a set of binary strings (like files). If the static portion of the system ever deviates from its original form, either an error has occurred or an intruder has altered the static portion of the system.

Dynamic anomaly detectors are harder to build since building them requires a definition of behavior, which is often defined as a sequence (or partially ordered sequence) of distinct events. Differentiating between normal and anomalous activity in dynamic anomaly detection systems is much harder than the problem of distinguishing changes in static elements. Dynamic anomaly detection systems usually create a *base profile* to characterize normal, acceptable behavior. A profile usually consists of a set of observed measures of behavior for a selected set of dimensions. After initializing the base profile the dynamic anomaly detection systems are similar to the static ones; they monitor the behavior by comparing the current behavior with that implied by the base profile. Typically, there is a wide variation of acceptable behaviors and statistical methods are employed to measure deviation from the base profile. The main challenge in dynamic anomaly detection systems is that they must build accurate base profiles and then recognize behaviors that significantly deviate from the profile.

The main advantage of dynamic anomaly detection systems is that they do not require any configuration since they automatically learn the behavior of large number of subjects. Lacking prior knowledge of how an intrusion would manifest itself anomaly detection systems are capable of identifying novel intrusions or variations of known intrusions. However, building base profiles and defining measures of deviations from them is not an easy computational task. For that reason it has been an active area of research, in which several machine learning, time-series analysis and other data-analysis techniques have been employed [3,4–7,11,12].

Misuse detection is concerned with identifying intruders who are attempting to break into a system using some known technique. If a system security administrator was aware of all the known vulnerabilities then a misuse detection system would be able to identify their occurrences and eliminate them. A fairly precisely known kind of intrusion is known as *intrusion scenario*. A misuse detection system compares current system activity to a set of intrusion scenarios in an attempt to identify a scenario in progress.

The differentiating factor between the various misuse detection techniques is the model used for describing bad behaviors that constitute intrusions. *Rules* have been primarily used to model the system-administrator's knowledge about the system. Rule-based systems accumulate large numbers of rules which usually prove difficult to interpret and modify. In order to overcome these problems model-based rule organizations and state-transition representations were proposed. These modeling approaches are more intuitive particularly in misuse detection systems where users need to express and understand scenarios.

The main advantage of a misuse detection systems is that the system knows for a fact how normal behavior should manifest itself. This leads to a simple and efficient processing of the audit data. The obvious disadvantage of such systems is that the specification of the signatures to be detected is a time-consuming task that requires lots of domain knowledge. At the same time, misuse detection systems lack the ability to identify novel intrusion profiles.

Key Applications

A generic classification of the types of attacks that ID systems have traditionally tried to cope with are described below. The classification is mainly inspired by the one provided in [1].

- *External break ins*: When an unauthorized user tries to gain access to a computer system.
- *Masquerander (internal) attacks*: When an authorized user makes an attempt to assume the identity of another user. These attacks are called also internal because they are caused by already authorized users.
- *Penetration attack*: In this attack, a user attempts to directly violate the system's security policy.
- *Leakage*: Moving potentially sensitive data from the system.

- *Denial of Service*: Denying other users the use of system resources, by making these resources unavailable to other users.
- *Malicious use*: Miscellaneous attacks such as file deletion, viruses, resource hogging etc.

Future Directions

One of the major concerns associated with IDSs and their utility is their run-time efficiency. More often than not, IDSs consume too many system resources in order to be effective. Developing resource-aware IDSs systems raises some interesting challenges. One possible way of addressing this concern is via building *Mega Intrusion Detection Systems*. These would be systems that simultaneously monitor all operational layers. That is, the system administrator will not have to run a different ID software for operating system and application specific attacks, but just a single system that will simultaneously be able to detect intrusions in all the desired operational layers. Such systems are expected to be less resource demanding, however their development will certainly create several new design challenges.

This entry has mainly focused on IDSs and described them as mechanisms that guarantee other systems' security. However, IDSs are themselves systems and as such they have their own security risks. Therefore, they also require some protection to prevent an intruder from manipulating the intrusion detection system itself.

Inverse Document Frequency

IADH OUNIS
University of Glasgow, Glasgow, UK

Synonyms

IDF

Definition

The inverse document frequency (*IDF*) is a statistical weight used for measuring the importance of a term in a text document collection. The document frequency *DF* of a term is defined by the number of documents in which a term appears.

Key Points

Karen Sparck-Jones first proposed that terms with low document frequency are more valuable than terms with high document frequency during retrieval [2]. In other words, the underlying idea of *IDF* is that the more frequently the term appears in the collection, the less informative the term is.

In its simplest form, the *IDF* weight of a term is assigned as follows [3]:

$$IDF = \log_2 \frac{N}{DF} \qquad (1)$$

where *N* is the number of documents in the collection, and *DF* is the document frequency of the term, i.e., the number of documents in which the term appears.

There have been different variations of the *IDF* weight in the literature. For example, Robertson and Walker proposed the following formula [1]:

$$IDF = \log \frac{N - DF + 0.5}{DF + 0.5} \qquad (2)$$

where *0.5* is added to avoid having infinite values brought by zero *DF* values.

Synonyms

Inverted index; Full text inverted index; Postings file

Definition

An Inverted file is an index data structure that maps content to its location within a database file, in a document or in a set of documents. It is normally composed of: (i) a vocabulary that contains all the distinct words found in a text and (ii), for each word t of the vocabulary, a list that contains statistics about the occurrences of t in the text. Such list is known as the inverted list of t. The inverted file is the most popular data structure used in document retrieval systems to support full text search.

Historical Background

Efforts for indexing electronic texts are found in literature since the beginning of the computational systems. For example, descriptions of Electronic Information Search Systems that are able to index and search text can be found in the early 1950s [4].

In a seminal work, Gerard Salton wrote a book in 1968, containing the basis for the modern information retrieval systems [6], including a description of a model largely adopted up to now for indexing texts, known as Vector Space Model. The inverted file was adopted as the index structure for implementing the Vector Space Model. It has been widely applied and studied since then.

Foundations

Inverted files allow fast search for statistics related to the distinct words found in a text. They are projected for using words as the search unit, which restricts their use in applications where words are not clearly defined or in applications where the system does not use words as the search unit.

The statistics stored in an inverted file may vary according to the target application. Two alternatives usually found in literature are to record the position of all word occurrences in given text and to record general statistics about the word occurrences across text units. Indexing all the word occurrences is useful in applications where positional information should be taken into account, such as when it is necessary to allow search for phrases or proximity queries. Inverted files that store word statistics are usually deployed in systems that adopt information retrieval models, such as the Vector Space Model. In this particular case the text is divided into units of information, usually documents. For instance, in web search engines, these units are the pages crawled from the web, while the whole set of pages compose the indexed text.

Querying a word in an inverted index consists in first locating the word in the vocabulary and getting the position of its inverted list. This operation can be performed in O(1) by using a hash algorithm. The inverted list of the word is then accessed in order to provide the search results. The vocabulary usually requires a sub-linear space when compared to the size of the inverted list, which makes it usually far smaller than these lists.

Word occurrences are stored in inverted files for applications where positional information should be taken into account, such as when it is desirable to provide support to phrase search or proximity queries. To search for a phrase or proximity pattern (where the words must appear consecutively or close to each other, respectively), each word is searched separately. Then, the resulting lists of occurrences are intersected considering the consecutiveness or closeness of the word positions in the text. The cost to perform such type of queries can be reduced by adopting an auxiliary data structure, known as next word index, which includes information about the next word in the positional inverted list entries. This alternative can significantly reduce the query processing times for phrase queries. Another choice could be to index pairs of consecutive words, but then the vocabulary would be much larger, which would make this option unfeasible.

Building an Inverted File

The texts indexed nowadays by search systems are usually too large for allowing the creation of inverted files completely in main memory. Disk-based algorithms for generating compressed inverted files have been extensively studied in the literature. An example is the *multiway merging* algorithm described in [7].

An implementation of this algorithm can be performed in three phases a, b, and c. In phase a, all documents are sequentially read from disk and parsed into index terms. This allows creating a perfect hashed vocabulary and also allows the application of filtering algorithms to remove undesired words from the index. For instance, search systems usually remove frequent words included in a pre-computed list, known as *stop words*. Heuristics for removing typos can also be adopted in this phase by analyzing the frequency of occurrences of each word in the text. In phase b, all documents are again sequentially read from disk and again parsed into index terms. Triplets composed of an index term number k_i, a document number d_j, and a frequency $f_{i,j}$ are then formed and inserted into a buffer B in main memory. Whenever this buffer fills (i.e., whenever a run is completed), the partial inverted lists are sorted in decreasing order of the frequencies $f_{i,j}$ (or another desired order according to the application), and stored in a temporary file F. In phase c, a disk-based multiway merge is done to combine the partial inverted lists into final lists. The details are shown in Fig. 1. Note that this example considers that the index stores the frequency of each word in each document. However, the algorithm can easily be adapted to create an index to store word occurrence positions or other type of statistics about the text, according to the target application.

The sequential algorithm shown above uses two passes for reading and parsing of the documents in the collection. This allows building a perfect hashed vocabulary which provides for direct access to any inverted

```
  (a1) read all documents sequentially, parse
       into index terms and create perfect hashed
       vocabulary
  (a2) create memory buffer B
a (a3) R = 0 /* initialize number of runs */

  foreach $d_j$ do
b begin
  (b1) read $d_j$, parse into index terms
  (b2) foreach $k_i \in d_j$ do B = B + [$k_i, d_j, f_{i,j}$]
  (b3)  if 'buffer B is full' then
       begin
       (b3.1) do sort triplets on $k_i, f_{i,j}$
       (b3.2) F = write-disk (B)
       (b3.3) B = $\phi$; R = R + 1
       end
  end
c multiway-disk-merge (F,R)
```

Inverted Files. Figure 1. A disk-based algorithm for building inverted files.

list with no need to lookup at a vocabulary entry. Thus, once the perfect hash has been built, it is no longer necessary to keep the vocabulary in memory (all significant memory consumption is now represented by the buffer *B* which stores the inverted lists).

In cases where the text is too large, as it happens in search engines that try to index the whole web, distributed algorithms should be adopted for building inverted files. The current best alternative for building distributed inverted files is also the simplest solution. It partitions the text into small sub-collections, each of them fitting in a single machine. A local index is built for each sub-collection; when queries arrive, they are submitted to every sub-collection and evaluated against every local index. A final step merges the answers produced by each individual machine yielding a single ranking of results to the final users.

Compression

A technique to reduce the space requirements of inverted files is to compress the index. The key idea to reduce the size of inverted files is that the inverted list entries related to each word can be sorted in increasing order, and therefore the gaps between consecutive positions can be stored instead of the absolute values. Then, compression techniques for small integers can be used. As the gaps are smaller for longer lists, longer lists can be compressed better. Previous work has shown that inverted files can be reduced up to 10% of their original size without degrading the performance, and even the performance may improve because of reduced I/O [7].

Another alternative for reducing the space requirements of an inverted file and the query processing regarding the access to the index is to minimize the number of indexed entries by applying static pruning methods. Pruning methods try to avoid processing index entries without cause loss of quality in the final results produced by the search system. They can be classified as *dynamic* and *static*. Dynamic methods maintain the index completely stored on disk and use heuristics to avoid reading unnecessary information at query processing time. In this case, the amount of pruning performed varies according to the user queries, which represents an advantage, since the methods can be better adapted to each specific query. In contrast, static methods try to predict, at index construction time, the entries which will not be useful at query processing time. These entries are then removed from the index. For this reason, static methods can be seen as lossy compression methods. Static methods offer the advantage of both reducing the disk storage costs and time to process each query. A system that uses both static and dynamic methods can also be implemented to take advantage of the two types of pruning options [5].

Updating Operations

In applications where the indexed text changes over the time, with portions being removed, added or changed in the text, it is necessary to reflect such changes in the inverted file. The simplest approach is to rebuild the whole index, which may be acceptable if the index can be updated offline and the indexing time is small. However, if such conditions do not apply, more sophisticated strategies should be adopted. Several index maintenance strategies can be found in literature [8]. They can be divided into three categories, with the index rebuilding being the first obvious choice. The second category is the intermittent merge, where small indexes to register updates are stored in main memory, making the update inexpensive. In this case, the temporary main memory index and the disk index should be merged at query processing time. A real update should be periodically performed to avoid a memory overflow in the temporary index. The third category is the incremental update. It updates the main index term by term using a process similar to the mechanisms used for maintaining variable-length records in conventional database management systems.

Query Processing

The query processing over inverted files can be performed in two distinct forms, being based on a term order or on a document order basis [2]. In the term order basis, each inverted list is processed one at a time. The partial list of results obtained after processing each list is stored in memory, which means this method may require additional memory. The second form of processing queries is the document order processing, where whenever a document information is found in one of the lists, all information about this document is automatically read from the remaining inverted lists of terms present in the query. The document ordering method requires the inverted lists to be stored sorted by document number, or by occurrence when the index store all term occurrences. Previous work indicate the term ordering method results in faster query evaluation. However, for small queries, which are common on many search applications, this difference becomes smaller. A combination of document order and term order may also be implemented, by processing the inverted lists in blocks.

A final comment about query processing is that it can be sped up by using cache strategies. At least three distinct cache layers have been proposed in literature. First, the system can adopt a cache of inverted lists to keep the most frequent portions of the lists in memory. Second, it can also be used a cache of results, which takes the final results provided to the users in a cache. Finally, a projection cache containing frequent intersections of lists can also be adopted. Previous work in literature conclude that these cache techniques can significantly increase the maximum capacity of systems for query processing [3].

Key Applications

Inverted files are by far the most applied indexing structures in text search systems. Such indexes are used, for instance, in the popular large scale web search engines.

IP Storage

KAZUO GODA
The University of Tokyo, Tokyo, Japan

Definition

IP Storage is a storage device which has the capability of communicating over an IP network. The term IP Storage is usually identified with a storage device which provides block-level I/O services rather than file access services. Derived from the original meaning, the term IP Storage is sometimes used to refer to an IP SAN.

Key Points

The benefit of utilizing IP technology is its cost efficiency. Having been used for several decades, IP technology is highly mature. IP family protocols have been standardized and cheap hardware products have wide interoperability. The market has a number of excellent administration tools and educated administration personnel for IP technology. Designing and operating SANs on top of IP technology is much cheaper and easier than with Fiber Channel technology. Thus IP technology is sometimes considered to be replacement of Fiber Channel technology in entry-level SANs.

Internet SCSI (iSCSI), Internet Fiber Channel Protocol (iFCP) and Fiber Channel over Internet Protocol

(FCIP) are three major network protocols used for IP Storage. iSCSI transmits the SCSI protocol over IP networks by encapsulating SCSI data in TCP/IP packets. That is, the idea of iSCSI is to replace classical SCSI bus cables with IP networks. iSCSI is used mainly for transferring data between servers and storage devices and among storage devices. A storage device which communicates over the iSCSI protocol is often called an iSCSI target, whereas a server which accesses such an iSCSI device is called an iSCSI initiator. In contrast, iFCP and FCIP can encapsulate Fiber Channel frames in TCP/IP packets. These protocols are usually implemented in network devices such as Fiber Channel switches and routers, thus enabling bridging two or more Fiber Channel SANs by the use of IP networks. Although iSCSI and iFCP/FCIP are both IP storage techniques, they are used in real systems in different ways. That is, iSCSI is mainly used for constructing a local SAN at low cost, whereas iFCP and FCIP are utilized for integrating remote Fiber Channel SANs (often called SAN islands.)

Definition

In general terms, a physical operator is an implementation of a relational operator. For a relational operator, there are many alternative physical operators that implement it, for instance, sort-merge and hash-join provide alternative algorithms for implementing join. The query execution engine provides generic implementations of all physical operators. Typically, each physical operator supports a uniform *iterator interface* that hides any internal implementation details and allows operators to be combined together. The iterator interface includes the functions: (i) *open()* that prepares an operator to produce data, (ii) *next()* that produces an output tuple, and (iii) *close()* that performs the final bookkeeping.

Key Points

During query processing, an input query is transformed to a plan to be executed by the query execution engine. An execution plan can be thought of as a dataflow graph where the nodes correspond to the physical operators and the edges represent the data flow among the physical operators. Generally speaking, a physical operator is an implementation of a relational operator, for instance, sort-merge and hash-join are physical operators providing alternative algorithms for the implementation of join. The query execution engine provides generic implementations of all physical operators. A plan is executed by calling its physical operators in some (possibly interleaved) order. In most modern database systems, each physical operator supports a uniform *iterator interface* that allows an operator in the plan to get results from its input operators one tuple at a time, hiding the internal implementation details of each operator.

The iterator interface for an operator includes the functions open(), next(), and close(). The *open()* function initializes the state of the operator by allocating the appropriate input and output buffers and passing any related arguments. The code for the *next()* function calls the next() function recursively on each input operator until an output tuple is generated. The state of the operator keeps track of how much input has been consumed. Finally, when all output tuples have been produced, through repeated calls of the next() function, the *close()* function deallocates the state information and performs any other final bookkeeping.

By providing a common interface to all physical operators, any two physical operators can be plugged together. Furthermore, the iterator interface supports a pipeline model for the execution of the plan.

The iterator interface is also employed to encapsulate access methods such as the various kinds of indexes that the database system supports. In this case, open() can be used to pass the corresponding selection condition. Finally, parallelism and network communications can be encapsulated within special *exchange iterators*.

JDBC

Definition

Java Database Connectivity (JDBC) [1] is an Application Programming Interface (API) for the Java programming language that enables Java programs to execute Structured Query Language (SQL) statements and defines how an application accesses a database. JDBC provides methods to query and update data in a database. Different from ODBC (Open Database Connectivity), JDBC is oriented towards relational databases only.

Key Points

JDBC (pronounced as separate letters) is similar to ODBC, but it is designed specifically for Java programs, whereas ODBC is language-independent. The Java Standard Edition includes the JDBC API as well as an ODBC implementation of the API enabling connections to any relational database that supports ODBC [1].

JavaSoft, a subsidiary of Sun Microsystems, developed JDBC. Since the release of Java Development Kit (JDK) 1.1, JDBC has been part of the Java Standard Edition. JDBC has been developed under the Java Community Process since version 3.0. JDBC 3.0 (included in Java 2 Standard Edition (J2SE) 1.4) is specified by Java Specification Request (JSR) 54, the JDBC Rowset additions are specified by JSR 114, and JDBC 4.0 (included in Java Standard Edition 6) is specified by JSR 221.

Multiple implementations of JDBC can exist and can be used by the same application. A mechanism is provided by the API to dynamically load the correct Java packages and register them with the JDBC Driver Manager, a connection factory for creating JDBC connections.

Creating and executing statements are supported by JDBC connections. These statements may either be update statements such as SQL CREATE, INSERT, UPDATE and DELETE or be query statements using the SELECT statement. In addition, a statement may invoke a stored procedure.

Because Java itself runs on most platforms, and since nearly all relational database management systems (DBMSs) support SQL, JDBC makes it possible to write a single database application that can run across different DBMSs on different platforms.

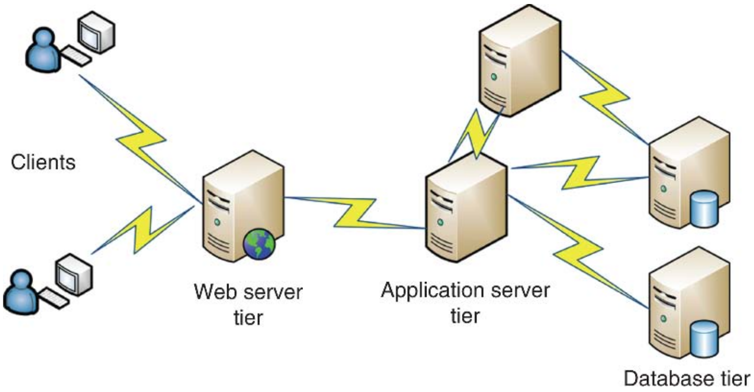
Definition

Java EE (JEE) is a Java Community Process (JCP) specification for Java application servers. JEE consists of a set of related specifications and APIs that shapes an ecosystem for building Java distributed applications over a multi-tier architecture, including web, business logic, and storage tiers. JEE provides components specific for each tier. JEE provides servlets and Java Server Pages (JSPs) for the web tier, Enterprise Java Beans (EJBs) for the business logic tier, and a data driver (JDBC) and an object-relational mapping (via entity beans) for the storage tier. Components can be distributed at different sites and interact with each other. The interaction among distributed JEE components is achieved via RMI (Remote Method Invocation), the JEE specification for remote procedure calls. In its latest editions, JEE has been smoothly integrated with XML processing and web services. It is possible to program web services using EJBs and a large set of APIs enable a standard way to effectively manipulate XML. JEE covers all important non-functional aspects such as transactions, security, etc. Transactions are core to JEE and are considered across all tiers in a consistent fashion through the Java Transaction Service and API (JTS/JTA). A number of specifications address various security issues such as authentication (JAAS, Java Authentication and Authorization Service), encryption, and so on.

Key Points

The JEE project originated back in 1998 when the JPE (the original name) initiative was announced by Sun Microsystems. J2EE 1.2 was released in Dec. 1999. The following versions have been released almost every two years, J2EE 1.3 in Sept. 2001 (1.3 was the first version to be developed as a JCP specification), J2EE 1.4 in Nov. 2003, JEE 1.5 (with version 1.5 J2EE was renamed as JEE) in May 2006, and JEE 1.6 is expected to be released sometime in 2008.

JEE is a multi-tier middleware framework to program all kinds of applications based on the Java language. Multi-tier architectures have become widely used since they allow an adequate separation of concerns. Each tier has a specific container with a component model tailored to the specific mission of the tier. Some of the most common tiers are: web tier, business logic tier, and persistent storage tier.



Java Enterprise Edition. Figure 1. JEE multi-tier architecture.

Figure 1 depicts a typical JEE multi-tier architecture. Clients interact with the system via the web server tier. The web server tier then delegates the business logic to the application server tier. The JEE application server tier can consist of multiple servers, that is, be distributed. Then, the persistent data are kept in the database tier. The data can be kept in multiple distributed databases. The database instances can be shared across application servers. Transactions are used to enforce data consistency across the entire system despite concurrent accesses to the data. Transactions also protect data against server failures providing failure atomicity.

For the web tier, JEE provides a component model for generating dynamic web content. This component model is based on Java Server Pages (JSPs) and servlets. JSPs provide a high level abstraction for dynamic content, whilst servlets provide a lower level view. In fact, JSPs are translated into servlets. Servlet containers are specialized web servers that support servlet execution. Typically servlets deal with the presentation aspects of an application and they are specialized to render dynamic web contents to users. Servlets delegate the business logic to the application server tier, that is, to the JEE application server.

The JEE application server provides a component model for writing general applications. The components in the JEE component model are termed Enterprise Java Beans (EJBs). Two different kinds of EJBs are distinguished: session beans and entity beans. Session beans enable to encapsulate the interaction with users. There are two flavors: stateless and stateful session beans. Stateless session beans provide support for non-conversational interactions, whilst stateful session beans support conversational interactions. Stateless session beans are instantiated per client invocation and their state is discarded after processing the client request that triggered their instantiation. On the other hand, stateful session beans are created upon the first client invocation and then, they are kept during all the client conversation. Their state enables to tracking of the status of the interaction across invocations (e.g., a shopping cart). From JEE 1.5, it is also possible to persist POJOs (Plain Old Java Object, that is, a Java Object) using JPA (Java Persistent API) without the need of a JEE application server.

JEE provides two models of interaction with the database: explicit and implicit. In the explicit model of interaction the EJBs access the database directly via a JDBC driver. The JDBC driver abstracts the database specifics of the underlying implementation providing a uniform vendor-independent interface. However, the object oriented paradigm has a different style than the relational model (the well-known object-relational impedance mismatch) that forces programmers to write a lot of repetitive code prone to errors to create queries and to transform query results into objects. The object-relational mapping (ORM) approach addresses this impedance mismatch by offering the programmer a view of an object oriented database, eliminating the need to write code.

The database tier access can be explicit via JDBC commands or implicit by using the object-relation mapping (ORM) of JEE. Explicit access implies issuing JDBC commands with SQL statements and dealing directly with the results sets returned by JDBC. Implicit access via ORM enables access to the persistent state using the object-oriented paradigm. Tuples are modeled as special kind of JEE components, entity beans, that are accessed as regular objects. Entity beans provide an object-oriented cache of the database. The JEE system takes care of updating the database and implementing the necessary concurrency control to provide transactional serializability.

JEE also provides support for the publish-subscribe paradigm. For that purpose it provides a specific component model and the associated container, Java Message Service (JMS). JMS provides message-driven beans that are components that are activated upon the reception of a particular kind of message. Message-driven beans can be invoked by client applications and EJBs and they can also invoke other EJBs. JMS provides an asynchronous interaction model that complements the synchronous one provided by EJBs and RMI.

In the last few years, a number of initiatives have tried to simplify JEE development. One of the initiatives with highest impact has been the Spring framework [2]. Spring provides a lightweight approach to JEE simplifying the development of JEE applications. Spring is based heavily on programming interfaces (as opposed to programming objects) and the use of aspect oriented programming. Spring has inspired some of the major changes in JEE 1.5 and 1.6.

Java Metadata Facility

David Buttler
Lawrence Livermore National Laboratory, Livermore, CA, USA

Synonyms

Java metadata facility; JSR 175; Java annotations

Definition

The Java Metadata Facility is introduced by Java Specification Request (JSR) 175 [1], and incorporated into the Java language specification [2] in version 1.5 of the language. The specification allows annotations on Java program elements: classes, interfaces, methods, and fields. Annotations give programmers a uniform way to add metadata to program elements that can be used by code checkers, code generators, or other compile-time or runtime components.

Annotations are defined by annotation types. These are defined the same way as interfaces, but with the symbol "@" preceding the "interface" keyword. There are additional restrictions on defining annotation types:

1. They cannot be generic.
2. They cannot extend other annotation types or interfaces.
3. Methods cannot have any parameters.
4. Methods cannot have type parameters.
5. Methods cannot throw exceptions.
6. The return type of methods of an annotation type must be a primitive, a String, a Class, an annotation type, or an array, where the type of the array is restricted to one of the four allowed types.

See [2] for additional restrictions and syntax.

The methods of an annotation type define the elements that may be used to parameterize the annotation in code. Annotation types may have default values for any of its elements. For example, an annotation that specifies a defect report could initialize an element defining the defect outcome to "submitted." Annotations may also have zero elements. This could be used to indicate serializability for a class (as opposed to the current Serializability interface).

Key Points

There are several annotation types that are predefined in the Java 1.5 programming language: "@Override," "@Deprecated," and "@SuppressWarnings" are the most common ones.

"@Override" indicates that a method in a subclass overrides a method from its superclass, as opposed to overloading it. This is an example of an annotation with zero elements. A common, yet difficult to identify, error in writing Java classes occurs when a programmer overloads the `equals` method, rather than overriding it. This leads to errors that are difficult to track down.

"@Deprecated" indicates that a class or method has been deprecated and that programmers should use an alternative. This replaces the javadoc "@deprecated" tag that served the same purpose.

"@SuppressWarnings" indicates that a compiler should not report warnings of a particular type. This particular annotation requires an element, such as "@SupressWarnings('unchecked')," defining the type of warning to ignore for the annotated compilation unit. Warning types are defined by the compiler and are not specified in the Java language specification.

► Join Dependency

JDBC

► Java Database Connectivity

Join

Cristina Sirangelo
University of Edinburgh, Edinburgh, Scotland, UK

Definition

The join is a binary operator of the relational algebra that combines tuples of different relations based on a relationship between values of their attributes. The primitive version of the join operator is called *natural join*. Given two relation instances R_1, over set of attributes U_1, and R_2 over set of attributes U_2, the natural join $R_1 \bowtie R_2$ returns a new relation, over set of attributes $U_1 \cup U_2$, consisting of tuples $\{t | t(U_1) \in R_1$ and $t(U_2) \in R_2\}$. Here $t(U)$ denotes the restriction of the tuple t to attributes in the set U.

A derivable version of the join operator is obtained by composing the natural join with the selection operator σ: the *theta-join* $R_1 \bowtie_\theta R_2$ is defined as $\sigma_\theta(R_1 \bowtie R_2)$, where θ is an arbitrary condition allowed in a generalized selection over set of attributes $U_1 \cup U_2$. In the case that θ is a conjunction of equality atoms of the form $A = B$, where A is an attribute in U_1 and B an attribute in U_2, the theta-join is called *equijoin*.

Another derivable join operator is the *semijoin*, denoted by $R_1 \ltimes R_2$; it is defined as $\pi_{U_1}(R_1 \bowtie R_2)$, where π_{U_1} denotes the projection on attributes U_1.

Key Points

In the natural join $R_1 \bowtie R_2$, tuples of R_1 and R_2 having the same values of common attributes are combined. If the sets of attributes of R_1 and R_2 are disjoint, $R_1 \bowtie R_2$ coincides with the cartesian product.

The natural join is often used to combine tuples based on attributes correlated by a foreign key-constraint: consider a relation *Students* over attributes (*student-number, student-name*), containing tuples {(1001, *Black*), (1002, *White*)}, and a relation *Exams* over attributes (*course-number, student-number, grade*), containing tuples {(*EH*1, 1001, *A*), (*EH*1, 1002, *A*), (*GH*5, 1001, *C*)}. Then the natural join *Students* ⋈ *Exams* is a relation over attributes (*student-number, student-name, course-number, grade*) with tuples {(1001, *Black*, *EH*1, *A*), (1001, *Black*, *GH*5, *C*), (1002, *White*, *EH*1, *A*)}.

In the absence of attribute names the only primitive notion of join is the cartesian product. In this case operators of theta-join and equijoin can be derived by composing selection and cartesian product. More precisely, if θ is a boolean combination of atoms of the form $j \alpha k$ with $j \leq arity(R_1)$ and $k \leq arity(R_2)$ and $\alpha \in \{=, \neq, <, >, \leq, \geq\}$, then the theta-join $R_1 \bowtie_\theta R_2$ in the unnamed algebra is defined as $\sigma_{\theta'}(R_1 \times R_2)$, where θ' is obtained from θ by replacing each atom $j \alpha k$ with $j \alpha (arity(R_1) + k)$.

In each of the join operators described above (except the semijoin) there can be tuples of the input relations which do not occur in the output, because they satisfy the join condition with no tuple of the other relation. The *left (right) outer join* adds to the join of R_1 and R_2 all tuples of R_1 (R_2) not occurring in the join, completed with nulls on attributes of R_2 (R_1). The *full outer join* adds both tuples of R_1 and R_2 to the join.

Join Dependency

Solmaz Kolahi
University of British Columbia, Vancouver, BC, Canada

Synonyms

JD

Definition

A *join dependency (JD)* over a relation schema $R[U]$ is an expression of the form $\bowtie [X_1,...,X_n]$, where $X_1 \cup \ldots \cup X_n = U$. An instance I of $R[U]$ satisfies $\bowtie [X_1,...,X_n]$ if $I = \pi_{X_1}(I) \bowtie \ldots \bowtie \pi_{X_n}(I)$. In other words, an instance satisfies the join dependency if it is equal to the join of its projections on the sets of attributes $X_1,...,X_n$. A multivalued dependency $X \twoheadrightarrow Y$ is a special case of a join dependency on two sets, and can be expressed as $\bowtie [XY, X(U - XY)]$, where XY represents $X \cup Y$.

Key Points

Join dependencies are particularly important in connection with the decomposition technique for schema design and normalization. The main goal of the decomposition technique is to avoid redundancies due to data dependencies by decomposing a relation into smaller parts. A good decomposition should have the *lossless join* property, meaning that no information should be lost after the decomposition. In other words, the original database instance should be retrievable by joining the smaller relations, and this can be expressed by a JD. The following figure shows an instance of the relation schema $R[A, B, C, D]$ that satisfies the join dependency $\bowtie [BC, AB, AD]$:

$$\begin{array}{|cccc|}\hline A & B & C & D \\ \hline 1 & 2 & 3 & 4 \\ 1 & 5 & 6 & 4 \\ 4 & 2 & 3 & 5 \\ 3 & 2 & 3 & 6 \\ \hline \end{array} = \begin{array}{|cc|}\hline B & C \\ \hline 2 & 3 \\ 5 & 6 \\ \hline \end{array} \bowtie \begin{array}{|cc|}\hline A & B \\ \hline 1 & 2 \\ 1 & 5 \\ 4 & 2 \\ 3 & 2 \\ \hline \end{array} \bowtie \begin{array}{|cc|}\hline A & D \\ \hline 1 & 4 \\ 4 & 5 \\ 3 & 6 \\ \hline \end{array}$$

Join dependencies are usually considered together with functional and multivalued dependencies (FDs and MVDs) in normalization. The implication problem of a JD from a set of JDs, MVDs, and FDs is known to be NP-hard. In addition, the implication problem of JDs cannot be axiomatized. That is, there is no sound and complete set of rules that can be used to check whether a dependency is implied by a set of JDs. However, there is a powerful tool, called *chase*, that could be used to reason about these dependencies in exponential time and space [1].

Join Index

Theodore Johnson
AT&T Labs – Research, Florham Park, NJ, USA

Definition

A join index is a collection of pairs $\{(r, s)\}$ such that the record in table R with record ID (RID) r joins with the record in table S with RID s, according to the *join* predicate which defines the index.

Key Points

The purpose of a join index is to accelerate common joins, even equijoins. One of the advantages of join indices is that they can be represented in a very compact way, allowing for highly efficient access. For example, suppose that the DBMS is to evaluate a query, "Select R.a from R,S where R.a = S.b." A conventional join would use a nested loop algorithm, with an indexed scan in the inner loop. With a join index, the join can be computed by scanning the join index, thus minimizing random I/O.

There are a variety of ways of implementing a join index. One can list pairs (clustered on R or clustered on S), or in the case of an equijoin, associate R and S RIDs with attribute values. The example below shows the join index for R.a = S.b, organized as a list of pairs.

Join Order

Jingren Zhou
Microsoft Research, Redmond, WA, USA

Synonyms

Join order; Join sequence

Definition

A database query typically contains multiple joins. When joins (for example, inner joins) are commutative and/or associative, there can more than one evaluation order for joins. The join order has an enormous impact on the query cost. One of the main responsibilities of the query optimizer is to determine the optimal join order for query evaluation.

Key Points

Choosing a good join order is very important to achieve a good query performance. One important consideration for choosing an join order is to reduce the size of intermediate results as much as possible. For example, it is beneficial to first evaluate a join that returns the least result. Other considerations include join methods, data properties, and access methods, etc.

Depending on the choice of join orders, query plans can be of different shapes.

- *Left-Deep* query plans use a base table as the inner table for each join.
- *Right-Deep* query plans use a base table as the outer table for each join.
- *Bushy* query plans use the intermediate result from other joins as join inputs.

Query optimizers typically use dynamic programming and heuristics to determine join orders.

K

k-Anonymity

Josep Domingo-Ferrer
Universitat Rovira i Virgili, Tarragona,
Catalonia

Synonyms

p-Sensitive *k*-Anonymity

Definition

A protected dataset is said to satisfy *k*-anonymity for $k > 1$ if, for each combination of key attribute values (e.g., address, age, gender, etc.), at least *k* records exist in the dataset sharing that combination [2,3].

Key Points

If, for a given *k*, *k*-anonymity is assumed to be sufficient protection, one can concentrate on minimizing information loss with the only constraint that *k*-anonymity should be satisfied. This is a clean way of solving the tension between data protection and data utility. Since *k*-anonymity is usually achieved via generalization (equivalent to global recoding, as said above) and local suppression, minimizing information loss usually translates to reducing the number and/or the magnitude of suppressions.

k-Anonymity bears some resemblance to the underlying principle of microaggregation and is a useful concept because quasi-identifiers are usually categorical or can be categorized, i.e., they take values in a finite (and ideally reduced) range. However, re-identification is not necessarily based on categorical key attributes: sometimes, numerical outcome attributes (which are continuous and often cannot be categorized) give enough clues for re-identification. Microaggregation was suggested as a possible way to achieve *k*-anonymity for numerical, ordinal and nominal attributes [1].

p-Sensitive *k*-anonymity is a stronger property whereby it is required that a dataset is *k*-anonymous and additionally that there are at least *p* distinct values for each confidential attribute within a group of records sharing a combination of key attributes [4].

KDD Pipeline

Hans-Peter Kriegel, Matthias Schubert
Ludwig-Maximilians-University, Munich, Germany

Synonyms

KDD process; Data mining process; Data mining pipeline

Definition

The KDD pipeline describes the complete process of knowledge discovery in databases (KDD), i.e., the process of deriving useful, valid and non-trivial patterns from a large amount of data. The pipeline consists of five consecutive steps:

Selection

The selection step identifies the goal of the current application and selects a data set that is likely to contain relevant patterns.

Preprocessing

The preprocessing step increases the quality of the data set by supplementing missing attributes, removing duplicate instances and resolving data inconsistencies.

Transformation

The transformation step deletes correlated and irrelevant attributes and derives new more meaningful attributes from the current data description.

Data Mining

This step selects a data mining algorithm with respect to the goal which was identified in the selection step and derives patterns or learns functions that are valid for the current data set.

Evaluation and Interpretation

In the last step, the found patterns are checked with respect to their validity. Furthermore, the user examines the usefulness of the found knowledge for the given application.

The quality of the found patterns depends on the methods being employed in each of these steps. Thus, the pipeline is usually repeated after adjusting the parametrization or even exchanging the methods in any of these steps until the quality of the results is sufficient. Figure 1 illustrates the complete KDD pipeline.

Key Points

The KDD pipeline was originally introduced as KDD process [1–3]. It describes a unifying framework containing all necessary and optional steps when deriving patterns using data mining algorithms. An important aspect of this view is that data mining is just one step in the complete KDD process, which emphasizes the importance of a meaningful and consistent data representation. The KDD pipeline is considered to be an interactive and adjustable framework rather than a strict work flow. The necessity for this flexibility arises from the large variety of methods and parameter selections that can be applied in each step. In the majority of cases, it is necessary to adjust parameters or even exchange the applied method in one of the steps if the final patterns do not display satisfactory quality in the evaluation step. Furthermore, the borders of each step cannot be outlined in a strict manner because the quality of results strongly depends on a well selected combination of the methods applied in each step. Additionally, there exist methods fulfilling the tasks of two consecutive steps, e.g., transformation and data mining.

Uniqueness constraint

Definition

In the relational model, a *key* for a relational schema is a set of attributes whose value(s) uniquely identify a tuple in a valid instance of the relation. Said another way, key value(s) appear at most once in a relation. Often the set of attributes constituting a key is a set with a single attribute. For example, in the relation the singleton set consisting of just *CustomerID* is a key and so is the set consisting of the pair of attributes (*Name*, *Address*). The values of *CustomerID* (here, 11111 and 22222) each uniquely identify a tuple. In any valid instance for this relation, no *CustomerID*-value may appear twice. Similarly, the pair (*Name*, *Address*) is a key. Pairs of (*Name*, *Address*) values (e.g., <*Pat*, *12 Maple* >) uniquely identify a tuple, and no value pair may appear twice.

Customer	(CustomerID	Name	Address)
	11111	Pat	12 Maple
	22222	Tracy	44 Elm

Designating a set of attributes as a key is a property of a relational schema, not a property of a relation instance. It may just happen that for some valid relation instances a value uniquely identifies a tuple, but a key must always uniquely identify a tuple for *all* valid relations. In this example, *Pat* and *Tracy* uniquely identify tuples, but it would also be valid for another *Tracy*, say, one living at *905 Lincoln Ave.*, to be a customer. Although *Name* uniquely identifies tuples in this *Customer* table instance, *Name* does not uniquely identify tuples in *all* valid *Customer* table instances and thus is not a key for the *Customer* relational schema.

Key Points

The term *key* is often ambiguous and may mean *minimal key*, *superkey*, *primary key*, or *candidate key*. A *minimal key* is a key that does not have superfluous attributes. Clearly, in the sample relational schema above, *CustomerID* together with *Name* uniquely identify a customer because *CustomerID* alone is enough. *Name* is superfluous, and thus the set consisting of the pair of attributes (*CustomerID*, *Name*) is not a minimal key. The set consisting of the pair of attributes (*Name*, *Address*), however, is a minimal key. Both are necessary – in the table above, for example, both <*Tracy*, *905 Lincoln Ave.* > and <*Lynn*, *12 Maple* > could appear so that neither *Name* alone nor *Address* alone would uniquely identify a tuple. Usually only minimal keys are of interest. Keys that may not be minimal are called *superkeys*. A *superkey* is any set of attributes, minimal or not, that uniquely identifies a tuple in any valid relation instance. A relational schema may have several minimal keys. The sample *Customer* relational schema above, for example, has two minimal keys – *CustomerID* and the pair (*Name*, *Address*). When there are several minimal keys, one is chosen as a *primary key*. When there is only one, it is also called a *primary key*. Because there can be a choice among minimal keys, they are often each referred to as *candidate keys*.

Keys and functional dependencies are strongly related. Indeed, keys can be defined in terms of functional dependencies. Let U be a set of attributes, and let F be a set of functional dependencies over U. Let R, a subset of U, be a relational schema. A subset K of R is a *superkey* of R if $K \rightarrow R \in F^+$, where F^+ includes F and any functional dependency implied by F. A subset K of R is a *candidate key* of R (also called a *minimal key* of R) if K is a superkey and there does not exist a proper subset K' of K such that $K' \rightarrow R \in F^+$.

Database normalization is largely about aligning keys and functional dependencies. A relational schema R is in Boyce-Codd Normal Form (BCNF) if for every non-trivial functional dependency $X \rightarrow Y$ (given or implied) that applies to R (satisfies $XY \subseteq R$), X is a superkey of R. More informally, the idea of aligning keys and functional dependencies to yield BCNF is intuitively captured by making every attribute in the relational schema depend functionally on a minimal key, the whole minimal key, and nothing but the whole minimal key.

K-means partition; PAM (Partitioning Around Medoids); CLARA (Clustering LARge Applications); CLARANS (Clustering large applications based upon randomized search)

Definitions

K-means

Given an integer k and a set of objects $S = \{p_1, p_2, ..., p_n\}$ in Euclidian space, the problem of k-means clustering is to find a set of centre points (means) P = $\{c_1, c_2, ..., c_k\}$, $|P| = k$ in the space, such that S can be partitioned into k corresponding clusters $C_1, C_2, ..., C_k$, by assigning each object in S to the closest centre c_i. The sum of square error criterion (SEC) measure, defined as $\sum_{i=1}^{k} \sum_{p \in C_i} |p - c_i|^2$, is minimized.

K-medoids

Given an integer k and a set of objects $S = \{p_1, p_2, ..., p_n\}$ in Euclidian space, the problem of k-medoids clustering is to find a set of objects as medoids P = $\{o_1, o_2, ..., o_k\}$, $|P| = k$ in the space, such that S can be partitioned into k corresponding clusters $C_1, C_2, ..., C_k$, by assigning each object in S to the closest medoid o_i. The sum of square error criterion (SEC) measure, defined as $\sum_{i=1}^{k} \sum_{p \in C_j} |p - o_j|^2$, is minimized.

Key Points

K-means

The k-means algorithm starts with a random selection of k objects as the centres or the means of k clusters. The challenge is to place these centres in a clever way because each different location of centres may result in different clustering. Hence, a reasonable initial choice is to locate them as far away from each other as possible. Then an iteration process is used to assign remaining objects to their nearest centres. After the membership of all clusters is considered according to the given initial centres, the cluster centres will all be reconsidered. Hence the new cluster centres are calculated a set of k means $P = \{c_1, c_2, \ldots, c_k\}$. For example, for the mean of a set of single-valued objects in cluster i with m points is defined as m_i:

$$m_i = \frac{1}{m} \sum_{j=1}^{m} p_{i,j}$$

The means of high-dimensional objects are calculated in a same by using this formula for each of the dimensions. When cluster centres are updated, the membership computations will be executed again to reallocate the objects to the nearest centers. The main idea of updating the cluster centres and the memberships is based on the computation of Euclidian distances such that the objects in a cluster have the minimum distances and the objects between clusters have the maximum distances. The process will continue until there are no more updates that could reallocate the centres and the memberships of clusters. Even though it is easy to prove that the procedure always terminates, the k-means algorithm does not necessarily find the global optimal solutions, corresponding to the global minimum of the objective function. Also, it is easy to demonstrate that this algorithm is significantly sensitive to the initial randomly selected centres. To mitigate this situation the k-means algorithm can be executed multiple times in order to identify a better global solution. The complexity of the algorithm is $O(nkt)$, for n objects, k clusters and t iterations.

The k-means algorithm is only applicable to the objects with mean defined. The user must specify an initial value k. The k-means approach is only suitable for finding convex shapes with all clusters having similar sizes. Moreover, when there is noise and outliers in the dataset, the means of clusters may appear at locations where the majority objects are far away.

K-medoids

K-medoids algorithm avoids calculating means of clusters in which extremely large values may affect the membership computations substantially. K-medoids can handle outliers well by selecting the most centrally located object in a cluster as a reference point, namely, medoid. The difference between k-means and k-medoids is analogous to the difference between mean and median: where mean indicates the average value of all data items collected, while median indicates the value around that which all data items are evenly distributed around it. The basic idea of k-medoids is that it first arbitrarily finds k objects amongst n objects in the dataset as the initial medoids. Then the remaining objects are partitioned into k clusters by computing the minimum Euclidian distances that can be maintained for the members in each of the clusters. An iterative process then starts to consider objects p_i, $i = 1,\ldots,n$, if a medoid o_j, $j = 1,\ldots,k$, can be replaced by a candidate object o_c, $c = 1,\ldots,n$, $c \neq i$. There are four situations to be considered in this process: (i) *Shift-out membership*: an object p_i may need to be shifted from currently considered cluster of o_j to another cluster; (ii) *Update the current medoid*: a new medoid o_c is found to replace the current medoid o_j; (iii) *No change*: objects in the current cluster result have the same or even smaller SEC for all the possible redistributions considered; (iv) *Shift-in membership*: an outside object p_i is assigned to the current cluster with the new (replaced) medoid o_c.

K-medoids algorithm needs to test if any existing medoids can be replaced by any other objects. By looking at all of these possible replacements, if the overall SEC is improved then the given medoid will be replaced. The computational cost of k-medoid is much higher than the k-means. For each iteration, computational cost is $k(n\text{-}k)^2$ for $k(n\text{-}k)$ pairs of objects to be considered with each $(n\text{-}k)$ evaluations of the SEC. K-meoids algorithm then is considered with a sampling method for the improvement on the computational complexity. In this way, several samples are taken from the dataset, and then the k-medoids algorithm is applied to each of the samples. The convergence of medoids is achieved by choosing the sample that performs the best.

Language Models

Djoerd Hiemstra
University of Twente, Enschede, The Netherlands

Synonyms

Generative models

Definition

A language model assigns a probability to a piece of unseen text, based on some training data. For example, a language model based on a big English newspaper archive is expected to assign a higher probability to "a bit of text" than to "aw pit tov tags," because the words in the former phrase (or word pairs or word triples if so-called *N-Gram Models* are used) occur more frequently in the data than the words in the latter phrase. For information retrieval, typical usage is to build a language model for each document. At search time, the top ranked document is the one whose language model assigns the highest probability to the query.

Historical Background

The term *language models* originates from probabilistic models of language generation developed for automatic speech recognition systems in the early 1980s [9]. Speech recognition systems use a language model to complement the results of the *acoustic model* which models the relation between words (or parts of words called phonemes) and the acoustic signal. The history of language models, however, goes back to the beginning of the twentieth century when Andrei Markov used language models (Markov models) to model letter sequences in works of Russian literature [3]. Another famous application of language models are Claude Shannon's models of letter sequences and word sequences, which he used to illustrate the implications of coding and information theory [17]. In the 1990s, language models were applied as a general tool for several natural language processing applications, such as part-of-speech tagging, machine translation, and optical character recognition. Language models were applied to information retrieval by a number of research groups in the late 1990s [4,7,14,15]. They became rapidly popular in information retrieval research. By 2001, the ACM SIGIR conference had two separate sessions on language models containing five papers in total [12]. In 2003, a group of leading information retrieval researchers published a research roadmap "challenges in information retrieval and language modeling" [1], indicating that the future of information retrieval and the future of language modeling can not be seen separate from each other.

Foundations

Language models are generative models, i.e., models that define a probability mechanism for generating language. Such generative models might be explained by the following probability mechanism: Imagine picking a term T at random from this page by pointing at the page with closed eyes. This mechanism defines a probability $P(T|D)$, which could be defined as the relative frequency of the occurrence of the event, i.e., by the number of occurrences of a term on the page divided by the total number of terms on the page. Suppose the process is repeated n times, picking one at a time the terms T_1, T_2,...,T_n. Then, assuming independence between the successive events, the probability of the terms given the document D is defined as follows:

$$P(T_1, T_2, \ldots, T_n|D) = \prod_{i=1}^{n} P(T_i|D) \tag{1}$$

A simple language modeling approach would compute (1) for each document in the collection, and rank the documents accordingly. A potential problem might be the following: The equation will assign zero probability to a sequence of terms unless all terms occur in the document. So, a language modeling system that uses (1) will not retrieve a document unless it contains all query terms. This might be reasonable for a web search engine that typically processes small queries to search a vast amount of data, but for many other information retrieval applications, this behavior is a problem. A standard solution is to use *linear interpolation smoothing* of the document model $P(T|D)$ with a collection model $P(T|C)$, which is defined as follows:

$$P(T_1, T_2, \ldots, T_n|D) = \prod_{i=1}^{n} \Big(\lambda P(T_i|D) + (1-\lambda) P(T_i|C)\Big) \tag{2}$$

This way, a term that does not occur in the document will not be assigned zero probability but instead a probability proportional to its number of occurrences in the entire collection C. Here, λ is an unknown probability that should be tuned to optimize retrieval effectiveness. Linear interpolation smoothing was used in several early language modeling approaches [7,14].

Implementation

Although the language modeling equations above suggest the need to compute probabilities for all documents in the collection, this is unnecessary in practice. In fact, most language modeling approaches can be implemented efficiently by the use of standard inverted index search systems. This can be seen by the equation below which can be derived from (2) by two basic transformations: First, dividing it by the probability of the collection model; and second, taking the logarithm.

$$P(T_1, T_2, \ldots, T_n|D) \propto \sum_{i=1}^{n} \log\left(1 + \frac{\lambda P(T_i|D)}{(1-\lambda) P(T_i|C)}\right) \tag{3}$$

Equation (3) no longer produces probabilities, but it ranks the documents in the exact same order as (2), because the collection model does not depend on the document, and the logarithm is a strictly monotonic function. Taking the logarithm prevents the implementation from running out of the precision of its (floating point) representation of probabilities, which can become very small because the probabilities are multiplied for every query term. Similar to for instance vector space models in information retrieval, ranking is defined by a simple sum of term weights, for which terms that do not match a document get a zero weight. Interestingly, the resulting "term weight" can be seen as a variant of *tf.idf* weights, which are often used in vector space models.

Document Priors

The equations above define the probability of a query given a document, but obviously, the system should rank by the probability of the documents given the query. These two probabilities are related by Bayes' rule as follows.

$$P(D|T_1, T_2, \ldots, T_n) = \frac{P(T_1, T_2, \ldots, T_n|D) P(D)}{P(T_1, T_2, \ldots, T_n)} \tag{4}$$

The left-hand side of (4) cannot be used directly because the independence assumption presented above assumes term independence given the document. So, in order to compute the probability of the document D given the query, (2) needs to be multiplied by $P(D)$ and divided by $P(T_1, \ldots, T_n)$. Again, as stated earlier, the probabilities themselves are of no interest, but the ranking of the document by the probabilities is. And since $P(T_1, \ldots, T_n)$ does not depend on the document, ranking the documents by the numerator of the right-hand side of (4) will rank them by the probability given the query. This shows the importance of $P(D)$: The marginal probability, or *prior probability* of the document, i.e., it is the probability that the document is relevant if the query is ignored. For instance, it might be assumed that long documents are more likely to be useful than short documents [5,6]. In web search, such a so-called static ranking (a ranking that is independent of the query) is commonly used. For instance, documents with many links pointing to them are more likely to be relevant, or documents with short URLs are more likely to be relevant. The prior probability of a document is a powerful way to incorporate static ranking in the language modeling approach [10].

Document Generation Models

An implicit assumption of the language models presented is that there is more information available about the documents than about the query. In some applications, however, the situation is reversed. For instance in *topic tracking*, a system has the task of tracking a stream of chronologically ordered stories. For each story in the stream, the system has to decide whether it is on topic. The target topic is usually based on a number of example stories on a certain topic, there is more information available about the topic than about a single story. Unlike query generation models, document generation models need some form of normalization because documents will have different lengths. The probability of generating a document tends to be smaller for long documents than for short documents. Therefore, several normalization techniques might be applied, such as normalization by document length and additional Gaussian normalization [10,18]. *Relevance feedback* (i.e, the user marked some documents as relevant) is another situation in which there is more knowledge available about the query than about each single document. If some relevant documents are known, or if the top ranked documents are assumed to be relevant, then those documents might be used to generate a new, improved query [20]. As an example, consider the following so-called *relevance models* approach [13]

$$P(Q|T_1,\ldots,T_n) \propto \sum_d \left(P(D=d)P(Q|D=d)\prod_{i=1}^{n} P(T_i=t_i|D=d) \right) \tag{5}$$

Here, the formula defines the probability of a new word Q, given the original query $T_1,\ldots,T_n$ by marginalizing over all documents. In practice, only the top ranked documents for the query $T_1,\ldots,T_n$ are used. Interestingly, the relevance model might be used to infer other information from the top ranked documents, for instance the person that is most often mentioned for a certain query, so-called *expert search* [2].

Translation Models

Language models for information retrieval are generative models, and therefore easily combined with other generative models. To add a model of term translation, the following probability mechanism applies: Imagine picking an English term T at random from this page by pointing at the page with closed eyes (which defines a probability $P(T|D)$), and then translate the term T by picking from the term's entry in a English–Dutch dictionary at random a Dutch term S (with probability $P(S|T)$). The model might be used in a cross-language retrieval system to rank English documents given a Dutch query $S_1,\ldots,S_n$ by the following probability [4,6,13,19]:

$$P(S_1, S_2,\ldots,S_n|D) = \prod_{i=1}^{n}\sum_t \Big(P(S_i=s_i|T_i=t) \\ (\lambda P(T_i=t|D) + (1-\lambda)P(T_i=t|C)) \Big) \tag{6}$$

Here, Dutch is the source language and English the target language. The formula uses linear interpolation smoothing of the document model with the target language background model $P(T|C)$ (English in the example) at the right-hand side of the formula. In some formulations, the translation model is smoothed with the source language background model $P(S|C)$ which a estimated on auxiliary data. The two background models are related as follows: $P(S|C) = \sum_t P(S|T=t)P(T=t|C)$. The translation probabilities are often estimated from parallel corpora, i.e., from texts in the target language and its translations in the source language [6,19]. Translation models might also be used in a monolingual setting to account for synonyms and other related words [4].

Aspect Models

In *aspect models*, also called *probabilistic latent semantic indexing* models, documents are modeled as mixtures of aspect language models. In terms of a generative model it can be defined in the following way [8]: (i) select a document D with probability $P(D)$, (ii) pick a latent aspect Z with probability $P(Z|D)$, (iii) generate a term $T$with probability $P(T|Z)$ independent of the document, (iv) repeat Step 2 and Step 3 until the desired number of terms is reached. This leads to (7).

$$P(T_1,T_2,\ldots,T_n|D) \propto \prod_{i=1}^{n}\left(\sum_z (P(T_i|Z=z)P(Z=z|D)) \right) \tag{7}$$

The aspects might correspond with the topics or categories of documents in the collection such as "health", "family", "Hollywood", etc. The aspect Z

is a hidden, unobserved variable, so probabilities concerning Z cannot be estimated from direct observations. Instead, the expectation maximization (EM) algorithm can be applied [9]. The algorithm starts out with a random initialization of the probabilities, and then iteratively re-estimates the probability of arriving at a local maximum of the likelihood function. It has been shown that the EM algorithm is sensitive to the initialization, and an unlucky initialization results in a non-optimal local maximum. As a solution, clustering of documents has been proposed to initialize the models [16]. Another alternative is latent semantic Dirichlet allocation [15] which has less free parameters, and therefore is less sensitive to the initialization.

Key Applications

This entry focuses on the application of language models to information retrieval. The applications presented include newswire and newspaper search [4,5,15], web search [11], cross-language search [6,19], topic detection and tracking [10,18], and expert search [2]. However, language models have been used in virtually every application that needs processing of natural language texts, including automatic speech recognition, part-of-speech tagging, machine translation, and optical character recognition.

Web scraping; Screen scraping; Web site wrappers; Web mining; Information extraction

Definition

Web data extraction is the process of automatically converting Web resources into a specific structured format. For example, if a collection of HTML web pages describes details about various companies (name, headquarters, etc) then web data extraction would involve converting this native HTML format into computer-processable data structures, such as entries in relational database tables. The purpose of web data extraction is to make web data available for subsequent manipulation or integration steps. In the previous example, the goal may be summarizing the results as some form of analytical report.

There are several approaches to Web data extraction. The most common approach is to specify the conversion process using a special-purpose programming *Language for Web Data Extraction*. Web data extraction then becomes a matter of executing a well-defined computer program.

Web data extraction languages are generally not intended to be general-purpose programming languages (although some are formally Turing complete). Rather, these special-purpose languages are intended to simplify various actions that are needed to navigate to and retrieve web documents, extract and clean their data, and populate the data into appropriate data structures for output. For example, most languages for web data extraction provide mechanisms for crawling hypertext links, submitting HTML forms, parsing HTML documents, decomposing a document into components using regular expressions, etc. Some languages also offer features such as natural language processing, web-, text- or data-mining algorithms, or access to structured data (e.g., ODBC sources or third-party applications).

This entry focuses primarily on the features of web data extraction languages. However, note that a key strength of some commercial Web data extraction products, and an active area of academic research, is graphical user interface for visually specifying the conversion process (see for example [2]). Similarly, there have been numerous attempts to automatically generate web data extraction programs using machine learning techniques (see for example [3,5,6,9]).

Note also that web data extraction is related to but distinct from web search technologies. Search engines crawl and index large numbers of web documents to facilitate subsequent ad-hoc keyword-based querying. In contrast, web data extractors retrieve a relatively small number of relevant documents (often in a specific sequence as the web sources perform various transactions), and then isolate specific document fragments in order to answer various predefined structured queries on their contents.

Historical Background

As the Web proliferated in the 1990s, computer science researchers from diverse backgrounds (databases, systems, artificial intelligence, information retrieval, etc) realized that the ability to integrate data across heterogeneous sources would give rise to a wide variety of compelling applications, such as shopping assistants that compare products across multiple retail sites. Many researchers who had been investigating traditional formulations of the data integration problem, turned their attention to integrating Web data. This attention revealed many new challenges. Data extraction quickly became prominent among these new challenges. Researchers simply could not demonstrate their Web data integration algorithms in a compelling manner until they developed systematic ways to automatically access large numbers of Web documents and then extract structured data from these documents' native formats.

The first approach to Web data extraction was simply to code up the necessary URL retrieval and data extraction in conventional programming languages. Indeed, many Web data integration applications continue to use this approach today. However, Web data extraction programs implemented in this manner tend to be relatively large, making it difficult to design, debug, re-use and maintain them.

Based on this experience, researchers quickly observed that web data extraction programs written in conventional programs exhibit many common software patterns. This observation led to efforts to encapsulate these patterns either as reusable libraries for existing languages, or as primitives in specialized web data extraction languages (see for example [1,4,7,8,10,11]). For instance, many web data extraction programs perform crawling behavior such as "parse an HTML document to find all its hyperlinks; then retrieve all newly discovered URLs, and repeat," or "submit a Web form several times, each time binding one of its input parameters to one of several values." To make it easier to build Web crawlers, this behavior could be encoded as a set of functions/classes in a library, or as primitives in a specialized Web data extraction language.

Foundations

From a theoretical perspective, it is meaningless to formally differentiate between Web data extraction languages and "regular" programming languages. Nearly every programming language has features of some aspect of web data extraction, such as retrieving URLs or applying regular expressions. Therefore, nearly any programming language can be used for web data extraction, and so every programming language is a web data extraction language. At the same time, some specialized web data extraction languages are Turing complete, so they can be used to implement arbitrary algorithms that have nothing in particular to do with Web data. Nevertheless, from a practical perspective, it can be much simpler to implement Web data extractors in some languages compared to others. This entry focuses on these practical issues, rather than formal distinctions.

Web data extraction comprises four distinct capabilities:

1. Access: Authenticating to web sites as needed, and fetching particular URLs
2. Extract: Populating data structures from retrieved documents
3. Process: Performing ancillary computations on extracted data
4. Output: Converting data to desired format and delivering to destination

Web data extraction languages vary in the sophistication with which they support these capabilities. All languages support some form of access and extraction, but some provide only limited support for data processing or output.

This entry explains these capabilities by examining one particular Web data extraction language, WebQL. WebQL is a product of QL2 Software Inc (www.QL2.com). While other languages offer a similar range of capabilities, WebQL is a good example for tutorial purposes because it has a familiar SQL-like syntax, and numerous features that address the four capabilities listed above.

WebQL programs consist of one or more *select* statements, which are similar to SQL select statements. When an SQL select statement retrieves values from database tables, a WebQL select statement retrieves data from a Web source. As in SQL, complete WebQL programs comprise a set of select statements that are combined using join, union and other data-flow operations.

Access

The simplest form of Web data access is fetching a single URL. The WebQL program

```
select
   source_content
from
   http://example.com/recipes.html
```

populates a table with one column, and one row, containing the HTML source for the given URL.

As discussed above, it is certainly true that URLs can be easily fetched in every modern programming language. However, web data retrieval languages usually offer a more compact syntax for performing actions that would be much more cumbersome in other languages. For example, the WebQL program

```
select
  source_content
from
  crawl of http://example.com/
  recipes.html
  to depth 3
  following if url matching 'potato'
```

implements a spider in WebQL that follows links that satisfy the stated criteria. This compact syntax takes care of numerous low-level details such as timing out, HTTP redirects, HTML parsing, broken links, etc. As a practical matter, this compact syntax generally leads to data extractors that are simpler to design, code, debug, maintain, and reuse. Just as it is formally possible but practically much more difficult to implement complex algorithms in low-level machine-level languages compared to high-level programming languages, web data extractors implemented in special-purpose programming languages are generally simpler to write and easier to extend and maintain.

Another aspect of data access is submitting HTML forms. For example, the WebQL statement

```
select
  source_content
from
  http://example.com/recipe_search
  submitting values ['potato', 'car-
  rot'] for 'ingredient'
```

parses the specified URL to detect HTML forms, and then submits each such form twice, each time binding the input parameter ingredient to one of the specified values. Again, the web data extraction language hides from the programmer details such as binding hidden form parameters.

Extract

After some specific web content has been accessed, web data extractors typically isolate particular fragments or properties of the document. Web programming languages offer numerous capabilities for data extraction. The simplest approach is to use the low-level string operations or regular expression matching capabilities that most programming languages provide. For example, the following WebQL segment extracts two text fragments from a particular URL using low-level operations:

```
select
  -- extract first paragraph, with low-
  level string functions
  substr(instr
  (source_content,'<p>')+3,instr
  (html,'</p>')
  as firstpara,
  -- extract first bold text, with regu-
  lar expression
  extract_pattern
  (source_content,'<b>(.*)</b>')
  as firstbold
from
  http://example.com/recipes.html
```

While these techniques suffice for many simple forms of extraction, most web data extraction languages provide extraction techniques that operate at a higher-level of abstraction. For example, an extractor may need to extract all images and the dimensions from a HTML document. One could do so using a regular expression such as:

```
<img src="([^"]*)" height="([^"]*)"
width="([^"]*)"
```

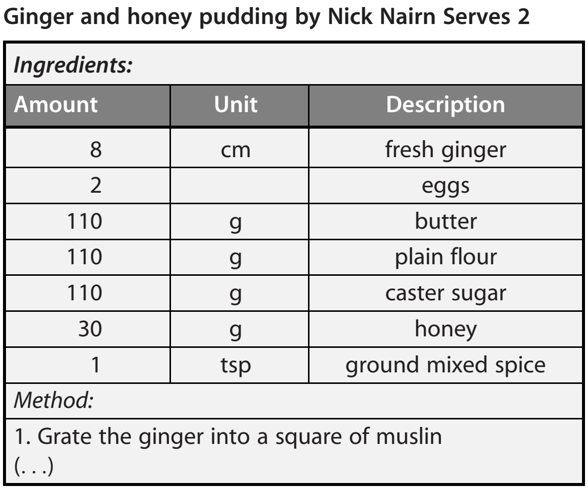
This is a very brittle approach. It assumes that the attributes are double-quoted, that none are missing, that they occur in the order listed, etc. This regular expression could be refined to accommodate these difficulties, but the resulting very long regular expression would need to be copied each time it is needed.

As an alternative, most web data extraction languages offer a suite of high-level extraction capabilities. For example, one can extract images from HTML documents using WebQL as follows:

```
select
  url,
  height,
  width
from
  images
within
  http://example.com/recipes.html
```

The “from images within” portion of this select statement is an example of a high-level extraction capability. WebQL and other web data extraction languages generally offer a range of such capabilities, including robustly parsing HTML forms, rendering HTML documents into plain text, invoking XPath queries on XML data, using linguistic rules to segment text into paragraphs, sentences, phrases, entities, words, etc, and extracting rows and/or columns from HTML tables.

As an example of the last capability, suppose that http://example.com/recipes.html contains tables embedded with text, such as the following:



Ginger and honey pudding by Nick Nairn Serves 2

Ingredients:		
Amount	Unit	Description
8	cm	fresh ginger
2		eggs
110	g	butter
110	g	plain flour
110	g	caster sugar
30	g	honey
1	tsp	ground mixed spice
Method:		
1. Grate the ginger into a square of muslin (. . .)		

The following WebQL select statement identifies the tables in this document and then retrieves the values of three specific columns by that are identified by name:

```
select
  amount,
  unit,
  description
from
  table values (amount, unit,
  description)
within
  http://example.com/recipes.html
```

While the details of these extraction techniques vary widely, and while low-level string or regular expression operations could be used to extract this data in any modern programming language, the general point holds: by providing abstract high-level data extraction operations, web data extraction languages make it much easier to implement extractors that are concise, correct, maintainable, and reusable.

Process

So far, this entry has focused on the advanced access and extraction functionality of web data extraction languages, compared to traditional programming languages. However, real web data extractors usually need to do more than simply access documents and extract their data; they also need to process this data in some way.

Web data extraction languages generally have a rich set of traditional programming language operators and control structures for manipulating and transforming data. For example, WebQL offers most of the data-flow operations in SQL dialects, such as joins, unions, grouping, sorting, and removing duplicates. WebQL also has a wide variety of functions for performing many kinds of operations. To illustrate these capabilities, consider the following query:

```
select as ExistingMeat
  ingredient as existing_ingredient,
  text_to_datetime("best before",
  'dd-mm-yy')
  as best_before_date
from
  table values (ingredient, catego-
  ry, "best before")
within
  http://www.example.com/current_fridge_
  contents.html
where
  category = 'meat'
join to ExistingMeat
select as RequiredIngredient
  description as
  required_ingredient,
  existing_ingredient
from
  table values (description)
within
  http://example.com/recipe_search
  submitting values existing_ingre-
  dient for 'ingredient'
join to ExistingMeat,
RequiredIngredient
  where ExistingMeat.existing_in-
  gredient =
  RequiredIngredient.
  existing_ingredient
select
  required_ingredient,
  best_before_date < now() + 24*60*60
  as urgent
sort by
  best_before_date desc
```

For the sake of this entry, there is no need to explain this program in detail. At a high level, it first extracts a list of ingredients currently in the refrigerator along with their category (meat, vegetables, etc) and expiration date; then requests recipes containing each meat that is in stock, and records which other ingredients are needed to make those recipe. And finally the program sorts the required ingredients by the expiration date of their meat, and also outputs a Boolean value that is true if the meat will soon expire. This example illustrates the ability to join intermediate tables, sort data, perform numerical and logical operations, and transform textual date/time values into a native numerical representation.

Output

After accessing, extracting and processing the required data, web data extractors must deliver the data to some destination in the appropriate format. Web data extraction languages vary in the range of output formats and delivery mechanisms that they support. To illustrate some of these capabilities, consider the following WebQL program:

```
select
  url,
  content
from
  links
within
  http://www.example.com/recipes.
  html
into
  -- write XML to local file
  file:links.xml,
  -- send CSV to an FTP site
  ftp://jsmith@mysecret:ftp.exam-
  ple.com/links.csv,
  -- write data as new rows in a database
  table
  'links'@docdb
```

The "into" clause causes the data to be encoded in specific formats and sent to specific destinations. This example program extracts the links from a web page, and then delivers them in various formats (comma-separated text file, XML) to both a local file and an FTP site, and also inserts the data directly into database table via ODBC.

Key Applications

Web data extraction languages are widely used in numerous commercial applications across a wide variety of industries The most common scenario is that an enterprise wants to extract data from external Web sources for which public Web Services or other programmatic APIs are not available. While numerous (often "Web 2.0"-oriented) data sources offer public APIs or structured data feeds such as RSS, many more sources do not. This is particularly true for high-value data extraction applications such as the gathering of real-time competitive market intelligence. For example, most large retailers, manufacturers and distributors employ some form of Web data extraction to monitor their competitor's prices. In most cases, the only way to harvest such data is by extracting it from public Web sources such as on-line retail catalogs or shopping sites.

Web data extraction is also used as a form of lightweight data integration for interconnecting legacy applications within an enterprise. Many companies are not in a position to modify critical business systems used for inventory management, pricing, customer management, etc., yet they want to integrate these systems. Web data extraction tools are frequently used to facilitate such integration by working with existing Web-based interfaces, rather than forcing the enterprise to modify their legacy systems.

A third important application area is so-called "mashups," applications that combine data from multiple sources into unified service. Web data extraction languages are clearly an appropriate technology with which to develop mashups. To many proponents, a key aspect of the mashup philosophy is the ability of ordinary users to generate their own applications. Therefore, most mashup technologies focus on visual interfaces that allows non-technical users to develop web data extraction programs.

While this entry focuses largely on technical issues, it is important to point out that the use of automated web data extractors may give rise to two sorts of legal issues. First, the terms of use of many Web sites explicitly prohibit automated content extraction. Second, republication of the extracted data may violate the original source's copyright on the data.

Future Directions

The core theoretical and scientific issues regarding web data extraction are well understood. While numerous companies are competing in the web data extraction/integration space, they compete primarily on the basis of the value-added services they deliver on top of the extracted data, rather than on the basis of their extraction technology. Nevertheless, as web technologies change, web data extraction languages will be enhanced to accommodate formats such as Flash/AMF in which more and more web data is embedded.

More significantly, some "web" data extraction languages provide access to a wide range of non-web sources (such as email, FTP sites, execution of external programs, etc) and formats (such as office documents and spreadsheets, archived and compressed data, etc). As these capabilities expand, these languages will not remain focused exclusively on web data, but rather they will evolve into powerful general-purpose tools for manipulating and integrating arbitrary structured and unstructured digital content.

URL to Code

There are several open-source Web data extraction tools, usually in the form of a library for a full-fledged programming language. Examples include:

1. Perl: WWW::Mechanize (search.cpan.org/dist/WWW-Mechanize)
2. PHP: Curl (www.php.net/curl)
3. Java: Web-Harvest (web-harvest.sourceforge.net)

Many companies compete in the Web data extraction market. These companies generally offer standalone data-extraction products, as well as on-demand services based on these technologies that are tailored to specific vertical industries. Examples include:

1. QL2 (www.ql2.com)
2. Fetch (www.fetch.com)
3. Kapow (www.kapowtech.com)
4. Lixto (www.lixto.com)
5. Connotate (www.connotate.com)

Learning Distance Measures

Flexible metric computation; Adaptive metric techniques

Definition

Many problems in data mining (e.g., classification, clustering, information retrieval) are concerned with the discovery of homogeneous groups of data according to a certain similarity (or distance) measure. The distance measure in use strongly affects the nature of the patterns (clusters, classes, or retrieved images) emerging from the given data. Typically, any chosen fixed distance measure, such as Euclidean or Manhattan distance, does not capture the underlying structure of the data, and fails to find meaningful patterns which correspond to the user's preferences. To address this issue, techniques have been developed that learn from the data how to compute dissimilarities between pairs of objects. Since objects are commonly represented as vectors of measurements in a given feature space, distances between two objects are computed in terms of the dissimilarity between their corresponding feature components. In this setting, learning a (local) distance measure for a query object $\mathbf{q} \in \Re^n$ (to be classified) and an arbitrary object $\mathbf{x} \in \Re^n$ means to learn a weighted p-norm distance metric on the Euclidean space of the input measurement variables (or features):

$$D_p(\mathbf{q},\mathbf{x}) = \{\sum_{i=1}^{n} |[W(\mathbf{q})(\mathbf{q}-\mathbf{x})]_i|^p\}^{1/p},$$

where $p > 0$ and $W(\mathbf{q}) \in \Re^{n\times n}$ is a matrix of weights reflecting the relevance or importance of features at the query $\mathbf{q}$. If $W(\mathbf{q})$ depends on the query point $\mathbf{q}$, the resulting distance measure is *local*; otherwise, if W is invariant to the query, a *global* distance measure is obtained.

Historical Background

The problem of learning distance measures from data has attracted considerable interest recently in the data mining and machine learning communities. Different methodologies have been developed for supervised, unsupervised, and semi-supervised problems. One of the earliest work that discusses the problem of clustering simultaneously both points and features is Hartigan, 1972 [9]. A model based on direct clustering of the data matrix and a distance-based model are introduced, both leading to similar results.

Foundations

The ability to classify patterns is certainly one of the key features of intelligent behavior, whether it is humans' or animals'. This ability emerged with the biogenetic evolution for survival purposes, not only of individuals but also of entire species. An individual receives sensory information that must be processed to perceive, and ultimately act, possibly for orientation in the environment, distinction between edible and poisonous food, or detection of dangerous enemies.

Machine perception and classification as features of artificial systems serve similar but more constrained purposes. Machine classification aims to provide artificial systems with the ability to react to situations and signals that come from the environment to perform specific tasks. As such, pattern classification is a fundamental building block of any cognitive automata.

Recent developments in data mining have posed new challenges to pattern classification. Data mining is a knowledge discovery process whose aim is to discover unknown relationships and/or patterns from a large set of data that make it is possible to predict future outcomes. As such, pattern classification becomes one of the key steps in attempting to uncover the *hidden knowledge* within the data. The primary goal is usually predictive accuracy, with secondary goals being speed, ease of use, and interpretability of the resulting predictive model.

The term *pattern* is a common word and means something exhibiting some form of regularity, able to serve as a model representing a concept of what was observed. As a consequence, a pattern is never an isolated observation, but rather a collection of observations connected in time or space (or both). A pattern exhibits, as a whole, a certain structure indicative of the underlying concept. The pattern classification task can then be seen as the task of inferring concepts from observations. Thus, designing a pattern classifier means defining a mapping from a measurement space into the space of possible meanings, that are viewed as finite and discrete target points.

From this perspective, it makes no difference what kind of observations are considered and to what kind of meanings they may be linked. The same approach can be used to recognize written text, spoken language, objects, or any other multidimensional signals as well. The selection of meaningful observations from a specific domain is a *feature extraction* process. From a theoretical viewpoint, the distinction between feature extraction and classification is arbitrary, but nevertheless useful. In general, the problem of feature extraction is much more domain dependent than the problem of classification.

Statistical Approach

A characteristic of patterns in the context of classification is that every concept (or class) may have multiple representative points in the measurement space. For example, for the task of character recognition from their images, there exists a potentially unlimited plurality of ways to design character images that correspond to the same character. Therefore, the very core of pattern classification is to cope with variability. The difficulty of the task depends on the degree to which the representatives of a class are allowed to vary and how they are distributed in the measurement space. This observation brings together two intrinsic components of the pattern classification task: the *statistical* component and the principle of *learning from examples*.

The problem of classification can be seen as one of partitioning the feature space into regions, one region for each category. Ideally, one would like to arrange this partitioning so that no decisions is ever wrong. This objective may not be achievable for two reasons. The distributions of points of different classes in the measurement space overlap; thus, it is not possible to reliably separate one class from the other. Moreover, even if a rule that does a good job of separating the examples can be found, one has no guarantee that it will perform as well on new points. In other words, that rule may not *generalize* well on data never seen before. It would certainly be safer to consider more points, and check how many of those are correctly classified by the rule. This suggests that one should look for a classification procedure that aims at minimizing the *probability of error*. The problem of classification then becomes a problem in statistical decision theory.

Challenges

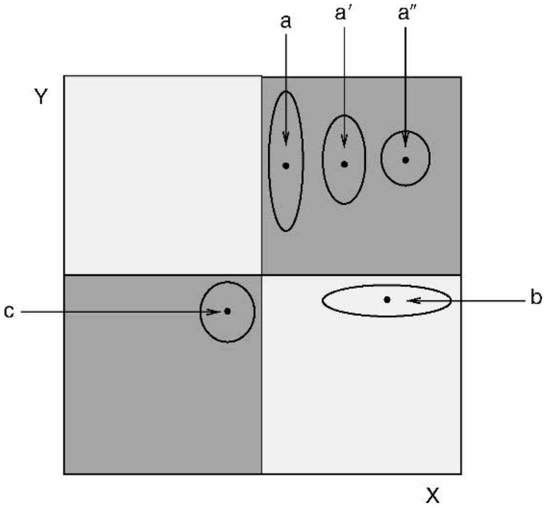
While pattern classification has shown promise in many areas of practical significance, it faces difficult challenges from real world problems, of which the most pronounced is Bellman's *curse of dimensionality* [1]. It states the fact that the sample size required to perform accurate prediction in problems with high dimensionality is beyond feasibility. This is because in high dimensional spaces, data become extremely sparse and are apart from each other. As a result, severe bias that affects any estimation process can be introduced in a high dimensional feature space with finite samples.

Consider, for example, the rule that classifies a new data point with the label of its closest training point in the measurement space (*1-Nearest Neighbor rule*). Suppose each instance is described by 20 attributes, but only three of them are relevant to classifying a given instance. In this case, two points that have identical values for the three relevant attributes may nevertheless be distant from one another in the 20-dimensional input space. As a result, the similarity metric that uses all 20 attributes will be misleading, since the distance between neighbors will be dominated by the large number of irrelevant features. This shows the effect of the curse of dimensionality phenomenon, that is, in high dimensional spaces distances between points within the same class or between different classes may be similar. This fact leads to highly biased estimates. Nearest neighbor approaches are especially sensitive to this problem.

In many practical applications things are often further complicated. In the previous example, the three relevant attributes for the classification task at hand may be dependent on the location of the query point, i.e., the point to be classified, in the feature space. Some features may be relevant within a specific region, while other features may be more relevant in a different region.

These observations have two important implications. Distance computation does not vary with equal strength or in the same proportion in all directions in the feature space emanating from the input query. Moreover, the value of such strength for a specific feature may vary from location to location in the feature space. Figure 1 illustrates a case in point, where class boundaries are parallel to the coordinate axes. For query *a*, dimension *X* is more relevant, because a slight move along the *X* axis may change the class label, while for query *b*, dimension *Y* is more relevant. For query *c*, however, both dimensions are equally relevant. Capturing such information, therefore, is of great importance to any classification procedure in high dimensional settings.

It is important to emphasize that the curse of dimensionality is not confined to classification. It affects any estimation process in a high dimensional feature space with finite examples. Thus, clustering equally suffers from the same problem. The clustering problem concerns the discovery of homogeneous groups of data according to a certain similarity measure. It is not meaningful to look for clusters in high dimensional spaces as the average density of points anywhere in input space is likely to be low. As a consequence, distance functions that equally use all input features may not be effective.



Learning Distance Measures. Figure 1. Feature relevance varies with query locations.

Adaptive Metric Techniques

This section presents an overview of relevant work in the literature on flexible metric computation for classification and clustering problems.

Adaptive Metric Nearest Neighbor Classification

In a classification problem, one is given l observations $\mathbf{x} \in \mathfrak{R}^n$, each coupled with the corresponding class label y, with $y = 1,\ldots,J$. It is assumed that there exists an unknown probability distribution $P(\mathbf{x}, y)$ from which data are drawn. To predict the class label of a given query $\mathbf{q}$, the class posterior probabilities $\{P(j|\mathbf{q})\}_{j=1}^{J}$ need to be estimated.

K nearest neighbor methods are based on the assumption of smoothness of the target functions, which translates to locally constant class posterior probabilities $P(j|\mathbf{q})$, that is: $P(j|(\mathbf{q} + \delta\mathbf{q})) \simeq P(j|\mathbf{q})$, for $\|\delta\mathbf{q}\|$ small enough. Then, $P(j|\mathbf{q}) \simeq \frac{\sum_{\mathbf{x}\in N(\mathbf{q})} P(j|\mathbf{x})}{|N(\mathbf{q})|}$, where $N(\mathbf{q})$ is a neighborhood of $\mathbf{q}$ that contains points $\mathbf{x}$ that are "close" to $\mathbf{q}$, and $|N(\mathbf{q})|$ denotes the number of points in $N(\mathbf{q})$. This motivates the estimates

$$\hat{P}(j|\mathbf{q}) = \frac{\sum_{i=1}^{l} 1(\mathbf{x}_i \in N(\mathbf{q}))1(y_i = j)}{\sum_{i=1}^{l} 1(\mathbf{x}_i \in N(\mathbf{q}))},$$

where $1()$ is an indicator function such that it returns 1 when its argument is true, and 0 otherwise.

The assumption of smoothness, however, becomes invalid for any fixed distance metric when the input observation approaches class boundaries. The objective of locally adaptive metric techniques for nearest neighbor classification is then to produce a modified local neighborhood in which the posterior probabilities are approximately constant.

The techniques proposed in the literature [5,6,10] are based on different principles and assumptions for the purpose of estimating feature relevance locally at query points, and therefore weighting accordingly distances in input space. The idea common to these techniques is that the weight assigned to a feature, locally at a given query point **q**, reflects its estimated relevance to predict the class label of **q**: larger weights correspond to larger capabilities in predicting class posterior probabilities. As a result, neighborhoods get constricted along the most relevant dimensions and elongated along the less important ones. The class conditional probabilities tend to be constant in the resulting neighborhoods, whereby better classification performance can be obtained.

Large Margin Nearest Neighbor Classifiers

The previously discussed techniques have been proposed to try to minimize bias in high dimensions by using locally adaptive mechanisms. The "lazy learning" approach used by these methods, while appealing in many ways, requires a considerable amount of on-line computation, which makes it difficult for such techniques to scale up to large data sets. Recently, a method (called LaMaNNA) has been proposed which, although still founded on a query based weighting mechanism, computes off-line the information relevant to define local weights [3].

The technique uses support vector machines (SVMs) as a guidance for the process of defining a local flexible metric. SVMs have been successfully used as a classification tool in a variety of areas [13], and the maximum margin boundary they provide has been proved to be optimal in a structural risk minimization sense. The decision function constructed by SVMs is used in LaMaNNA to determine the most discriminant direction in a neighborhood around the query. Such direction provides a local feature weighting scheme. This process produces highly stretched neighborhoods along boundary directions when the query is close to the boundary. As a result, the class conditional probabilities tend to be constant in the modified neighborhood, whereby better classification performance can be achieved. The amount of elongation-constriction decays as the query moves farther from the vicinity of the decision boundary. This phenomenon is exemplified in Fig. 1 by queries a, a' and a''.

Adaptive Metrics for Clustering and Semi-Supervised Clustering

Adaptive metric techniques for data without labels (unsupervised) have also been developed. Typically, these methods perform clustering and feature weighting simultaneously in an unsupervised manner [2,4,7,8,12]. Weights are assigned to features either globally or locally.

The problem of feature weighting in K-means [11] clustering has been addressed in [12]. Each data point is represented as a collection of vectors, with "homogeneous" features within each measurement space. The objective is to determine one (global) weight value for each feature space. The optimality criterion pursued is the minimization of the (Fisher) ratio between the average within-cluster distortion and the average between-cluster distortion.

COSA (Clustering On Subsets of Attributes) [7] is an iterative algorithm that assigns a weight vector (with a component for each dimension) to each data point. COSA starts by assigning equal weight values to each dimension and to all points. It then considers the k nearest neighbors of each point, and uses the resulting neighborhoods to compute the dimension weights. Larger weights are credited to those dimensions that have a smaller dispersion within the neighborhood. These weights are then used to compute dimension weights for each pair of points, which in turn are utilized to update the distances for the computation of the k nearest neighbors. The process is iterated until the weight values become stable. At each iteration, the neighborhood of each point becomes increasingly populated with data from the same cluster. The final output is a pairwise distance matrix based on a weighted inverse exponential distance that can be used as input to any distance-based clustering method (e.g., hierarchical clustering).

LAC (Locally Adaptive Clustering) [4] develops an exponential weighting scheme, and assigns a weight vector to each cluster, rather than to each data point. The weights reflect local correlations of data within each discovered cluster, and reshape each cluster as a dense spherical cloud. The directional local reshaping of distances better separates clusters, and allows for the discovery of different patterns in different subspaces of the original input space.

Recently, to aid the process of clustering data according to the user's preferences, a semi-supervised framework has been introduced. In this scenario, the user provides examples of similar and dissimilar points, and a distance metric is learned over the input space that satisfies the constraints provided by the user [14].

Key Applications

Almost all problems of practical interest are high dimensional. Thus, techniques that learn distance measures have significant impact in fields and applications as diverse as bioinformatics, security and intrusion detection, document and image retrieval. An excellent example, driven by recent technology trends, is the analysis of microarray data. Here one has to face the problem of dealing with more dimensions (genes) than data points (samples). Biologists want to find "marker genes" that are differentially expressed in a particular set of conditions. Thus, methods that simultaneously cluster genes and samples are required to find distinctive "checkerboard" patterns in matrices of gene expression data. In cancer data, these checkerboards correspond to genes that are up- or downregulated in patients with particular types of tumors.

Lexical Analysis of Textual Data

Chris D. Paice
Lancaster University, Lancaster, UK

Synonyms

Lexical processing; Term processing

Definitions

Lexical analysis refers to the association of meaning with explicitly specified textual strings, referred to here as *lexical terms*. These lexical terms are typically obtained from texts (whether natural or artificial) by a process called *term extraction*. The association of meaning with lexical terms involves a data structure known generically as a *lexicon*. The characteristic operation in using a lexicon is a *lookup*, where the input is a lexical term, and the output is a representation of one or more associated meanings. A lexicon consists of a collection of *entries*, each of which comprises an *entry term* and a meaning structure. Lookup entails finding any entries whose entry term matches the lexical term in question.

Here, the term lexical analysis is used to refer only to operations performed on complete words or word groups. Operations on the characters within words is the concern of *morphology*.

The use of *text corpora* for obtaining data on the properties of words may also be regarded as a branch of lexical analysis. A text corpus provides a large representative sample of a language or sublanguage, and may be used for generating data-sets such as lexicons (see later), for providing statistical information, and for identifying examples of particular language constructs for researchers. Operations on corpora include annotating words or word groups with grammatical or other information. [9,11]

Historical Background

The need for automatic lexical analysis dates back to the 1950s, when the need arose for programing language compilers to recognize variable names and reserved words, and assign an appropriate role to each one. As soon as computers started being used for processing natural language texts, lexical processing was required for extracting, recognizing, organizing, and correlating words and phrases. At first, lexicons for term recognition were compiled by hand, or adapted from existing dictionaries and lists, but later, automatic tools were developed, either for generating lexicons outright, or for reducing the amount of human effort involved in constructing them.

Foundations

A natural language word is a sign whose meaning cannot be inferred (except in special cases such as onomatopoeic words) from its phonological or morphological structure. *Lexical analysis* is a process by which meanings are associated with specific words or other textual strings. These strings, which can be referred to as *lexical terms*, or just *terms*, are typically extracted during the scanning of some document.

Lexical terms may be individual words belonging to a natural or artificial language, but they may also include abbreviations such as "IBM" and "USAAF", 'pseudowords' such as "PL/1" and "B12", and even multiword expressions (MWEs) such as "winter wheat" or "Boeing 747." The key point is that the term must represent a known concept which is, or may be, relevant to some current need. The function of lexical analysis is to return information enabling that need to be satisfied.

A data structure or data collection which associates a set of lexical terms with their meanings is known as a *lexicon*. The meaning associated with a specified lexical term may be referred to as an *output* of the lexicon. The structure of the lexicon and the nature of the output vary according to what kind of information is required for the task at hand. Some applications may require access to two or more different lexicons, covering different (or partly different) sets of terms, and yielding different kinds of output.

Although the detailed arrangements can vary, a lexicon consists essentially of a set of *entries*, each of which maps a term to a meaning. In some lexicons, a given term can yield a number of alternative meanings. In such a case, the application program must choose the most appropriate meaning or (depending on the task at hand) make use of them all.

The archetypal lexicon is a traditional *dictionary*, in which each natural language word is accompanied by a definition of each distinct meaning of the word, together with indicators for pronunciation, syntax, etymology, etc. [11]

In a lexicon, the key operation is the *lookup*, which takes a term and returns an output representing the required meaning or meanings. In cases where the term is not present in the lexicon, a "null" or "false" output is returned.

In applications where the range of terms and meanings are very small, lexical analysis may be performed by encoding (or "hard wiring") the relevant terms as literals in decision structures in a computer program.

Lexical Analysis in Text Processing

1. Lexical extraction Reference to a lexicon is frequently required by an application program designed to process textual data, whether this consists of text in a natural language, or in an artificial language such as a programming language. In extracting terms from a text, the first step is normally to *tokenize* the text – that is, to divide the stream of characters into coherent groups called *tokens*, as appropriate for the task at hand. In a natural text, the tokens may include words, numbers, punctuation symbols, brackets, etc.

As noted earlier, lexical analysis typically involves the lookup of significant items such as words and phrases. Tokenization therefore usually involves, or is immediately followed by, a filtering process which recognizes and discards irrelevant items such as punctuation marks. In fact, in a language like English, extraction of single words can be achieved by regarding all characters except letters, and perhaps digits, as token delimiters. There remain only certain specific issues, such as the handling of hyphens and apostrophes, where the extracted terms need to conform to the practice used in the lexicon. [6,8]

If the lexicon includes terms which are multiword expressions (MWEs), there is a problem in that MWEs are not explicitly flagged in a text, and so cannot be extracted directly. The only exception is the names of places, people and organizations, such as "Department for Transport" or "United Arab Emirates," where the main component words are capitalized.

Lexical terms are almost always represented by grammatical noun phrases (NPs). Hence, one approach to the extraction of MWEs is to parse the text and then extract the NPs as potential terms. Parsing is however a slow process, and only likely to be worthwhile if the output of the parser is to be used for other purposes as well. Fortunately, NPs can also be identified by a more limited syntactic process based on recognizing patterns of grammatical tags, which can be done reasonably quickly. [11]

A more simple-minded approach to term extraction involves generating all sequences of successive tokens up to a specified length, and checking each against the lexicon in decreasing order of length. With a four-token limit, this would seem to involve checking four potential terms per token, but in fact this is an overestimate. Firstly, sequences starting or finishing with a trivial word like "of" or "for", or containing a punctuation symbol, might be discarded at once (though this begs the question of how efficiently these cases can be recognized). Secondly, if the first word of a long sequence fails to match, the shorter sequences starting with that word need not be tested. All in all, with its avoidance of syntactic processing, this can be quite an effective approach.

A different method is to only extract single tokens. but if the current token happens to match the first word of a multiword term, the succeeding tokens of the text are checked against the remainder of that entry (and also against any other entries starting with the same word).

If it is known that the terms of interest will only occur in certain specific contexts, rules can be used for defining those contexts. For instance, a rule may be devised for extracting surnames from personal names, covering examples such as "Mrs Robinson," "John F. Ratley, Jr," and "Revd Ben Wiles". Alternatively, data may need to be extracted from semiformatted texts such as clinical reports. Rules of this kind may consist of, or be based on, regular expressions – see URL below, and reference [4].

As noted later, extracted terms are sometimes compiled into an index before further processing, but for the present it is assumed that each term is immediately passed on for lookup.

Besides terms extracted from a text, lexical processing may need to be applied to terms retrieved from a database or knowledge base, extracted from a user query, or entered into a text box in a user interface. In some cases, the lexical terms might be artificial values, such as employee numbers assigned by a company or internal identifiers assigned by a database system.

2. *Lookup* For a lexicon of any size, the efficiency of the lookup is of major importance. The techniques here are well known, including simple binary searching in arrays, the use of access trees, and hashing techniques. For fixed sets of terms, hashing is potentially the fastest of all methods, but if terms are likely to be added or deleted frequently access trees are probably better. Further details about these methods can be found in any good book on data structures.

Of course, in the case of a lexicon designed for use by human beings, alphabetical ordering is the almost invariable rule.

3. ***Use of the Output*** The output of a lexicon, unless it is simply to be displayed on a user's workstation, will be subjected to further processing by the application program. As noted earlier, the output of each lexicon is designed according to its intended uses.

Each entry in a lexicon consists of an entry term and an output structure. Besides the outputs explicitly defined in the lexicon, there is normally a default output which is returned in cases where the lexical term is not included among the entry terms.

The simplest form of lexicon is one in which the explicit outputs are all void; in other words, the lexicon is simply a *list* of terms. In effect, the lookup process returns the value "true" or "false," depending on whether or not the term was found. Such a lexicon defines a *set* of terms, and the lookup is a test for *set membership.*

The simplest form of nonvoid lexicon is a simple association list, in which each output is a single value. In general, however, the outputs can have an arbitrarily complicated structure, as defined by two factors: multiplicity and complexity.

Multiplicity of output refers to the fact that, in many lexicons, a given entry term may be associated with a number of different outputs (or equivalently, there may be a number of separate entries which have the same entry term). In many natural language tasks, multiplicity of output equates to ambiguity (as in the various distinct meanings of the English word "dock"), which represent a problem to be resolved. In other cases (e.g., when the outputs enumerate the members of a set) the multiplicity is not a problem; for example, in an inverted file (see below) multiple outputs are the norm.

Complexity of output. In many lexicons each output consists of several differentiated data items. The output may for example be structured as a record or tuple, or it may have a deeper structure, as in some examples below.

Types of Lexicon

Word lists and Stoplists As noted above, the simplest form of lexicon is a simple term list representing a set of terms which share some common property. Membership of such a set can result in the acceptance of a term for further processing by the application, or alternatively can cause its rejection. An example of the latter case is a *stoplist*, which is routinely used in information retrieval systems to eliminate trivial words ("stopwords") which can serve no purpose for retrieval. These are mainly syntactic function words ("closed class words") such as the English words "the," "of," "and," "for," "over," "because," etc.

Indexes and Inverted files An *index* is a secondary structure which is provided to facilitate access to the items held in some primary body of information. A back-of-book index provides a familiar everyday example, but computer-based indexes can be generated automatically for any kind of information object which includes lexical data. An important example is the use of *inverted files* for assisting the retrieval of records in databases. Given a database in which each record contains a set of terms summarizing the properties of a particular entity, inspecting all of the records individually will likely be a slow process. Instead, an inverted file is generated in which each distinct term is associated with an entry listing the identifiers of the specific records which contain that term. Searching can then be performed quickly by accessing and comparing only those few entries which relate to the specified search terms [6].

Machine Readable Dictionaries The outputs of traditional dictionaries and glossaries were designed for perusal by human beings. However, with their generally predictable structure, they proved to be a valuable lexical resource for natural language processing applications [2]. Their great advantage was that they provided a ready-made summary of the whole of the language, apart from specialized technical terms. Their disadvantage was that their presentation of information was often inconsistent and incomplete. Experience of such problems soon led to the development of electronic dictionaries with more formally defined structures; perhaps the best-known example is the Longman Dictionary of Contemporary English (LDOCE), which is now available on CD-ROM.

Thesauruses A thesaurus is a structure which records and classifies relationships between distinct lexical terms. Probably its best-known use is for detection of synonyms, to enable distinct but equivalent terms to be merged or conflated. In information retrieval, a thesaurus may be used for expanding a set of query terms, thus improving the recall performance of a query. Some of the most detailed thesauruses provide information about the terminology of a technical domain, such as medicine or agriculture.

In fact, a well-developed thesaurus provides information about a range of distinct interterm relationships, and may support two distinct types of operation: (i) vocabulary control, and (ii) classification of relationships. Vocabulary control consists of mapping each lexical term onto a *preferred term*, denoting some specific concept in the domain, thus effectively conflating different (synonymous) mentions of that concept. Such a thesaurus also includes information about semantic relationships between distinct concepts, including antonymy and various hierarchical relations. The latter almost always include genus/type relations (e.g., plant/tree/oak), and often also whole/part relations (e.g., tree/branch/twig) and others. [11]

The WordNet is an online thesaurus developed at Princeton University in the early 1990s [5,10]. In WordNet, groups of synonymous words are organized into "synsets" (but no preferred terms are designated). Words which are polysemous (i.e., possess more than one meaning) will occur in two or more synsets – for example, (board, plank) and (board, committee). This means that the entry term "board" returns two distinct outputs. WordNet also allows five further relations to be recorded between synsets – antonymy, genus/type, whole/part, manner, and logical entailment.

Although WordNet is an attractive and useful tool, it is really quite "weak" in terms of completeness and consistency. Thus, its use for supplementing search terms in information retrieval systems has led to disappointing results [13]. It may be more useful for providing suggestions or asking questions in an online context.

The EDR dictionary, now administered by the Japanese National Institute of Information and Communications Technology, provides an impressive range of lexical resources [14]. One of its main purposes is to support the development of robust and effective machine translation tools. Primary lexical access is via word dictionaries in Japanese and English, and these include links to a "concept dictionary" containing semantic information and hierarchical links to related concepts. Other components include co-occurrence dictionaries and a Japanese/English bilingual dictionary.

A thesaurus or online dictionary provides a kind of sketchy model of the world (or partial world), and the language used to describe it. The most fully developed systems of this kind are *ontologies* which, besides the features outlined above, may include definitions of processes, interactions, constraints, and temporal relationships [11].

Construction of Lexicons

Any body of text can be converted automatically into an *index* of words (or, with a little more trouble, of phrases) by extracting the words/phrases as discussed earlier and organizing them into an alphabetical list. An index thus produced is of course a kind of lexicon – one in which the outputs are restricted, e.g., to positional information or frequency. Many language processing applications start off by generating an index of extracted terms, which can then be inspected or manipulated at a later stage. Note that an inverted file is a form of index.

The compilation of more complex forms of lexicon can only be automated to a limited extent. Statistical analysis of text corpora can provide useful lexical resources, or at least resources which can be used to facilitate the construction of practically useful lexicons [9]. A key activity is looking for associations (collocations) between words in a text corpus [3]. This involves taking the corpus, dividing it into suitable segments (e.g., paragraphs, sentences, or fixed-size windows) and then measuring the extent to which different terms tend to occur together using, e.g., the mutual information measure. One application of this approach is in the construction of a *statistical thesaurus*, by which strongly associated terms may be used for expanding sets of query terms in information retrieval systems [1].

In a statistical thesaurus, the associations between terms are undifferentiated "tending-to-occur-together" relationships. More detailed analysis of patterns of word association may be used, tentatively, to differentiate between relationships of various types. One noteworthy example of this approach is the work of Greffenstette [7], while some further efforts in this direction have been reviewed by Matsumoto [11] and Srinivasan [6].

Key Applications

As has already been noted, some kind of lexical analysis is performed by almost every program which operates on textual data, including systems for text retrieval, question-answering, summarization, information extraction, data mining, and machine translation.

Data Sets

The URLs given below provide datasets as well as lexical analysis tools.

Licensing and Contracting Issues in Databases

MICHAEL W. CARROLL
Villanova University School of Law, Villanova, PA, USA

Synonyms

License

Definition

A contract is a legally binding agreement between two or more parties usually formed when each party promises to do some action not otherwise required or to refrain from taking some action not otherwise required. In this context, a license is a grant of rights or permission by the owner of rights under copyright in a database. The key differences between a copyright license and a contractual database license are who is subject to the license and the consequences of breaching the license. A breach of a copyright license usually exposes the breaching party to liability for copyright infringement, which can include remedies such as injunctions, statutory damages, and disgorgement of profits. In contrast, a breach of contract exposes the breaching party to liability for the database owner's actual damages, which must be proven with reasonable certainty. Oftentimes, legal agreements styled as "terms of use" or as licenses in relation to databases are technically only partially copyright licenses and are otherwise merely contracts. This is because such agreements often contain terms governing the use of copyrightable elements of a database – such as its structure – and non-copyrightable data, such as numerical or other factual information. One who copies an entire database without permission would likely face liability for copyright infringement; whereas, one who copies factual data only without permission would be liable only for breach of contract.

Historical Background

Contract law has ancient roots, but it evolved into a general field relatively recently. In "common law" countries, such as the United States, the United Kingdom, Canada, and Australia, the law of contract is defined and applied by the courts. In "civil law" countries, which comprise the large majority of nations, the principles of contract are codified by the legislature and applied by the courts. Under both systems of law, a contract is enforceable if there has been an offer, an acceptance, and an exchange or "consideration," which means that each party has agreed to give the other something of value or has promised to for bear from taking action that would otherwise be lawful.

Foundations

To fill perceived gaps in copyright law, some database owners also have come to require agreement to contracts or license agreements in exchange for access to their databases. Three sets of legal issues arise with respect to these licenses: (i) what are the requirements to make them enforceable; (ii) are they enforceable if they control uses of non-copyrightable data; and (iii) what law applies if there are disputes about interpretation or enforcement of the license.

In the United States, a contract is enforceable if there is an offer, an acceptance, and consideration, which means that the parties have entered into a bargained-for-exchange. If the terms of a license are that the database owner agrees to make the database accessible and usable in exchange for the user's promises to pay for access or to refrain from making certain uses of the data – such as redistributing or copying data, the contract will be enforceable.

Outside of the United States, the requirement of exchange is supplemented by other methods of enforcement such that database licenses will generally be held enforceable under the applicable law of contract or obligations.

The key differences between a copyright license and a contractual database license are who is subject to the license and the consequences of breaching the license. Copyright is a right against the public, and a copyright owner may therefore grant the public a license to use the copyrighted elements of a database subject to a public license, such as a Creative Commons license. Most copyright licenses are drafted to say that if the user breaches, the copyright license terminates and any further use of the copyrighted elements becomes copyright infringement. The remedies for copyright infringement are more severe than for breach of contract.

A contractual database license is enforceable only against one who is a party to the agreement. If the license is from party *A* to party *B*, and party *C* obtains the database or data from party *B*, party *A* cannot enforce the contract against party *C*. To avoid this result, owners of digital databases often include terms in the database to the effect that any person who uses the database becomes a party to the license agreement.

There is some doubt about whether this approach comports with traditional requirements for enforceable contracts. Nonetheless, with respect to "terms of use" on web sites housing electronic databases courts have relaxed the requirement of exchange and have held that users accept such terms through the act of visiting or using the site.

With respect to whether a database owner may control uses of non-copyrightable data or databases by a contractual license when copyright law permits such uses, the question is one of preemption. Does contract law, which is a matter of state law in the United States, conflict with federal copyright law? If there is a conflict, federal law prevails. However, the few courts that have addressed this issue have reasoned that such licenses are not in conflict with copyright because the license applies only to the other party whereas copyright applies to the whole world.

Finally, the issue of which law governs the interpretation and enforcement of a contractual database license is an example of a choice-of-law issue. Often the license will specify what law applies, and courts will generally accept this term as long as the jurisdiction chosen has a nexus with the parties. Otherwise, the question of choice of law is determined through fact-specific balancing of the location of the parties, the place where the contract was formed, and, in the case of a digital library, the location of the server(s).

Key Applications

After the United States Supreme Court held in 1991 that a white pages telephone directory was not copyrightable, a case arose in which a database of more than 3,000 white pages directories had been compiled and released on CD-ROM with a license agreement that restricted those who purchased it to non-commercial uses. The defendant copied the data and resold it through his web site. The question presented was whether the non-commercial use restriction in the license agreement was enforceable even though the data was not protected by copyright. The court of appeals held that the agreement was enforceable. The court held that there was no conflict between the contract's restriction on copying the data and copyright law's position that the data could be freely copied because the contract only restricted those who agreed to its terms. The court reached this result only with respect to a particular section of the Copyright Act and did not address the argument that the constitution also preempted enforcement of the license agreement.

Other courts have largely followed this approach of enforcing similar agreements referred to as "shrinkwraps," when the license terms are inside a shrinkwrapped box of software; "clickwraps," where a user clicks an "I Agree" button to signal agreement to license terms; and, more controversially, to "browsewraps," in which the issue is whether a user of a web site has agreed to its terms of use merely by browsing the site. In this last category, the courts reach different results depending upon whether the user had adequate notice of the terms of use and whether those terms of use were reasonable.

Lifespan

CHRISTIAN S. JENSEN
Aalborg University, Aalborg, Denmark

Synonyms

Existence time; Temporal domain

Definition

The *lifespan* of a database object is the time during which the corresponding real-world object exists in the modeled reality.

Key Points

Some temporal data models, e.g., conceptual models, provide built-in support for the capture of lifespans, while other models do not. It may be observed that lifespans can be reduced to valid times, in the sense that the lifespan of an object *o* is the valid time of the fact "*o* exists."

In the general case, the lifespan of an object is an arbitrary subset of the time domain and is naturally captured by a temporal element timestamp.

The synonym "existence time" is also used for this concept.

Lightweight Ontologies

Synonyms

Controlled vocabularies; Taxonomies; Thesauri; Business catalogues; Faceted classifications; Web directories; Topic hierarchies; User classifications

Definition

Ontologies are *explicit specifications of conceptualizations* [7]. They are often thought of as directed graphs whose nodes represent *concepts* and whose edges represent *relations* between concepts. The notion of a concept is understood as defined in Knowledge Representation, i.e., as a set of objects or individuals [2]. This set is called the *concept extension* or the *concept interpretation*. Concepts are often *lexically defined*, i.e., they have natural language names which are used to describe the concept extensions (e.g., concept `mother` denotes the set of all female parents). Therefore, when ontologies are visualized, their nodes are often shown with corresponding natural language concept names. The backbone structure of the ontology graph is a taxonomy in which the relations are "is-a," whereas the remaining structure of the graph supplies auxiliary information about the modeled domain and may include relations like "part-of," "located-in," "is-parent-of," and many others [8].

In their simplest version, one can think of *lightweight ontologies* as ontologies consisting of backbone taxonomies only. In this entry, the "is-a" relationship is generalized to concept subsumption which still allows it to respect the intrinsic properties of backbone taxonomies: namely, in a lightweight ontology, the extension of the concept of a child node is a subset of the extension of the concept of the parent node. Formally, the notion of lightweight ontology is defined as:

A *(formal) lightweight ontology* is a triple $O = \langle N, E, C\rangle$, where N is a finite set of nodes, E is a set of edges on N, such that $\langle N, E\rangle$ is a rooted tree, and C is a finite set of *concepts* expressed in a *formal language* F, such that for any node $n_i \in N$, there is one and only one concept $c_i \in C$, and, if n_i is the parent node for n_j, then $c_j \sqsubseteq c_i$.

The formal language F, used to encode concepts in C, belongs to the family of Description Logic (DL) languages [2] and it may differ in its expressive power and reasoning capability. However, the less expressive one with still useful reasoning capability has shown to be the *propositional DL language*, i.e., a DL language without roles (see [6,3,5] for examples of practical applications of formal lightweight ontologies based on the propositional DL language).

Taxonomies (e.g., NCBI (See http://www.ncbi.nlm.nih.gov/taxonomy)), thesauri (e.g., GLIN (See http://www.loc.gov/lexico/servlet/lexico.)), business catalogues (e.g., UNSPSC (See http://www.unspsc.org.)), faceted classifications (e.g., Flamenco (See http://flamenco.berkeley.edu.)), web directories (e.g., Yahoo! (See http://www.yahoo.com.)), and user classifications are examples of informal prototypes of formal lightweight ontologies. Hereinafter, they are referred to as *(informal) lightweight ontologies*. Note that lightweight ontologies are easier to understand and construct. In fact, as shown in [15], formal lightweight ontologies can be automatically constructed from user classifications as a by-product of a normal computer use, whereas designing a full-fledged ontology (expressed, for example, in OWL-DL (See http://www.w3.org/TR/owl-features.)) is a difficult and error-prone task even for experienced users [13].

Historical Background

The notion of ontology was borrowed from philosophy and adopted in Computer Science under multiple definitions, where, probably, the first credible and most commonly quoted one is "an explicit specification of a conceptualization" [7]. As ontology research evolved, new definitions and examples of what can be considered to be an ontology started to appear. It is typical to characterize ontologies based on the degree of formality and expressivity of the language used to describe them. This characteristic form a continuum of ontology types (see Fig. 1), starting from terms and web directories, and continuing to rigorously formalized logical theories [14]. However, most specifications agree that an ontology should be defined in a formal language, which, in practice, usually means a logic-based language suitable for automating reasoning.

For a long time, lightweight ontologies were not formally defined but were referred to by examples. For instance, they were referred to as terms, as controlled vocabularies, as thesauri, and as web directories like Yahoo! [14]. As observed, informal lightweight ontologies largely cover the spectrum of informal ontology types shown in Fig. 1. In some other approaches, lightweight ontologies are formal ontologies which use a computationally inexpensive logic language (e.g., see [3,10,11]). In practice, these ontologies often encode a hierarchy of classes which can be (automatically or semi-automatically) derived from web directories like Yahoo! (as in [3,11]) or from more strictly defined but still informal structures such as thesauri and taxonomies (as in [10]).

The first attempt to formally define the notion of lightweight ontology as a type of formal ontology was made in [3]. Here, the definition was restricted to formal web directories, whereas in the present document it has been generalized to provide a formal model for a larger spectrum of informal lightweight ontologies, such as controlled vocabularies, taxonomies, thesauri, business catalogues, faceted classifications, web directories, and user classifications.

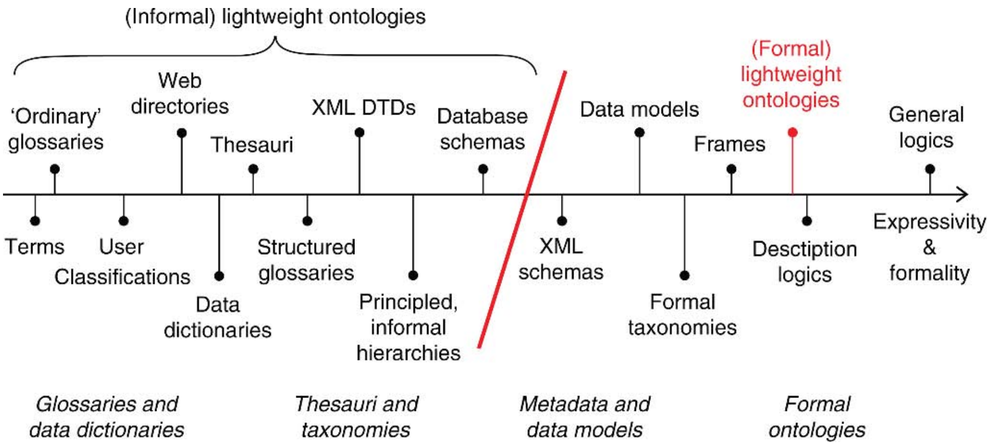
Foundations

This section discusses the main types of lightweight ontologies and their properties and proposes how formal lightweight ontologies can be generated from their informal prototypes.

Types of Lightweight Ontologies

Lightweight ontologies fall into two main types based on their usage: *descriptive* and *classification* lightweight ontologies. Descriptive lightweight ontologies are primarily used for defining the meaning of terms as well as the nature and structure of a domain [9]. Classification lightweight ontologies are primarily used for describing, classifying, and accessing (large) collections of documents or, more generally, data items [9,3]. Due to this difference, formal classification lightweight ontologies have a different domain of interpretation for their concepts. Namely, the extension of a concept in a formal classification lightweight ontology is the *set of documents about* the objects or individuals referred to by the (lexically defined) concept. For example, the extension of concept `mother` is the set of documents about female parents.

Any descriptive lightweight ontology can be used as a classification lightweight ontology, but not vice versa. The two types differ in some principal properties, which are summarized in Table 1 and discussed as follows. Classification lightweight ontologies are usually more complex than descriptive ones, whereas



Lightweight Ontologies. Figure 1. Types of ontologies. Adopted from [14].

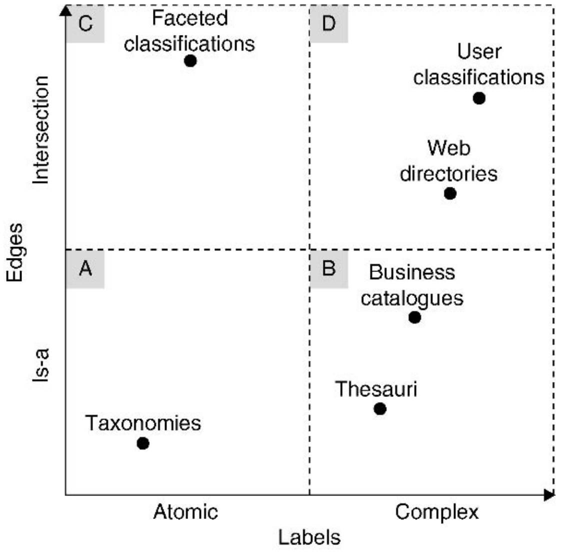
Lightweight Ontologies. Table 1. A classification of lightweight ontologies

	Descriptive lightweight ontologies	Classification lightweight ontologies
	Informal	
Primary use	Defining the meaning of terms as well as the nature and structure of a domain	Describing, classifying, and accessing (large) collections of documents or, more generally, data items
Labels	Single nouns or simple noun phrases denoting atomic concepts as the most typical case	Often, compound noun phrases denoting complex concepts
Edge relations	"is-a" relation	"is-a," "part-of," or, more generally, "intersection" relation
Examples	Taxonomies (e.g., NCBI), thesauri (e.g., GLIN)	Business catalogues (e.g., UNSPSC), faceted classifications (e.g., Flamenco), web directories (e.g., Yahoo!), user classifications
	Formal	
Concept extension	Set of objects or individuals belonging to the class denoted by the concept	Set of documents about the objects or individuals belonging to the class denoted by the concept
Node concepts	Atomic concepts	Atomic and complex concepts

the complexity is defined along two dimensions: *label complexity* (atomic vs. complex labels) and *edge complexity* ("is-a" vs. "intersection" edges). The dimensions of complexity are illustrated in Fig. 2 and discussed in the following.

Category A: atomic labels and "is-a" edges. Ontology labels in this category usually represent single atomic concepts (e.g., "theft," "cellular organisms") and relations between labels are usually "is-a" relations (e.g., "pens" is a child of "writing materials"). Typical examples of this category are (biological) taxonomies such as NCBI. Ontologies in this category are mainly descriptive.

Category B: complex labels and "is-a" edges. Ontology labels in this category can be compound noun phrases which represent complex concepts (e.g., "Open Source and Linux in Education," "Pressure groups representation or participation services") and relations between labels are usually "is-a" relations. Typical examples of this category are thesauri such as GLIN and business catalogues such as UNSPSC. A higher complexity of labels (with regard to category A) in these domains is conditioned by the need for richer descriptions of indexing terms in thesauri and of e-commerce items in business catalogues. Most ontologies in this category are descriptive but some can be classification as well. For instance, the business catalogue UNSPSC can be used as a descriptive ontology or as a classification ontology in which e-commerce items are classified. Note that even if the labels can be complex, they are still mapped to atomic concepts in formal descriptive lightweight ontologies. In classification lightweight ontologies, complex labels represent a dimension of *power of classification* as one label can describe one complex concept that identifies a (very) specific set of documents. Moreover, complex labels can be mapped into complex concepts in formal classification ontologies, which allows for higher modularity in concept definitions. For instance, concept `baby_pictures` can be defined as the intersection



Lightweight Ontologies. Figure 2. Types of labels and edges in lightweight ontologies.

of two concepts, `baby` and `picture`, whereas the interpretation of the former concept is the set of documents about babies (including pictures of babies as a kind of documents) and the interpretation of the latter concept is the set of pictures (including baby pictures). Note that in formal descriptive lightweight ontologies, the extension of concept `baby_pictures` (the set of baby pictures in the world) cannot be expressed as a function of the extension of concept `baby` (the set of babies in the world) and the extension of concept `picture` (the set of pictures in the world).

Category C: atomic labels and "intersection" edges. Ontology labels in this category usually represent single atomic concepts, and relations between labels are usually "intersection" relations, which means that the label of a parent node *specifies* the meaning of the label of its child node. For example, parent node "Italy" specifies the meaning of its child node "Vacation" to the meaning "Vacation in Italy." A typical example of this category is a faceted classification such as Flamenco, in which child nodes represent aspects or facets of their parent nodes along atomic orthogonal dimensions (e.g., time, space, function, material, etc). All ontologies in this category are classification ontologies, for which the "intersection" relation creates an additional dimension of power of classification by allowing it to describe a specific set of documents by means of a set of categories in the ontology. Note that the interpretation domain of formal classification ontologies allows it to treat edges as the *intersection* of parent and child concepts and, therefore, compute concepts of nodes given their position in the ontology tree. For example, the intersection of root concept `italy` with its child concept `vacation` results in a concept whose extension is the set of documents about vacations in Italy, which is the actual meaning of the child node, given its position in the tree.

Category D: complex labels and "intersection" edges. Ontology labels in this category usually represent complex concepts, and relations between labels are usually "intersection" relations. All ontologies in this category are classification ontologies for which the combination of complex labels and "intersection" edges creates the maximum classification power. Labels in this category can represent names of individuals. These labels are mapped to concepts whose extension is the set of documents about the individuals (e.g., the extension of concept `moscow` is the set of documents about the city Moscow). Typical examples of this category are web directories like Yahoo! (in which web pages are classified) and user classifications (in which email messages, favorites, and files are classified). Note that user classifications may have more complex labels and more "intersection" relations than web directories due to the fact that there are basically no rules and restrictions for user classifications that are commonly followed in web directories.

Note that the propositional DL is sufficient for representing formal descriptive lightweight ontologies in categories A and B, as the only thing that needs to be encoded is the subsumption hierarchy of atomic classes. It is also sufficient for representing formal classification lightweight ontologies in categories A and C, since the only relations that need to be represented are subsumption and intersection of atomic classes. The propositional DL is capable of capturing the semantics of labels in classification lightweight ontologies in categories B and D to a significant extent, while approximating the meaning of labels in some cases, as it is discussed in the following section.

From Informal to Formal Lightweight Ontologies

Formal descriptive lightweight ontologies can be generated from informal ones by transforming their organizational structure into a rooted tree (where necessary) and by converting their term labels, expressed in natural language, into concepts in the formal language *F*. The generation of formal classification lightweight ontologies requires an extra step where node concepts are computed as the intersection of the concepts corresponding to the term labels on the path to the root node [3]. Note that the rooted tree structure of formal lightweight ontologies allows it to capture the backbone organization of many informal prototypes. In fact, taxonomies, business catalogues, faceted classifications, web directories, and user classifications use rooted trees to organize their categories. In the simplest case, the hierarchy of thesaurus terms, built based on the Broader Term relation, is a rooted tree; and, a controlled vocabulary can be seen as one level rooted tree, where the root node represents the Top concept and its child nodes are the controlled vocabulary terms. The principal steps of the process of converting term labels into concepts in *F* for classification lightweight ontologies are described below. The conversion of labels of descriptive lightweight ontologies follows the same principles even if it is an easier case due to the relative simplicity of their labels. In the following, it is assumed that *F* is the Propositional DL language.

WordNet [12] senses of adjectives and common nouns in the label become atomic concepts in *F*. The extension of a common noun concept is the set of documents about objects of the class, denoted by the noun; and, the extension of an adjective concept is the set of documents about objects, which possess the qualities, denoted by the adjective. Proper names become atomic concepts as well, whose extension is the set of documents about the individual referenced by the proper name. Notationally, adjective and common noun atomic concepts are represented in the following syntax: *lemma-pos-sn*, where *lemma* is the lemma of the word, *pos* is its part of speech, and *sn* is the sense number in WordNet [12]. Proper name atomic concepts are tagged with $_{NNP}$.

Syntactic relations between words in the label are translated into logical connectives of *F* in order to build complex concepts from atomic concepts. For example, a set of adjectives followed by a noun group is translated into the logical conjunction (⊓) of the concepts corresponding to the adjectives and to the nouns; prepositions like "of" and "in" are translated into the conjunction; coordinating conjunctions "and" and "or" are translated into the logical disjunction (⊔). The final formula for the label is built following these rules and taking into account how words are coordinated in the label.

Consider a relatively complex label: "*Bank and personal details of George Bush*." Its correct translation to *F* produces the following concept:

- ► (bank-noun-1 ⊔ personal-adj-1) ⊓ detail-noun-1 ⊓ george_bush NNP

The extension of the concept above is the intersection of three sets of documents: (1) documents about the President George W. Bush, (2) documents containing isolated facts about something (i.e., details), and (3) the union of documents about bank institutions and documents concerning a particular person or his/her private life. Note that the extension comprises (all and only) documents one would classify under the above mentioned label.

Despite its seeming simplicity, the translation process is subject to various mistakes originating from incorrect natural language processing (NLP). (How the NLP problems, described in this paragraph, can be solved is beyond the scope of this document. Interested readers are referred to [15] for a first account.) For instance, due to a mistake in part-of-speech tagging, the word *personal* might be recognized as a noun, which has only one sense in WordNet defined as "*a short newspaper article about a particular person or group*." Due to a mistake in word sense disambiguation, the sense of the word *bank* might be identified as "*sloping land (especially the slope beside a body of water)*." Due to a mistake in named entity detection, the proper name *George Bush* might not be detected and might then be considered as two distinct nouns, where the noun *bush* means "*a low woody perennial plant usually having several major branches*." Finally, due to a mistake in (syntax) parsing, the input label might be erroneously translated into:

- ► bank-noun-1 ⊔ personal-adj-1 ⊓ detail-noun-1 ⊓ george_bush NP

a concept, whose extension is the union of documents about bank institutions and documents discussing personal details of the President George W. Bush.

Note that the propositional DL can capture the semantics of complex labels to a significant extent only when these labels are built from noun phrases possibly connected through coordinating conjunctions such as "and" and "or" (e.g., "Big city life and civil protection"). It approximates the meaning of some other types of labels, e.g., labels with prepositions. For instance, labels "life in war" and "life after war" will collapse into the same formula, which approximates the meaning of both labels.

Key Applications

Formal (descriptive and classification) lightweight ontologies can be used in various domains, such as document classification (e.g., see [6]), semantic search (e.g., see [3]), and data integration (e.g., see [5]). In the following subsections these three application domains are briefly discussed.

Document Classification

Document classification is the problem of assigning a document to one or more categories based on the document contents. In the context of lightweight ontologies, document classification refers to assigning a document to: (1) controlled vocabulary terms; (2) categories in taxonomies, business catalogues, faceted classifications, web directories, or user classifications. The approach reported in [6] presents fully automatic classification of documents into web directories based on the *get-specific* document classification algorithm.

The underlying idea is that a web directory is converted into a formal lightweight ontology, that a document is assigned a concept, and that the document classification problem is then reduced to reasoning about subsumption on the formal lightweight ontology. Note that this classification approach does not require the creation of a training dataset which would normally be required in machine learning approaches [6].

Semantic Search

In the context of lightweight ontologies, semantic search is the problem of finding categories and/or documents (when applicable) classified in categories of (informal) lightweight ontologies, such that the found objects *semantically* correspond to a provided natural language query. Loosely speaking, semantic correspondence of an object to a query indicates that the meaning associated with the object is more specific or equivalent to the meaning given to the query under common sense interpretation. For instance, document about *Ethiopian villages* semantically corresponds to a query about *African settlements*. The approach reported in [3] formalizes the above informal description and introduces a semantic search algorithm for lightweight classification ontologies populated with documents. The underlying idea is that the user query is converted to a concept in the way presented earlier in this document and that the answer to the query is computed as the set of documents whose concepts are more specific or equivalent to the concept of the query. In order to reduce the computation complexity, the query is first run on the structure of the corresponding formal lightweight ontology in order to identify the scope of relevant nodes and then it is run on the documents populated in some of the nodes from the scope.

Data Integration

Data integration is the process of combining data residing at different sources and providing the user with a unified view of these data. Often, a data source can be represented in the form of a rooted tree, whose nodes are assigned natural language labels, and, in this case, data integration can be facilitated by discovering semantic relations which exist between nodes of the source trees [5]. A semantic relation between two nodes can be more/less general, equivalent, or disjoint. In the domain of lightweight ontologies, semantic relations can be found between elements of controlled vocabularies, taxonomies, thesauri, business catalogues, faceted classifications, web directories, and user classifications. Such relations can then be used for enabling integration or inter-operation of web directories, for merging business catalogues, and so on.

Future Directions

There are two major problems related to formal lightweight ontologies which drive future directions of research in this area. The problems are:

- *Natural language processing.* Since formal lightweight ontologies are supposed to be often generated from their informal prototypes, the quality of these ontologies strongly depends of the correctness and completeness of NLP procedures involved in the conversion process. Note that NLP for informal lightweight ontologies is a potentially new domain in the NLP research due to the particular characteristics of term labels (e.g., they are usually short noun phrases with little context) [15];
- *Lack of background knowledge.* Reasoning on formal lightweight ontologies, which is used, for example, in document classification, in semantic search, and in data integration as discussed above, strongly depends on the set of axioms which must be known a priori [3]. These axioms are extracted from a knowledge base such as WordNet [12]. It was shown that lack of background knowledge is the main source of a relatively low recall in reasoning-based tasks on formal lightweight ontologies [4].

Experimental Results

First evaluation studies of document classification show that re-classification of 1217 HTML pages into a part of the DMoz hierarchy, (See http://www.dmoz.org.) that has 157 nodes distributed in a tree of depth 6, allows it to reach 41% in the micro-averaged F1 measure [6]. Document concepts in the conducted experiments were built by computing the conjunction of the formulas corresponding to the first ten most frequent words appearing in the documents (excluding stop words).

The performance of S-Match, a tool that, among other things, facilitates the integration of lightweight ontologies, reaches up to 65% in recall in some data sets [1].

Data Sets

Some informal lightweight ontologies are available for download in the form of data files. These include the

DMoz web directory, (See http://rdf.dmoz.org.) business catalogues UNSPSC and eCl@ss, (See http://www.eclassdownload.com.) NCBI taxonomy, and many others.

Definition

Linear Hashing is a dynamically updateable disk-based index structure which implements a hashing scheme and which grows or shrinks one bucket at a time. The index is used to support exact match queries, i.e., find the record with a given key. Compared with the B+-tree index which also supports exact match queries (in logarithmic number of I/Os), Linear Hashing has better expected query cost O(1) I/O. Compared with Extendible Hashing, Linear Hashing does not use a bucket directory, and when an overflow occurs, it is not always the overflown bucket that is split. The name Linear Hashing is used because the number of buckets grows or shrinks in a linear fashion. Overflows are handled by creating a chain of pages under the overflown bucket. The hashing function changes dynamically and at any given instant there can be at most two hashing functions used by the scheme.

Historical Background

A hash table is an in-memory data structure that associates keys with values. The primary operation it supports efficiently is a lookup: given a key, find the corresponding value. It works by transforming the key using a hash function into a hash, a number that is used as an index in an array to locate the desired location where the values should be. Multiple keys may be hashed to the same bucket, and all keys in a bucket should be searched upon a query. Hash tables are often used to implement associative arrays, sets and caches. Like arrays, hash tables have O(1) lookup cost on average.

Foundations

The Linear Hashing scheme was introduced by [2].

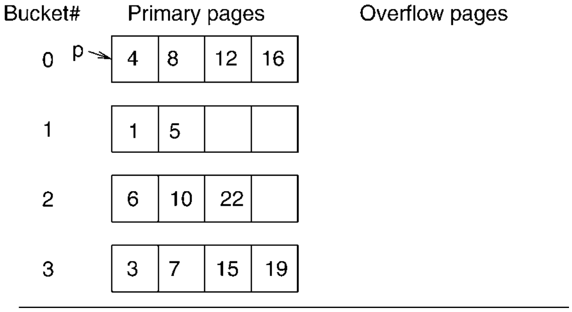
Initial Layout

The Linear Hashing scheme has m initial buckets labeled 0 through $m - 1$, and an initial hashing function $h_0(k) = f(k)\ \%\ \ m$ that is used to map any key k into one of the m buckets (for simplicity assume $h_0(k) = k\ \%\ m$), and a pointer p which points to the bucket to be split next whenever an overflow page is generated (initially $p = 0$). An example is shown in Fig. 1.

Bucket Split

When the first overflow occurs (it can occur in any bucket), bucket 0, which is pointed by p, is split (rehashed) into two buckets: the original bucket 0 and a new bucket m. A new empty page is also added in the overflown bucket to accommodate the overflow. The search values originally mapped into bucket 0 (using function h_0) are now distributed between buckets 0 and m using a new hashing function h_1.

As an example, Fig. 2 shows the layout of the Linear Hashing of Fig. 1 after inserting a new record with key 11. The circled records are the existing records that are moved to the new bucket. In more detail, the record is inserted into bucket $11\%4 = 3$. The bucket overflows and an overflow page is introduced to accommodate the new record. Bucket 0 is split and the records originally in bucket 0 are distributed between bucket 0 and bucket 4, using a new hash function $h_1(k) = k\ \%\ 8$.



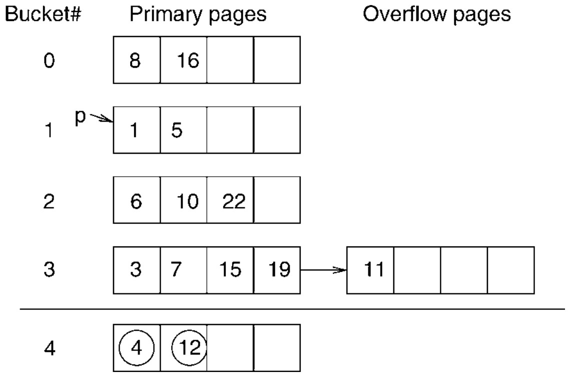
Linear Hashing. Figure 1. An initial Linear Hashing. Here $m = 4$, $p = 0$, $h_0(k) = k\ \%\ 4$.

The next bucket overflow, such as triggered by inserting two records in bucket 2 or four records in bucket 3 in Fig. 2, will cause a new split that will attach a new bucket $m + 1$ and the contents of bucket 1 will be distributed using h_1 between buckets 1 and $m + 1$. A crucial property of h_1 is that search values that were originally mapped by h_0 to some bucket j must be remapped either to bucket j or bucket $j + m$. This is a necessary property for Linear Hashing to work. An example of such hashing function is: $h_1(k) = k\ \%\ 2m$. Further bucket overflows will cause additional bucket splits in a linear bucket-number order (increasing p by one for every split).

Round and Hash Function Advancement

After enough overflows, all original m buckets will be split. This marks the end of splitting-round 0. During round 0, p went subsequently from bucket 0 to bucket $m - 1$. At the end of round 0 the Linear Hashing scheme has a total of $2m$ buckets. Hashing function h_0 is no longer needed as all $2m$ buckets can be addressed by hashing function h_1. Variable p is reset to 0 and a new round, namely splitting-round 1, starts. A new hash function h_2 will start to be used.

In general, the Linear Hashing scheme involves a family of hash functions h_0, h_1, h_2, and so on. Let the



Linear Hashing. Figure 2. The Linear Hashing after inserting 11 into Fig. 1. Here $p = 1$, $h_0(k) = k\ \%\ 4$, $h_1(k) = k\ \%\ 8$.

initial function be $h_0(k) = f(k)\ \%\ m$, then any later hash function $h_i(k) = f(k)\ \%\ 2^i m$. This way, it is guaranteed that if h_i hashes a key to bucket $j \in [0..2^i m - 1]$, h_{i+1} will hash the same key to either bucket j or bucket $j + 2^i m$. At any time, two hash functions h_i and h_{i+1} are used.

Figures 3 and 4 illustrates the cases at the end of splitting-round 0 and at the beginning of splitting-round 1. In general, in splitting round i, the hash functions h_i and h_{i+1} are used. At the beginning of round i, $p = 0$ and there are $2^i m$ buckets. When all of these buckets are split, splitting round $i + 1$ starts. p goes back to 0. The number of buckets becomes $2^{i+1} m$. And hash functions h_{i+1} and h_{i+2} will start to be used.

Component Summary and Search Scheme

In summary, at any time a Linear Hashing scheme has the following components:

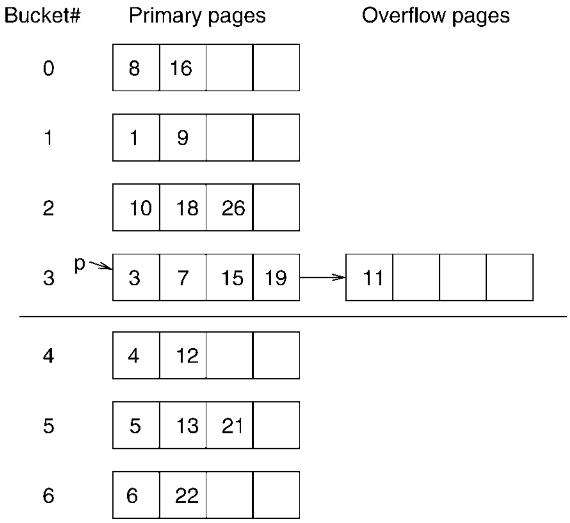
- A value i which indicates the current splitting round.
- A variable $p \in [0..2^i m - 1]$ which indicates the bucket to be split next.
- A total of $2^i m + p$ buckets, each of which consists of a primary page and possibly some overflow pages.
- Two hash functions h_i and h_{i+1}.

A search scheme is needed to map a key k to a bucket, either when searching for an existing record or when inserting a new record. The search scheme works as follows:

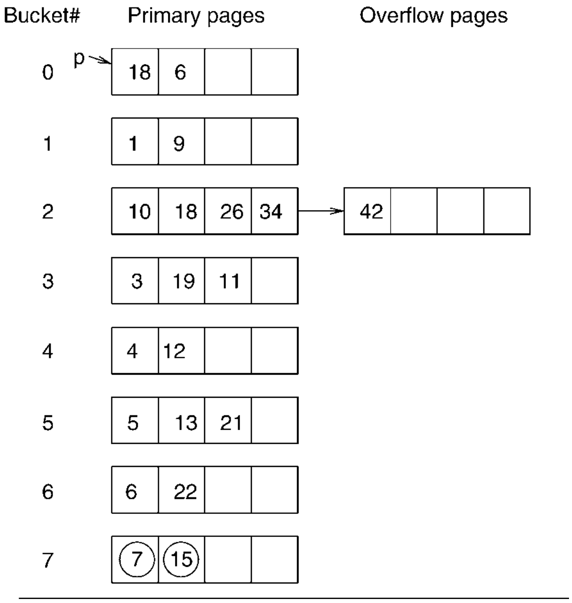
(a) If $h_i(k) \geq p$, choose bucket $h_i(k)$ since the bucket has not been split yet in the current round.

(b) If $h_i(k) < p$, choose bucket $h_{i+1}(k)$, which can be either $h_i(k)$ or its spit image $h_i(k) + 2^i m$.

For example, in Fig. 2, $p = 1$. To search for record 5, since $h_0(5) = 1 \geq p$, one directly goes to bucket to find the record. But to search for record 4, since $h_0(4) = 0 < p$, one needs to use h_1 to decide the actual bucket. In this case, the record should be searched in bucket $h_1(4) = 4$.



Linear Hashing. Figure 3. The Linear Hashing at the end of round 0. Here $p = 3$, $h_0(k) = k\ \%\ m$, $h_1(k) = k\ \%\ 2^1 m$.



Linear Hashing. Figure 4. The Linear Hashing at the beginning of round 1. Here $p = 0$, $h_1(k) = k\ \%\ 2^1 m$, $h_2(k) = k\ \%\ 2^2 m$.

Variations

A split performed whenever a bucket overflow occurs is an uncontrolled split. Let l denote the Linear Hashing scheme's load factor, i.e., $l = S/b$ where S is the total number of records and b is the number of buckets used. The load factor achieved by uncontrolled splits is usually between 50–70%, depending on the page size and the search value distribution [2]. In practice, higher storage utilization is achieved if a split is triggered not by an overflow, but when the load factor l becomes greater than some upper threshold. This is called a controlled split and can typically achieve 95% utilization. Other controlled schemes exist where a split is delayed until both the threshold condition holds and an overflow occurs.

Deletions will cause the hashing scheme to shrink. Buckets that have been split can be recombined if the load factor falls below some lower threshold. Then two buckets are merged together; this operation is the reverse of splitting and occurs in reverse linear order. Practical values for the lower and upper thresholds are 0.7 and 0.9 respectively.

Linear Hashing has been further investigated in an effort to design more efficient variations. In [3] a performance comparison study of four Linear Hashing variations is reported.

Key Applications

Linear Hashing has been implemented into commercial database systems. It is used in applications where exact match query is the most important query such as hash join [4]. It has been adopted in the Icon language [1].

Linear Regression

Jialie Shen
Singapore Management University, Singapore, Singapore

Definition

Linear regression is a classical statistical tool that models relationship between a dependent variable or regress and Y, explanatory variable or regressor $X = \{x_1,..,x_I\}$ and a random term ε by fitting a linear function,

$$Y = \alpha_0 + \alpha_1 x_1 + \alpha_2 x_2 + ... + \alpha_I x_I + \varepsilon$$

where α_0 is the constant term, the α_is are the respective parameters of independent variable, and I is the number of parameters to be estimated in the linear regression.

Key Points

Linear regression analysis is an important component for several tasks such as clustering, time series analysis, and information retrieval. For instance, it is a very powerful forecasting method for time series data. It helps identify the long-term movement of a certain data set based on given information and explore the dependent variable as function of time.

To solve the linear regression problem, there are various kinds of approaches available to determine suitable regression coefficients [1,2]. They include: (i) least-squares analysis, (ii) assessing the least-squares model, (iii) modifications of least-squares analysis, and (iiii) polynomial fitting. The primary objective is to select a straight line which minimizes the error between the real data and the line estimated to provide a best fit.

Linking and Brushing

Matthew O. Ward
Worcester Polytechnic Institute, Worcester, MA, USA

Synonyms

Linked brushing; Linked views

Definition

Within the context of visual data exploration, *Linking* refers to the process in which user interactions in one display of a multi-display system are applied to some or all other displays. In this same context, *brushing* consists of the interactive selection of a subset of the displayed data by either dragging the mouse over the data of interest or using a bounding shape to isolate this subset. Together, linked brushing is one of the most powerful interactive tools for doing exploratory data analysis using visualization.

Historical Background

Perhaps the earliest reference to linked brushing was by McDonald [10] as a mechanism for cross-referencing between multiple plots. The term *brushing* was introduced in 1978 by Newton [11], who defined it as an interactive method for painting a group of points with a square, circular, or polygonal brush. Since then, researchers have expanded on these concepts, as described in the next section.

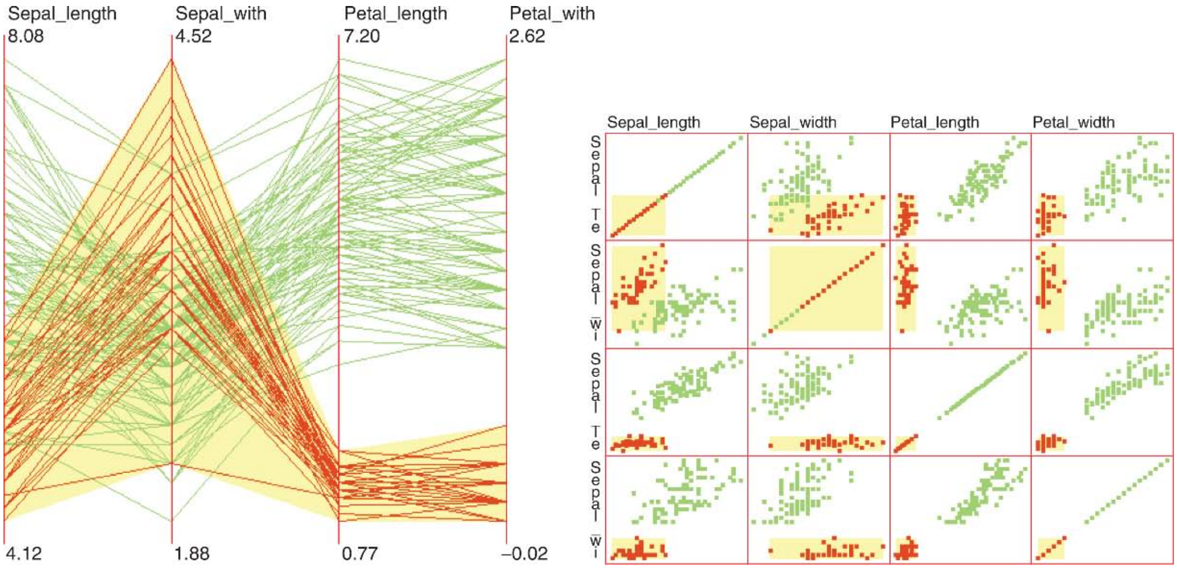
Foundations

Many operations within the process of visual data analysis begin with the process of *Selection*, in which a subset of the data being analyzed is isolated. Once isolated, the subset may be highlighted, deleted, masked, aggregated, or otherwise subjected to some operation. Many methods for performing interactive selection have been developed, including clicking on items in a list, specifying a range query for one or more data variables, typing a set of constraints, and sampling. These methods are sometimes referred to as *indirect*, as their specification is most often done separate from the data visualization. Indeed, most, if not all, can be performed without even viewing the data.

Brushing is a selection method that is specified in a *direct* fashion, i.e., by indicating elements or constraints on the data visualization itself. Many variations on brushing have been proposed over the years, each with its own strengths and weaknesses in terms of ease of use and degree of control a user has on the constitution of the result set. Brushing techniques usually consist of combinations of mouse/cursor motions and button clicks, though more unusual methods, such as using eye/head tracking or gestures in virtual reality environments, have also been proposed.

One key aspect that differentiates many brushing techniques is the *space* in which the interaction is specified. Early brushing implementations, e.g., [1], used screen-space as a constraint. Thus data that mapped to a particular range of pixels in the display were considered selected. Later, brushing was expanded to data-space [9], in which a selection from a multivariate data visualization consisted of a bounding box whose dimensionality matched the number of variables in the data (see Fig. 1). These N-dimensional brushes could be generated either by painting over a subsection of the display or directly manipulating a visual depiction of the boundaries of the N-dimensional hyperbox enveloping the selection. A third space that has been proposed for brushing is structure-space [6], where the structure of a data set, e.g., an ordering, hierarchy, or other organization, is used as a mechanism for data selection. In this case, a visual representation of the structure is provided to the user, and he or she brushes over parts of the structure. Data falling into this part are then considered as selected (see Fig. 2). This type of selection could conceivably be considered both direct and indirect, as the operation is performed on a visualization, but not on the data display itself. Similar to structure-based brushing, other attributes of a data set, such as the uncertainty or quality of the data [13], could be used as a focus for brushing.

Brushing techniques also differ in the manner in which data is isolated. Common methods include bounding boxes, bounding circles, lassos, and arbitrary



Linking and Brushing. Figure 1. Example of linked brushing in data space. Cluster isolated in parallel coordinates, with linked selection in scatterplot matrix. Selected data is dark, brush extents are shown as light bands or rectangles.

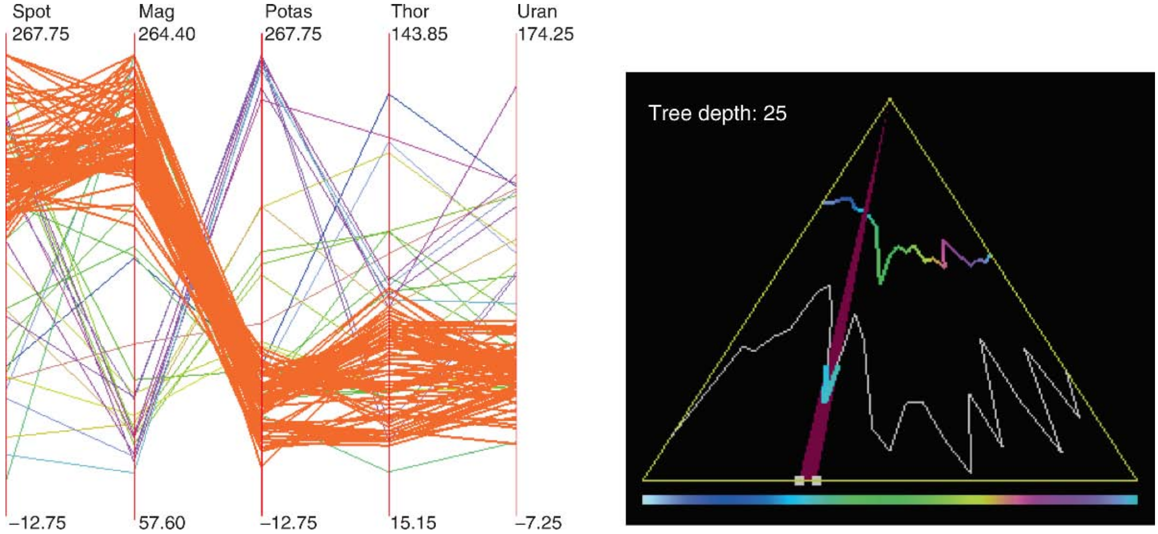
polygons for specifying a boundary around the selection and painting over specific data points. One can even specialize the behavior of a brush based on a specific type of visualization. Hauser et al. [7], for example, use an angled brush on parallel coordinates displays to select only data points whose representation on the display form lines with angles similar to that specified in the brush. In this way, data points that are well correlated with each other between a given pair of dimensions can be readily isolated.

Many approaches have been proposed to increase the richness of the types of selections that are possible. Martin and Ward [9] allow the user to not only control up to four separate brushes, but also allowed selections to be formed by logical combinations of brushes, including unions, intersections, negations, and exclusive or's. Wills [12] expanded on this idea by developing what might be called *incremental* brushes, where by a composite brush could be formed by augmenting an existing selection with additional data and/or constraints. This can result, for example, in selections with nearly arbitrary shapes, including holes.

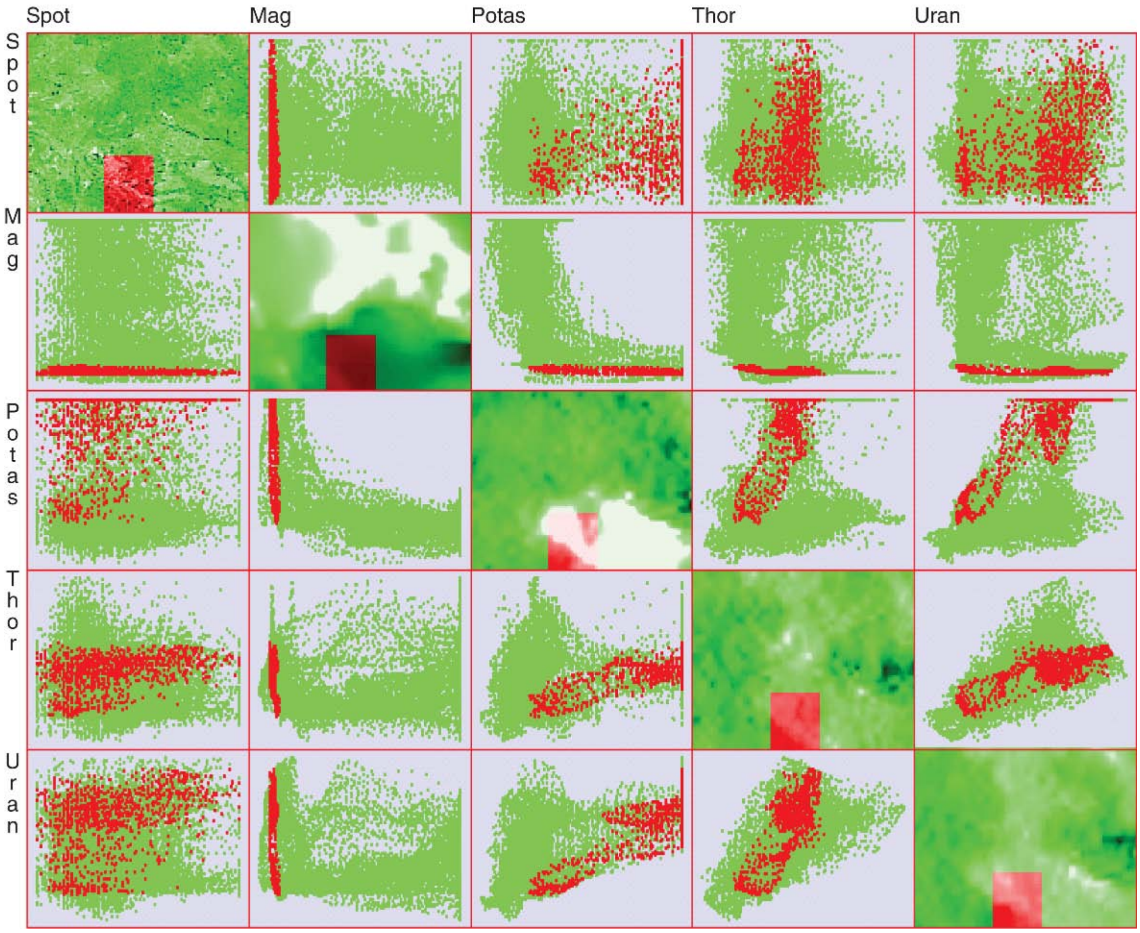
Thus far, the assumption has been that the result of brushing is that every data point in the set is either in the brush or outside the brush. However, some researchers [5,9] have experimented with what might be called *fuzzy* brushes, in which data can have a degree of membership in a brush. Using linear or non-linear functions emanating either from the brush center or from the edge of a plateau, the user can distinguish between points that are entirely covered by a brush versus those near the edge of the brush versus those a significant distance from the brush. This is a crucial functionality in multivariate data brushing, as the concept of distance is distributed across all the dimensions and thus difficult to estimate visually.

A frequent use for brushing is *linking* operations in one view to generate corresponding actions in other views. While other forms of linking between subwindows of an application exist, such as when opening a new data file, linked brushing, especially to highlight corresponding data from several views, is probably the most common form of linking found in modern visualization tools. Its popularity stems in a large part from the fact that each view of one's data can reveal interesting features, and by highlighting such a feature in one view, it is possible to build a more complete mental model of the entity by seeing how it appears in other views. This can also help reveal relationships between this entity and others in the data set. For example, when examining multivariate spatial data, it is often useful to jump between the spatially referenced view and the dependent variable view, which often does not preserve the spatial attributes (see Fig. 3).

Another strength of linked brushing is in specifying complex constraints on one's selection. Each type of view is optimized for both conveying certain types



Linking and Brushing. Figure 2. Example of structure-based brushing. Hierarchy view on right shows shape of cluster tree. Area of interest and its level of detail is isolated in red. Corresponding data highlighted in parallel coordinates view on left, with unselected cluster centers shown at a higher level of the hierarchy.



Linking and Brushing. Figure 3. Example of linking spatial and non-spatial views. Diagonal plots are spatial views of remote sensing data, while non-diagonal plots are parameter views. Characteristics of selected region of spatial views are highlighted in other views.

of information as well as specifying conditions on particular types and with a particular degree of accuracy. Thus, for example, one might specify a temporal constraint using a visualization containing a timeline, a constraint on a name field using a sorted list view, and a geographic constraint using a map. While each is effective as a tool for accurate and intuitive specification of a part of a query, none could be used for the complete query.

In some situations the user may want to *unlink* some visualizations in order to maintain a given view while exploring a different area of the data or different data set. Some systems allow the user to indicate for each window whether it is transmitting information to other views and from which other windows it will receive input. A user may also want to constrain the type of information being communicated, as well as its direction. Some types of interaction may be local to a particular window, e.g., zooming in and out, while others are meant to be shared, such as reordering dimensions. Also, in some situations, such as with hierarchically related windows, it may make more sense for the information to move from parent to child, but not the other way. Thus a fairly rich set of connection and communication options may be needed to maximize flexibility.

Key Applications

Linked brushing had its roots in the field of statistics, but is now commonly employed in any field in which visual data analysis is used, including earth and space science, engineering, homeland security, economics, and bioinformatics.

URL to Code

Many commercial and freeware visualization systems support linked brushing. Two such freeware systems are GGobi (http://www.ggobi.org) and XmdvTool (http://davis.wpi.edu/∼xmdv).

Load Balancing in Peer-to-Peer Overlay Networks

Anwitaman Datta
Nanyang Technological University, Singapore,
Singapore

Definition

Load balancing in peer-to-peer (P2P) overlay networks is a mechanism to spread various kinds of loads like storage, access and message forwarding among participating peers in order to achieve a fair or optimal utilization of contributed resources such as storage and bandwidth.

Historical Background

Load balancing is a general and critical requirement in distributed and parallel processing systems in order to make efficient and fair use of available resources. In the context of P2P systems, the early works on load-balancing heavily relied on consistent hashing [11], which was proposed in 1997 to originally deal with load-balancing in web caches with minimal movement of data even if new caches are added or if existing ones crash. Consistent hashing was used to achieve storage load-balancing in many early distributed hash table (DHT) P2P networks proposed around 2001.

When a new object is stored, uniform hashing (as used in consistent hashing) helps choosing a peer uniformly from the set of all peers. But the storage load distribution still has high variation as observed in the *balls into bins* phenomenon [14]. The imbalance caused by such variation can be mitigated using an uncoordinated randomized approach called "power of two choices" [13], (More generally, multiple choices.) and was employed for P2P overlays [5] in 2003.

Using uniform hashing leads to loss of existing order relationships such as lexicographic ordering. Objects can be located only based on exact queries. For data-oriented applications involving complex queries like approximate or range queries, uniform hashing is unsuitable. Retaining the ordering relationships however means skewed distribution of the corresponding keys over the key-space of the overlay network. Several new mechanisms and alternate data-structures to dynamically and adaptively partition the key-space based on local load [1,3] and using adaptive reassignment of peers to a different part to the key-space [8] were proposed around 2004–2005 in order to deal with the skewed storage load distribution. Besides workload heterogeneity, the peers themselves have heterogeneous capacities, and assigning proportionally more load to a computer with more resources is another commonly employed approach [4,9] since 2005. Timeline of load-balancing mechanisms developed for P2P overlays is shown in Fig. 1.

While there is an extensive body of work related to storage load-balancing in P2P overlays, it has often been assumed that access load can be dealt with merely by caching. But if each cache is uniformly randomly chosen to answer query for a hot key, it nevertheless suffers from high load imbalance caused by variance, just like the balls into bins problem of uniform hashing. Furthermore, structured overlay routing algorithms do not account for balancing the traffic through each peer, which if unbalanced, may lead to systematic congestion that network level congestion control mechanisms can not deal with. Use of redundant overlay routes to dynamically route requests (e.g., queries) based on load at peers has been proposed in 2007 to deal with traffic and access load balancing [7].

While there have thus been several approaches dealing specifically with diverse kind of load-imbalances, research on a holistic approach (dealing with potentially arbitrary workload skews in terms of storage load, request distribution as well as message forwarding traffic load in the network on one hand, and the capacity of heterogeneous peers particularly in terms of the storage space and bandwidth they have and are willing to contribute) is in an early stage [9].

Foundations

Load in a P2P overlay network is typically either because peers need to store an object, or for answering requests (such as queries) by forwarding them to relevant peers, which may in turn reply back with the

Load Balancing in Peer-to-Peer Overlay Networks. Figure 1. Evolution of load-balancing techniques for P2P overlays over time.

appropriate stored objects. A request may originate at any peer, and the routing algorithm of the overlay is used to forward the request to peers which can respond to it. Thus a request in turn creates both request forwarding and answering loads.

Each of these loads – storage and access load (which in turn leads to request forwarding and answering requests) – have different characteristics, both in terms of the resources they need, as well as the temporal characteristics. Storage load is permanent in that a object need to be stored persistently unless it is removed (deleted) based on application logic. Furthermore, even though storage load distribution changes over time, in general it is expected to change gradually. In contrast, access load is typically temporary, however the load-distribution may change abruptly (e.g., flash crowds). These distinct characteristics provide different opportunities and limitations in load-balancing.

Note that various load-balancing issues may also arise in unstructured and super-peer based overlay networks. These are dealt with heuristically. For instance, super-peers take into account the heterogeneity of peers' resources while designating some peers as super-peers. So the discussion here is primarily restricted to structured overlays.

Approaches for Balancing Storage Load

There have been various approaches to balance storage load among peers. Historically, uniform hashing has been used in many structured overlays as the first step to balance storage load. These are generally called distributed hash tables (DHTs). Subsequent networks overcome the limitations of using uniform hashing. An overlay to store range partitioned data has additional challenges in achieving load-balance. (The term "range-partitioned data" was introduced in 2004 [8] to distinguish structured overlays preserving ordering information from those using uniform hashing (DHTs). The same nomenclature is used here. Though structured overlays supporting range partitioned data came to mainstream focus in 2004–2005 with several new developments [1,3,8], P-Grid [1] supports range-partitioned data but was originally proposed in 2001, making it contemporary to the early DHT proposals.). Next is the discussion of load-balancing issues and mechanisms in both these categories of structured overlays.

Distributed Hash Tables (DHTs)

Hashing. Several pioneering structured overlays used uniform hashing as the primary means to balance storage load. The idea was to hash the object descriptor to generate a key uniformly (e.g., using cryptographic hashing like SHA) distributed over the key-space. Assignment of the peers to a partition of the key-space was also done uniformly at random, generally using hashing again. This category of structured overlay networks are commonly called distributed hash tables (DHTs). The rationale of the original DHT approach was that if peers were delegated sub-portions of the key-space uniformly randomly, and the keys were distributed uniformly randomly over the key-space, then the peers will have uniform load.

This intuition fails in practice because of what is known as the "balls into bins" effect. If m balls are put in n bins by choosing the bins independently and uniformly randomly for each of the balls, the variation of the number of balls per bin is high [14], and is of the order of m/n where $m >> n$. Since there are usually many more objects than the number of peers (i.e., high m/n), uniform hashing is inadequate to achieve good load-balance. There has been several approaches to reducing the effect of such statistical noise to improve storage load-balancing in DHTs.

Virtual servers (peers). One potential approach to reduce the variance is to have more peers. This can be achieved by creating multiple mutually independent virtual peers per physical computer [6]. Instantiating multiple virtual peers have several down-sides, including the fact that system states (e.g., routing table entries) need to be maintained for each of these virtual peers. Allocating independent key space partitions to more logical (virtual) peers also lead to inefficient search as more overlay level query forwarding are required.

Power of two (multiple) choices. The variance observed in the "balls into bins" process can be reduced without global coordination or knowledge by using an uncoordinated randomized algorithm. Instead of choosing one bin randomly uniformly, several (say two) distinct bins are chosen randomly uniformly as potential destination for a ball. Then the bin with fewer balls is actually chosen to put the current ball in. This mechanism significantly reduces load-imbalance for little extra overhead of choosing multiple (but constant) bins for each ball, instead of picking one [13]. In the context of DHTs, this can be realized by having multiple hash functions to generate multiple possible keys for the same object. The object is actually stored corresponding to that key which belongs to the key-space partition which is stored by the less loaded peer. In order to query an object, all the potential keys for that object need to be queried, thus significantly increasing the query overhead. An alternative is to store pointers at all the other keys to the actual location of the object. This however leads to higher storage and maintenance cost of these pointers.

Virtual peers for heterogeneous physical peers. Use of multiple but equal number of virtual peers was originally proposed to deal with the load-imbalance caused by the balls into bins effect for homogeneous peers [6]. The same idea of virtual peers has also been extended to deal with peer heterogeneity. Proportionally more virtual peers can be created corresponding to a physical node with more resources [10]. To deal with the drawbacks of virtual peers as mentioned earlier, allocation of contiguous partition of the key-space to virtual peers corresponding to the same physical node has been proposed subsequently [4]. Having contiguous key-space allocated to a physical peer has several advantages. There are fewer routing table links to maintain. Also fewer stored objects need to be moved among physically different peers. Note that using such contiguous partitions of the key-space among virtual peers of the same physical node means that there is actually no need of the "virtual peers" abstraction. It is a special case of partitioning the key-space adapted to the granularity of the load and the capacity of the peers as has been used in several other approaches dealing with range partitioned data [3,8,9].

Beyond DHTs

Using uniform hashing to generate keys lead to loss of ordering relationships such as lexicographic ordering, thus uniform hashing based DHTs are ill suited to deal with any queries other than exact queries. DHTs are not suitable for even simple crucial data-oriented queries like approximate queries or range queries. On the other hand, using an order preserving hashing to generate keys leads to potentially arbitrarily skewed and dynamic distribution of keys over the key-space, calling for different load-balancing mechanisms in structured overlays supporting *range partitioned data.* Several overlays exist to support range-partitioned data. While using slightly different data structures, each of these proposals deal with two critical impacts of skewed distributions of keys over the key-space – namely (i) partitioning the key space among peers in a granularity adaptive to the load distribution, and (ii) establishing a data-structure to keep routing and searching efficient despite non-uniform partitioning of the key-space.

Load-balancing (despite skewed load distribution) leads to allocation of key-space partitions to peers in an uneven manner. This is achieved by re-partitioning key-space of overloaded peers with newly joining peers, or by migrating peers from an under-loaded region. Migration and repartitioning are relatively drastic and need some (partial) global information. The advantage is that it can use any under-loaded peer to alleviate load imbalance for any other peer. In contrast, a localized strategy of readjustment of the key-space partitions with immediate neighbors in the key-space complements the above strategies. By shrinking or expanding the partitions, peers shed (or steal) load by transferring keys to (from) a neighboring peer in the key-space. These strategies are shown in Fig. 2.

In each of these strategies, in absence of global knowledge or coordination, peers need to make autonomous decision about whether it is over-loaded or underloaded with respect to other peers. The load information is obtained by sampling. Often peers exploit their routing topology for sampling a small nevertheless representative subset of the peers. Depending on their local view of the global state, overloaded peers may then request underloaded peers to share load (e.g., as in Mercury [3]), or some underloaded peers may spontaneously decide to relieve overloaded peers (e.g., as in P-Grid [2]). The sampling based load estimate is approximate, moreover the sampling is neither instantaneous nor concurrent over the network, and even if peers had perfect global knowledge, in the absence of coordination, peers make autonomous decisions for load-balancing. All this leads to the risk of oscillatory behavior, which is undesirable. Load-balancing mechanisms do not come free – all of them need transfer of objects, moreover migration also leads to inconsistent routing states at other peers which in turn causes route maintenance overheads. So it is desirable to dampen the load-balancing mechanism somewhat in order to avoid oscillatory effects [2].

Consequence of load-balancing in overlays supporting range partitioned data. An immediate consequence of load-balancing in structured overlays supporting range partitioned data is that the key-space is partitioned unevenly, and new mechanisms than what is traditionally used in DHTs are required to decide efficient routing table entries and corresponding routing algorithms. Randomized choice of routing tables ensure efficient average routing latency in P-Grid [1] even if the routing tables abstract a (potentially highly) unbalanced trie, while Mercury [3] and Oscar [9] uses randomized routing in a slightly different way, extending the idea of small-world routing [12] over skewed key-space partitions.

Approaches for Balancing Requests Related Load

Relative popularity of different objects vary, and also change over time. As a consequence, even if storage-load is balanced, peers storing popular objects or services are prone to be overloaded. Replication or caching is the intuitive remedy to deal with hot-spots and dissipate load. If, however, one considers that there are n copies of an object (or service), and there are $m >> n$ requests for the same object, and each request is catered by any one of the copies randomly uniformly, again one encounters a "balls into bins" scenario with high variation in load distribution. Likewise, the load of forwarding messages at different peers have high variation if the routing algorithm of the corresponding overlays are used in a load-agnostic manner. This may in turn lead to congestion caused by the overlay layer, even when there is underutilized resources at other peers. Both these request related load imbalances can be mitigated with the use of simple heuristics exploiting the redundancy of routing choices (which is anyway necessary for fault-tolerance) to the least loaded of the peers that satisfy the routing criterion of the routing algorithm [7]. It has also been shown in the work that either caching or load aware routing is inadequate as stand-alone solutions, but complement each other, and hence need to be used together in order to balance request related loads.

Key Applications

Load-balancing is a critical and desirable property in distributed systems, and is necessary to achieve good performance and make fair and judicious use of available resources. Structured overlays provide indexing mechanism to locate objects distributed over the network with a guaranteed recall based on either exact or range queries, and also support other queries like approximate queries. The basic index can in turn be used to support diverse applications including cooperative file systems, P2P information retrieval, peer data management systems (PDMS) and collaborative work-spaces. For good performance (e.g., response time, fewer failures, etc.) at

application level, it is imperative that the underlying overlay has good load-balancing.

Future Directions

Peer-to-peer systems have dynamic and skewed workloads, and participating peers have heterogeneous capacities. Consequently, rather than distributing load equally among peers, which is what most current literature aims at, a more pragmatic approach is to look at how to distribute the whole load without violating the autonomous peers' contribution, desirably with minimal wastage of resources. Complementing this, it is also important to find incentive or punishment mechanisms which ensure that peers do contribute resources and do not participate in the system as parasites or free-riders. A holistic design, looking into mechanisms to ensure that autonomous peers contribute sufficient resources, and then allocating these heterogeneous resources to efficiently and effectively cater to dynamic and skewed workloads is the fundamental open problem in the context of load-balancing in peer-to-peer overlays.

Load Shedding

NESIME TATBUL
ETH Zurich, Zurich, Switzerland

Definition

Data stream management systems may be subject to higher input rates than they can immediately process with their available system resources (e.g., CPU, memory). When input rates exceed the resource capacity, the system becomes overloaded and the query answers are delayed. Load shedding is a technique to remove excess load from the system in order to keep query processing up with the input arrival rates. As a result of load shedding, the system delivers approximate query answers with reduced latency.

Historical Background

Load shedding is a term that originally comes from electric power management, where it refers to the process of intentionally cutting off the electric current on certain lines when the demand for electricity exceeds the available supply, in order to save the electric grid from collapsing. The same term has also been used in computer networking to refer to a certain form of congestion control approach, where a network router drops packets when its buffers fill up. More recently, load shedding has been proposed as a way to deal with overload in data stream processing systems [4].

Foundations

The goal of load shedding is to make sure that limited system resources operate below their capacity levels in case of unpredictable bursts in data arrival rates. This is achieved by selectively discarding some of the data items, thereby reducing the load at the expense of producing an approximate query answer. The main challenge in this problem is to minimize the loss in answer accuracy.

Assume a set of continuous queries Q, represented as a query plan of operators, where some of these operators may be shared among multiple queries. A set of inputs I feed these queries with streaming data, exerting a total load of $Load(Q(I))$ on a particular system resource with capacity C. A load shedding scheme must address the following key questions:

1. When to shed load? Conceptually, load needs to be shed whenever $Load(Q(I)) > C$.
2. Where to shed load? Load can be discarded at any point in the query plan. Dropping load at earlier points avoids wasting work; however, because of shared operators in the query plan, an early drop might adversely affect the accuracy of too many query answers.
3. How much load to shed? Just enough of the load at the chosen point(s) in the query plan must be shed so that the total resource demand gets below the available capacity with minimal total loss in accuracy.
4. Which data items must be discarded? The data items to be discarded should be chosen based on the approximation model and the properties of the operators in the query plan.

Furthermore, any load shedding scheme must have low run-time overhead in order not to further stress the limited system resources.

Various approaches have been proposed as solutions to the above listed issues. These approaches differ in their assumptions along several dimensions, including:

1. The limited resource under consideration (e.g., CPU, memory, communication bandwidth),
2. The way to reduce load (e.g., drop data, create summaries),
3. The approximation model/objective (e.g., maximum subset, minimum relative error, maximum throughput),
4. The query operator(s) under consideration (e.g., sliding window aggregates, windowed joins),
5. The data arrival model (e.g., stochastic models, temporal models),
6. The control loop (open vs. closed)
7. The system architecture (centralized vs. distributed).

Within the scope of the Aurora Project, Tatbul et al. have proposed a solution framework for load shedding which focuses on CPU as the main scarce resource, and discarding tuples by inserting special drop operators into the running query plan as the load reduction method [14]. The goal in this work is to minimize utility loss in query answers in terms of two alternative QoS (Quality of Service) dimensions: (i) percent tuple delivery, using a *random drop*, or (ii) output values delivered, using a *semantic drop*. A random drop discards tuples based on a drop probability, whereas a semantic drop does so based on a predicate on the tuple content. The earlier the load is reduced in a query plan, the larger is the saving in processing resources. However, shedding load early in a shared query plan may hurt the accuracy for multiple queries. To address this conflict, it is shown that load reduction should be applied either on the input streams, or on streams that immediately follow a shared operator in the query plan. Furthermore, these potential drop locations are ranked in terms of a metric, called *loss/gain ratio*. The drop location that causes the smallest QoS utility loss for the corresponding CPU processing power gained in return per unit drop of data, is preferred over the other drop locations with larger ratios. This way, the overall loss in QoS utility is minimized. For low run-time overhead, this work has proposed to pre-compute a set of load shedding plans based on system statistics, and insatiate these plans at run time based on the observed input rates. The proposed framework has also been extended to handle load shedding on windowed aggregation queries [15]. The key idea is to use a third type of drop operator, called a *window drop*, which semi-probabilistically discards load in units of windows instead of on a per-tuple basis. This way, window integrity can be preserved throughput a query plan, and query answers are guaranteed to be subsets of the original answers. An alternative to the window drop approach was earlier proposed by Babcock et al. [3]. This work also targets load shedding on aggregation queries under CPU constraints, but uses a different approximation model where the goal is to minimize the maximum relative error across all queries. Drops are applied on a per-tuple basis, leading to query answers with errors in their values. Window statistics and well-known statistical bounds such as the Hoeffding inequality are used to control these errors for a certain set of aggregate functions, including sum, count, and average. A close alternate to dropping tuples under CPU limitations is the selective processing approach proposed by Gedik et al. [8]. This work selectively processes tuples in the stream windows for join operators, in order to maximize the output rate or semantic utility of the query results, in the presence of variations in input rates as well as time correlations between two join inputs.

Load shedding can also be used to deal with memory limitations. Das et al. have focused on this problem for stream joins, where the maximum subset measure is used as the approximation metric [7]. This work assumes a frequency-based data arrival model and proposes two practical heuristics: (i) PROB, which drops tuples from an input stream which had the smallest frequency of occurrence on the opposite stream in the past (assuming that those tuples are the least likely to produce join results also in the future); (ii) LIFE, which drops tuples from an input stream whose product of frequency of occurrence on the opposite stream and remaining window lifetime is the smallest (i.e., the goal is to avoid investing on soon to be expired tuples). Within the scope of the STREAM Project, Srivastava and Widom have proposed an alternative load shedding approach for windowed stream joins in memory-limited environments [12]. This work is based on an age-based data arrival model, where it is assumed that the rate at which a tuple produces join results is solely determined by its age, specified as an age curve. To deal with memory shortage, tuples of a certain age are selectively discarded from the join window to make room for others, which have higher expectation of producing matches. The goal here is again to maximize the size of the join result set. A secondary concern in this work is to be able to produce a random sample from the join in case that the join is followed by an aggregate. In this case, the final output will not be a subset of the exact answer, and the overall goal is then to minimize the relative error, in line with the work of Babcock et al. [3].

Jain et al. have proposed a load shedding approach to reduce the network bandwidth usage [9]. This approach is based on Kalman Filters which can be used to model data streams as processes with states that evolve over time. As new tuples arrive at a source site, it is checked if the current model installed at the remote server site can still answer the query within given precision bounds. If so, there is no need to send the new tuple to the server, i.e., it can be discarded. Otherwise, the server model has to be updated, hence the new tuple is transmitted. Adaptivity is achieved by adjusting model parameters to changing load characteristics.

Stream load can also be reduced based on creating summaries of data instead of discarding data. This idea was pursued by two different lines of work within the scope of the TelegraphCQ Project: (i) Reiss and Hellerstein have proposed a load shedding technique called *data triage*, where excess data is not dropped, but stored in synopsis data structures [11]. At the end of a well-defined query window, the stored synopses are processed through a shadow query plan to compute an approximate result on the summarized portion of the data. Finally, exact and approximate results are merged into one composite result for that query window. This works using an error model based on Minkowski distance. (ii) Chandrasekaran and Franklin have focused on hybrid queries that process live data streams in correlation with historical data archived on disk [5]. In this case, disk becomes the bottleneck resource. To keep processing of disk data up with processing of live data, disk data is organized into multiple resolutions of reduced summaries. Depending on the live data rates, the system picks the right resolution summary to use in query processing. This is a form of load shedding that tries to cut down from disk access cost using data summaries.

The NiagaraCQ Project has taken an integrated approach where load shedding is seen as an extension to continuous query optimization. Kang et al. use a unit-time-based cost model where total cost of join processing is broken into two components, one for each join direction [10]. The optimal index and join algorithm combination for each direction is determined so as to maximize query throughput. Under CPU and memory limitations, the optimizer determines the ideal rate for each input and accordingly places a random drop to control the input rates. Ayad and Naughton use a similar analytical cost model, but extend it to plans with multiple joins [2]. It is shown that if computational resources are enough, then all join plans have the same throughput, however, they may substantially differ in their resource utilization. If all of these plans are infeasible (i.e., lead to CPU overload), then load must be shed via random drops. The focus is on picking the right join plan, the locations on the plan to insert the drops, and the amount of drops. An interesting result shown in this work is that the optimal join plan (i.e., with the lowest utilization) when resources are sufficient is not necessarily the optimal plan (i.e., with the highest throughput) when resources are insufficient.

All of the above described approaches assume that stream processing is performed on a single server. The overload problem can also arise in distributed stream processing systems where queries are distributed onto multiple servers. In a distributed environment, there is load dependency among the nodes that are assigned to run pieces of the same query. As a result, shedding load at an upstream node affects the load levels at its downstream nodes, and the load shedding actions at all nodes along a query plan will collectively determine the quality degradation at the query end-points. Within the scope of the Borealis Project, Tatbul et al. have modeled this problem as a linear optimization problem, and proposed two alternative solutions: (i) a centralized approach, where a coordinator node produces globally optimal plans with the help of an LP solver, and the rest of the nodes adopt their share of these global plans; (ii) a distributed approach, where nodes exchange metadata information (represented in the form of a feasible input table (FIT) which shows input rate combinations that are feasible for a given node) with their neighbors, and each node produces its own plan based on the available metadata [13]. Both of these solutions are based on the idea of pre-computing the load shedding plans in advance and storing them in a quadtree-based plan index. It is shown that the FIT-based plan generation is more efficient than its solver-based counterpart. Furthermore, the distributed solution is expected to be more responsive in dynamic environments due to its ability to incrementally update previously computed load shedding plans, reducing the amount of run-time communication needed among the nodes.

These approaches are all open-loop solutions in that the system load is periodically monitored and the load shedding algorithms are triggered as necessary. There has also been recent work that applies control-theoretic concepts to finer-grained adaptive load shedding on data streams [1,16]. These approaches are based on constructing a feedback loop that continually monitors the high-frequency variations in system parameters and makes the necessary adjustments in the load controllers accordingly. Such closed-loop approaches are shown to be more adaptive for input workloads with higher frequency fluctuations in stream data rates.

Load shedding finds use also in resource-intensive data stream mining applications. As argued by Chi et al. [6], in common data mining tasks such as classification and clustering of multiple data streams, the impact of load shedding on performance is not known a priori as the mining quality often depends on specific feature values observed in the stream in a non-monotonic way. This requires feature value prediction and adaptation. The Loadstar scheme uses a Markov model to predict the distribution of future feature values whose parameters are adaptively updated in time in order to maximize the classification quality under CPU constraints [6]. The high-level idea in this work is to allocate more resources to data streams that carry more uncertainty while shedding the ones whose class labels are more certain for the upcoming time window.

Key Applications

Load shedding can be used in all data-intensive streaming applications for which low latency answers can be more critical than full answer accuracy. These include sensor-based monitoring (e.g., habitat monitoring, bio-medical monitoring, weather monitoring, road traffic monitoring), RFID-based asset tracking, GPS-based location tracking, video-based security monitoring, and network traffic monitoring.

Future Directions

Load shedding in data stream management systems is currently an active area of research. A significant body of research results has been produced in this area since circa 2002. The future directions include development of new load shedding schemes for other sets of assumptions along the dimensions listed above. There is also a need to integrate the complementary and alternative solution schemes under a single framework, which could automatically select the right set of techniques for a broad range of system resources, based on the characteristics of the received workload as well as the application-specific quality of service criteria.

LOC METS

Prasenjit Mitra
The Pennsylvania State University, University Park, PA, USA

Synonyms

Metadata encoding and transmission standard; Library of congress METS

Definition

The Library of Congress (LOC) Metadata Encoding and Transmission Standard (METS) is an XML (Extensible Markup Language) based format used for encoding metadata. The metadata is used to markup digital library objects in a repository or for exchange across repositories. METS is a Digital Library Federation initiative that is a successor to the Making of America II project (MOA2).

Key Points

The MOA2 project attempted to provide encoding formats for descriptive, administrative, and structural metadata for text and image-based documents. (http://www.loc.gov/standards/mets/METSOverview.v2.html) The Digital Library Federation (DLF) sponsored the project and the National Endowment for the Humanities funded it. MOA2 involved discussions led by the University of California, Berkeley with participants from New York Public Library and the libraries of Cornell, Penn State, and Stanford universities. The project produced a Document Type Definition

(DTD) that specifies a vocabulary and syntax for encoding digital objects. (http://www.lib.berkeley.edu/digicoll/bestpractices/mets_history.html) The library community realized that the MOA2 DTD was too restrictive, because, MOA2 did not provide some basic functionality required for multimedia objects like video and audio. METS arose from efforts to address these problems in MOA2.

Digital objects and the metadata needed to describe them are different from the metadata required for documents. Digital objects require structural metadata that indicates how the components of the object are glued together and technical metadata that specifies how the digital object was produced. For example, if a digital object contains image and text files, the structural metadata indicates the hierarchical structure of these objects and files. Furthermore, without these metadata, the authenticity of a digital object could be in doubt. METs allows specifications of the structural technical metadata, as well as metadata required for internal management and administration.

A METS document consists of seven sections:

- *METS header*: describes the document itself and publishes information about the creator, editor, etc.
- *Descriptive metadata*: both external, i.e., residing outside the document and internal.
- *Administrative metadata*: describes how the object was created and stored, specifies intellectual property rights, etc. Like the descriptive metadata, administrative metadata can also be both external or internal.
- *File Section*: lists all files that comprise the digital object. Groups of files can be specified using <fileGrp> with individual file elements specified using <file>.
- *Structural Map*: specifies the hierarchical structure of the digital object.
- *Structural Links*: allows creators to link different nodes in the hierarchy using hyperlinks.
- *Behavioral*: associates executable behaviors with content in the METS object.

METS is specified as an XML Schema and can be used in the role of a Submission Information Package (SIP), Archival Information Package (AIP) or Dissemination Information Package (DIP) within the Open Archival Information System (OAIS) Reference Model (http://ssdoo.gsfc.nasa.gov/nost/isoas/ref_model.html) [1–3].

Locality of Queries

Pablo Barceló
University of Chile, Santiago, Chile

Synonyms

Locality; Hanf-locality; Gaifman-locality

Definition

Let σ be a relational signature without constant symbols. Given a σ-structure $\mathcal{A}$, its *Gaifman graph*, denoted by $G(\mathcal{A})$, has A (the domain of $\mathcal{A}$) as the set of nodes. There is an edge (a_1, a_2) in $G(\mathcal{A})$ iff there is a relation symbol R in σ such that for some tuple t in the interpretation of this relation in $\mathcal{A}$, both a_1, a_2 occur in t. The *distance* $d(a_1, a_2)$ is the distance in the Gaifman graph, with $d(a, a) = 0$. If $\bar{a}$ and $\bar{b}$ are tuples of elements, then $d(\bar{a}, \bar{b})$ stands for the minimum of $d(a, b)$, where $a \in \bar{a}$ and $b \in \bar{b}$.

Let $\mathcal{A}$ be a σ-structure, and $\bar{a} = (a_1,...,a_m) \in A^m$. The *radius r ball around $\bar{a}$* is the set $B_r^{\mathcal{A}}(\bar{a}) = \{b \in A \mid d(\bar{a}, b) \leq r\}$. The *$r$-neighborhood of $\bar{a}$ in $\mathcal{A}$* is the structure $N_r^{\mathcal{A}}(\bar{a})$ over signature σ expanded with m constant symbols, where the universe is $B_r^{\mathcal{A}}(\bar{a})$, the σ-relations are restrictions of the σ-relations in $\mathcal{A}$ to $B_r^{\mathcal{A}}(\bar{a})$, and the m additional constants are interpreted as $a_1,...,a_m$. Notice that any isomorphism h between $N_r^{\mathcal{A}}(a_1, ..., a_m)$ and $N_r^{\mathcal{B}}(b_1,...,b_m)$ imposes that $h(a_i) = b_i$, $1 \leq i \leq m$.

Let $\mathcal{A}, \mathcal{B}$ be σ-structures, $\bar{a} \in A^m$ and $\bar{b} \in B^m$. Then $(\mathcal{A}, \bar{a}) \rightleftarrows_r (\mathcal{B}, \bar{b})$ if there exists a bijection $f: A \to B$ such that $N_r^{\mathcal{A}}(\bar{a}c) \cong N_r^{\mathcal{B}}(\bar{b}f(c))$, for every $c \in A$.

Hanf-locality. An m-ary query Q on σ-structures is *Hanf-local*, if there exists $r \geq 0$ such that for every σ-structures $\mathcal{A}$ and $\mathcal{B}$, and every $\bar{a} \in A^m$ and $\bar{b} \in B^m$, if $(\mathcal{A}, \bar{a}) \rightleftarrows_r (\mathcal{B}, \bar{b})$ then $(\bar{a} \in Q(\mathcal{A}) \iff \bar{b} \in Q(\mathcal{B}))$.

Gaifman-locality. An m-ary query Q, $m > 0$, on σ-structures, is *Gaifman-local* if there exists $r \geq 0$ such that for every σ-structure $\mathcal{A}$, and every $\bar{a}, \bar{b} \in A^m$, if $N_r^{\mathcal{A}}(\bar{a}) \cong N_r^{\mathcal{A}}(\bar{b})$ then $(\bar{a} \in Q(\mathcal{A}) \iff \bar{b} \in Q(\mathcal{A}))$.

Key Points

Locality is a property of queries that finds its origins in the work by Hanf [1] and Gaifman [2], and that has shown to be very useful in the contexts of finite model theory and relational database theory. In very rough terms, a query is local if its truth value only depends on a small neighborhood of the input around its free variables. Locality is primarily used to prove inexpressibility results over finite structures, but it can also be used for establishing normal forms for logical formulae. It is a particularly helpful tool for finding easy winning strategies for the duplicator in the Ehrenfeucht-Fraïssé game, avoiding complicated combinatorial arguments.

The abstract study of the concepts behind the locality theorems of Hanf and Gaifman was initiated in [3]. It is shown there that the two notions of locality presented above are related: Every m-ary query (with $m > 0$) that is Hanf-local is also Gaifman-local, but the converse does not hold. The most paradigmatic example of a query that is neither Hanf- nor Gaifman-local is the one that computes the transitive closure of a graph.

A typical application of locality to prove the inexpressibility of query Q over logic $\mathcal{L}$ is done in two steps. First, show that Q is not local, and second, prove that every query defined by a formula in $\mathcal{L}$ is local. It follows from [3,4] that first-order logic, as well as many of its extensions with counting and generalized quantifiers, only define queries that are both Hanf- and Gaifman-local. This gives a simple proof of the fact that none of these logics can compute the transitive closure of a graph.

Location services; Geographic information services; Mobile map services; LBS

Definition

Location-based services (LBS) provide targeted information to individuals based on their geographic location in real or near-real time, typically through wireless communication networks and clients such as portable computers, personal digital assistants, mobile phones, and in-vehicle navigation systems.

Historical Background

LBS have emerged from the convergence of three major technological trends: (i) *geospatial technologies*, including location-aware technologies, geographic information systems (GIS) and spatial databases; (ii) *the Internet*, and; (iii) *information and communication technologies*, in particular, personal computing devices and mobile communication. Some of these technologies date to the late 1960s and early 1970s. For example, the first GIS was developed in the mid-1960s, while the global positioning system, the Integrated Services Digital Network (ISDN), mobile telephony and TCP/IP as a dominant network protocol emerged in the 1970s. The personal computer was introduced in early 1980s, an era that also experienced the deregulation of the telecommunications industry in the USA and Europe. Through the 1990s and early twenty-first century, these technologies matured, diffused and converged sufficiently such that LBS in the contemporary sense is possible [4,8].

Foundations

Location-Aware Technologies

Location-aware technologies (LATs) are devices that can report their geographic location in real or near-real time. Technologies for determining geographic location include the global positioning system, radiolocation methods and interpolation [2]. These can be used in combination.

The *global positioning system* (GPS) exploits time differences of signals arriving from subset of a satellite constellation in Earth orbit. The GPS is traditionally the most common LAT due to its high accuracy and low cost. GPS receivers are becoming small and light enough to embed in many other mobile technologies. However, the GPS requires line-of-sight with orbital satellites; this can be a problem in places with dense foliage or tall buildings, as well as inside built structures.

Radiolocation methods exploit wireless communication systems and determine location using methods such as those based on the time, time difference or angle of the signals' arrivals at base stations from mobile clients. The configuration of the network determines the precision of this method, with greater precision for areas with higher population densities and larger numbers of base stations. Radiolocation methods are less accurate in rural areas and have caused difficulties for wireless carriers attempting to achieve the E911 standards.

Other radiolocation methods include Bluetooth, WiFi, and Radio Frequency Identification (RFID) tags. These methods utilize a fixed network of sensory objects that sense objects in close proximity, interact with other sensors to triangulate the locations of an object based on some measure of signal strength, or utilize training information containing combinations of spatial coordinates and signal strengths. However, these methods are expensive and only cover small coverage areas. Their integration with positioning mechanisms outside of the building may also prove difficult.

Interpolation methods use distances and directions along a route from a known location to determine the current location.

Locational and Spatial Data Management

Since LBS users are likely to be mobile, a fundamental issue concerns the process whereby user locations are communicated to the central database and location server that supports LBS queries. At the time of the query the location service must have an accurate estimate of the user's location. The strategies used to communicate this information vary depending on the capabilities of the mobile device, the required accuracy for a particular query and the costs levied against the application server. This is essentially a question of how often the location of a moving object should be updated in the database.

Simple update strategies update a user's location whenever their location changes. This assumes there is no uncertainty in the tracking process and places high communication burdens on the servers. Temporal update strategies provide periodic updates of a user's location based on a recurring time interval. In the interval between updates, a user's location must be estimated according to an interpolation function. The accuracy of this estimate is based on the duration of the temporal recurrence interval, the distance the user travels between samples and assumed maximum travel speed. Distance or spatial update strategies provide updates when the user has moved a specified distance. This has the advantage of being more sensitive to the behavior of the user than temporal strategies. Dead-reckoning strategies integrate the temporal and distance approaches by comparing an estimated location with a measured location; this usually occurs on the client device. Updates to the database or location server occur when the difference between the estimated and measured location exceeds a given threshold.

Additional spatial data management issues include representations of geographic space and georeferenced content of real-world services such as restaurants and shops. While the former often includes physical features such as mountains, coastlines, and so forth, of critical importance is the transportation network. Transportation networks are important since they serve as the basis for navigation as well as the basis for georeferencing through street addresses. Required are multiple and integrated network representations that can support both navigation and locational referencing. The latter includes both the user's position provided by the LAT as well as linear referencing within the network [3].

Middleware, Open Standards and Interoperability

LBS middleware provides standard mechanisms for connecting the software components necessary for a given service. These components may be entirely present within a single device or distributed across a network of location, data and application servers. The primary objective of middleware is to support the interoperability of applications across devices and mobile service networks with different locational positioning methods and protocols. Middleware also provides a generic interface for querying geographic information stored in different formats and database systems.

The *Java ME Location API* is an example of device-oriented middleware. The API provides an interface defining methods for querying the location of the user with information corresponding to the confidence or uncertainty of the estimated location. This application resides on the device.

The *Open Location Services* (OpenLS) initiative is an example of set of standards to support network-oriented middleware. The OpenLS defines a set of core services and functions that are expected to satisfy most LBS applications. These services are similar database query languages in that they define an explicit structure for asking questions and interpreting the answers. Queries and results are structured using the eXtensible Markup Language (XML). Gateway services provide the mechanisms for querying the location of the user or other users required for the given application (e.g., friend finding); applications utilizing this service may exist on the device or be accessed through the network. Locational utility services provide the means for translating street addresses to geographical coordinates and vice versa. Directory services allow for querying points of interest (POI) such as restaurants. Route services provide a route, between two locations according to the preferences of the user. Presentation services allow for displaying querying results on a graphical map. Each of these services may exist on different providers. Using this framework, an LBS application developer could chain these services together in a similar manner to importing a software library or querying a relational database [7].

Locational Privacy

Detailed movement patterns in space and time are a signature that reveals much about an individual. Locational privacy is an emerging concept that suggests individuals have rights to their signature in space and time and can determine when, how and to what extent location information is communicated to others. Strategies for protecting locational privacy include regulation, privacy policies, anonymity and obfuscation. Regulation and privacy policies are trust-based mechanisms for defining unacceptable uses of location information. However, trust can be broken, making these strategies vulnerable to unintentional and intentional disclosure. Anonymity detaches locational information from an individual's identity. However, GIS can integrate locational information with other data such as remotely sensed imagery, geo-referenced social, economic and cadastral data, point-of-sale data, credit card transactions, traffic monitoring and video surveillance imagery, and other geosensor network data, allowing identity to be inferred. Obfuscation techniques deliberately degrade locational information, using error and uncertainty to protect privacy. Obfuscation techniques include geographic masking for static and mobile data (see [1]).

Location-Based Services. Table 1. Common LBS applications

• News	• Emergency response
• Navigation	• Person finding (friends, children)
• Traffic information	• Pet tracking
• Points of interest	• Electronic toll collection
• Advertising	• Car tracking
• Gaming	• Fleet management
• Weather forecasts	• Asset management

Key Applications

Key LBS applications span a large spectrum from convenient, "concierge" services to critical emergency response. Table 1 lists common LBS applications [9].

Two possible dimensions for classifying LBS applications are person versus device-oriented and push versus pull services [9]. *Person-oriented LBS* encompasses applications that are user-based. The user typically has control of the service: these intend to locate the person and/or use that location to enhance a service. These applications include news, navigation, points of interest, traffic, emergency response, and so on. *Device-oriented LBS* are not controlled by a person. Rather, the intent is to track an object or a set of objects. Applications include asset and fleet management.

Push services are LBS where a person receives information as a result of his or her location without actively requesting it. This information could be sent to the user based on prior consent (e.g., weather or traffic warnings) or without consent (e.g., advertising). *Pull services* are those where the user activity requests the information (e.g., points of interest, navigation, weather forecasts, traffic information).

Locking granularity and lock types

Definition

Databases are usually organized hierarchically, with tablespaces containing tables, which in turn contain records. In multigranularity locking, this organization is exploited for a more efficient lock management by allowing transactions to lock objects of different granularities like tables or records. Thus, instead of locking each record of a table separately, a transaction can lock the complete table. To ensure a correct execution when transactions use different granularities for locking, additional lock modes are introduced to avoid non-serializable executions.

Key Points

Transactions that acquire many locks on small items like records or pages incur a non-negligible performance and memory overhead for managing these locks. Such transactions can benefit from acquiring locks on coarser granules like tables or complete tablespaces, avoiding many fine-grained locks. However, concurrency may be lower due to an increased number of conflicts with coarser locks. On the other hand, for transactions that access only a few records, locking these records directly will usually be the best solution.

Concurrent transactions that use different granularities for locking cannot easily coexist if any guarantees on the serializability of the execution should be provided, as locks of different granularities do not conflict with each other and hence cannot prevent any nonserializable executions. In such a *multi-granularity locking scheme*, transactions wanting to acquire a lock on a smaller granule must first acquire locks on all larger granules. While it would be sufficient if the locks on the coarser granules were acquired in the same mode as the lock on the smaller granule, this would lead to many unnecessary blockings due to conflicts on the coarser granules. As an example, consider two concurrent transactions that want to modify different records of the same table and hence need to acquire an exclusive lock on these records. As they modify different records, they do not conflict with each other. However, they would additionally have to acquire an exclusive lock on the table, too, which would make the second transaction wait until the first released the lock again.

Such performance penalties can be circumvented with additional lock types for coarser granules that express the *intended* lock type the transaction wants to acquire on the smaller granule: The lock modes *IS (intentional shared)* and *IX (intentional exclusive)* on the coarse granules correspond to *S (shared)* and *X (exclusive)* on the smaller granule. These lock types coexist with the standard shared and exclusive lock types on the coarse granule (that are used to get shared or exclusive access to *all* items of the smaller granule).

Locking Granularity and Lock Types. Table 1. Compatibility matrix of lock types

	S	X	IS	IX	SIX
S	+	–	+	–	–
X	–	–	–	–	–
IS	+	–	+	+	+
IX	–	–	+	+	–
SIX	–	–	+	–	–

The additional lock type *SIX (shared intentional exclusive)* combines an S and an IX lock. It is used when the transaction plans to read most of the items within the granule and additionally modify some of them. In this situation, an X lock would be too restrictive as it would lock out any other transaction from reading items in that table.

To ensure serializability in a system with multi-granularity locking, a transaction wanting to acquire a lock on any granule (for example, on a record of a table) must first acquire *warning locks* with the corresponding intentional lock type on all coarser granules. Table 1 shows the compatibility matrix for the different lock types.

The best locking granularity for a transaction may change throughout its execution. For example, if the transaction initially plans to access only a few records, it may be best to lock only records; if the access pattern changes later and it turns out that it is necessary to access all or almost all records of the table, it may be better to *escalate* the record-level locks to a single lock on the table. To do this, the transaction must first convert the warning lock (of type IS or IX) on the table to a "real" lock (of type S or X), for which it may have to wait until other transactions have released incompatible locks. It can release any record-level locks subsumed by the new lock on the table without compromising serializability.

Logging and Recovery

Erhard Rahm
University of Leipzig, Leipzig, Germany

Synonyms

Failure handling; Rollback; Undo; Redo; Checkpoint; Backup; Dump

Definition

Logging and recovery ensure that failures are masked to the users of transaction-based data management systems by providing automatic treatment for different kinds of failures, such as transaction failures, system failures, media failures and disasters. The main goal is to guarantee the atomicity (A) and durability (D) properties of ACID transactions by providing undo recovery for failed transactions and redo recovery for committed transactions. Logging is the task of collecting redundant data needed for recovery.

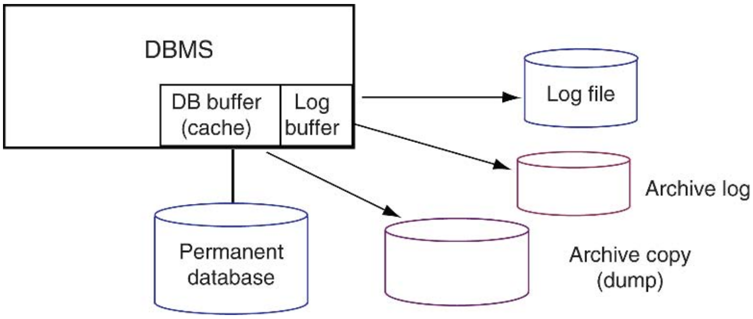
Key Points

The ACID concept requires that no data changes of failed transactions remain in the database. Failed transactions thus have to be rolled back by undoing all their changes (undo recovery). On the other hand, data changes of successfully ended (committed) transactions must not be lost but have to survive possible failures. Failure treatment thus implies a redo recovery for committed transactions. Recovery support is typically provided for transaction failures during normal processing (transaction recovery), for system failures (system recovery), and media failures (media recovery). System and media recovery are also known as two kinds of "crash recovery." In addition, disaster recovery can deal with the complete destruction of a computer center, e.g., due to an earthquake or terror attack. Recovery is typically based on logging, i.e., the collection of protocol data recording which transactions have been executed and which changes have been performed by them.

Figure 1 shows components of a central database management system (DBMS) involved in logging and recovery. The database objects (e.g., tables, records) are persistently stored in the *permanent database*, typically on one or several disks. All database operations including updates are performed in main memory. For this reason, pages of the database are cached in a main memory buffer (database buffer). Log records are persistently stored in a sequential *log file* on dedicated disks. Log records are written for the start, rollback and commit of transactions as well for every database change. For performance reasons log records are first collected in a log buffer in main memory, which is written to the log file when it becomes full or when a transaction commits. A transaction is committed when its commit record is logged on the log file.

Numerous approaches have been proposed and current database management systems provide efficient implementations for logging and recovery. The major tasks to be solved for dealing with the mentioned types of failures are:

- *Transaction recovery* (rollback) is performed when a transaction fails during normal processing, e.g., due to a program error or invalid input data. The log records in the log buffer and in the log file are used to undo the changes of the failed transaction in reverse order.
- *System (crash) recovery* is needed when the whole database (transaction) system fails, e.g., due to a hardware or software error. All transactions which were active and not yet committed at crash time



Logging and Recovery. Figure 1. DBMS components involved in logging and recovery.

have failed so that their changes must be undone. The changes for transactions that have committed before the crash must survive. A redo recovery is needed for all changes of committed transactions that have been lost by the crash because the changed pages resided only in main memory but were not yet written out to the permanent database. Periodically writing out modified pages, e.g., within so-called *checkpoints*, help to reduce the amount of redo work during crash recovery. Furthermore, the number of relevant log records and thus the size of the log file can be reduced by checkpoints.

- *Media (crash) recovery* deals with failures of the storage media holding the permanent database, in particular disk failures. The traditional database approach for media recovery uses archive copies (dumps) of the database as well as archive logs (see Fig. 1). Archive copies represent snapshots of the database and are periodically taken. The archive log contains the log records for all committed changes which are not yet reflected in the archive copy. In the event of a media failure, the current database can be reconstructed by using the latest archive copy and redoing all changes in chronological order from the archive log. A faster recovery from disk failures is supported by disk organizations like RAID (redundant arrays of independent disks) which store data redundantly on several disks. However, they do not eliminate the need for archive-based media recovery since they cannot completely rule out the possibility of data loss, e.g., when multiple disks fail.
- *Disaster recovery* can be achieved by maintaining a backup copy of the database at a geographically remote location. By continuously transferring log data from the primary database to the backup and applying the changes there, the backup can be kept (almost) up-to-date.

Synonyms

Audit trail; Log component; Log manager; Recovery manager

Definition

The logging/recovery subsystem (LRS) of a DBMS is responsible for implementing the fault tolerance mechanisms needed to support database transactions.

The log component stores the information needed to undo the updates performed by a transaction in case it has to be rolled back, either to an internal save point or to the beginning. It also stores information needed to reapply the updates of committed transactions to the database in case they are (partially) lost due to a system crash or after a storage media failure. In addition, the log component keeps track of all relevant state transitions such as begin-transaction, prepare, commit, abort, checkpoint, etc. The log is the first resource that is activated when restarting the database after a crash [1]. The recovery component orchestrates the activities needed to repair the database, depending on the situation. For example, after a crash, it first locates the last log record written and then reads the log backward, initiating undo for the operations of all transactions for which no "prepare" or "commit" entry has been found. Going backward, it looks for two specific records: The "begin" record of the oldest incomplete transaction – this is where undo stops, and the youngest checkpoint record. From that record, the recovery will read the log in forward direction and initiate a redo for the operations of all transactions that were completed before the crash. The log also plays a crucial role in implementing the two-phase commit protocol, and it can be used to detect security breaches.

Key Points

The log is the starting point of any recovery activity, so it has to be very reliable; therefore, the log devices are stored on devices that will retain their data in case of a power failure – typically disks, with current technology. Since all update operations, some read operations and a number of other activities create records to the log, it has to be very fast in order not to create a bottleneck. For that reason, the log is divided in to two portions: an online log containing all information that would be needed to support crash recovery, and an archive log that contains all information needed to recover from the loss of storage media. Data no longer needed in the online log is continuously moved to the archive by a background process that does not affect the overall system performance.

The recovery manager uses the log component for implementing some variation of the "write ahead log" protocol [2]. It basically states that before any update is applied to the database that may need to be rolled back, the data supporting the undo must be written to the log. Before a transaction is committed, all data needed to repeat the updates must be written to the log. Neither the log manager nor the recovery manager "understand" the structure of the log records. They are created and used by the resource managers that implement the objects (e.g., tuples, B-trees, queues). The log manager writes log records on behalf of those resource managers, and the recovery managers feeds them back to the resource managers when they are needed for undo and/or redo.

Logical schema design; Data model mapping

Definition

Logical database design is the process of transforming (or mapping) a conceptual schema of the application domain into a schema for the data model underlying a particular DBMS, such as the relational or object-oriented data model. This mapping can be understood as the result of trying to achieve two distinct sets of goals: (i) representation goal: preserving the ability to capture and distinguish all valid states of the conceptual schema; (ii) data management goals: addressing issues related to the ease and cost of querying the logical schema, as well as costs of storage and constraint maintenance. This entry focuses mostly on the mapping of (Extended) Entity-Relationship (EER) diagrams to relational databases.

Historical Background

In the beginning, database schema design was driven by analysis of the prior paper or file systems in place in the enterprise. The use of a conceptual schema, in particular Entity Relationship diagrams, as a preliminary step to logical database design was proposed by Chen in 1975 [2,3], and the seminal paper on the mapping of EER diagrams to relational databases was presented by Teorey et al. in 1986 [7]. Major milestones in the deeper understanding of this mapping include [1,6], which separate the steps of the process, and pay particular attention to issues such as naming and proofs of correctness. Among others, the correct mapping of subclass hierarchies requires a careful definition of table keys [5], and the *maintenance* of optimized relational representations of ER schemas is discussed in [4].

Foundations

The mapping from an Extended Entity Relationship schema to a relational (logical) schema handles the issue of representing the different states of the conceptual schema through a function that provides for every "object set" *O* (entity set or relationship set) in the EER schema a relational table `T_O`. The data management-related issues are handled by merging, partitioning or otherwise reorganizing the tables obtained in the previous step, while making sure that there is no loss of information.

To begin with, some notation and assumptions concerning the conceptual schema expressed in EER notation are required. A unique set of identifying attributes *id*(*E*) is assumed to be available for every strong entity set *E* (i.e., one that is not a weak entity or a subclass). Each object set *O* participating in a relationship set *R* can be marked as being: *total*, indicating that each instance of *O* must participate in at least one relationship instance of *R*; *functional*, indicating that an instance of *O* can participate in at most one relationship instance of *R*; and as playing a particular *role* in the relationship, if *O* (or its sub/super-class) can participate in other relationships or as different arguments of *R*. For every relationship set *R*, *id*(*R*) is assumed to return a subset of participants that uniquely determine each relationship instance. This is needed in examples such as "Exactly one faculty advises each student for each major area," where *id*(`advises`)=`{Student,Major}`, because students can major in several areas. Of course, if the relationship set *R* has one functional participant *O*, then *id*(*R*) returns *O*; when there are multiple functional participants, *id*(*R*) is assumed to return one that is total, if available. Entities can be organized in a ISA/subclass hierarchy, with the ability to declare subclasses as *disjoint*, and/or *covering* the superclass.

In a relational schema, for each table *T*, one must specify its attributes/columns, its primary key, any foreign key referential constraints, and non-null constraints on columns. The notation $T[\underline{K}Y]$ is used to refer to a table named *T*, with columns *KY*and primary key *K*; *key*(*T*) returns *K*.

The Basic E2R Mapping

The initial mapping from entity and relationship sets in the conceptual schema to relational tables (referred to as the E2R mapping) is defined recursively as follows: For a strong entity set *E*, the attributes of *E* form the columns of table `T_E`, and its key is set to *id*(*E*). For example, for entity set `Student`, with attributes `sid`, `name` and `age`, and *id*(`Student`)=`sid`, the E2R mapping will generate a table `T_Student [sid,name,age]`.

To preserve first-normal form `T_E` does not include multi-valued attributes of *E*. For any such attribute *M* of *E*, one adds a separate table `T_EM`, whose attributes are those in *id*(*E*) plus a new attribute $\hat{M}$ that holds the individual values that occur in *M*; the full set of columns forms the key of this table, and a foreign key constraint is added from column *id*(*E*) of `T_EM` to `T_E`. Thus, if the entity set `Student` has a multi-valued attribute `phone`, then the E2R mapping will generate a table `T_StudentPhone[sid,phone]`, with `sid` being a foreign key with respect to `T_Student`.

If *E* is a subclass of some class *F*, then the columns of `T_E` consist of the attributes of *E* together with those in *key*(`T_F`) – the key "inherited" from `T_F`.

Therefore *key*(T_F) is the key of T_E, and a foreign key reference to T_F is needed to ensure that every subclass instance is in the super-class. For example, supposing that GradStudent is given as a subclass of Student, then T_GradStudent will have, among others, a column sid, which will also be its key and a foreign key referencing T_Student. In case subclasses are disjoint or cover the super-class, appropriate SQL assertions need to be added to check these constraints.

For a relationship set *R*, T_R has as attributes all the attributes of *R*, as well as the union of the sets of attributes X_O=*key*(T_O) of all object sets *O* participating in *R*; for each such set of attributes X_O, a foreign key constraint from T_R to T_O is added, in order to avoid dangling references. Moreover, a NOT NULL constraint is added to the corresponding columns of X_O. The keys of the tables generated from the object sets in *id*(*R*) jointly become the key of T_R. For example, suppose that admits is defined as a relationship set with participating entity sets Professor and Student, plus attribute Year. Assuming that *id* (Professor)=pid, then the relational representation of admits would be T_admits[pid,sid,year], with pid and sid being foreign keys that reference T_Professor and T_Student, respectively. Additional constraints found in some EER schemas, such as numeric lower and upper bounds on relationship participation (e.g., a child has between 2 and 2 parents), can only be enforced using general SQL assertions.

For a weak entity set *W*, T_W includes the attributes of *W*, any attributes of the identifying relationship set of *W*, and the identifying attributes *key*(T_E) of the entity set *E* that "owns" *W*. The key of T_W is the union of the local identifier *id*(W) of *W* with the key attributes *key*(T_E) of *E*. A foreign key constraint from T_W to T_E must also be added. For example, suppose that Section is specified as a weak entity set with respect to Course, with local identifier sectionNr and identifying relationship set sectionOf; furthermore, assume that *key*(T_Course)=courseNr. Then, the relational representation of Section would be T_Section[courseNr,sectionNr], with courseNr as a foreign key referencing T_Course.

Refinements

In the creation of tables for relationship sets and for weak entity sets, special attention needs to be paid when duplicate column names arise (because the same object can be involved in a relation in multiple ways). In this case, role names need to be used to disambiguate the columns. For example, if *id*(Professor)=*id*(Student)=ssn (because both are subclasses of Person say), then T_admits should have columns named prof_ssn and student_ssn, or admitter_ssn and admitted_ssn.

The treatment of subclass hierarchies which are not trees and where subclasses may inherit different identifiers from different parents also requires special care, and is discussed in [5].

The previous constructions provide a relational schema that allows every instance of the conceptual schema to be captured precisely. Relational schema restructuring by relation merging and sometimes partitioning is then undertaken for a number of reasons. The cardinal rule of all techniques is the need to be able to recover precisely the original relation instances from the merged instance (viz. lossless join). An additional rule observed in the techniques here is to avoid duplicating information in ways that lead to "update anomalies."

Table Merging

The most familiar technique replaces tables by their outer join, with the goal of making it easier to express and evaluate queries by avoiding the join. For example, one can merge table student[sid,name,age] with minorsIn[sid,minor], to obtain student2 [sid,name,age,minor]. Conceptually, such a change usually merges a functional relationship with the entity it is about, or a sub-class with its super-class. The main disadvantage of this change is the need to store null values as part of the outer join (in the above example, for students who do not have a minor).

The rule being applied in this case can be stated as:

Rule 1: Tables $T[\underline{K}X]$ and $R[\underline{\hat{K}}Y]$, where $\hat{K}$ is a foreign key referencing *T*, can be replaced by table $T_R[\underline{K}XY]$, whose intended use is as the left outer join of *T* and *R*.

Applying the above transformation, one must be mindful of a number of potential problems. First, identical column names occurring in *X* and *Y* cause conflicts, which must be avoided by renaming. Second, this merge may prevent making previously possible distinctions when there is no guarantee that for every tuple in table *T* there is a corresponding tuple in *R* referencing it. For example, in the original schema one can distinguish the case of a student who has a minor that is not known (represented by a tuple with NULL in column minor of table minorsIn) from the case of a student without a minor (represented by the absence of a the student's sid in minorsIn); but in student2 both cases have NULL in the minor column. To capture such distinctions one can add a Boolean attribute isInMinorsIn? to table student2. This technique becomes essential when merging the table of a subclass (e.g., T_GradStudent) into that of the superclass (e.g., T_Student) in case all the additional attributes of the subclass (e.g., advisor) may have null values, and therefore cannot be used to detect membership in the subclass.

Third, previously easy-to-state constraints may now become more convoluted. For example, if graduate students must have both an advisor and a department attribute (hence these columns have NOT NULL constraints in T_GradStudent), then since nulls must be allowed into these columns of T_Student after the merge, one must ensure (using an SQL check constraint) that nulls in the two columns *correlate*. Moreover, foreign key references to table T_GradStudent now become references to T_Student, and must be supplemented by SQL assertions verifying that some attribute associated with graduate students has a non-null value.

Table Partitioning

Tables can also be reorganized by so called "horizontal splitting" as stated by the following rule:

Rule 2: Table $T[\underline{K}X]$ can be replaced by tables $T_1[\underline{K}X]$, $T_2[\underline{K}X]$,...,with the intended use of T_1,T_2,... being as a partition of the tuples in T.

In logical (as opposed to physical) schema design, the partition tables usually have semantic interpretation as subclasses of relationship sets (e.g., T_admitted replaced by T_currentlyAdmitted and T_previouslyAdmitted) or of entitie sets (e.g., T_Student[sid,name,age] replaced by gradStudent$_0$[sid,name,age], undergradStudent$_0$ [sid,name,age], and student$_0$[sid,name, age] – the latter with students that are neither undergraduate nor graduate). Note that after such a split, one can merge gradStudent$_0$[sid,name,age] with gradStudent[sid,office] to get another variant of mapping subclass hierarchies to tables; this one is particularly good for cases when the subclasses cover the superclass.

Table partitioning can be seen as encoding into each table selection criteria, which therefore once again facilitates query statement and evaluation. The down side is that once again built-in constraints, such as foreign keys, now need to be stated as more complex SQL inter-table assertions.

Mapping from Non-ER Conceptual Schemas

UML class diagrams are increasingly popular for the specification of conceptual schemas. The correspondences "class" ⇌ "entity set," "association" ⇌ "relationship set" make it easy to reformulate the E2R mapping as a UML-to-Relational (U2R) mapping. Higher arity relationships (such as assignedTo (Professor,Course,Semester)) need to be reified in UML (i.e., represented as classes of objects Assignment related by functional associations f_1, f_2 and f_3 to Professor, Course and Semester respectively), but these end up producing a similar relational schema as E2R because tables T_f$_i$ are merged into T_Assignment; the artificial key *id*(Assignment) should however be removed.

As in the above example, the main difficulty in U2R is dealing with identifying ("key") attributes for entities, which are not mandated by the UML data model, since it assumes objects have intrinsically unique identity.

Key Applications

Database Design

The mapping of the conceptual schema into a logical schema is the central step of the database design process. A carefully crafted mapping will guarantee that the logical schema correctly represents the application domain that the conceptual schema models.

Future Directions

The publication of the SQL:2003 language standard provides additional mapping opportunities, exploiting some of the object-oriented features of the language.

As a simple example, SQL:2003 introduces the MULTISET data type, which can be used to avoid defining a separate table to accommodate multi-valued attributes of entity or relationship sets.

More importantly, SQL:2003 supports the declaration of an "*identity attribute*" for a table (designated with the special keyword IDENTITY). The value of an identity attribute is unique and automatically generated whenever a new row is inserted into the table. This construct is useful to the E2R and, especially, to the

U2R mapping process since it avoids the creation of an *artificial* key for entity *E* by adding an identity attribute for table T_E.

Logical Foundations of Web Data Extraction

CHRISTOPH KOCH
Cornell University, Ithaca, NY, USA

Definition

Several wrapper programming languages for extracting information from Web pages have been based on logic, specifically on fragments of datalog. This entry shows how logical languages can be used for Web information extraction, and surveys expressiveness and complexity aspects of a foundational logical wrapping language, monadic datalog.

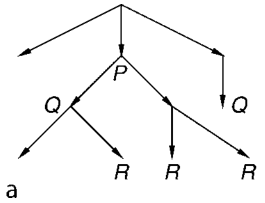
Historical Background

A substantial amount of research has studied the problem of learning wrapper programs from examples (see Wrapper Induction). Unfortunately, it is now known that the expressive power of learnable wrappers is fundamentally limited. This has motivated further work on visual wrapper programming languages, which simplify and speed up wrapper definition. Visual wrapping is now supported by several implemented systems (cf. XWrap [3] and W4F [4]; Lixto [1], a commercial product). The Lixto project was the first to emphasize and study expressiveness of visual wrapper languages. Its approach is based on a datalog-like language, ELog, whose core was shown to be expressively equivalent to monadic second-order logic over finite node-labeled trees, a natural yardstick for such languages. The datalog approach to wrapping has since then be adopted by other researchers; for instance, the recent XLog wrapper language [5] is closely related to ELog.

Foundations

Information Extraction Functions and Wrappers

The core notion on which logic-based wrapping is based is that of an *information extraction function*, which takes a labeled unranked tree (representing a Web document) and returns a subset of its nodes. In other words, an information extraction function is a unary query. A wrapper is a program which implements one or several such functions, and thereby assigns unary predicates to document tree nodes. Based on these predicate assignments and the structure of the input document viewed as a tree, a new tree can be computed as the result of the information extraction process in a natural way, along the paths of the input tree but using the new labels and omitting nodes that have not been assigned a new label. (see Fig. 1 for an example of such a transformation.) That way, the nodes of a document tree can be re-labeled, and some can be dropped as irrelevant, but it is not possible to significantly transform the original tree structure. This coincides with the intuition that a wrapper may change the presentation of relevant information, its packaging or data model (which does not apply in the case of *Web wrapping*), but should not handle substantial data



Logical Foundations of Web Data Extraction. Figure 1. Tree annotated with predicates *P*, *Q*, and *R* defined by information extraction functions (a), and wrapping result (b). (Original node labels of the input tree are not shown.)

transformation tasks. There is wide agreement that wrapping should exclude operations such as joins which are not necessary for information extraction but may be part of data transformation and integration tasks that may follow extraction.

A main goal is thus to find a language for specifying expressive unary queries over trees which nevertheless can be efficiently computed.

Tree Structures

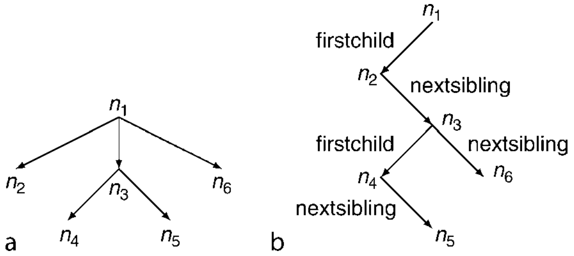
Unranked finite ordered trees with node labels from a finite set of symbols Σ correspond closely to parsed HTML or XML documents. In an unranked tree, each node may have an arbitrary number of children. An unranked ordered tree can be considered as a structure of relational schema

$$\tau_{ur} = \langle \text{dom}, \text{ root}, \text{ leaf}, \text{ } (\text{label}_a)_{a \in \Sigma}, \\ \text{firstchild}, \text{ nextsibling}, \text{ lastsibling}\rangle$$

where “dom” is the set of nodes in the tree, “root”, “leaf”, “lastsibling”, and the “label$_a$” relations are unary, and “firstchild” and “nextsibling” are binary. All relations are defined according to their intuitive meanings. “root” contains exactly one node, the root node. “leaf” consists of the set of all leaves. “firstchild(n_1, n_2)” is true if n_2 is the leftmost child of n_1; “nextsibling(n_1, n_2)” is true if, for some i, n_1 and n_2 are the ith and $(i + 1)$th children of a common parent node, respectively, counting from the left (see also Fig. 2). label$_a(n)$ is true if n is labeled a in the tree. Finally, “lastsibling” contains the set of rightmost children of nodes.

Monadic Datalog

Monadic datalog is obtained from full datalog (see Datalog) by requiring all intensional predicates to be



Logical Foundations of Web Data Extraction. Figure 2. (a) An unranked tree and (b) its representation using the binary relations “firstchild” (↙) and “nextsibling” (↘).

unary. A unary query is a function that assigns a predicate to some elements of dom (or, in other words, selects a subset of dom). For monadic datalog, one obtains a unary query by distinguishing one intensional predicate as the *query predicate*. In the remainder of this entry, a monadic datalog query will always be understood to be a unary query specified as a monadic datalog program with a distinguished query predicate. Of course, monadic datalog allows for the the definition of multiple unary queries within a single program; thus a set of information extraction functions that defines a wrapper can be given through a single monadic datalog program.

Monadic second-order logic (MSO) is obtained from second-order logic by requiring all second-order quantifiers to range over sets (i.e., unary relations). A unary MSO *query* is defined by an MSO formula φ with one free first-order variable. Given a tree t, it evaluates to the set of nodes $\{x \in \text{dom} \mid t \vDash \varphi(x)\}$.

It has been argued in [2] that unary queries in monadic second-order logic (MSO) over trees are an appropriate expressiveness yardstick for information extraction functions. MSO over trees is well-understood theory-wise and quite expressive. It has also been used as an expressiveness yardstick for node-selecting XML query languages.

By restricting the structures considered to trees, monadic datalog acquires a number of nice properties. First, the query evaluation complexity is linear in the size of the data and of the program:

Theorem 1 ([2]). *Over τ_{ur}, monadic datalog has $O(|\mathcal{P}|*|dom|)$ combined complexity (where $|\mathcal{P}|$ is the size of the program and $|dom|$ the size of the tree).*

This is is stark contrast to full datalog, which is EXPTIME-complete w.r.t. combined complexity over arbitrary finite structures and NP-complete over trees. Monadic datalog has some other nice properties which have been studied; in particular, the containment and boundedness properties – which are both considered relevant to query optimization – for monadic datalog are decidable, while they are undecidable for full datalog.

A unary query over trees is MSO-definable exactly if it is definable in monadic datalog.

Theorem 2 ([2]). *A unary query over τ_{ur} unranked ordered finite trees is MSO-definable if and only if it is definable in monadic datalog.*

Theorem 2 asserts that monadic datalog programs can define "universal" properties over trees, such as that a certain fact holds everywhere or nowhere in a tree. This may seem somewhat unintuitive because monadic datalog does not feature negation. Still, it follows from the fact that the relations defining the tree in τ_{ur} allow us to traverse the tree (starting from its "ends" such as the leaves or the root) using a recursive program and to compute universal properties along the way.

Example 1. Consider the problem of selecting all those nodes from an HTML tree which do *not* contain an HTML "table" in their subtrees. A monadic datalog program for this (with query predicate Q) can be defined as follows.

$$\begin{aligned}
NoTableBelow(x) &\leftarrow leaf(x).\\
NoTableBelow(x) &\leftarrow firstchild(x,y), NoTable(y).\\
NoTableRight(x) &\leftarrow lastsibling(x).\\
NoTableRight(x) &\leftarrow nextsibling(x,y), NoTable(y).\\
NoTable(x) &\leftarrow \overline{label}_{table}(x), NoTableBelow(x),\\
& NoTableRight(x).\\
Q(x) &\leftarrow \overline{label}_{table}(x), NoTableBelow(x).
\end{aligned}$$

Here it may either be assumed that there is a predicate $\overline{\text{label}}_{table}$ true for those nodes not labeled "table" (this predicate then needs to be added to τ_{ur}) or $\overline{\text{label}}_{table}$ can be defined in monadic datalog by the rules $\{\overline{\text{label}}_{table}(x) \leftarrow \text{label}_l(x). \mid l \in \Sigma, l \neq \text{"table"}\}$.

Note that both $\overline{\text{label}}_{table}$ and *NoTableBelow* are true for a node if it does not contain a "table" in its subtree, while *NoTable* is true for a node if the same holds (i.e., it does not contain a "table" in its subtree) in the binary-tree model of Fig. 2b.

Each monadic datalog program over trees can be efficiently rewritten into an equivalent program using only very restricted syntax. This motivates a normal form for monadic datalog over trees.

Definition 1. A monadic datalog program $\mathcal{P}$ over τ_{ur} is in *Tree-Marking Normal Form* (TMNF) if each rule of $\mathcal{P}$ is of one of the following four forms:

$$\begin{aligned}
&(1)\ p(x) \leftarrow p_0(x).\\
&(2)\ p(x) \leftarrow p_0(x_0), R(x_0, x).\\
&(3)\ p(x) \leftarrow p_0(x_0),\ R(x, x_0).\\
&(4)\ p(x) \leftarrow p_0(x),\ p_1(x).
\end{aligned}$$

where the unary predicates p_0 and p_1 are either intensional or from τ_{ur} and R is a binary predicate from τ_{ur}.

In the next result, the schema for unranked trees may extend τ_{ur} to include the natural child relation – likely to be the most common form of navigation in trees.

Theorem 3 ([2]). *For each monadic datalog program $\mathcal{P}$ over $\tau_{ur} \cup \{child\}$, there is an equivalent TMNF program over τ_{ur} which can be computed in time $O(|\mathcal{P}|)$.*

Syntax as simple as that of TMNF is important for visual wrapping. A single rule in monadic datalog may still consist of an arbitrary number of joins involving the binary relations of τ_{ur}. TMNF is much simpler and a visual rule definition process is not hard to define (cf. [1]). Nevertheless, TMNF has the full power of MSO and admits efficient evaluation. TMNF is the core of the ELog language of the Lixto system [1].

Logical Models of Information Retrieval

Fabio Crestani
University of Lugano, Lugano, Switzerland

Definition

Logical models of Information Retrieval (IR) are defined as those that follow a *logical definition of relevance*. For Cooper logical relevance is defined as "logical consequence." To make this possible both queries and documents need to be represented by sets of declarative sentences. The query is represented by two formal statements called "component statements" of the form *p* and ¬*p*. A subset of the set of stored sentences is called "premiss set" if and only if the component statement is a logical consequence of that subset. A "minimal premiss set" for a component statement is one that is as small as possible. Logical relevance is therefore defined as a two-place relation between stored sentences and the query represented as component statements:

- ► "A stored sentence is logically relevant to (a representation of) an information need if and only if it is a member of some minimal premiss set of stored sentences for some component statement of that need."

This definition of relevance is essentially just a proof-theoretic notion that has been later generalized to be applicable to information needs involving more than one component statement.

An early common belief was that the logical implication needed to capture relevance was not the classical material implication. The reasons why the use of the classical material implication is not appropriate for IR is in the definition of material implication itself (see the historical background section). The idea that a non-classical form of logical implication was needed for defining relevance was proposed by Van Rijsbergen in the form of the *logical uncertainty principle*, which is defined as follows:

- ► "Given any two sentences *x* and *y*; a measure of the uncertainty of *y* → *x* related to a given data set is determined by the minimal extent to which we have to add information to the data set, to establish the truth of *y* → *x*."

This principle made an explicit connection between non-classical logics and IR uncertainty modelling. However, when proposing the above principle, Van Rijsbergen was not specific about which logic and which uncertainty theory to use. As a consequence, various logics and uncertainty theories have been proposed and investigated. The choice of the appropriate logic and uncertainty mechanisms has been central to logical IR modeling, leading to a number of different approaches (see the Foundations section).

Historical Background

Relevance is one of the most important, if not "the fundamental," concept in the theory of IR. The concept arises from the consideration that if a user of an IR system has an information need, then some information stored in some documents in a document collection may be "relevant" to this need.

A logical definition of relevance was considered for the first time in the context of IR by Cooper in 1971 [4]. For Cooper, *logical relevance* was another name for topic-appropriateness, and he addressed the problem of giving a definition of logical relevance for IR by analogy with the same problem in question-answering systems. The analogy goes only as far as having questions with a yes-no (true-false) type of answer, and while Cooper's work started by analyzing question-answering systems, later he abandoned the analogy. Relevance is defined by Cooper as "logical consequence." To make this possible both queries and documents need to be represented by sets of declarative sentences. In the case of a yes-no query, the query is represented by two formal statements of the form *p* and ¬*p*. The two statements representing the query are called "component statements." A subset of the set of stored sentences is called "premiss set" if and only if the component statement is a logical consequence of that subset. A "minimal premiss set" for a component statement is one that is as small as possible in the sense that if any of its members were deleted, the component statement would no longer be a logical consequence of the set. Logical relevance is defined as a two-place relation between stored sentences and the query represented as component statements (see definitions section).

This definition of relevance is essentially just a proof-theoretic notion that has been generalised to be applicable to information needs involving more than one component statement. Although logical relevance was initially defined only for sentences, it can be easily extended to apply to stored documents: a document is relevant to an information need if and only if it contains at least one sentence which is relevant to that need.

Cooper also attempted to tackle a generalization of such a definition to natural language queries and documents. However, without a formalized language, no precise definition of the logical consequence relation is at hand, and thus one loses a precise definition of relevance. The problems of ambiguity and vagueness of natural language deny the possibility of extending the previous logical notion of relevance, despite the fact that the general idea of implication in natural language is a reasonably clear one. The definition of relevance, so far as natural language in concerned, is only a definition-in-principle – a conceptual definition – but not yet defined on a mathematical level.

Finally, Cooper also tried to tackle the problem of having "degrees of relevance," or as he wrote: "shades of grey instead of black and white." The idea was to extend the system of deductive reasoning used to access logical relevance to a system of plausible reasoning. Cooper argued that plausible or probabilistic inference was not as well defined as deductive inference, even for formalized languages. However, he added that when such tools are formalized enough then this development would become a "sensible and indeed inescapable idea," because it would enable the ranking of documents according to an estimated probability of relevance. What he proposed was to assign a higher probability of relevance to a sentence or a document that has greater probability of belonging to a residual minimal premiss set.

Cooper was the first to associate the topic-appropriateness sense of relevance with logical implication and recognized the importance of evaluating the uncertainty of such implication to rank documents in relation to their estimated measure of relevance. Many other researchers followed this idea proposing the use of different logics to capture relevance. In fact, the use of logic to build IR models enables one to obtain models that are more general than earlier well known IR models. Indeed, some logical models are able to represent within a uniform framework various features of IR systems, such as hypermedia links, multimedia content, users knowledge, cross-lingual, and structured documents. It also provides a common approach to the integration of IR systems with logical database systems. Finally, logic makes it possible to reason about an IR model and its properties. This latter possibility is becoming increasingly important since conventional evaluation methods, although good indicators of the effectiveness of IR systems, often give results which cannot be predicted, or satisfactorily explained.

An early common belief was that the logical implication needed to capture relevance was not the classical material implication. The reasons why the use of the classical material implication $d \supset q$ is not appropriate for IR is in the definition of material implication itself, and there are many ways of explaining why material implication is not suitable for IR. For reasons of brevity, these arguments will not be repeated here. It suffices to say that the material implication is acceptable only for the Boolean model of IR , where it expresses the "modus ponens." In the Boolean model if one observes d (that is if d is true) and if $d \rightarrow q$ is true (that is if all the query terms are all in the documents) then q is also true and thus one retrieves d. Only in this case if $d \rightarrow q$ is equivalent to $d \supset q$. In all other cases this would not hold ant it would necessary to find a way to define a suitable notion of implication that measures the extent in which the implication holds.

More recently, the thought that logic by itself could not fully model IR started to find a number of followers. In fact, in determining the relevance of a document to a query, the success or failure of an implication relating the two is not enough. It is necessary to take into account the *uncertainty* inherent in such an implication. The introduction of uncertainty can also be motivated from the consideration that a collection of documents cannot be regarded as a consistent and a complete set of statements. In fact, documents in the collection could and often do contradict each other in any particular logic, and not all the necessary knowledge is available. To cope with uncertainty a logic for *uncertain inference* was introduced. In fact, if $d \rightarrow q$ is uncertain, then one can measure its degree of uncertainty by $P(d \rightarrow q)$.

In 1986, Van Rijsbergen proposed the use of a non-classical conditional logic for IR [16]. This would enable the evaluation of $P(d \rightarrow q)$ using the *logical uncertainty principle* (see definitions). This principle was the first attempt to make an explicit connection between non-classical logics and IR uncertainty modelling. However, when proposing the above principle, Van Rijsbergen was not specific about which logic and which uncertainty theory to use. As a consequence, various logics and uncertainty theories have been proposed and investigated. This lead to a number of different approaches being proposed over the years.

Foundations

In the following, a brief overview of the most important logical models of IR is provided. It divides them into three classes: local models, local-uncertainty models, and meta-models.

Logical Models

The best known class of logical models of IR is that of the Boolean models, but their inability to capture the uncertainty inherent in the IR process (except by some extension of these models) has always confined them to the margins of modern IR.

Some logical models are able to capture the uncertainty of IR process, mainly in two ways: qualitatively by the logic itself (for example, via default rules, nonmonotonicity, or background conditions), or quantitatively by adding an uncertainty theory to the logic (for example, fuzzy logic). A first example of this class of models is represented by models based on Modal Logic and Conceptual Graphs. Modal Logic adopts the notion of possible worlds that correspond to the interpretations in classical logic, but which are connected to each other via an accessibility relation. The evaluation of the truth of a proposition is with respect to a possible world, and may involve the evaluation of the truth of the proposition in connected worlds. *Modal Logic* was first used to develop a logical model for IR by Nie [12]. Documents are worlds, and queries are formulae. A document represented by a world d is relevant to a query represented by a formula q if q is "true" in d, or if it is true in a world d' accessible from d. The accessibility relation captures the transformation of documents; the fact that the world d is connected to the world d' is interpreted as d being transformed into d'. The accessibility relationship can have different properties. For example, transitivity, meaning that if a world d is related to a world d', which is itself related to a world d'', then the world d is also related to the world d''. Consider the example of a hypertext system. Using Modal Logic, worlds can represent texts (nodes) and the accessibility relation can represent the links between the texts. The model also allows the transformation of both the query and the data set. One query can be transformed into another one using, for example, thesaural information. Query transformation is not a new approach in IR (e.g., query expansion). The novelty is that the transformation process can be formally represented, and hence reasoned upon. Transforming a data set can capture the modeling of a user's state in the retrieval process. The data set can be transformed until it reaches one that reflects the user's state.

Another set of logical models belonging are based on Situation Theory and the related Channel Theory. Situation Theory is a theory of information that provides an analysis of the concept of information and the manner in which cognitive agents handle and respond to the information picked up from their environment. The theory defines the nature of information flow and the mechanisms that give rise to such a flow. A document is a situation s and the query is a type ϕ. The document is relevant to the query if there exists a flow of information from a situation s to a situation s' such that $s' \models \phi$. The nature of the flow depends on the so-called "constraints" which capture semantic relationships. Flows of information do not always materialize because of the unpredictable nature of situations, thus flows are often uncertain. In Situation Theory, an uncertain flow is modeled by a conditional constraint of the form $\phi \rightarrow \psi | B$, which highlights the fact that $\phi \rightarrow \psi$ holds if some background conditions captured within B are met. If the background conditions are satisfied, the corresponding flow arises. However, it is often the case that two situations are systematically related to each other, by way of a flow of information. Therefore, in addition to constraints, there are relationships that link situations. The concept of a channel is introduced to express the relationships, by way of an information flow, between two situations. *Channel theory* defines formally channels, together with the mathematical properties that support the flow of information. The use of Situation and Channel theory to model IR has been investigated in [17], where the connection between IR, logic, probability and information containment was made. It was indicated that the use of channels present many potentials for theoretical IR modelling because they can apply to various IR processes present in advanced IR systems.

A successful class of logical models is based on *Terminological logics*. This family of logics come from the area of artificial intelligence, in particular, knowledge representation. Terminological logics derive from a large group of knowledge representation language (such as, for example, KL-ONE) based on semantic networks and inspired by the notion of frames. They provide object-oriented flavored representations. The use of terminological logic for IR was proposed in [11]. There, documents are represented by individual constants, whereas a class of documents is represented as a concept. Queries are described as concepts. Given a query represented by a concept Q, the retrieval task is to find all those documents d such that $Q[d]$ holds. The evaluation of $Q[d]$ uses the set of assertions describing documents, that is, one is not evaluating whether $d \rightarrow q$, but rather whether individual d is an instance of the class concept Q.

An important class of logical models is based on Belief Revision. *Belief Revision* provides a way to formalize changes done to a knowledge base after the arrival of new information. The use of belief revision in IR was attempted in [10] as a way to compute the similarity of a document to a query for retrieval purpose. The Dalal's revision operator was chosen for implementing the belief revision process, since it provides an order among proposition interpretations, where propositions model index terms. The ordering is used to formulate a similarity measure between a document and a query (expressed as formulae) based on the number of revisions necessary for the document to "reach" the query. It should be noted that both documents and queries can have, each, several interpretations, so normalization becomes necessary.

Finally, there is the class of models based on *Fuzzy logic*. This is a formal framework that is well suited to model vagueness and imprecision. In IR it has been successfully employed at several levels in particular for the definition of a superstructure of the Boolean model, with the appealing consequence that existing Boolean IR systems can be improved without redesigning them completely [2]. Through these extensions the gradual nature of relevance of documents to user queries can be modeled.

Logical-Uncertainty Models

Logical-uncertainty models are based on an uncertainty theory (for instance, probability theory, semantic theory, imaging) that is defined on a logical basis. They enable a more complex definition of relevance than other IR models (than probabilistic relevance model, for instance, which are based mainly upon statistical estimations of the probability of relevance). With logical-uncertainty models, information not present in the query formulation may be included in the evaluation of the relevance of a document. Such information might be domain knowledge, knowledge about the user, user's relevance feedback, or other.

The main example of logical-uncertainty models of IR is represented by models based on Probability Theory. In IR, probabilistic modeling refers to the use of a model that ranks documents in decreasing order of their evaluated probability of relevance to a user's information need. Past and present research has made use of formal theories of probability and of statistics in order to evaluate, or at least estimate, those probabilities of relevance. These attempts are to be distinguished from looser ones like, for example, the vector space model in which documents are ranked according to a measure of similarity with the query. A measure of similarity cannot be directly interpreted as a probability. In addition, similarity based models generally lack the theoretical soundness of probabilistic models. A treatment of models based on Probability Theory is beyond the scope of this entry and is reported in the relevant entries; the models presented in this section are based on the idea that IR is a process of uncertain inference.

A probabilistic formalism for describing inference relations with uncertainty is provided by *Bayesian inference networks*. Turtle and Croft [15] applied such networks to IR. Nodes represent IR entities such as documents, index terms, concepts, queries, and information needs. One can choose the number and kind of nodes one wishes to use according to how complex one wants the representation of the document collection or the information needs to be. Arcs represent probabilistic dependencies between entities and represent conditional probabilities, that is, the probability of an entity being true given the probabilities of its parents being true.

In a Bayesian inference network, the truth value of a node depends only upon the truth values of its parents. To evaluate the strength of an inference chain going from one document to the query the document node d_i is set to "true" and $P(q_k = true \mid d_i = true)$ is evaluated. This gives an estimate of $P(d_i \rightarrow q_k)$. It is possible to implement various traditional IR models on this network by introducing nodes representing Boolean operators or by setting appropriate conditional probability evaluation functions within nodes.

Another important set of examples of logical-uncertainty models is represented by models based on *Probabilistic Datalog*. Datalog is a predicate logic that has been developed in the database field, and makes the link between the relational model and rule-based systems. *Probabilistic Datalog* is the probabilistic extension of Datalog. Probabilistic Datalog is not itself a logical IR framework, but more a platform in which logical probabilistic IR models, as well as other IR models can be expressed. One of the major assets of Probabilistic Datalog is that, since it is a generalization of the Datalog model, it can be used as standard query language for both database and IR. It can then deal with both structured data (as in database) and unstructured data (as in IR) within the same system. It also allows the uniform representation, retrieval and querying of content, fact and structural knowledge [8]. The work has been further extended via the development, implementation and evaluation of the POOL (Probabilistic Object-Oriented Logic) model, which allows the representation of inconsistency (using then a four-valued logic), the modeling of the document and query representation using the object-oriented paradigm.

A very interesting example of logical-uncertainty models and certainly the one that more reflects Van Rijsbergen's Logical Uncertainty Principle is that of models based on Logical Imaging. *Logical imaging* is an approach that defines the probability of conditional $P(d \rightarrow q)$ based on the notion of possible-worlds. In this approach the possible worlds (e.g., retrieval situation, document representation) are spanned by an accessibility relation defined in terms of similarity. The truth value of the implication $p \rightarrow q$ in a world w depends on two cases. If p is true in w, then $p \rightarrow q$ is true (false) in that world if q is also true (false) in that world. However, if p is not true in w, then the implication is evaluated in the worlds that differ minimally from w and in which p is true. The worlds in which p is true are referred to as p-worlds. The set of worlds comes with a probability distribution P, reflecting the probability of each world. The probability of a proposition p is the summation of the probability of those worlds in which p is true. The computation of the probability of $p \rightarrow q$ involves a shift of probability (the imaging process) from non-$p - worlds$ to their closest p-worlds. It can be proved that: $P(p \rightarrow q) = P_p(q)$, where P_p is a new probability distribution, a "posterior probability," derived from P by imaging on p. Therefore, conditioning by imaging causes a revision of the prior probability on the possible worlds w in such a way that the posterior probability is obtained by shifting the original probabilities from non-p-worlds to p-worlds. Each non-p-world moves its probability to its closest p-world (or set of p-worlds in the case of general imaging). Bayesian conditioning, on the other hand, is obtained by cutting off all non-p-worlds and then proportionally magnifying the probabilities of the p-worlds so that the posterior probabilities still add up to one, as required by Probability Theory. The magnification is done in the same way for every p-world, thus keeping constant the ratios between the probabilities assigned to these worlds. It is therefore clear that imaging and Bayesian conditionalization yield, in general, different results. Since the transfer of probabilities is directed towards the closest p-worlds, this technique is just what it is needed to implement Van Rijsbergen's logical uncertainty principle.

Two logical-probabilistic IR models have been developed on the concept of imaging. In the first one [7], worlds model terms, and propositions model documents and queries. A term t "makes a document true" if that term belongs to that document. Imaging with respect to d gives the closest term to t that is contained in d. Of course, this is t itself if t is contained in the document. Imaging consists then of shifting the probabilities from term not contained in d to the terms contained in d (i.e., the terms that make d true). The evaluation of the relevance takes into account the semantics between terms by shifting probabilities to those (semantically) closer terms contained in the document. A second model based on imaging includes user's knowledge in the evaluation of the relevance of a document to a query [13]. In this model both documents and queries are propositions. Possible worlds represent different states of the data set, for example possible states of knowledge that can be held by users. A document d is true in a world w if the document is "consistent" (the term is used here in a broad sense) with the state of knowledge associated with that world. Worlds differ because they represent different states of knowledge and, given a metric on the world space, one can identify the closest world to w for which d is true.

Other logical-probabilistic models are based on *Semantic Information Theory*. The work on Semantic

Information Theory in IR concerns two research directions: the axiomatization of the logical principles for assigning probabilities or similar weighting functions to logical sentences and the relationship between information content of a sentence and its probability [1].

Meta-Models

Meta-models are a completely different class of models from those presented earlier. Meta-models attempts to formally study the properties and the characteristics of IR systems within a uniform logical framework. The advantage is that they make it possible to compare IR systems not only with respect to their effectiveness, but also with respect to formal properties of the underlying models.

The use of logic to formally conduct proofs for IR purposes was thoroughly investigated in [3], where a framework was proposed in which different models of IR could be theoretically expressed, formally studied and compared. The framework was developed within a logic, thus allowing formal proofs to be conducted. The framework defines the aboutness relationship, denoted $\models$, which aims at capturing the notion of information containment primary to IR. Given two objects *a* and *b*, $a \models b$ means that object *a* is about object *b*. Axioms are defined that represent possible properties of IR systems. Examples of simple axioms include reflexivity, symmetry, and transitivity, but more complex ones have also been identified, like for example weakening and monotonicity, borrowed from non-monotonic reasoning. This research has led to the theoretical comparison of IR models. The IR models are mapped down into a logic-based framework and they are compared by looking at the particular aboutness properties they each embody. Through this research, IR has gained a clearer understanding of what aboutness is, and what properties are desirable and not desirable.

Due to space limitations this entry cannot even briefly report here on other logical models of IR. A good survey of a number of these models can be found in [5]. An analysis of the strengths and limitations of logical modelling of IR can be found in [9,14]. Finally, many of the models briefly introduced here are described in details in [6].

Key Applications

The main application area of the models presented in this section is Information Retrieval.

Future Directions

This entry reviewed a number of approaches to logical modelling of IR. So far, no consensus has been reached regarding what the best approach is due to the small number of operational systems based on these approaches. It is hoped that further investigations into various logic-based frameworks accompanied by more evaluation might lead to a unified information-based model theory for expressing the semantics of information retrieval. Such a theory will enable to predict the behavior of IR systems, compare them and prove properties about them. This would be a major strength of logical models of IR.

Logical Structure

Thijs Westerveld
Teezir Search Solutions, Ede, The Netherlands

Definition

Logical structure refers to the way information in a document is organized; it defines the hierarchy of information and the relation between different parts of the document. Logical structure indicates how a document is built, as opposed to what a document contains.

Key Points

Logical structure is mainly used in the context of XML document to distinguish the logical organization of the content from its physical organization, to distinguish the flow of content from the documents layout and from the presentation of the document. In XML documents, text, images and metadata can be organized in a meaningful, logical manner independently of the document's layout when presented to a user. This contrasts with HTML documents in which logical organization and layout necessarily are the same. The logical structure of a document is of particular interest in structured document retrieval, where it may provide knowledge regarding the organization of information which may lead to better identification of relevant document parts given a user's request.

Logical Unit Number

Kaladhar Voruganti
Network Appliance, Sunnyvale, CA, USA

Synonyms

LUN; Volume

Definition

LUN is a SCSI protocol term that refers to a logically contiguous piece of storage. This usually corresponds to a volume in a storage array or an individual disk drive on a parallel SCSI bus. The storage volume identifier gets mapped to a LUN by the host operating system and they are usually different.

Key Points

A volume on a storage controller can be assigned different LUN numbers on different hosts. A volume on a storage controller can be partitioned into multiple volumes, and thus, LUNs by storage virtualization software. The storage virtualization software can reside on hosts or network virtualization boxes.

Synonyms

LUN mapping

Definition

This is the process by which the host operating system assigns a LUN value to a particular storage volume. LUN Mapping is typically used in cases where the higher level applications require specific LUN numbers for specific storage devices. When there are multiple paths between a SCSI initiator and SCSI target, multi-pathing software is used to properly map target volumes via both the paths. Storage controllers provide access control mechanisms (LUN Masking) that can control how initiators access target storage volumes.

Key Points

At host, LUN mapping is performed by operating system software. If one wants to properly manage multiple paths to a storage volume from a host, then one needs to install a multi-pathing driver on the host. LUN mapping is also performed by virtualization software that is present in network virtualization boxes. These boxes perform mapping between virtual volumes that are exported to hosts and the physical volumes residing on the storage controllers.

Logical Volume Manager

Kenichi Wada
Hitachi Limited, Tokyo, Japan

Synonyms

Virtual disk manager; Volume set manager; LVM

Definition

Logical Volume Manager (LVM) is a kind of storage virtualization. LVM collects one or more disk drives or partitions, creating a storage pool in a host. Furthermore, LVM provides applications with logical volumes consisting of multiple chunks of disk drives or partitions.

Key Points

Figure 1 shows volume manager implementation. LVM implementations often start with physical volume (PVs), which can be disk drives or partitions. PVs are spilt into chunks called physical extents (PEs). Some LVM implementations have PEs of a uniform size; others have variable-sized PEs that can be split and merged at will.

A logical extent (LE) consists of one or more PEs. For example, users can create an LE which is simply mapped to an PE, or create a striped LE which consists of multiple PEs with a conventional RAID technique. LEs are pooled into a volume group (VG).

A logical volume (LV) consists of one or more LEs in a VG. Users also can create an LV which is simply mapped to an LE, or create a striped LV which consists of multiple LEs with a conventional RAID technique.

In some implementations, LVs can be grown or shrunken by concentrating more LEs from, or returning them to, a VG. Some volume managers allow LVs

Log-Linear Regression

Jialie Shen
Singapore Management University, Singapore, Singapore

Definition

In statistic, log-linear regression is a powerful regression technique that models relationship between a dependent variable or regressand Y, explanatory variable or regressor $X = \{x_1,\ldots,x_I\}$ and a random term ε by fitting a log-linear model,

$$\ln Y = \alpha_0 + \alpha_1 \ln x_1 + \alpha_2 \ln x_2 + \ldots. + \alpha_I \ln x_I + \varepsilon$$

where α_0 is the constant term, the α_i s are the respective parameters of independent variables, and I is the number of parameters to be estimated in the log-linear regression.

Key Points

The goal of log-linear regression is to explore effect a set of covariance $X = \{x_1,\ldots,x_I\}$ on the expected rate [1]. It assumes that a linear relationship exists between the log of the regressand Y and the regressor $X = \{x_1,\ldots,x_I\}$. The log-linear regression is appropriate for categorical variables.

When applied to continuous variables, discretization is an essential step for preprocessing. There are two basic steps to using log-linear regression: (i) determining how many factors to be considered and sets of attributes related to each factor and (ii) estimating the numerical values of the parameters.

Loop

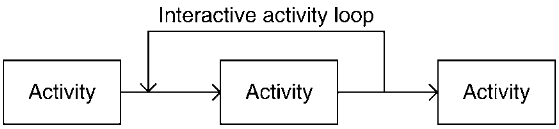
Nathaniel Palmer
Workflow Management Coalition, Hingham, MA, USA

Synonyms

Iteration; Workflow loop; While loop

Definition

A workflow activity cycle involving the repetitive execution of one (or more) workflow activity(s) until a condition is met.



Key Points

A Loop is a control flow statement that allows an activity or activity block to be executed repeatedly, rather than proceeding to the next activity, until a specific condition has been met. Following the execution of the activity (or last activity in the block) the condition of the loop is evaluated.

Loose Coupling

Serguei Mankovskii
CA Labs, CA, Inc., Thornhill, ON, Canada

Synonyms

Weak coupling; Low coupling

Definition

Word coupling refers to a notion of interdependence between components of software systems. Word loose refers to a mode of coupling where components possess significant degree of autonomy.

Key Points

Term loose coupling consists of two opposite notions of dependency and autonomy. It initially emerged out of study of educational organizations. Organizational scientist Karl Weick noticed that some organizations can be mechanistic (coupled) and organic (loose) at the same time. Loosely coupled organizations are under influence of forces or conditions that hold them together, but at the same time they are acting with the high degree of independence.

In software engineering, loose coupling has similar notion to organizational theory. A loosely coupled system usually consists of a framework or architecture linking together otherwise independent components. The components are usually highly cohesive and have well defined responsibilities. Cohesive components allow for creation of stable interfaces exposing less implementation details through the component interface. Loosely coupled system uses stable interfaces of the components to hold the system together.

As a design, goal loose coupling is desirable when system components need to be developed or used independently of each other and when they need to change over time. This goal can be achieved by deliberate decoupling of system components. De-coupling leads to a more reliable system design and reduces maintenance costs over the life time of system and its components.

Software components developed for loose coupling can be readily re-purposed for use in a broad class of systems leading to higher re-use. They can also be used at the same time by a broad class of systems through standards-based interfaces. In this case they are often called services. Service Oriented Architecture is a special case of software systems built around of loosely coupled services.

Definition

Advances in high throughput sequencing and "omics" technologies and the resulting exponential growth in the amount of macromolecular sequence, structure, gene expression measurements, have unleashed a transformation of biology from a data-poor science into an increasingly data-rich science. Despite these advances, biology today, much like physics was before Newton and Leibnitz, has remained a largely descriptive science. Machine learning [6] currently offers some of the most cost-effective tools for building predictive models from biological data, e.g., for annotating new genomic sequences, for predicting macromolecular function, for identifying functionally important sites in proteins, for identifying genetic markers of diseases, and for discovering the networks of genetic interactions that orchestrate important biological processes [3]. Advances in machine learning e.g., improved methods for learning from highly unbalanced datasets, for learning complex structures of class labels (e.g., labels linked by directed acyclic graphs as opposed to one of several mutually exclusive labels) from richly structured data such as macromolecular sequences, three-dimensional molecular structures, and reliable methods for assessing the performance of the resulting models, are critical to the transformation of biology from a descriptive science into a predictive science.

Historical Background

Large scale genome sequencing efforts have resulted in the availability of hundreds of complete genome sequences. More importantly, the GenBank repository of nucleic acid sequences is doubling in size every 18 months [4]. Similarly, structural genomics efforts have led to a corresponding increase in the number of macromolecular (e.g., protein) structures [5]. At present, there are over a thousand databases of interest to biologists [16]. The emergence of high-throughput "omics" techniques, e.g., for measuring the expression of thousands of genes under different perturbations, has made possible system-wide measurements of biological variables [8]. Consequently, discoveries in biological sciences are increasingly enabled by machine learning.

Some representative applications of machine learning in computational and systems biology include: identifying the protein-coding genes (including gene boundaries, intron-exon structure) from genomic DNA sequences; predicting the function(s) of a protein from its primary (amino acid) sequence (and when available, structure and its interacting partners); identifying functionally important sites (e.g., protein-protein, protein-DNA, protein-RNA binding sites, post-translational modification sites) from the protein's amino acid sequence and, when available, from the protein's structure; classifying protein sequences (and structures) into structural classes; Identifying functional modules (subsets of genes that function together) and genetic networks from gene expression data.

These applications collectively span the entire spectrum of machine learning problems including supervised learning, unsupervised learning (or cluster analysis), and system identification. For example, protein function prediction can be formulated as a supervised learning problem: given a dataset of protein sequences with experimentally determined function labels, induce a classifier that correctly labels a novel protein sequence. The problem of identifying functional modules from gene expression data can be formulated as an unsupervised learning problem: given expression measurements of a set of genes under different conditions (e.g., perturbations, time points), and a distance metric for measuring the similarity or distance between expression profiles of a pair of genes, identify clusters of genes that are co-expressed (and hence are likely to be co-regulated). The problem of constructing gene networks from gene expression data can be formulated as a system identification problem: given expression measurements of a set of genes under different conditions (e.g., perturbations, time points), and available background knowledge or assumptions, construct a model (e.g., a boolean network, a bayesian network) that explains the observed gene expression measurements and predicts the effects of experimental perturbations (e.g., gene knockouts).

Foundations

Challenges presented by computational and systems biology applications have driven, and in turn benefited from, advances in machine learning. Some of these developments are described below.

Multi-Label Classification: In the traditional classification problem, an instance $\mathbf{x}_i$, i = 1,...,n, is associated with a single class label y_j from a finite, disjoint set of class labels Y , j = 1,...,k, k = |Y| (*single-label classification problem*). If the set Y has only two elements, then the problem is referred to as the *binary classification problem*. Otherwise, if Y has more than two elements, then it is referred to as *multi-class classification problem*. However, in many biological applications, an instance $\mathbf{x}_i$ is associated with a subset of, not necessarily disjoint, class labels in Y (*multi-label classification problem*). For example, many genes and proteins are multi-functional. Most of the existing algorithms cannot simultaneously label a gene or protein with several, not necessarily mutually exclusive functions. Each instance is then assigned to a subset of nodes in the hierarchy, yielding a *hierarchical multi-label classification problem* or a *structured output classification problem*. The most common approach to dealing with *multi-label classification problem* [7] is to transform the problem into k binary classification problems, one for each different label $y_j \in Y$, j = 1,...,k. The transformation consists of constructing k datasets, D_j, each containing all instances of the original dataset, such that an instance in D_j, j = 1,...,k, is labeled with 1 if it has label y_j in the original dataset, and 0 otherwise. During classification, for a new unlabeled instance $\mathbf{x}_{test}$, each individual classifier C_j,j = 1,...,k, returns a prediction that $\mathbf{x}_{test}$ belongs to the class label y_j or not. However, the transformed datasets that result from this approach are highly unbalanced, typically, with the number of positively labeled instances being significantly smaller than the number of negatively labeled instances, requiring the use of methods that can cope with unbalanced data. Alternative evaluation metrics need to be developed for assessing the performance of multi-label classifiers. This task is complicated by correlations among the class labels.

Learning from Unbalanced Data: Many of the macromolecular sequence classification problems present the problem of learning from highly *unbalanced* data. For example, only a small fraction of amino acids in an RNA-binding protein binds to RNAs. Classifiers that are trained to optimize accuracy generally perform rather poorly on the minority class. Hence, if accurate classification of instances from the minority class is important (or equivalently, the false positives and false negatives have unequal costs or risks associated with them), it is necessary to change the distribution of positive and negative instances *during training* by randomly selecting a subset of the training data for the majority class, or alternatively, assigning different *weights* to positive and negative samples (and learn from the resulting weighted samples). More recently, *ensemble classifiers* [11] have been shown to improve the performance of sequence classifiers on unbalanced datasets. Unbalanced datasets also complicate both the training and the assessment of the predictive performance of classifiers. *Accuracy* is not a useful performance measure in such scenarios. Indeed, no single performance measure provides a complete picture of the classifier's performance. Hence, it is much more useful to examine ROC (Receiver Operating Characteristic) or precision-recall curves [3]. Of particular interest are methods that can directly optimize alternative performance measures that take into account the unbalanced nature of the dataset and user-specified tradeoff between false positive and false negative rates.

Data Representation: Many computational and systems biology applications of machine learning present challenges in data representation. Consider for example, the problem of identifying functionally important sites (e.g., RNA-binding residues) from amino acid sequences. In this case, given an amino acid sequence, the classifier needs to assign a binary label (1 for an RNA-binding residue and 0 for a non RNA-binding residue) to each letter of the sequence. To solve this problem using standard machine learning algorithms that work with a fixed number of input features, it is fairly common to use a *sliding window* approach [12] to generate a collection of fixed length windows, where each window corresponds to the target amino acid and an equal number of its sequence neighbors on each side. The classifier is trained to label the target residue. Similarly, identifying binding sites from a three-dimensional structure of the protein requires transforming the problem into one that can be handled by a traditional machine learning method. Such transformations, while they allow the use of existing machine learning methods on macromolecular sequence and structure labeling problems, complicate the task of assessing the performance of the resulting classifier (see below).

Performance Assessment: Standard approaches to assessing the performance of classifiers rely on k-fold cross-validation wherein a dataset is partitioned into k disjoint subsets (folds). The performance measure of interest is estimated by averaging the measured performance of the classifier on k runs of a cross-validation experiment, each using a different choice of the $k - 1$ subsets for training and the remaining subset for testing the classifier. The fixed length window representation described above complicates this procedure on macromolecular sequence labeling problems. The training and test sets obtained by random partitioning of the dataset of labeled windows can contain windows that originate from the same sequence, thereby violating a critical requirement for cross-validation, namely, that the training and test data be disjoint. The resulting overlap between training and test data can yield overly optimistic estimates of performance of the classifier. A better alternative is to perform sequence-based (as opposed to window-based) cross-validation by partitioning the set of sequences (instead of windows) into disjoint folds. This procedure guarantees that training and test sets are indeed disjoint [9]. Obtaining realistic estimates of performance in sequence classification and sequence labeling problems also requires the use of *non-redundant* datasets [13].

Learning from Sparse Datasets: In gene expression datasets, the number of genes is typically in the hundreds or thousands, whereas the number of measurements (conditions, perturbations) is typically fewer than ten. This presents significant challenges in inferring genetic network models from gene expression data because the number of variables (genes) far exceeds the number of observations or data samples. Approaches to dealing with this challenge require reducing the effective number of variables via variable selection [17] or abstraction i.e., by grouping variables into clusters that behave similarly under the observed conditions. Another approach to dealing with sparsity of data in such settings is to incorporate information from multiple datasets [18].

Key Applications

Protein Function Prediction: Proteins are the principal catalytic agents, structural elements, signal transmitters, transporters and molecular machines in cells. Understanding protein function is critical to understanding diseases and ultimately in designing new drugs. Until recently, the primary source of information about protein function has come from biochemical, structural, or genetic experiments on individual proteins. However, with the rapid increase in number of genome sequences, and the corresponding growth in the number of protein sequences, the numbers of experimentally determined structures and functional annotations has significantly lagged the number of protein sequences. With the availability of datasets of protein sequences with experimentally determined functions, there is increasing use of sequence or structural homology-based transfer of annotation from already annotated sequences to new protein sequences. However, the effectiveness of such homology-based methods drops dramatically when the sequence similarity between the target sequence and the reference sequence falls below 30%. In many instances, the function of a protein is determined by conserved local sequence motifs. However, approaches that assign function to a protein based on the presence of a single motif (the so-called characteristic motif) fail to take advantage of multiple sequence motifs that are correlated with critical structural features (e.g., binding pockets) that play a critical role in protein function. Against this background, machine learning methods offer an attractive approach to training classifiers to assign putative functions to protein sequences. Machine learning methods have been applied, with varying degrees of success, to the problem of protein function prediction. Several studies have demonstrated that machine learning methods, used in conjunction with traditional sequence or structural homology based techniques and sequence motif-based methods outperform the latter in terms of accuracy of function prediction (based on cross-validation experiments). However, the efficacy of alternative approaches in genome-wide prediction of functions of protein-coding sequences from newly sequenced genomes remains to be established. There is also significant room for improving current methods for protein function prediction.

Identification of Potential Functional Annotation Errors in Genes and Proteins: As noted above, to close the sequence-function gap, there is an increasing reliance on automated methods in large-scale genome-wide annotation efforts. Such efforts often rely on transfer of annotations from previously annotated proteins, based on sequence or structural similarity. Consequently, they are susceptible to several sources of error including errors in the original annotations from which new annotations are inferred, errors in the algorithms, bugs in the software used to process the data, and clerical errors on the part of human curators. The effect of such errors can be magnified because they can propagate from one set of annotated sequences to another. Because of the increasing reliance of biologists on reliable functional annotations for formulation of hypotheses, design of experiments, and interpretation of results, incorrect annotations can lead to wasted effort and erroneous conclusions. Hence, there is an urgent need for computational methods for checking consistency of such annotations against independent sources of evidence and detecting potential annotation errors. A recent study has demonstrated the usefulness of machine learning methods to *identify and correct* potential annotation errors [1].

Identification of Functionally Important Sites in Proteins: Protein-protein, protein-DNA, and protein-RNA interactions play a pivotal role in protein function. Reliable identification of such interaction sites from protein sequences has broad applications ranging from rational drug design to the analysis of metabolic and signal transduction networks. Experimental detection of interaction sites must come from determination of the structure of protein-protein, protein-DNA and protein-RNA complexes. However, experimental determination of such complexes lags far behind the number of known protein sequences. Hence, there is a need for development of reliable computational methods for identifying functionally important sites from a protein sequence (and when available, its structure, but not the complex). This problem can be formulated as a sequence (or structure) labeling problem. Several groups have developed and applied, with varying degrees of success, machine learning methods for identification of functionally important sites in proteins (see [21,14,22] for some examples). However, there is significant room for improving such methods.

Discovery and Analysis of Gene and Protein Networks: Understanding how the parts of biological systems (e.g., genes, proteins, metabolites) work together to form dynamic functional units, e.g., how genetic interactions and environmental factors orchestrate development, aging, and response to disease, is one of the major foci of the rapidly emerging field of systems biology [8]. Some of the key challenges include the following: uncovering the biophysical basis and essential macromolecular sequence and structural features of macromolecular interactions; comprehending how temporal and spatial clusters of genes, proteins, and signaling agents correspond to genetic, developmental and regulatory networks [10]; discovering topological and other characteristics of these networks [19]; and explaining the emergence of systems-level properties of networks from the interactions among their parts. Machine learning methods have been developed and applied, with varying degrees of success, in learning predictive models including boolean networks [20] and bayesian networks [15] from gene expression data. However, there is significant room for improving the accuracy and robustness of such algorithms by taking advantage of multiple types of data and by using active learning.

Future Directions

Although many machine learning algorithms have had significant success in computational biology, several challenges remain. These include the development of: efficient algorithms for learning predictive models from distributed data; cumulative learning algorithms that can efficiently update a learned model to accommodate changes in the underlying data used to train the model; effective methods for learning from sparse, noisy, high-dimensional data; and effective approaches to make use of the large amounts of unlabeled or partially labeled data; algorithms for learning predictive models from disparate types of data: macromolecular sequence, structure, expression, interaction, and dynamics; and algorithms that leverage optimal experiment design with active learning in settings where data is expensive to obtain.

Main Memory

Peter Boncz
CWI, Amsterdam, The Netherlands

Synonyms

Primary memory; Random access memory (RAM)

Definition

Primary storage, presently known as main memory, is the largest memory directly accessible to the CPU in the prevalent Von Neumann model and stores both data and instructions (program code). The CPU continuously reads instructions stored there and executes them. Also called Random Access Memory (RAM), to indicate that load/store instructions can access data at any location at the same cost, it is usually implemented using DRAM chips, which are connected to the CPU and other peripherals (disk drive, network) via a bus.

Key Points

The earliest computers used tubes, then transistors and since the 1970s in integrated circuits. RAM chips generally store a bit of data in either the state of a flip-flop, as in SRAM (static RAM), or as a charge in a capacitor (or transistor gate), as in DRAM (dynamic RAM). Some types have circuitry to detect and/or correct random faults called memory errors in the stored data, using parity bits or error correction codes (ECC). RAM of the read-only type, ROM, instead uses a metal mask to permanently enable/disable selected transistors, instead of storing a charge in them.

The main memory available to a program in most operating systems, while primarily relying on RAM, can be increased by disk memory. That is, the memory access instructions supported by a CPU work on so-called virtual memory, where an abstract virtual memory space is divided into pages. At any time, a page either resides in a swap-file on disk or in RAM, where it must be in order for the CPU to access it. When memory is accessed, the Memory Management Unit (MMU) of the CPU transparently translates the virtual address into its current physical address. If the memory page is not in RAM, it generates a page fault, to be a handled by the OS which then has to perform I/O to the swap file. If a high percentage of the memory access generates a page fault, this is called thrashing, and severely lowers performance.

Over the past decades, the density of RAM chips has increased, following a planned evolution of finer chip production process sizes, popularly known as "Moore's Law." This has led to an increase in RAM capacity as well as bandwidth. Access latency has also decreased, however, the physical distance on the motherboard between DRAM chips and CPU results in a minimum access latency of around 50ns (real RAM latencies are often higher). In current multi-GHz CPUs this means that a memory access instruction takes hundreds of cycles to execute. Typically, a high percentage of instructions in a program can be memory access instructions (up to 33%) and the RAM latency can seriously impact performance. This problem is known as the "memory wall."

To counter the performance problems of the memory wall, modern computer architecture now features a memory hierarchy that besides DRAM also includes SRAM cache memories, typically located on the CPU chip. Memory access instructions transfer memory in units of cache-lines, typically 64 bytes at a time (this cache line size is also related to the width of the memory bus). Memory access instruction first checks whether the accessed cache line is in the highest (fastest/smallest) L1 cache. This takes just a few CPU cycles. If a cache miss occurs, the memory access instruction checks the next cache level. Only if no cache contains the cache line, memory access is performed. Therefore, like virtual memory page thrashing, the CPU cache hit ratio achieved by a program now materially affects performance.

While in the past access to the DRAM chips over the bus was typically performed by a chipset, in between CPU and memory, some modern CPU architectures have moved the memory controller logic onto the CPU chip itself, which tends to reduce access latency. Also, to better serve the memory bandwidth requirement multi-CPU systems, modern architectures often have a dedicated memory bus between the CPU and DRAM. In a Symmetric Multi-Processing (SMP) this leads to a so-called Non-Uniform Memory Access architecture (NUMA), where access to the memory directly connected to a CPU is faster than access to the memory connected to another CPU.

While database systems traditionally focus on the disk access pattern (i.e., I/O), modern database systems, as well as main-memory database systems (that do not rely on I/O in the first place) now must carefully plan the in-memory data storage format used as well as the memory access patterns caused by query processing algorithms, in order to optimize the use of the CPU caches and avoid high cache miss ratios. The increased RAM sizes as well as the increased impact of I/O latency also leads to a trend to rely more on main memory as the preferred storage medium in database processing.

Main Memory DBMS

Peter Boncz
CWI, Amsterdam, The Netherlands

Synonyms

In-memory DBMS; MMDBMS

Definition

A main memory database system is a DBMS that primarily relies on main memory for computer data storage. In contrast, conventional database management systems typically employ hard disk based persistent storage.

Key Points

The main advantage of MMDBMS over normal DBMS technology is superior performance, as I/O cost is no more a performance cost factor. With I/O as main optimization focus eliminated, the architecture of main memory database systems typically aims at optimizing CPU cost and CPU cache usage, leading to different data layout strategies (avoiding complex tuple representations) as well as indexing structures (e.g., B-trees with lower-fan-outs with nodes of one or a few CPU cache lines).

While built on top of volatile storage, most MMDB products offer ACID properties, via the following mechanisms: (i) Transaction Logging, which records changes to the database in a journal file and facilitates automatic recovery of an in-memory database, (ii) Non-volatile RAM, usually in the form of static RAM backed up with battery power (battery RAM), or an electrically erasable programmable ROM (EEPROM). With this storage, the MMDB system can recover the data store from its last consistent state upon reboot, (iii) High availability implementations that rely on database replication, with automatic failover to an identical standby database in the event of primary database failure.

Main-memory database systems were originally popular in real-time systems (used in e.g., telecommunications) for their fast and more predictable performance, and this continues to be the case. However, with increasing RAM sizes allowing more problems to be addressed using a MMDBMS, this technology is proliferating into many other areas, such as on-line transaction systems, and recently in decision support. Main memory database systems are also deployed as drop-in systems that intercept read-only queries on cached data from an existing disk-based DBMS, thus reducing its workload and providing fast answers to a large percentage of the workload.

Examples of main-memory database systems are MonetDB, SolidDB, TimesTen and DataBlitz. MySQL offers a main-memory backend based on Heap tables. The MySQL Cluster product is a parallel main memory system that offers ACID properties through high availability.

Maintenance of Materialized Views with Outer-Joins

Per-Åke Larson
Microsoft Corporation, Redmond, WA, USA

Definition

An materialized outer-join view is a materialized view whose defining expression contains at least one outer join. View maintenance refers to the process of bringing the view up to date after one or more of the underlying base tables has been updated. View maintenance can always be done by recomputing the result, known as a full refresh, but this is usually prohibitively expensive. Incremental view maintenance, that is, only applying the minimal changes required to bring the view up to date, is normally more efficient.

Historical Background

Full outer join (called generalized join) was proposed by Lacroix and Pirotte in 1976 [4]. During the 1980's, there was considerable discussion in the research literature about the use and power of outer joins. Commercial systems began supporting outer joins in the late 1980's and at the time of writing (2007) all major commercial systems do. Optimization of outer-join queries was an active research area during the 1990's. Outer join was first included in the 1992 SQL standard. The first view matching algorithm for outer-join views was published by Larson and Zhou [5] in 2005.

In 1998 Griffin and Kumar [2] published the first paper covering incremental maintenance of materialized outer-join views. A paper 2006 by Gupta and Mumick [3] described a more efficient procedure but, unfortunately, it does not always produce the correct result. In 2007, Larson and Zhou [6] introduced an method for efficient incremental maintenance of outer-join views. At the time of writing, only Oracle allows (a limited form of) materialized outer-join views.

Foundations

Larson and Zhou [6] showed that incremental maintenance of an outer-join view can be divided into two steps: computing and applying a *primary delta* and a *secondary delta*. The first step is very similar to maintaining an inner-join view while the second step is a "clean-up" step.

This entry describes Larson's and Zhou's maintenance procedure for a view without aggregation when the update consists of insertions into one of its base tables. The reader is referred to the original paper [6] for a more complete description of how to handle deletions, views with aggregation, and how to exploit foreign-key constraints to simplify maintenance. Examples illustrating the procedure use a database consisting of the following three tables. Primary keys are underlined.

```
O(Okey, Odate, Ocustomer),
L(okey, pkey, Qty, Price),
P(Pkey, Pname).
```

The following materialized view consisting of two full outer joins will be used as a running example.

$$MV = \left(L \bowtie^{fo}_{p(l,p)} P\right) \bowtie^{fo}_{p(l,o)} O$$

where the join predicates are defined as $p(l,p) \equiv (l.pkey = p.pkey)$ and $p(l,o) \equiv (l.okey = o.okey)$.

Join-Disjunctive Normal Form

The view maintenance procedure builds on the join-disjunctive normal form for outer-join expressions introduced by Galindo-Legaria [6]. The normal form is described in this section by an example; more details can be found in [6,1].

Let T_1 and T_2 be tables with schemas S_1 and S_2, respectively. The *outer union*, denoted by $T_1 \uplus T_2$, first null-extends (pads with nulls) the tuples of each operand to schema $S_1 \cup S_2$ and then takes the union of the results (without duplicate elimination).

Let t_1 and t_2 be tuples with the same schema. Tuple t_1 is said to *subsume* tuple t_2 if t_1 agrees with t_2 on all columns where they both are non-null and t_1 contains fewer null values than t_2. The operator *removal of subsumed tuples* of T, denoted by $T\downarrow$, returns the tuples of T that are not subsumed by any other tuple in T.

The *minimum union* of tables T_1 and T_2 is defined as $T_1 \oplus T_2 = (T_1 \uplus T_1)\downarrow$. Minimum union is both commutative and associative.

Left outer join can be rewritten as $T_1 \bowtie_p^{lo} T_2 = T_1 \bowtie_p T_2 \oplus T_1$ and right outer join as $T_1 \bowtie_p^{ro} T_2 = T_1 \bowtie_p T_2 \oplus T_2$. Full outer join can be rewritten as $T_1 \bowtie_p^{fo} T_2 = T_1 \bowtie_p T_2 \oplus T_1 \oplus T_2$.

The example view was defined as

$$MV = \left(L \bowtie_{p(l,p)}^{fo} P\right) \bowtie_{p(l,p)}^{fo} O.$$

Conversion to normal form is done bottom up by applying the rewrite rules above. First rewrite the join between L and P in terms of inner joins and minimum union, which yields

$$MV = (\sigma_{p(l,p)}(L \times P) \oplus L \oplus P) \bowtie_{p(l,o)}^{fo} O.$$

Then apply the same rewrite to the second outer join, which produces

$$MV = ((\sigma_{p(l,p)}(L \times P) \oplus L \oplus P) \bowtie_{(l,o)} O) \\ \oplus (\sigma_{p(l,p)}(L \times P) \oplus L \oplus P) \oplus O.$$

Inner join distributes over minimum union in the same way as over regular union. Applying this transformation to the join with O produces

$$MV = \sigma_{p(l,p) \wedge p(l,o)}(O \times L \times P) \\ \oplus \sigma_{p(l,o)}(O \times L) \oplus \sigma_{p(l,o)}(O \times P) \\ \oplus \sigma_{p(l,p)}(L \times P) \oplus L \oplus P \oplus O.$$

The view expression is now in join-disjunctive form but it can be further simplified. The term $\sigma_{p(l,o)}(O \times P)$ can be eliminated because the join predicate will never be satisfied.

$$MV = \sigma_{P(l,p) \wedge P(l,o)}(O \times L \times P) \oplus \sigma_{p(l,o)}(O \times L) \\ \oplus \sigma_{p(l,p)}(L \times P) \oplus L \oplus P \oplus O.$$

The normal form shows what form of tuples are found in MV. For example, it "contains" all tuples in the join of O and L. Most such tuples are represented implicitly by being included in a wider tuple composed of tuples from O, L and P; only the non-subsumed tuples are stored explicitly in the view.

As illustrated by this example, an outer-join expression E over a set of tables $\mathcal{U}$ can be converted to a normal form consisting of the minimum union of terms composed from selections and inner joins (but no outer joins). More formally, the join-disjunctive normal form of E equals

$$E = E_1 \oplus E_2 \oplus \cdots \oplus E_n$$

where each term E_i is of the form $E_i = \sigma_{pi}(T_{i1} \times T_{i2} \times \ldots \times T_{im})$. $\mathcal{T}_i = \{T_{i1}, T_{i2} \ldots T_{im}\}$ is a (unique) subset of the tables in $\mathcal{U}$. Predicate p_i is the conjunction of a subset of the selection and join predicates found in the original form of the query.

The Subsumption Graph

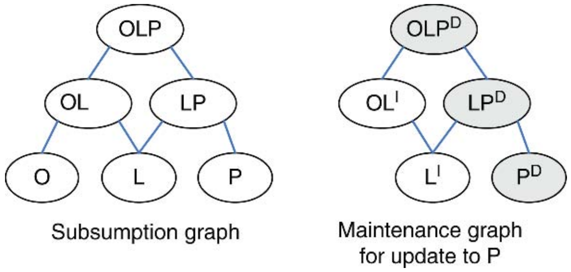
Every term in the normal form of the view has a unique set of source tables drawn from $\mathcal{U}$ and is null-extended on all other tables in the view. The set of source tables of term E_i is denoted by $\mathcal{T}_i$ and the set of tables on which it is is null-extended by $\mathcal{S}_i, \mathcal{S}_i = \mathcal{U} - \mathcal{T}i$.

A tuple produced by a term with source tables $\mathcal{T}_i$ can only be subsumed by tuples produced by terms whose source set is a superset of $\mathcal{T}_i$. The subsumption relationships among terms can be modeled by a DAG called the subsumption graph.

The *subsumption graph* of E contains a node n_i for each term E_i in the normal form and the node is labeled with the source table set $\mathcal{T}_i$ of E_i. There is an edge from a node n_i to a node n_j, if $\mathcal{T}_i$ is a minimal superset of $\mathcal{T}_j$. $\mathcal{T}_i$ is a minimal superset of $\mathcal{T}_j$ if there does not exist a node n_k in the graph such that $\mathcal{T}_j \subset \mathcal{T}_k \subset \mathcal{T}_i$.

The subsumption graph for view MV is shown to the left in Fig. 1. The importance of the subsumption graph lies in the following observation: when checking whether a tuple of a term is subsumed, it is sufficient to check against tuples in the term's immediate parent terms. For example, to determine whether a P tuple p_1 is subsumed, all that is needed is to check whether it joins with an L tuple. If it does, the resulting tuple, which subsumes p_1, is included in the LP term.

The result of an outer-join expression is represented in a minimal form. Only the non-subsumed



Maintenance of Materialized Views with Outer-Joins. Figure 1. Subsumption graph and maintenance graph for view *MV*.

tuples produced by a term E_i in the normal form are explicitly represented. A subsumed tuple is represented implicitly by being included in a subsuming tuple. The *net contribution* of a term, denoted by D_i, is the set of non-subsumed tuples of term E_i in the normal form of expression E. Then E can then be written in the form

$$E = D_1 \uplus D_2 \uplus \cdots \uplus D_n.$$

Consider a view V and suppose one of the its base tables T is modified. This may affect the net contribution of a term D_i in one of three ways:

1. Directly, which occurs if T is among the tables in $\mathcal{T}_i$;
2. Indirectly, which occurs if T is not among the tables in $\mathcal{T}_i$ but it is among the source tables of at least one of its parent nodes;
3. No effect, otherwise.

Based on this classification of how terms are affected, a *view maintenance graph* is created as follows.

1. Eliminate from the subsumption graph all nodes that are unaffected by the update of T.
2. Mark the remaining nodes by D or I depending on whether the node is affected directly or indirectly.

The maintenance graph for view when updating P is shown to the right in Fig. 1. The maintenance graph is used primarily to identify which terms of a view are indirectly affected and thus may require maintenance.

Maintenance Procedure

Suppose table T has been updated. If so, any view V that references T needs to be maintained. The first step is to compute the view's maintenance graph and classify the terms as directly affected, indirectly affected, and unaffected. Without loss of generality, assume that the view has n terms, of which terms $1, 2,\ldots,k$ are directly affected, terms $k + 1$, $k + 2,\ldots,k+ m$ are indirectly affected, and terms $k + m + 1$, $k + m + 2,\ldots,n$ are not affected. The view expression can then be rewritten in the form

$$V = V^D \uplus V^I \uplus V^U \text{where}$$
$$V^D = \uplus_{i=1}^{k} D_i, \quad V^I = \uplus_{i=k+1}^{k+m} D_i,$$
$$V^U = \uplus_{i=k+m+1}^{n} D_i.$$

From this form of the expression, one can see that to update the view, two delta expressions must be evaluated and applied to the view

$$\Delta V^D = \uplus_{i=1}^{k} \Delta D_{i,} \, \Delta V^I = \uplus_{i=k+1}^{k+m} \Delta D_i.$$

ΔV^D is called the *primary delta* and ΔV^I the *secondary delta*. In summary, maintenance of a view V after insertions into one of its underlying base tables can be performed in two steps.

1. Compute the primary delta ΔV^D and insert the resulting tuples into the view.
2. If there are indirectly affected terms, compute the secondary delta ΔV^I and delete the resulting tuples from the view.

Computing the Primary Delta

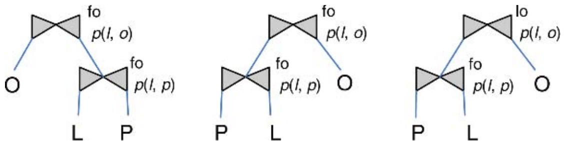
An expression that computes the primary delta, ΔV^D, can be constructed by the following simple algorithm.

1. Traverse the operator tree for V along the path from T to the root. On any join operator encountered, apply commutativity rules to ensure that the input referencing T is on the left.
2. Traverse the path from T to the root of V. Convert any full outer join operator encountered to a left outer join and any right outer join operator to an inner join.
3. Substitute T by ΔT.

Step 1 is a normal rewrite of the view expression and does not change the result. Step 2 modifies the expression so that it computes only V^D. After Step 2, the operators on the path from T to the root consists only of selects, inner joins, and left outer joins and the delta expression is always the left input.

Figure 2 illustrates the transformation process for the example view MV when table P is updated. The resulting expression for computing the primary delta is

$$\Delta MV^D = \left(\Delta P \bowtie^{lo}_{p(l,p)} L\right) \bowtie^{lo}_{p(l,o)} O$$



Maintenance of Materialized Views with Outer-Joins. Figure 2. Constructing primary-delta expression for insertions into table P.

Computing the Secondary Delta

The secondary delta can be computed efficiently from the primary delta and either the view or base tables. Only the case when using the view is described here. Recall that the base tables have already been updated and the primary delta has been applied to the view.

The primary delta ΔV^D contains the union of the deltas for all directly affected terms. However, deltas for individual terms are needed to compute the secondary delta. Each term is defined over a unique set of tables and null extended on all others so tuples from a particular term are easily identified and can be extracted from ΔV^D by simple selection predicates.

Let $null(T)$ denote a predicate that evaluates to true if a tuple is null-extended on table T. $null(T)$ can be implemented in SQL as "$T.c$ is null" where c is any column of T that does not contain nulls, for example, a column of a key. When applying $null$ and $\neg null$ to a set of tables $T = \{T_1, T_2 ..., T_n\}$, the shorthand notations $n(\mathcal{T}) = \bigwedge_{T_i \in \mathcal{T}} null(T_i)$ and $nn(\mathcal{T}) = \bigwedge_{T_i \in \mathcal{T}} \neg null(T_i)$ are used.

For the example view, MV, the primary delta contains deltas of three directly affected terms, see Fig. 1. Non-subsumed tuples from, for example, the LP-term are uniquely identified by the fact that they are composed of a real tuple from L and from P but are null extended on O. Hence, $\mathit{\Delta} D_{LP}$ can be extracted from ΔV^D as follows:

$$\Delta D_{LP} = \pi_{(LP).*} \sigma_{nn(LP) \wedge n(o)} \Delta MV^D$$

where $nn(LP) = \neg null(L) \wedge \neg null(P)$ and $n(O) = null(O)$.

ΔD_{LP} contains only the delta of the net contribution of the term. ΔE_{LP} contains the complete delta of the term, including both subsumed and non-subsumed tuples. Tuples in ΔE_{LP} are composed of real tuples from L, and from P, and may or may not be null extended on O. Hence, ΔE_{LP} can be extracted from ΔV^D as follows:

$$\Delta E_{LP} = \delta \pi_{(LPo).*} \sigma_{nn}(LP) \Delta MV^D.$$

The duplicate elimination (δ) is necessary because an LP tuple may have joined with multiple O tuples.

Continuing with the running example, the secondary delta consists of ΔD_{OL} and ΔD_L. ΔD_{OL} is null extended on P and the OLP-term is its only parent so it can be computed as:

$$\Delta D_{OL} = \sigma_{nn(OL) \wedge n(P)} (MV + \Delta MV^D) \bowtie^{ls}_{eq(OL)} \sigma_{nn(OLP)} \Delta MV^D.$$

This expression makes sense intuitively. The first part selects from the view all orphaned (non-subsumed) tuples of term E_{OL} contained in the view after the primary delta has been applied. The second part extracts from the primary delta all tuples added to the parent term E_{OLP}. The join is a left semijoin and outputs every tuple from the left operand that joins with one or more tuples in the right operand. The complete expression thus amounts to finding all currently orphaned tuples of the term and retaining those that cease to be orphans because of the insert. Those tuples should be deleted from the view.

D_L is null extended on O, and P and has one directly affected parent, the LP-term. ΔD_L can be computed as:

$$\Delta D_L = \sigma_{nn(L) \wedge n(OP)} (MV + \Delta MV^D) \bowtie^{ls}_{eq(L)} \sigma_{nn}(LP) \Delta MV^D.$$

Summary

In summary, after insertion into table P of a set of tuples ΔP, the example view MV can be brought up to date as follows. First compute the primary delta

$$\Delta MV^D = (\Delta P \bowtie^{lo}_{p(l,p)} L) \bowtie^{lo}_{p(l,o)} O$$

and insert the resulting tuples into the view, resulting in $MV + \Delta MV^D$. Then compute the secondary delta

$$\begin{aligned} \Delta MV^I &= \Delta D_{OL} \uplus \Delta D_L \\ &= \sigma_{nn(OL) \wedge n(P)} (MV + \Delta MV^D) \\ &\quad \bowtie^{ls}_{eq(OL)\, \sigma_{nn}(OLP)} \Delta MV^D \uplus \\ &\quad \sigma_{nn(L) \wedge n(OP)} (MV + \Delta MV^D) \\ &\quad \bowtie^{ls}_{eq(L)\, \sigma_{nn}(LP)} \Delta MV^D \end{aligned}$$

and delete the resulting tuples from the view.

Key Applications

Queries containing outer joins are often used in analysis queries over large tables in data warehouses. Materialized outer-join views, especially when aggregated, can be very beneficial in such scenarios.

Maintenance of Recursive Views

Suzanne W. Dietrich

Synonyms

Incremental maintenance of recursive views; Recursive view maintenance

Definition

A view is a derived or virtual table that is typically defined by a query, providing an abstraction or an alternate perspective of the data that allows for more intuitive query specifications using these views. Each reference to the view name results in the retrieval of the view definition and the recomputation of the view to answer the query in which the view was referenced. When views are materialized, the tuples of the computed view are stored in the database with appropriate index structures so that subsequent access to the view can efficiently retrieve tuples to avoid the cost of recomputing the entire view on subsequent references to the view. However, the materialized view must be updated if any relation that it depends on has changed. Rather than recomputing the entire view on a change, an incremental view maintenance algorithm uses the change to incrementally compute updates to the materialized view in response to that change. A recursive view is a virtual table definition that depends on itself. A canonical example of a recursive view is the transitive closure of a relationship stored in the database that can be modeled as directed edges in a graph. The transitive closure essentially determines the reachability relationship between the nodes in the graph. Typical examples of transitive closure include common hierarchies such as employee-supervisor, bill-of-materials (parts-subparts), ancestor, and course prerequisites. The incremental view maintenance algorithms for the maintenance of recursive views have additional challenges posed by the recursive nature of the view definition.

Historical Background

A view definition relates a view name to a query defined in the query language of the database. Initially, incremental view maintenance algorithms were explored in the context of non-recursive view definitions involving select, project, and join query expressions, known as SPJ expressions in the literature. The power of recursive views was first introduced in the *Datalog* query language, which is a declarative logic programming language established as the database query language for deductive databases in the 1980s. Deductive databases assume the theoretical foundations of relational data but use Datalog as the query language. Since its relational foundations assume first normal form, Datalog looks like a subset of the Prolog programming language without function symbols. However, Datalog does not assume Prolog's top-down left-to-right programming language evaluation strategy. The evaluation of Datalog needed to be founded on the fundamentals of database query optimization. In a database system, a user need only specify a correct declarative query, and it is the responsibility of the database system to efficiently execute that specification. The evaluation of Datalog was further complicated by the fact that Datalog allows for relational views that include union and recursion in the presence of negation. Therefore, the view definitions in Datalog were more expressive than the traditional select-project-join views available in relational databases at that time. Therefore, the incremental view maintenance algorithms for recursive views in the early 1990s are typically formulated in the context of the evaluation of Datalog. The power to define a recursive union in SQL was added in the SQL:1999 standard.

Historically, it is important to note that the incremental maintenance of recursive views is related to the areas of integrity constraint checking and condition monitoring in active databases. These three areas were being explored in the research literature at around the same time. In integrity constraint checking, the database is assumed to be in a consistent state and when a change occurs in the database, it needs to incrementally determine whether the database is still in a consistent state. In active databases, the database is responsible for actively checking whether a condition that it is responsible for monitoring is now satisfied by incrementally evaluating condition specifications affected by changes to the database. Although closely related, there are differences in the underlying assumptions for these problems.

Foundations

Recursive View Definition

A canonical example of a recursive view definition is the reachability of nodes in a directed graph. In Datalog, the reach view consists of two rules. The first non-recursive rule serves as the base or seed case, and indicates that if the stored or base table edge defines a directed edge from the source node to the destination node, then the destination can be reached from the source. The second rule is recursive. If the source node can reach some intermediate node and there is an edge from that intermediate node to a destination node, then the source can reach the destination.

```
reach(Source, Destination):-
   edge(Source, Destination).
reach(Source, Destination):-
   reach(Source, Intermediate),
   edge(Intermediate, Destination).
```

Intuitively, one can think of the recursive rule as an unfolding of the joins required to compute the reachability of paths of length two, then paths of length three, and so on until the data of the underlying graph is exhausted.

In SQL, this recursive view is defined with the following recursive query expression:

```
with recursive reach(source, destina-
tion) as
(select E.source, E.destination
from edge E)
union
(select S.source, D.destination
from reach S, edge D
where S.destination = D.source)
```

SQL limits recursive queries to linear recursions, which means that there is at most one direct invocation of a recursive item. The specification of the reach view above is an example of a linear recursion. There is another linear recursive specification of reach where the direct recursive call appears on the right side of the join versus the left side of the join:

```
reach(Source, Destination):-
   edge(Source, Intermediate),
   reach(Intermediate, Destination).
```

However, there is a logically equivalent specification of reach that is non-linear:

```
reach(Source, Destination):-
   reach(Source, Intermediate),
   reach(Intermediate, Destination).
```

The goal of Datalog evaluation is to allow the user to specify the recursive view declaratively in a logically correct way, and it is the system's responsibility to optimize the evaluation of the query.

SQL also restricts recursions to those defined in deductive databases as stratified *Datalog with negation*. Without negation, a recursive Datalog program has a unique solution that corresponds to the theoretical fixpoint semantics or meaning of the logical specification. In the computation of the reach view, each unfolding of the recursion joins the current instance of the recursive view with the edge relation until no new tuples can be added. The view instance has reached a fixed point and will not change. When negation is introduced, the interaction of recursion and negation must be considered. The concept of stratified negation means that there can be no negation through a recursive computation, i.e., a view cannot be defined in terms of its own negation. Recursive views can contain negation but the negation must be in the context of relations that are either stored or completely computed before the application of the negation. This imposed level of evaluation with respect to negation and recursion are called strata. For stratified Datalog with negation, there also exists a theoretical fixpoint that represents the intuitive meaning of the program.

Consider an example of a view defining a peer as two employees that are not related in the employee-supervisor hierarchy:

```
peer(A, B):- employee(A,...), employee(B,...),
   not (supervisor(A,B)), not(supervisor(B,A)).
supervisor(Emp, Sup):-
   immediateSupervisor(Emp,Sup).
```

```
supervisor(Emp, Sup):-
   supervisor(Emp, S),
   immediateSupervisor(S, Sup).
```

Since peer depends on having supervisor materialized for the negation, peer is in a higher stratum than supervisor. Therefore, the strata provide the levels in which the database system needs to compute views to answer a query.

Evaluation of Recursive Queries

Initial research in the area emphasized the efficient and complete evaluation of recursive queries. The intuitive evaluation of the recursive view that unions the join of the current view instance with the base data at each unfolding is known as a naïve bottom-up algorithm. In a bottom-up approach to evaluating a rule, the known collection of facts is used to satisfy the subgoals on the right-hand side of the rule, generating new facts for the relation on the left-hand side of the rule. To improve the efficiency of the naïve algorithm, a semi-naïve approach can be taken that only uses the new tuples for the recursive view from the last join to use in the join at the next iteration. A disadvantage of this bottom-up approach for evaluating a query is that the entire view is computed even when a query may be asking for a small subset of the data. This eager approach is not an issue in the context of materializing an entire view.

Another recursive query evaluation approach considered a top-down strategy as in Prolog's evaluation. In a top-down approach to evaluation, the evaluation starts with the query and works toward the collection of facts in the database. In the context of the reach recursive view, the reach query is unified with the left-hand side of the non-recursive rule and rewritten as a query involving edge. The edge facts are then matched to provide answers. The second recursive rule is then used to rewrite the reach query with the query consisting of the goals on the right-hand side of the rule. This evaluation process continues, satisfying the goals with facts or rewriting the goals using the rules. The unification of a goal with the left-hand side of a rule naturally filters the evaluation by binding variables in the rule to constants that appear in the query. However, the evaluation of a left-recursive query using Prolog's evaluation strategy enters an infinite loop on cyclic data by attempting to prove the same query over and over again. A logic programmer would not write a logic program that enters an infinite loop, but the deductive database community was interested in the evaluation of truly declarative query specifications.

The resulting evaluation approaches combine the best of top-down filtering with bottom-up materialization. The magic sets technique added top-down filtering by cleverly rewriting the original rules so that a bottom-up evaluation would take advantage of constants appearing in the query [1]. Memoing was added to a top-down evaluation strategy to achieve the duplicate elimination feature that is inherent in a bottom-up evaluation of sets of tuples [3]. This duplicate elimination feature avoids the infinite loops on cyclic data. Top-down memoing is complete for subsets of Datalog on certain types of queries [4]. For stratified Datalog with negation, top-down memoing still requires iteration to guarantee complete evaluation. Further research explored additional optimizations as well as implementations of deductive database systems [12] and led to research in active databases and materialized view maintenance.

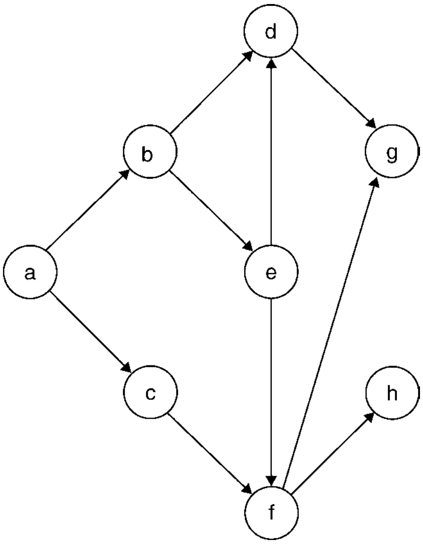
Incremental Evaluation of Recursive Views

A view maintenance algorithm uses the change to incrementally determine updates to the view. Consider a change in the underlying graph for the transitive closure example. If a new edge is inserted, this edge may result in a change to the materialized reach view by adding a connection between two nodes that did not exist before. However, another possibility is that the new edge added another path between two nodes that were already in the materialized view. A similar situation applies on the removal of an edge. The deletion could result in a change in the reachability between nodes or it could result in the removal of a path but the nodes are still connected via another route. In addition, in the general case, a view may depend on many relations including other (recursive) views in the presence of negation. Therefore, the approaches for the incremental maintenance of recursive views typically involve a propagation or derivation phase that determines an approximation or overestimate of the changes, and a filtering or rederivation phase that checks whether the potential change represents a change to the view. There are differences in the underlying details of how these phases are performed.

The two incremental view maintenance algorithms that will be presented by example are the DRed algorithm [7] and the PF Algorithm [8]. Both the DRed and PF algorithms handle recursive stratified Datalog programs with negation. There are other algorithms developed for special cases of Datalog programs and queries, such as the counting technique for nonrecursive programs, but this exposition will explore these more general approaches for incremental view maintenance. Historically, the PF algorithm was developed in the context of top-down memoing whereas DRed assumes a bottom-up semi-naïve evaluation. To assist with the comparison of the approaches, the notation introduced for the DRed algorithm [7] will be used to present both algorithms in the context of the transitive closure motivational example.

Figure 1 provides a graphical representation of an edge relation. Assume that the view for reach is materialized, and the edge (e,f) is deleted from the graph. The potential deletions or overestimates for reach, denoted by δ^-(reach), are computed by creating Δ^- rules for each rule computing reach. Each reach rule has k Δ^- rules where k corresponds to the number of subgoals in the body of the rule. The ith Δ^- rule uses the current estimate of deleted tuples (δ^-) for the ith subgoal. For the nonrecursive rule, there is only one subgoal. Therefore, there is only one Δ^- rule indicating that potential edge deletions generate potential deletions to the reach view.

Δ^-(r1): δ^-(reach(S, D)):- δ^-(edge(S, D)).



Maintenance of Recursive Views. Figure 1. Sample Graph.

Since the recursive rule has two subgoals, there are two Δ^- rules:

Δ^-(r21): δ^-(reach(S, D)):- δ^-(reach(S, I)), edge(I, D).
Δ^-(r22): δ^-(reach(S, D)):- reach(S, I), δ^-(edge(I, D)).

Potential deletions to the reach view as well as the edge relation can generate potential deletions to the view.

These potential deletions need to be filtered by determining whether there exist alternative derivations or paths between the nodes computed in the potential deletion. There is a Δ^r rule defined for each reach rule that determines the rederivation of the potential deletions, which is denoted by δ^+ (reach):

Δ^r(r1): δ^+ (reach(S, D)):- δ^-(reach(S, D)), edge^v(S, D).
Δ^r(r2): δ^+ (reach(S, D)):- δ^-(reach(S, D)), reach^v(S, I), edge^v(I, D).

The superscript v on the subgoals in the rule indicates the use of the current instance of the relation corresponding to the subgoal. If the potential deletion is still reachable in the new database instance, then there exists another route between the source and destination, and it should not be removed from the materialized view. The actual removals to reach, indicated by Δ^-(reach), is the set of potential deletions minus the set of alternative derivations:

Δ^-(reach) = δ^-(reach) – δ^+ (reach)

Table 1 illustrates the evaluation of the DRed algorithm for incrementally maintaining the reach view on the deletion of edge(e,f) from Fig. 1. The DRed algorithm uses a bottom-up evaluation of the given rules, starting with the deletion δ^-(edge(e, f)). In the first step, the Δ^- rules compute the overestimate of the deletions to reach. The result of the Δ^- rules are shown in the right column, which indicates the potential deletions to reach as δ^-(reach). The second step uses the Δ^r rules to filter the potential deletions. The right column illustrates the source destination pairs that are still reachable after the deletion of edge(e,f) as δ^+ (reach). The tuples that must be removed from the materialized view are indicated by Δ^-(reach): {(e,f) (e,h) (b,f) (b,h)}.

The PF (Propagate Filter) algorithm on the same example is shown in Table 2. PF starts by propagating the edge deletion using the nonrecursive rule, which generates a potential deletion of reach(e,f). This approximation is immediately filtered to determine whether there exists another path between e and f.

Maintenance of Recursive Views. Table 1. DRed algorithm on deletion of edge (e,f) on materialized reach view

DRed algorithm		
Step 1	*Compute overestimate of potential deletions*	δ^{-}(reach)
	Δ^{-}(r1): δ^{-}(reach(S, D)):- δ^{-}(edge(S, D)).	(e,f)
	Δ^{-}(r21): δ^{-}(reach(S, D)):- δ^{-}(reach(S, I)), edge(I, D).	(e,g) (e,h)
	Δ^{-}(r22): δ^{-}(reach(S, D)):- reach(S, I), δ^{-}(edge(I, D)).	(a,f) (b,f)
	Repeat until no change: No new tuples for Δ^{-}(r1) and Δ^{-}(r22)	
	Δ^{-}(r21): δ^{-}(reach(S, D)):- δ^{-}(reach(S, I)), edge(I, D).	(a,g) (a,h) (b,g) (b,h)
	Last iteration does not generate any new tuples	
Step 2	*Find alternative derivations to remove potential deletions*	δ^{+} (reach)
	Δ^{r}(r1): δ^{+} (reach(S, D)):- δ^{-}(reach(S, D)), edge(S, D).	
	Δ^{r}(r2): δ^{+} (reach(S, D)):- δ^{-}(reach(S, D)), reach^{v}(S, I), edge^{v}(I, D).	(e,g) (a,f) (a,g) (a,h) (b,g)
Step 3	*Compute actual changes to reach*	Δ^{-}(reach)
	Δ^{-}(reach) = δ^{-}(reach) – δ^{+} (reach)	(e, f) (e,h) (b,f) (b,h)

Maintenance of Recursive Views. Table 2. PF algorithm on deletion of edge (e,f) on materialized reach view

PF algorithm				
Propagate			**Filter**	
	Rule	**δ^{-}(reach)**	**δ^{+} (reach)**	**Δ^{-}(reach)**
δ^{-}(edge):{(e, f)}	Δ^{-}(r1)	(e,f)	{}	(e,f)
Δ^{-}(reach): {(e,f)}	Δ^{-}(r21)	(e,g) (e,h)	(e,g)	(e,h)
Δ^{-}(reach): {(e,h)}	Δ^{-}(r21)	{}		{}
δ^{-}(edge): {(e, f)}	Δ^{-}(r22)	(a,f) (b,f)	(a,f)	(b,f)
Δ^{-}(reach): {(b,f)}	Δ^{-}(r21)	(b,g) (b,h)	(b,g)	(b,h)
Δ^{-}(reach): {(b,h)}	Δ^{-}(r21)	{}		{}

Since there is no alternate route, the tuple (e,f) is identified as an actual change, and is then propagated. The propagation of Δ^{-}(reach): {(e,f)} identifies (e,g) and (e,h) as potential deletions. However, the filtering phase identifies that there is still a path from e to g, so (e, h) is identified as a removal to reach. The propagation of (e,h) does not identify any potential deletions. The propagation of the initial edge deletion δ^{-}(edge): {(e, f)} must be propagated through the recursive rule for reach using Δ^{-}(r22). The potential deletions are immediately filtered, and only actual changes are propagated. The PF algorithm also identifies the tuples {(e,f) (e,h) (b,f) (b,h)} to be removed from the materialized view.

As shown in the above deletion example, the DRed and PF algorithms both compute overestimates or approximations of tuples to be deleted from the recursive materialized view. The PF algorithm eagerly filters the potential deletions before propagating them. The DRed algorithm propagates the potential deletions within a stratum but filters the overestimates before propagating them to the next stratum. There are scenarios in which the DRed algorithm outperforms the PF algorithm and others in which the PF algorithm outperforms the DRed algorithm.

For the case of insertions, the PF algorithm operates in a manner similar to deletions, by approximating the tuples to be added and filtering the potential additions by determining whether the tuple was provable in the old database state. However, the DRed algorithm uses the bottom-up semi-naïve algorithm for Datalog evaluation to provide an inherent mechanism for determining insertions to the materialized view. In semi-naïve evaluation, the original rules are executed once to provide the seed or base answers. Then incremental versions of the rules are executed until a fixpoint is reached. The incremental rules are formed by creating k rules associated with a rule where k corresponds to the number of subgoals in the right-hand side of the rule. The i^{th} incremental rule uses only the new tuples from the last iteration for the i^{th} subgoal. However, when the i^{th} subgoal is a stored relation, then the corresponding incremental rules are removed since they will not contribute to the incremental evaluation. For the motivational example, the incremental rule for reach is

Δreach(S,I), edge(I, D)

where Δreach represents the new reach tuples computed on the previous iteration. Since a set of tuples is being computed, duplicate proofs are automatically filtered and are not considered new tuples. This is the inherent memoing in bottom-up evaluation that handles cycles in the underlying data.

Key Applications

Query Optimization; Condition Monitoring; Integrity Constraint Checking; Data Warehousing; Data Mining; Network Management; Mobile Systems.

Managing Compressed Structured Text

Gonzalo Navarro
University of Chile, Santiago, Chile

Synonyms

Searching compressed XML; Compressing XML

Definition

Compressing semi-structured text is the problem of creating a reduced-space representation from which the original data can be re-created exactly. Compared to plain text compression, the goal is to take advantage of the structural properties of the data. A more ambitious goal is being able to manipulate this text in compressed form, without decompressing it. This entry focuses on compressing, navigating, and searching semi-structured text, as those are the areas where more advances have been made.

Historical Background

Modeling data using semi-structured text has been a topic of interest at least since the 1980's, with a significant burst of activity in the 1990's [2]. Since then, the widespread adoption of XML (appearing in 1998, see the current version at http://www.w3.org/TR/xml) as the standard to represent semi-structured data has unified the efforts of the community around this particular format. Very early, however, the same features that made XML particularly appealing for both human and machine processing were pointed out as significant sources of redundancy and wasting of storage space and bandwidth. This was especially relevant for wireless transmission and triggered the proposal of the WAP Binary XML Content Format as early as 1999 (see http://www.w3.org/TR/wbxml), where simple techniques to compress XML prior to its transmission were devised.

In parallel, there has been a growing interest in not only compressing the data for storage or transmission, but in manipulating it in compressed form. The reason is the long-standing tradeoff between faster/smaller/more expensive and slower/larger/cheaper memories. A more compact data representation has the potential of fitting in a faster memory, where manipulating it can be orders of magnitudes faster, even if it requires more operations, than a naive representation fitting only in a slower memory.

Foundations

For concreteness, this entry will focus on the de-facto standard XML, where the structure is a tree or a forest marked with beginning and ending tags in the text. In fact this encompasses many other semi-structured text proposals, hence most of the material of the entry applies to semi-structured text in general, with minimal changes. In XML, the tags can have attributes and associated values, and there might be available a grammar giving the permissible context-free syntax of the semi-structured document.

Compression of Semi-Structured Text

An obvious approach to compressing semi-structured text is to regard it as plain text and use any of the well-known text compression methods [5]. Yet, considering the structure might yield improved compression performance compared to ignoring it. Many compressors have been proposed trying to exploit structure in different ways. Rather than describing them individually, the main principles behind them will be presented.

1. The data is a mix of structure and content. The structure can be regarded as a labeled tree, where the labels are the tag names, and the content as free text, which can appear between every consecutive pair of tree nodes, and within tree leaves. Attribute information can be handled as text as well, or as special data attached to tree nodes.
2. The structure and the content can be compressed separately, which has proved to give good results. Later, encoded tags and contents can be stored in the file in their original order, so that the document can be handled as a plain uncompressed document. Alternatively, structure and content can be stored separately with some pointer information to reconstruct the tree, in which case the structure pointers may help to point out relevant content to scan in the querying process.
3. The text content can be compressed using any text compression method. Semi-static compressors permit accessing the content at random without decompressing all from the beginning, whereas adaptive compressors tend to achieve better compression ratios. Splitting the text into blocks that are compressed adaptively permits trading random access time for compression ratio.
4. The structure can be compressed in several ways, which can range from a simple scheme of assigning numbers to the different tag names, to sophisticated grammar-based compression methods. The latter may take advantage of the explicit grammar when it is available.
5. Structure can be used, in addition, to boost compression. If the text contents are grouped according to the structural path towards the root, and each group is compressed separately, compression ratios improve noticeably. This can be as simple as grouping texts that are under the same tag (that is, considering only the deepest tree node containing the text) or as sophisticated as considering the full path towards the root.

A sample of different open-source systems that compress XML based on diverse combinations of these principles is

XMill [13],
Millau [10],
XMLPPM [6],
XGrind [15],
XCQ [12],
XPress [14], and
SCM [1].

See http://pages.cpsc.ucalgary.ca/~gleighto/research/xml-comp.html for a more exhaustive reference.

Navigating and Searching in Compressed Form

The most popular retrieval operations on semi-structured text are related to *navigating* the tree and to *searching* it. Navigating means moving from a node to its children, parent, and siblings. Searching means various *path matching* operations such as finding all the paths where a node labeled A is the parent of another labeled B and that one is the ancestor of another labeled C, which in turn contains text where word W appears. A popular language combining navigation and searching operations is XPath (see http://www.w3.org/TR/xpath20).

Several of the schemes above permit accessing and decompressing any part of the text at random positions. This is because they retain the original order of the components of the document and compress using a semi-static model. Those compression methods are transparent, in the sense that the classical techniques to navigate and search XML data, sequentially or using indexes, can be used almost directly over this compressed representation.

Other techniques, such as *SCM* (Huffman variant) or *XCQ*, allow random access under a slightly more complex scheme, because some work is needed in order to start decompression at a specific point. Finally, techniques based on adaptive compression (such as *XMLPPM* or the PPM variant of *SCM*) usually achieve better compression ratios but need to decompress the whole data before they can operate on it.

Some of these techniques, on the other hand, take some advantage of the separation between structure and content in order to run queries faster than scanning all the data. This is the case of *XCQ*, where the table that points from each different tree path to all the contents compressed under the corresponding model, is useful to avoid traversing those contents if the path does not match a path matching query. Another example is *XPress*, which encodes paths in a way that the codes themselves permit checking containment between two paths. A concept that deviates from the ideas presented is that of using a tree representation that permits sharing repeated subtrees. A good exponent is [5], which permits running a large subset of XPath directly over this compressed representation. The structure can be navigated almost transparently, and path matching operations can be sped up by factoring out the work done on repeated substructures.

Succinct Encodings for Labeled Trees

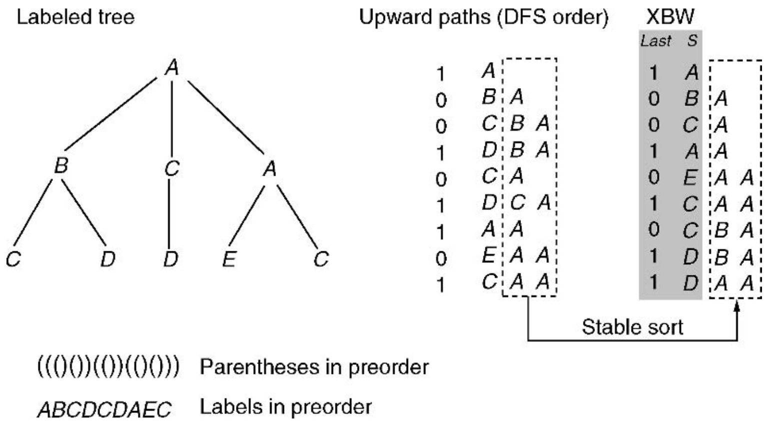
Succinct representations of labeled trees are an algorithmic development that finds applications in navigating semi-structured text in compressed form. In its simplest form, a general labeled tree of n nodes can be represented using a sequence P of $2n$ balanced parentheses and a sequence L of n labels (which correspond to tag names and will be regarded as atomic for simplicity).

This is obtained by traversing the tree in preorder (that is, first the current node and then recursively each of its children). As the tree is traversed, an opening parenthesis is added to P each time one goes down to a child, and a closing parenthesis when going up back to the parent. In L, the labels are added in preorder.

Figure 1 (left) shows an example representation of a labeled tree as a sequence of parentheses and labels in preorder. It is not hard to rebuild the tree from this representation. However, what is really challenging is to navigate the tree directly in this representation (where a node is represented by the position of its opening parenthesis). For this sake, only sublinear extra space on top of the plain representation is needed [9].

An essential operation to achieve efficient navigation in compressed form is the *rank* operation on bitmaps: $rank(P, i)$ is the number of 1s (here representing opening parentheses) in $P[1, i]$. One immediate application of *rank* is to obtain the label of a given node i, as $L[rank(P, i)]$. For example, consider the second child of the root in Fig. 1. It is represented by the opening parenthesis at position 8 in the sequence. Its label is therefore $L[rank(\text{“((()())(())(()()))”}, 8)] = L[5] = \text{“}C\text{”}$. Another application of *rank*, is to compute the depth of a node i. This is the number of opening minus closing parenthesis in $P[1, i]$, that is, $rank(P, i) - (i - rank(P, i)) = 2 \cdot rank(P, i) - i$. For example, the depth of the second child of the root is $2 \cdot rank(\text{“((()())(())(()()))”}, 8) - 8 = 2 \cdot 5 - 8 = 2$.

It is not possible to fully explain, in a short entry, the constant-time solutions to *rank* and other more complex operations needed to navigate the compressed tree. To have a flavor of how those solutions operate, consider the case of supporting *rank* in constant time and $o(n)$ extra bits. Absolute *rank* values are stored at every sth position of P (for some parameter s), and also relative (to the beginning of the last absolute sample) *rank* values at every bth position of P (for some parameter $b < s$). Note that each relative *rank* value



Managing Compressed Structured Text. Figure 1. An example labeled tree and two compression techniques. On the left (*bottom*), as a parentheses plus labels sequence in preorder. On the right, its *xbw* transform. The *dashed boxes* highlight the upward paths. The *grayed box* is the *xbw* transform of the tree.

needs only log s bits to be stored. Then, two table accesses (absolute plus relative *rank*) give the partial *rank* answer up to the b-bit chunk where position i belongs. To complete the query in constant time, a universal table is precomputed, which gives the number of 1-bits in *every possible* chunk of b bits. Some bit masking and a final access to this table suffice to count the remaining 1s within the chunk. By properly choosing s and b one achieves $o(n)$ extra bits overall, and still answers $rank(P, i)$ with three table accesses.

Other basic queries can be computed with similar mechanisms (coarse sampling to store absolute values, finer sampling to store relative values, and universal tables to process short chunks). For example, one can compute $select(P, i)$, the position of the ith opening parenthesis in P, so as to find the tree node corresponding to the ith label in L. Other essential operations for the navigation are $close(i)$, the position of the parenthesis that closes i (that is, the next parenthesis with the same depth of i); and $enclose(i)$, the lowest parenthesis that contains i (that is, the preceding parenthesis with depth smaller than that of i).

With these two operations one can navigate the tree as follows. The next sibling of i is $close(i) + 1$ (unless it is a closing parenthesis, in which case i is the last child of its parent). The first child of i is $i + 1$ unless $P[i + 1]$ is a closing parenthesis, in which case i is a leaf and hence has no children. The parent of i is $enclose(i)$. The size of the subtree rooted at i is $(close(i) - i + 1)/2$. For example, consider the first child of the root in Fig. 1, such that $i = 2$. It finishes at $close(i) = 7$. Its next sibling is $close(i) + 1 = 8$, the node of the previous examples. Its first child is $i + 1 = 3$, the leftmost tree leaf. Its parent is $enclose(i) = 1$, the root. The size of its subtree is $(close(i) - i + 1)/2 = (7 - 2 + 1)/2 = 3$.

In order to enrich the navigation using the labels, sequence $L[1, n]$ is also processed for symbol *rank* and *select* operations, where $rank_c(L, i)$ is the number of occurrences of c in $L[1, i]$ and $select_c(L, j)$ is the position of the jth occurrence of c in L. For example, the following procedure finds all the descendants of node i which are labeled c: (*i*) Find the position $j = rank(P, i)$ of node i in the sequence of labels. (*ii*) Compute $k = rank_c(L, j - 1)$, the number of occurrences of c prior to j. (*iii*) Find the positions $p_r = select_c(L, k + r)$ of c from j onwards, for successive r values until $select(P, p_r) > close(i)$, that is, until the answers are not anymore descendants of i. For example, consider again the first child of the root in Fig. 1, where $i = 2$ and $close(i) = 7$, and find its descendants labeled "D". The first step is to compute $j = rank(P, 2) = 2$, the position of its label in L. Now, $k = rank_{\text{“}D\text{”}}(L, 1) = 0$ tells that there are zero occurrences of "D" before $L[2]$. Now the next occurrences of "D" in L are found as $select_{\text{“}D\text{”}}(L, 1) = 4$, $select_{\text{“}D\text{”}}(L, 2) = 6$, ... The first such occurrence is mapped to the tree node $select(P, 4) = 5$ (the second tree leaf), which is within the subtree of i because $i \leq 5 \leq close(i)$. The second occurrence of "D" is already outside the tree because $select(P, 6) = 9$ exceeds $close(i) = 7$.

Many other powerful navigational operations can be supported, although a more sophisticated parentheses representation and much more technical developments are necessary. A good example can be seen in [4]. Empirical results have been given for the basic preorder parentheses represenation [9].

Integrating Indexing and Compression

In recent work [7,8], by means of introducing a so-called *xbw transform*, indexing and compression are made part of a single integrated process, so that the compressed data represents at the same time the structured text and an index built on it. This is is a very original idea which is likely to have practical impact in the next years.

A brief description of the transform follows. Imagine one takes all the upward paths in the labeled tree. There is one such path per tree node: given a node, its path starts from its parent and finishes in the root. Regard the upward paths as a sequence of labels, and assume for simplicity that labels are atomic symbols that can be sorted. If the tree has n nodes, the resulting n sequences of labels are collected in depth-first order and then stably sorted in lexicographical order. Finally, one forms a sequence with the nodes that originated each of the upward paths, once they are sorted. The *xbw transform* of a labeled tree is the sequence obtained plus a bitmap telling which of those nodes are the last child of their parent.

For example, take the tree of Fig. 1. The upward path from the root is the empty string. The upward path from the three root children are all "*A*", and so on. The list of all the upward paths found in a depth-first traversal is shown in the middle of the figure, and on the right one can see the paths after a stable lexicographical sorting. Now, collecting the nodes that originated those paths in order one gets the labels in the grayed area, S = "*ABCAECCDD*" (the other element is the bitmap marking the last children of their parents, *last* = "100101011"). Sequence S is essentially a permutation of the tree labels. As the sorting is stable, all the nodes originating the same path (e.g., "*A*") stay in depth-first order. In particular, sibling nodes are contiguous.

It turns out that it is possible to compute the *xbw* transform in linear time and space, and moreover to recover the original tree from these two sequences in linear time and space. Furthermore, it is possible to efficiently navigate the tree in *xbw*-transformed form, with operations such as moving to the parent of the current node, ith child, next sibling, ith child labeled X, and so on. Those operations also build on the *rank* and *select* operations described. For example, the third child of the root is represented by the upward path "*AA*". Its position after the *xbw* sorting is $i = 4$, which acts as the identifier for the node in this representation, note $S[4]$ = "*A*" is its label. The process to find its children is as follows: (*i*) Find how many "*A*"s are there before in S, $j = rank_{\text{“}A\text{”}}(S, i-1) = 1$. (*ii*) Find the beginning of the range of the upward paths starting with $S[i]$ = "*A*" in the dashed box, $k = 2$ (this is precomputed in a table storing such value for each different label). (*iii*) Find the number of 1s in *last* before that range, $l = rank(last, k-1) = 1$. (*iv*). Find the area corresponding to the children of i, $select(last, l+j)+1 = 5$ to $select(last, l+j+1) = 6$.

The key operation that makes the *xbw* transform unique compared to other tree representations its its path searching ability: It can identify all the nodes in the tree that descend from a given path sequence in time proportional to the length of the sequence and independent of the collection size (the nodes can then be retrieved one by one). That is, the *xbw*-transformed sequence acts not only as a navigable representation of the tree but also as a powerful index to carry out some path searching operations very efficiently.

Apart from saving all the pointer information, the *xbw*-transformed sequence groups together the node labels that descend from the same paths. Therefore, if root-to-node paths are good predictors of the contents of nodes (this is the property that most sophisticated techniques like *XMLPPM* exploit), the transformed sequence will contain long regions with similar contents. Those are easily compressible by block-wise encoding methods.

In [8] they showed how to apply this conceptual method to real XML data, mixing location path operations with queries on the text content. They present a practical implementation and empirical results showing that it is competitive with the best XML compressors, which do not offer simultaneous indexing capabilities.

Key Applications

Any application managing semi-structured text, particularly if it has to transmit it over slow channels or operate within limited fast memory, even if there is an unlimited supply of slower memory, benefits from these techniques.

Future Directions

Several problems remain open. A fundamental one is the definition of an adequate notion of entropy for semi-structured data, that is, a compressibility limit. While there is reasonable consensus on the entropy of plain text without structure (by taking it as a sequence in general), there is no agreement even on how to measure the entropy of a tree, which is a key part of the entropy of semi-structured text. The fact that this issue is open implies that it is hard to determine how good, in absolute terms, is a compression scheme.

The future of the area is likely to be in manipulating XML in compressed form, and in this aspect the *xbw* transform is a promising direction. Yet, the area is far from offering a competitive and complete path search engine over compressed XML, for example. Similarly, the state of the art in permitting manipulating compressed XML, for example updating a semi-structured text collection, is very preliminary (see [11] for a recent, still theoretical, work on dynamizing the *xbw* transform).

Experimental Results

Experiments can be found in the papers cited. In particular, for the *xbw* transform, see [8].

URL to Code

Several public XML compressors are available, for example

XMill (http://sourceforge.net/projects/xmill), *XMLPPM* (http://sourceforge.net/projects/xmlppm), *SCMPPM* (http://www.infor.uva.es/∼jadiego/download.php), and

XGrind (http://cvs.sourceforge.net/viewcvs.py/xmill/xmill/XGrind).

Mandatory Access Control

Bhavani Thuraisingham
The University of Texas at Dallas, Richardson, TX, USA

Synonyms

Multilevel security

Definition

As stated in [1], "*in computer security, 'mandatory access control (MAC)' refers to a kind of access control defined by the National Computer Security Center's Trusted Computer System Evaluation Criteria (TCSEC) as a means of restricting access to objects based on the sensitivity (as represented by a label) of the information contained in the objects and the formal authorization (i.e., clearance) of subjects to access information of such* *sensitivity.*" With operating systems, the subjects are processes and objects are files. The goal is to ensure that when a subject accesses a file, no unauthorized information is leaked.

Key Point

MAC Models: MAC models were developed initially for secure operating systems mainly in the 1970s and early 1980s, and started with the Bell and La Padula security model. This model has two properties: the simple security property and the *-property (pronounced the star property). The simple security property states that a subject has read access to an object if the subject's security level dominated the level of the object. The *-property states that a subject has write access to an object if the subject's security level is dominated by that of the object [2]. Since then, variations of this model as well as a popular model called the noninterference model [3] have been proposed. The noninterference model is essentially about higher-level processes not interfering with lower level processes. Note that with the Bell and La Padula model, a higher level process can covertly send information to a lower level process by manipulating the file locks, even though there can be no write down due to the star property. The noninterference model prevents such covert communication.

MAC for Database Systems: While Database Management Systems (DBMS) must deal with many of the same security concerns as operating systems (identification and authentication, access control, auditing), there are characteristics of DBMSs that introduce additional security challenges. For example, objects in DBMSs tend to be of varying sizes and can be of fine granularity such as relations, attributes and elements. This contrasts with operating systems where the granularity tends to be coarse such as files or segments. Because of the fine granularity in database systems the objects on which MAC is performed may differ. In operating systems MAC is usually performed on the same object such as a file whereas in DBMSs it could be on relations and attributes. The simple security and * property are both applicable for database systems. However many of the database systems have modified, the *-property to read as follows: *A subject has write access to an object if the subject's level is that of the object.* This means a subject can modify relations at its level. Various commercial secure DBMS products have emerged. These products have been evaluated using the Trusted Database Interpretation which interprets the TCSEC for database systems.

MAC for Networks: For applications in defense and intelligence multilevel secure networks are essential. The idea here is for the network protocols such as a TCP/IP (Transmission Control Protocol/Internet Protocol) protocols operate at multiple security levels. The Bell and La Padula model has been extended for networks. Furthermore, the commercial multilevel networks have been evaluated using the Trusted Network Interpretation that interprets the TCSEC for networks.

Mobile ad hoc network databases

Definition

A mobile ad hoc network (MANET) database is a database that is stored in the peers of a MANET. The network is composed by a finite set of mobile peers that communicate with each other via short range wireless protocols, such as IEEE 802.11, Bluetooth, Zigbee, or Ultra Wide Band (UWB). These protocols provide broadband (typically tens of Mbps) but short-range (typically 10–100 m) wireless communication. On each mobile peer there is a local database that stores and manages a collection of data items, or reports. A report is a set of values sensed or entered by the user at a particular time, or otherwise obtained by a mobile peer. Often a report describes a physical resource such as an available parking slot. All the local databases maintained by the mobile peers form the

MANET database. The peers communicate reports and queries to neighbors directly, and the reports and queries propagate by transitive multi-hop transmissions. Figure 1 below illustrates the definition.

MANET databases enable matchmaking or resource discovery services in many application domains, including social networks, transportation, mobile electronic commerce, emergency response, and homeland security.

Communication is often restricted by bandwidth and power constraints on the mobile peers. Furthermore, reports need to be stored and later forwarded, thus memory constraints on the mobile devices constitute a problem as well. Thus, careful and efficient utilization of scarce peer resources (specifically bandwidth, power, and memory) are an important challenge for MANET databases.

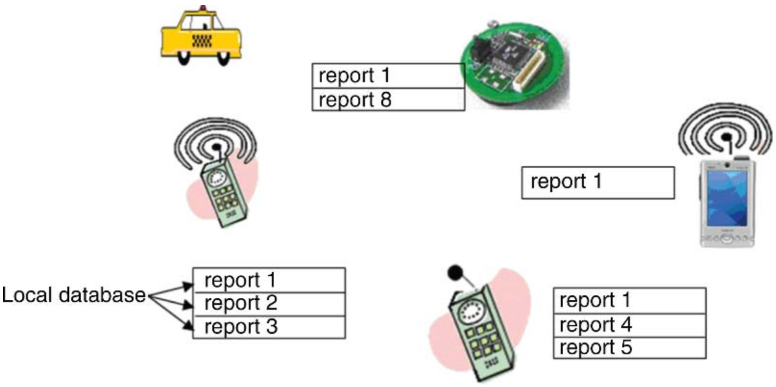
Historical Background

Consider mobile users that search for local resources. Assuming that the information about the existence and location of such a resource resides on a server, a communication infrastructure is necessary to access the server. Such an infrastructure may not be available in military/combat situations, disaster recovery, in a commercial flight, etc. Even if the infrastructure and a server are both available, a user may not be willing to pay the dollar-cost that is usually involved in accessing the server through the cellular infrastructure. Furthermore, cellular bandwidth is limited (e.g., 130 character text messages). In other words, a client-server approach may have accessibility problems.

Currently, Google and local.com provide static local information (e.g., the location of a restaurant, pharmacy, etc.), but not dynamic information such as the location of a taxi cab, a nearby person of interest, or an available parking slot. These dynamic resources are temporary in nature, and thus require timely, real-time update rates. Such rates are unlikely to be provided for the country or the world by a centralized server farm, e.g., Google. Thus, dynamic local resources may require local servers, each dedicated to a limited geographic area. However, for many areas such a local server may not exist due to lack of a profitable business model, and if it exists it may be unavailable (such servers are unlikely to have the reliability of global sites such as Google). Furthermore, the data on the server may be unavailable due to propagation delays (think of sudden-brake information that needs to be propagated to a server and from there to the trailing vehicles), or due to device limitations (e.g., a cab customer's cell-phone may have Bluetooth but not internet access to update the server), or due to the fact that updates from mobile devices may involve a communication cost that nobody is willing to pay, or due to the fact that the local server (e.g., of Starbucks) may accept only updates from certain users or certain applications but not others. In short, a client-(local)-server may have both accessibility and availability problems.

Thus, a MANET database can substitute or augment the client-(local)-server approach. Communication in the MANET is free since it uses the unlicensed spectrum, and larger in bandwidth than the cellular infrastructure, thus can provide media rich information, such as maps, menus, and even video. A mobile user may search the MANET database only, or combine it with a client-server search.

Currently, there are quite a few experimental projects in MANET databases. These can be roughly classified into pedestrians and vehicular projects. Vehicular



MANET Databases. Figure 1. A MANET database.

projects deal with high mobility and high communication topology change-rates, whereas pedestrians projects have a strong concern with power issues. The following are several active experimental MANET database projects for pedestrians and vehicles:

Pedestrians Projects

- *7DS* – Columbia University
  - http://www.cs.unc.edu/~maria/7ds/
  - Focuses on accessing web pages in environments where only some peers have access to the fixed infrastructure.
- *iClouds* – Darmstadt University
  - http://iclouds.tk.informatik.tu-darmstadt.de/
  - Focuses on the provision of incentives to brokers (intermediaries) to participate in MANET databases.
- *MoGATU* – University of Maryland, Baltimore County
  - http://mogatu.umbc.edu/
  - Focuses on the processing of complex data management operations, such as joins, in a collaborative fashion.
- *PeopleNet* – National University of Singapore
  - http://www.ece.nus.edu.sg/research/projects/abstract.asp?Prj=101
  - Proposes the concept of information Bazaars, each of which specializes in a particular type of information; reports and queries are propagated to the appropriate bazaar by the fixed infrastructure.
- *MoB* – University of Wisconsin and Cambridge University
  - http://www.cs.wisc.edu/~suman/projects/agora/
  - Focuses on incentives and the sharing among peers of virtual information resources such as bandwidth.
- *Mobi-Dik* – University of Illinois at Chicago
  - http://www.cs.uic.edu/~wolfson/html/p2p.html
  - Focuses on information representing physical resources, and proposes stateless algorithms for query processing, with particular concerns for power, bandwidth, and memory constraints.

Vehicular Projects

- *CarTALK 2000* – A European project
  - http://www.cartalk2000.net/
  - Develops a co-operative driver assistance system based upon inter-vehicle communication and MANET databases via self-organizing vehicular ad hoc networks.
- *FleetNet* – Internet on the Road Project
  - http://www.ccrle.nec.de/Projects/fleetnet.htm
  - Develops a wireless multi-hop ad hoc network for intervehicle communication to improve the driver’s and passenger’s safety and comfort. A data dissemination method called “contention-based forwarding” (CBF) is proposed in which the next hop in the forwarding process is selected through a distributed contention mechanism based on the current positions of neighbors.
- *VII* – Vehicle Infrastructure Integration, a US DOT project
  - http://www.its.dot.gov/vii/
  - The objective of the project is to deploy advanced vehicle-to-vehicle and vehicle-to-infrastructure communications that could keep vehicles from leaving the road and enhance their safe movement through intersections.
- *Grassroots, Trafficview* – Rutgers University

TrafficInfo – University of Illinois at Chicago

- http://paul.rutgers.edu/~gsamir/dataspace/grassroots.html
- http://discolab.rutgers.edu/traffic/veh_apps.htm
- http://cts.cs.uic.edu/
- These projects develop an environment in which each vehicle contributes a small piece of traffic information (its current speed and location) to the network, using the P2P paradigm, and each vehicle aggregates the pieces into a useful picture of the local traffic.

Foundations

There are two main paradigms for answering queries in MANET databases, one is report pulling and the other one is report pushing.

Report pulling means that a mobile peer issues a query which is flooded in the whole network, and the answer-reports will be pulled from the mobile peers that have them (see e.g., [2]). Report pulling is widely used in resource discovery, such as route discovery in mobile ad hoc networks and file discovery by query flooding in wired P2P networks like Gnutella. Flooding in a wireless network is in fact relatively efficient as compared to wired networks because of the wireless broadcast advantage, but there are also disadvantages which will be explained below.

Another possible approach for data dissemination is report pushing. Report pushing is the dual problem of report pulling; reports are flooded, and consumed by peers whose query is answered by received reports. So far there exist mechanisms to broadcast information in the complete network, or in a specific geographic area (geocast), apart from to any one specific mobile node (unicast/mobile ad hoc routing) or any one arbitrary node (anycast). Report pushing paradigm can be further divided into stateful methods and stateless methods. Most stateful methods are topology-based, i.e., they impose a structure of links in the network, and maintain states of data dissemination. PStree [4], which organizes the peers as a tree, is an example of topology based methods.

Another group of stateful methods is cluster- or hierarchy-based method, such as [14], in which moving peers are grouped into some clusters or hierarchies and the cluster heads are randomly selected. Reports are disseminated through the network in a cluster or hierarchy manner, which means that reports are first disseminated to every cluster head, and each cluster head then broadcasts the reports to the member peers in its group. Although cluster- or hierarchy-based methods can minimize the energy dissipation in moving peers, these methods will fail or cost more energy in highly mobile environments since they have to maintain a hierarchy structure and frequently reselect cluster heads.

Another stateful paradigm consists of location-based methods (see [9]). In location-based methods, each moving peer knows the location of itself and its neighbors through some localization techniques, such as GPS or Atomic Multilateration (see [9]).

The simplest location-based data dissemination is Greedy Forwarding, in which each moving peer transmits a report to a neighbor that is closer to the destination than itself. However, Greedy Forwarding can fail in some cases, such as when a report is stuck in local minima, which means that the report stays in a mobile peer whose neighbors are all further from the destination. Therefore, some recovery strategies are proposed, such as GPSR (Greedy Perimeter Stateless Routing [6]). Other location-based methods, such as GAF (Geographic Adaptive Fidelity [17]) and GEAR (Geographical and Energy Aware Routing [18]), take advantage of knowledge about both location and energy to disseminate information and resources more efficiently.

In stateless methods, the most basic and simplest one is flooding-based method, such as [11]. In flooding-based methods, mobile peers simply propagate received reports to all neighboring mobile peers until the destination or maximum hop is reached. Each report is propagated as soon as it is received. Flooding-based methods have many advantages, such as no state maintenance, no route discovery, and easy deployment. However, they inherently cannot overcome several problems, such as implosion, overlap, and resource blindness. Implosion refers to the waste of resources taking place when a node forwards a message to a neighbor although the latter may have already received it from another source. Overlap occurs when two nodes read the same report, and thus push into the network the same information. Resource blindness denotes the inability of the protocol to adapt the node's behavior to its current availability of resources, mainly power [12]. Therefore, other stateless methods are proposed, such as gossiping-based methods and negotiation-based methods.

Gossiping-based methods, such as [3], improve flooding by transmitting received reports to a subset of randomly selected neighbors; another option is to have some neighbors simply drop the report. For example, the neighbors that are not themselves interested in the report drop it. The advantages of gossiping-based methods include reducing the implosion and lowering the system overhead. However, dissemination, and thus performance, is reduced compared to pure flooding.

Negotiation-based methods solve the implosion and overlap problem by transmitting first the id's of reports; the reports themselves are transmitted only when requested (see [7]). Thus, some extra data transmission is involved, which costs more memory, bandwidth, and energy. In addition, in negotiation-based methods, moving peers have to generate meta-data or a signature for every report so that negotiation can be carried out, which will increase the system overhead and decrease the efficiency.

Another important stateless paradigm for data dissemination in MANET databases is store-and-forward. In contrast to flooding, store-and-forward does not propagate reports as soon as they are received; rather they are stored and rebroadcast later. This obviously introduces storage and bandwidth problems, if too many reports need to be saved and rebroadcast at the same time. To address these, methods such as [5] rank all the reports in a peer's database in terms of their relevance (or expected utility), and then the reports are communicated and saved in the order of their relevance. Or, the reports requested and communicated are the ones with the relevance above a certain threshold. The notion of relevance quantifies the importance or the expected utility of a report to a peer at a particular time and at a particular location. Other store-and-forward methods include PeopleNet [10] and 7DS [13].

In summary, the paradigms for data dissemination in MANET databases are summarized in Fig. 2 below.

Key Applications

MANET databases provide mobile users a search engine for transient and highly dynamic information in a local geospatial environment. MANET databases employ a unified model for both the cellular infrastructure and the mobile ad hoc environments. When the infrastructure is available, it can be augmented by the MANET database approach.

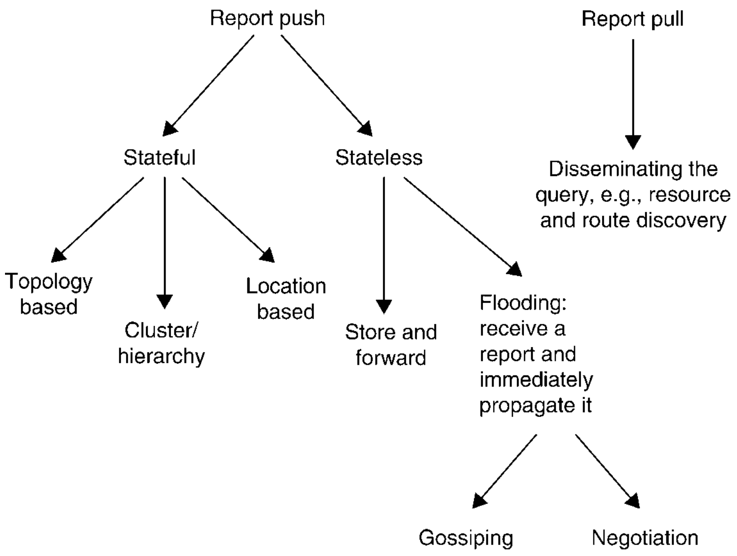
Consider a MANET database platform, i.e., a set of software services for data management in a MANET environment; it is similar to a regular Database Management System, but geared to mobile P2P interactions. Such a platform will enable quick building of matchmaking or resource discovery services in many application domains, including social networks, emergency response and homeland security, the military, airport applications, mobile e-commerce, and transportation.

Social Networks

In a large professional, political, or social gathering, MANET databases are useful to automatically facilitate a face-to-face meeting based on matching profiles. For example, in a professional gathering, MANET databases enable attendees to specify queries (interest profiles) and resource descriptions (expertise) to facilitate face-to-face meetings, when mutual interest is detected. Thus, the individual's profile that is stored in MANET databases will serve as a "wearable web-site." Similarly, MANET databases can facilitate face-to-face meetings for singles matchmaking.

Emergency Response, Homeland Security, and the Military

MANET databases offer the capability to extend decision-making and coordination capability. Consider workers in disaster areas, soldiers and military personnel operating in environments where the wireless fixed infrastructure is significantly degraded or non-existent. As mobile users involved in an emergency response naturally cluster around the location of interest, a self-forming, high-bandwidth network that allows database search without the need of potentially



MANET Databases. Figure 2. Query answering methods in MANET databases.

compromised infrastructure could be of great benefit. For instance, the search could specify a picture of a wanted person.

Airport Applications

A potential opportunity that will benefit both the consumer and the airport operations is the dissemination and querying of real-time information regarding flight changes, delays, queue length, parking information, special security alerts and procedures, and baggage information. This can augment the present audio announcements that often cannot be heard in nearby restaurants, stores, or restrooms, and augment the limited number of displays.

Mobile E-commerce

Consider short-range wireless broadcast and mobile P2P dissemination of a merchant's sale and inventory information. It will enable a customer (whose cell phone is query-capable) who enters a mall to locate a desired product at the best price. When a significant percentage of people have mobile devices that can query retail data, merchants will be motivated to provide inventory/sale/coupons information electronically to nearby potential customers. The information will be disseminated and queried in a P2P fashion (in, say, a mall or airport) by the MANET database.

Transportation Safety and Efficiency

MANET databases can improve safety and mobility by enabling travelers to cooperate intelligently and automatically. A vehicle will be able to automatically and transitively communicate to trailing vehicles its "slow speed" message when it encounters an accident, congestion, or dangerous road surface conditions. This will allow other drivers to make decisions such as finding alternative roads. Also, early warning messages may allow a following vehicle to anticipate sudden braking, or a malfunctioning brake light, and thus prevent pile-ups in some situations. Similarly, other resource information, such as ridesharing opportunities, transfer protection (transfer bus requested to wait for passengers), will be propagated transitively, improving the efficiency of the transportation system.

Future Directions

Further work is necessary on data models for mobile P2P search applications. Work on sensor databases (e.g., Tinydb [8]) addresses data-models and languages for sensors, but considers query processing in an environment of static peers (see e.g., POS [1]). Cartel [5] addresses the translation of these abstractions to an environment in which cars transfer collected data to a central database via fixed access points. Work on MANET protocols deals mainly with routing and multicasting. In this landscape there is a gap, namely general query-processing in MANET's; such processing needs to be cognizant of many issues related to peer-mobility. For example, existing mobile P2P query processing methods deal with simple queries, e.g., selections; each query is satisfied by one or more reports. However, in many application classes one may be interested in more sophisticated queries, e.g., aggregation. For instance, in mobile electronic commerce a user may be interested in the minimum gas price within the next 30 miles on the highway. Processing of such P2P queries may present interesting optimization opportunities.

After information about a mobile resource is found, localization is often critical for finding the physical resource. However, existing (self)-localization techniques are insufficient. For example, GPS is not available indoors and the accuracy of GPS is not reliable. Thus, furthering the state of the art on localization is important for mobile P2P search.

As discussed above, MANET databases do not guarantee answer completeness. In this sense, the integration with an available infrastructure such as the internet or a cellular network may improve performance significantly. This integration has two aspects. First, using the communication infrastructure in order to process queries more efficiently; and second, using data on the fixed network in order to provide better and more answers to a query. The seamless integration of MANET databases and infrastructure databases introduces important research challenges.

Other important research directions include: incentives for broker participation in query processing (see [16]), and transactions/atomicity/recovery issues in databases distributed over mobile peers (virtual currency must be transferred from one peer to another in an atomic fashion, otherwise may be lost).

Of course, work on efficient resource utilization in mobile peers, and coping with sparse networks and dynamic topologies is still very important for mobile P2P search.

[2]Twitter, Inc., San Fransisco, CA, USA
[3]Georgetown University, Washington, DC, USA

Synonyms

Mean average precision

Definition

The Mean Average Precision (MAP) is the arithmetic mean of the average precision values for an information retrieval system over a set of *n* query topics. It can be expressed as follows:

$$MAP = \frac{1}{n}\sum_{n} AP_n$$

where *AP* represents the Average Precision value for a given topic from the evaluation set of *n* topics.

Key Points

The Mean Average Precision evaluation metric has long been used as the de facto "gold standard" for information retrieval system evaluation at the NIST Text Retrieval Conference (TREC) [1]. Many TREC tracks over the years have evaluated run submissions using the *trec_eval* program, which calculates Mean Average Precision, along with several other evaluation metrics. Much of the published research in the information retrieval field over the last 25 years relies on observed difference in MAP to draw conclusions about the effectiveness of a studied technique or system relative to a baseline.

Recently, the explosive growth of the World Wide Web and the corresponding difficulty of creating test collections that are representative, robust, and of appropriate scale has created new challenges for the research community. One such challenge is how to best evaluate systems in cases of incomplete relevance information. It has been shown that ranking systems by their MAP scores when relevance information is incomplete does not correlate highly with their rankings with complete judgments. This is a key weakness of MAP as a metric. In response to this problem, new metrics (such as BPref, for example) have been proposed that attempt to compensate for often incomplete relevance information [2].

Map Matching

Christian S. Jensen, Nerius Tradišauskas
[1]Aalborg University, Aalborg, Denmark

Synonyms

Position snapping

Definition

Map matching denotes a procedure that assigns geographical objects to locations on a digital map. The most typical geographical objects are point positions obtained from a positioning system, often a GPS receiver. In typical uses, the GPS positions derive from a receiver located in a vehicle or other moving object traveling in a road network, and the digital map models the embedding into geographical space of the roads by means of polylines that approximate the center lines of the roads. The GPS positions generally do not intersect with the polylines, due to inaccuracies. The aim of map matching is then to place the GPS positions at their "right" locations on the polylines in the map.

Map matching is useful for a number of purposes. Map matching is used when a navigation system displays the vehicle's location on a map. In many applications, information such as speed limits are assigned to the representations of roads in a digital map–map matching offers a means of relating such information to moving objects. Map matching may also be used for the representation of a route of a vehicle by means of the (sub-) polylines in the digital map.

Two general types of map matching exist, namely on-line map matching and off-line map matching. With on-line map matching, the map location of an object's current position needs to be determined in real time. Only past, but not future, positions are available. Vehicle navigation systems exemplify this type of map matching. In off-line map matching, a static data set of positions is given, meaning that all future positions are available when map matching a position. Thus better map matching may result when compared to on-line map matching. For example, off-line map matching may be used for billing in pay-per-use scenarios (insurance, road pricing).

Historical Background

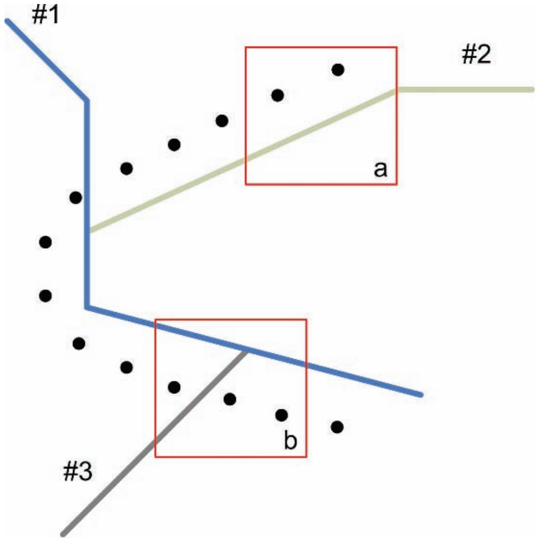
One of the earliest map matching algorithms found in the literature dates back to 1971 and is due to R.L.

French (see the overview in reference [1]). A 1996 paper by Berstein and Kornhauser [2] offers a brief introduction to the map matching problem and its variations.

The scientific literature contains a range of papers that address different aspects of the map matching problem. White et al. [3] study techniques that pay special attention to intersection areas, where map matching can be particularly challenging. Taylor et al. [4] propose a map matching technique that uses differential corrections and height, which leads to improved performance. Quddus et al. [5] provide a summary of different on-line and off-line map matching algorithms and describe advantages and disadvantages of these. Quddus et al. [6] have most recently proposed a map matching algorithm that utilizes techniques from fuzzy logic. This technique shows improved accuracy of polyline identification and the positioning on polylines. A complex off-line map matching algorithm was recently developed by Bratkatsoulas et al. [7] that uses the Fréchet distance to map match GPS position samples recorded only every 30 seconds. (While GPS receivers typically output a position every second, it may be that only some of these are saved for use in subsequent off-line map matching).

Foundations

Basics. The most common use of map matching occurs in transportation where the GPS positions obtained from a GPS receiver in a vehicle are map matched to a digital representation of a road network. An example of GPS positions from a vehicle (dots) and a digital road network are shown in Fig. 1. The vehicle's trip started on road #2 and continued along road #1. In Fig. 2a the start of the trip is enlarged. The dots represent the vehicle's GPS locations, and the triangles represent the corresponding positions map matched onto the road network. The road network locations are typically expressed by using linear referencing, which is a standard means of indicating such locations. With linear referencing, a tuple (#2,5.2,+1) captures the road that the vehicle is driving on (#2), a position on that road measured as a distance from the beginning of the road (5.2 distance units). The third element captures a perpendicular distance from the road location given by the first two elements. In the tuple, the displacement is one distance unit to the left. Because a GPS position is typically mapped to the closest location in the road digital network (i.e., a perpendicular projection is used), the third element is capable of capturing the GPS position that was map matched to the road network location. Linear referencing is supported by, e.g., the Oracle DBMS [6].



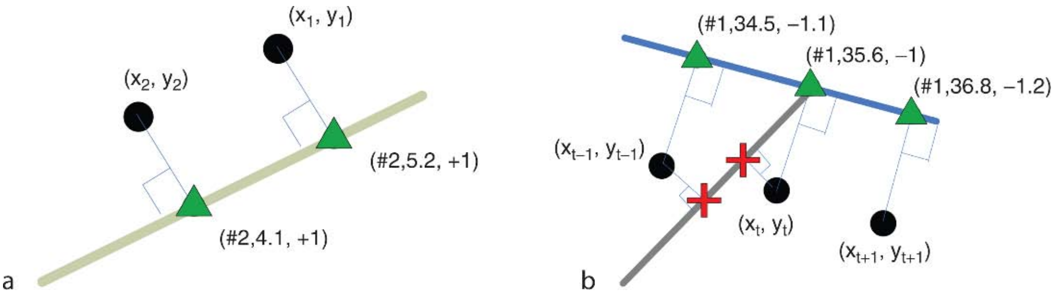
Map Matching. Figure 1. Map and vehicle location example.

In Fig. 2b, a place where map matching is challenging is enlarged. The crosses represent two instance of wrong map matching to the nearest road, and the triangles represent the correct map matching.

Categorization of Map Matching Algorithms. Map matching can be divided into on-line and off-line map matching. On-line map matching occurs in real-time. Here, the map matching algorithm tries to identify the network location of a GPS position every time a new position is received. The algorithm has available the current position as well as information about the map matching of previous positions.

This contrasts off-line map matching, which occurs after a trip is over and all the positions from the start to the end are known. Off-line map matching is more accurate than on-line map matching, as more information (i.e., future positions) is available. An off-line algorithm does not provide a map matching result until the entire trip has been map matched.

On-line map matching is mostly used in vehicle navigation, tracking, and other applications that need the most recent network location of a vehicle. Off-line map matching is mostly used to determine as accurately as possible which route a vehicle was driving. Off-line map matching may also be used in scenarios where



Map Matching. Figure 2. Map matching example.

GPS data are received in batches from content providers and where the purpose is to build speed maps that capture the expected travel speeds for different road segments and time intervals. Network locations of vehicles are essential in road load analysis, road pricing, and similar applications.

Map matching algorithms can also be divided into point-to-point, point-to-polyline, and polyline-to-polyline approaches. In point-to-point map matching, a point out of a point set is identified as a match for the given position. In point-to-polyline matching, a polyline in a polyline set is identified, and a point on the polyline is identified that represents the given point as a polyline-set location. In the typical scenario, the polyline set represents a road network, and the position is a GPS position. Finally, in polyline-to-polyline map matching, polylines are identified from the polylines in a road network that best match a given polyline that is usually constructed from point positions.

Map Matching Principles. This section follows the explanation of the basic principles of map matching by considering in some detail the commonly used point-to-polyline map matching for the on-line case.

Map matching algorithms often consist of two overall steps (some algorithms skip the first of these two steps or include an extra step).

In the start-up step, the polyline in the digital road network on which the vehicle is initially located is found. Specifically, map matching is done for the first GPS position received. The correct outcome of this step is very important, as the map matching algorithms use the connections between roads, or the road network topology, to determine the ensuing polylines of the vehicle's movement path. Therefore, algorithms often perform special operations to determine a reliable match for the first GPS position.

In the steady-state step, the subsequent polylines in the digital road network are identified to form the route along which the vehicle is moving. This subsequent map matching follows a standard pattern:

1. Extract the relevant information from the record received from the GPS receiver.
2. Select candidate polylines from the digital road network.
3. Use algorithm-specific heuristics to determine the most suitable polyline among the candidate polylines.
4. Determine the vehicle position on the selected polyline.

First, information such as latitude, longitude, speed, and heading is extracted from the record obtained from the positioning unit and is converted into an appropriate format (a unified coordinate and metric system consistent with the digital road network).

Second, the candidate polylines are selected. Usually the polylines that are within a certain threshold distance of the GPS position are selected. An alternative approach is to select the *n* polylines nearest to the GPS position. The polylines found make up the candidate polyline set.

Third, specific heuristics are used to select the best polyline among the candidates. A common approach is to assign weights to the candidate polylines according to different criteria. The polyline with the highest sum of weights is then chosen. Some algorithms reduce the set of candidate polylines prior to assigning weights. For example, polylines that are perpendicular to the vehicle's heading may be disregarded, as may polylines that are not connected with the polyline currently being considered.

Fourth, the vehicle position on the selected polyline is found. The usual approach is to select the location on the polyline that is closest to the vehicle's position. This is a point-to-polyline projection. The projection of the position may be an end point of a line segment in the polyline, or it may be in the interior of a line segment. Quddus et al. [5] propose a more sophisticated approach that uses both the distance traveled since the last map matching and the "raw" projection of the GPS position onto the polyline.

Dead Reckoning. In certain regions, the signals emitted by the GPS satellites may be very weak due to obstacles. This in turn degrades the accuracies of the positions produced by GPS receivers in those regions, and in some cases no GPS position may be produced. In such cases, both on-line and off-line map matching algorithms may utilize dead reckoning to estimate the movement of a vehicle in the road network. The use of dead reckoning is particularly attractive when the average speed of the vehicle is known (preferably every second) and when the road on which the vehicle is driving neither splits nor has intersections. This occurs when the road is inside a tunnel with no exits.

Heuristics for the Selection of a Polyline. Different algorithms use different heuristics and weights when attempting to identify the best polyline among the candidate polylines. Each candidate polyline is assigned a weight for each criterion considered, and the polyline with the highest sum of weights is then selected. Common weighting criteria include the following:

- Weight for the proximity of a polyline. A polyline is assigned a weight according to its proximity to the GPS position being map matched. It is natural to assume that the closer a polyline is to the position, the better a candidate the polyline is.
- Weight for the continuity of a polyline. This weight is assigned to each polyline for being a continuation of the previously map matched polyline. This weight represents the reasoning that vehicles tend to drive on the same road most of the time.
- Weight for direction similarity. Polylines whose bearing is similar to the vehicle's heading are assigned higher values.
- Weight for topology. Higher weights are added to polylines that are connected to the polyline currently being map matched to.

Algorithms may also include weights for speed limit changes, shortest distance, road category, one-way streets, etc. Off-line map matching algorithms may use fewer, but more robust weights that are not suitable for the on-line map matching algorithms.

Execution Time Constraints and Accuracy. In on-line map matching, the algorithms must keep up with the GPS device that usually emits one position per second. With current on-board computing units, it is usually not a problem for on-line map matching algorithms map match a GPS position within 1 second. For off-line map matching, there are no real-time constraints.

Key Applications

Map matching is essential for applications that rely on the positioning of a user within a road network.

This occurs in vehicle navigation where the user's position is to be displayed so that it coincides with the road network. When GPS data is used for the construction of speed maps, map matching is used. Such speed maps may be used for travel time prediction, route construction, and capacity planning. In metered services such as insurance and road pricing, map matching is also used.

Further, map matching is used in location-based services where the content to be retrieved is positioned within the road network. Services that offer network-context awareness utilize map matching. These including current network location context awareness [9], and route context awareness [10].

Tracking also plays a key role in intelligent speed adaptation [11] where drivers are alerted when they exceed the current speed limit. The speed limits are attached to the digital road network, so map matching is needed to identify the current speed limit. Finally, map matching is important for a range of other application within intelligent transportation systems.

Future Directions

In the near future, digital road networks will have accurate lane information embedded, and positioning technologies will be accurate enough to enable lane-level positioning. This will necessitate the extension of map matching techniques to function at the lane level.

Markup Language

ETHAN V. MUNSON
University of Wisconsin-Milwaukee, Milwaukee, WI, USA

Definition

A markup language is specification language that annotates content through the insertion of *marks* into the content itself. Markup languages differ from programming languages in that they treat data, rather than commands or declarations, as the primary element in the language.

Key Points

Markup languages were initially developed for text document formatting systems, though they are not limited to text. In fact, the term *markup* was taken directly from the jargon of the publishing business, where editors and typographers would "mark up" draft documents to indicate corrections or printing effects. Markup languages are generally quite declarative and have little, if any, computational semantics. The marks inserted into the content are often called "tags" because that term is used by XML.

MashUp

ALEX WUN
University of Toronto, Toronto, ON, Canada

Definition

A MashUp is a web application that combines data from multiple sources, creating a new hybrid web application with functionality unavailable in the original individual applications that sourced the data.

Key Points

An emerging trend in web applications is to provide public APIs for accessing data that has traditionally been used only internally by those applications. The main purpose of providing access to traditionally private web application data is to encourage user-driven development. In other words, consumers are expected to take that public data and build custom applications for other consumers – thereby adding value to the original data sources. MashUps are web applications that take advantage of these publicly accessible data sources by correlating the data obtained from different sources and deriving some novel functionality. A simple and common example is correlating a data source that has location information (such as wireless hotspot locations) with cartographic data (from Google or Yahoo maps for example) to produce a graphical map of wireless hotspots.

MashUps are conceptually related to portals, which also collect data from multiple sources for presentation. However, portals perform server-side aggregation whereas MashUps can also perform this aggregation on the client-side (i.e., correlation can occur in the scripts of a web page). Additionally, portals present data collected from disparate sources together but without interaction between data sets. In contrast, MashUps focus heavily on merging disparate data sets into one unified representation. For example, a news portal would simply present a set of interesting articles gathered from various sources on a single page while a news MashUp would correlate textual news with related images and multimedia as well as automatically linking related articles in a single view.

While similar to MashUps, service composition is a more generic concept that focuses on orchestrating web service calls as part of some higher level application logic. The coordination of web service calls in a service composition are often more process-centric rather than data-centric. For example, a flight-booking composite service would query the flight reservation services of different airlines to book a flight based on customer requirements, while a flight-booking MashUp would gather flight data from various airlines and present the data to customers in a single unified view – likely correlated with other useful data such as weather.

There is currently no standardization of technologies or tools used to develop MashUps. In fact, many industry leaders such as Google, Microsoft, and Yahoo are pushing their own MashUp development tools. In particular, many of these tools are targeting non-programmers in hopes of expanding the base of users capable of contributing to and developing MashUps.

Massive Array of Idle Disks

Kazuo Goda
The University of Tokyo, Tokyo, Japan

Synonyms

MAID

Definition

The term Massive Array of Idle Disks refers to an energy-efficient disk array which has the capability of changing its disk drives into a low-power mode when the disk drives are not busy. Disk drives of the array may be controlled individually or in a group. The term Massive Array of Idle Disks is often abbreviated to MAID. A MAID disk array may have additional functions such as data migration/replication and access prediction to improve the energy saving.

Key Points

The basic idea of MAID is to save energy by exploiting storage access locality. That is, some disk drives which are installed in a disk array are frequently accessed whereas the others are rarely busy. MAID tries to spin down or power off such "low-temperature" disk drives to decrease the total energy consumption. The original papers [1,2] which introduced MAID in 2002 studied different design choices and configurations. MAID disk arrays are mainly used for archival storage (replacing conventional tape libraries) or near-line storage (which falls between online storage and archival storage).

Matrix Masking

Stephen E. Fienberg, Jiashun Jin
Carnegie Mellon University, Pittsburgh, PA, USA

Synonyms

Adding noise; Data perturbation; Recodings; Sampling; Synthetic data

Definition

Matrix Masking refers to a class of statistical disclosure limitation (SDL) methods used to protect confidentiality of statistical data, transforming an $n \times p$ (cases by variables) data matrix Z through pre- and post-multiplication and the possible addition of noise.

Key Points

Duncan and Pearson [3] and many others subsequently categorize the methodology used for SDL in terms of transformations of an $n \times p$ (cases by variables) data matrix Z of the form

$$Z \rightarrow AZB + C, \qquad (1)$$

where A is a matrix that operates on the n cases, B is a matrix that operates on the p variables, and C is a matrix that adds perturbations or noise.

Matrix masking includes a wide variety of standard approaches to SDL: (i) adding noise, i.e., the C in matrix masking transformation of equation [1]; (ii) releasing a subset of observations (delete rows from Z), i.e., sampling; (iii) cell suppression for cross-classifications; (iv) including simulated data (add rows to Z); (v) releasing a subset of variables (delete columns from Z); (vi) switching selected column values for pairs of rows (data swapping). Even when one has applied a mask to a data set, the possibilities of both identity and attribute disclosure remain, although the risks may be substantially diminished.

Maximal itemset mining

Definition

Let $I = \{i_1, i_2 ..., i_n\}$ be a set of items and $D = \{t_1, t_2 ..., t_N\}$ be a transaction database, where $t_i (i \in [1,N])$ is a transaction and $t_i \subseteq I$. Every subset of I is called an *itemset*. If an itemset contains k items, then it is called a k-itemset. The support of an itemset X in D is defined as the percentage of transactions in D containing X, that is, $sup(X) = |\{t|t \in D \wedge X \subseteq t\}|/|D|$. If the support of an itemset exceeds a user-specified minimum support threshold, then the itemset is called a *frequent itemset* or a *frequent pattern*. If an itemset is frequent but none of its supersets is frequent, then the itemset is called a *maximal pattern*. The task of maximal pattern mining is given a minimum support threshold, to enumerate all the maximal patterns from a given transaction database.

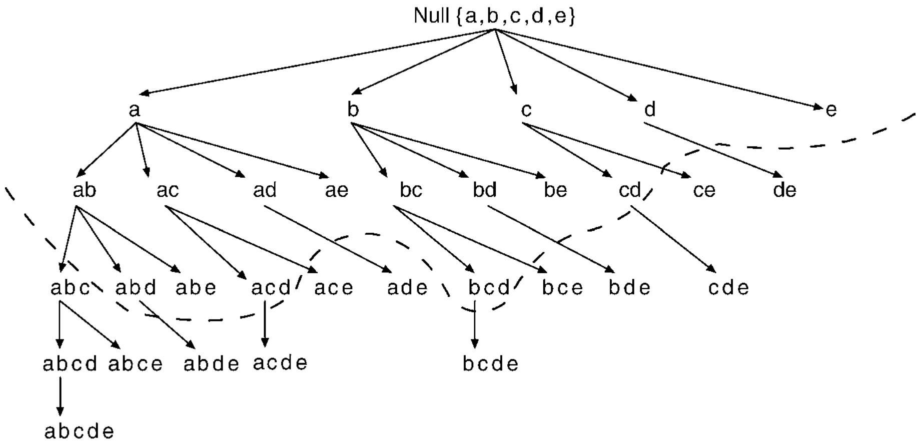
The concept of maximal patterns can be and has already been extended to more complex patterns, such as sequential patterns, frequent subtrees and frequent subgraphs. For each type of pattern, a pattern is maximal if it satisfies the given constraints but none of its super-patterns satisfies the given constraints.

Historical Background

If a k-itemset is frequent, then all of its subsets are frequent and the number of them is $2^k - 1$. Datasets collected from some domains can be very dense and contain very long patterns. Any algorithm which produces the complete set of frequent itemsets suffers from generating numerous short patterns on these datasets, and most of the short patterns may be useless. Some researchers have noticed the long pattern problem and suggested mining only maximal frequent patterns [1,3,8]. The set of maximal patterns provides a concise view of the frequent patterns, and it can be orders of magnitude smaller than the complete set of frequent patterns. The complete set of frequent patterns can be derived from the set of maximal patterns, but the support information is lost.

A different concept called *closed itemset* or closed pattern has also been proposed to reduce result size. A pattern is closed if none of its supersets has the same support as it does. Closed patterns retain the support information of frequent patterns. The complete set of frequent patterns can be derived from the set of frequent closed patterns without information loss. A maximal pattern must be a closed pattern, but not vice versa.

Given a set of items I, the search space of the *frequent itemset* mining problem is the power set of I, and it can be represented as a set-enumeration tree given a specific order of I [9]. Figure 1 shows the search space tree for $I = \{a, b, c, d, e\}$, and the items are sorted lexicographically. Every node in the search space tree represents an itemset. For every itemset X in the tree, only the items after the last item of X can be appended to X to form a longer itemset. These items are called *candidate extensions* of X, denoted as $cand\_ext(X)$. For example, items d and e are candidate extensions of ac, while item b is not a candidate extension of ac because b is before c in lexicographic order. Mining maximal patterns can be viewed as finding a border through the search space tree such that all the nodes below the border are infrequent and all the nodes above the border are frequent. As shown in Fig. 1, the dotted line represents the border. All the nodes above the dotted line are frequent and all the nodes below the dotted line are infrequent. Among all the nodes above the border, only leaf nodes can be maximal, but not all the leaf nodes are maximal; every internal node has at least one frequent child (superset) thus cannot be maximal. The goal of maximal pattern mining is to find the border by counting support for as less as



Max-Pattern Mining. Figure 1. Search space tree for $I = \{a, b, c, d, e\}$.

possible itemsets. Most, if not all, existing maximal pattern mining algorithms try to find some frequent long patterns first, and then use these long patterns to prune non-maximal patterns.

The first attempt at mining maximal patterns is made by Gunopoulos et al. [6], and an algorithm called *dualize and advance* is proposed. The algorithm is based on the observation that given a set of maximal patterns, any other maximal pattern not in the set must contain at least one common item with the complement of every maximal pattern in the set, where the complement of an itemset X is defined as $I - X$. The algorithm works as follows. It first uses a greedy search to generate some maximal patterns, denoted as $\mathcal{H}$, and then finds the minimal patterns that contain at least one common item with the complement of every maximal pattern in $\mathcal{H}$. Here a pattern is minimal if none of its subsets satisfies the condition. These minimal patterns are called minimal transversals of $\mathcal{H}$. If all the minimal transversals of H are infrequent, it means that all the maximal patterns are all in $\mathcal{H}$ already. Otherwise, there exists some minimal transversal X of $\mathcal{H}$ such that X is frequent, the algorithm then finds a maximal superset of X, denoted as Y, and Y must be a maximal pattern. The algorithm puts Y in $\mathcal{H}$, and then generates the minimal transversals of the updated $\mathcal{H}$. This process is repeated until no frequent minimal transversals of $\mathcal{H}$ exists. The upper bound for the time complexity of this algorithm is sub-exponential to the output size.

Pincer-search [7] combines the bottom-up and top-down search strategy, and approaches the border from both directions. The bottom-up search is similar to the A priori algorithm [2], and the top-down search is implemented by maintaining a set called maximum-frequent-candidate-set (MFCS). MFCS is a minimum cardinality set of itemsets such that the union of all the subsets of its elements contains all the frequent itemsets that have been discovered so far but does not contain any itemsets that have been determined to be infrequent. Pincer-search uses MFCS to prune those candidate itemsets that have a frequent superset in MFCS to reduce the database scan times and the support counting cost.

Both the dualize and advance algorithm and the Pincer-search algorithm maintain the set of candidate maximal patterns during the mining process and use them to prune short non-maximal patterns. The main difference between the two algorithms is that Pincer-Search considers large sets that may be frequent first, and then shrinks them to find the real maximal patterns, while the dualize and advance algorithm starts from some seed maximal patterns and uses them to find other maximal patterns. Both algorithms can prune non-maximal patterns effectively, but maintaining and manipulating the set of candidate maximal patterns can be very costly.

Zaki et al. propose two maximal pattern mining algorithms MaxClique and MaxEclat [13]. Both algorithms rely on a preprocessing step to cluster itemsets, and then use a hybrid bottom-up and top-down approach to find maximal patterns from each cluster with a vertical data representation. The two algorithms differ in how the itemsets are clustered. The purpose of the clustering step is to find some potential maximal patterns, and the two algorithms use these potential maximal patterns to restrict the search space. However, the cost of the clustering step can be very high.

Max-Miner [3] is the first successful and practical algorithm for mining maximal patterns. It uses the bottom-up search strategy to traverse the search space as the A priori algorithm [2], but it always attempts to look ahead in order to quickly identify long patterns. By identifying a long pattern first, Max-Miner can prune all its subsets from consideration. Two pruning techniques are proposed in the Max-Miner algorithm: pruning based on superset frequency and the dynamic reordering technique. These two pruning techniques are very effective in removing non-maximal patterns, and have been adopted by all later maximal pattern mining algorithms.

1. *Superset frequency pruning*. This technique is also called the lookahead technique. It is based on the observation that the itemsets in the sub search space tree rooted at X are subsets of $X \cup cand\_ext(X)$. Therefore, if $X \cup cand\_ext(X)$ is frequent, then none of the itemsets in the subtree rooted at X can be maximal and the whole branch can be pruned. There are two ways to check whether $X \cup cand\_ext(X)$ is frequent. One way is to check whether $X \cup cand\_ext(X)$ is a subset of some maximal pattern that has already been discovered. The other way is to look at the support of $X \cup cand\_ext(X)$ in the database, which can be done when counting the support of X's immediate supersets.
2. *Dynamic item reordering*. At every node X, Max-Miner sorts the items in $cand\_ext(X)$ in ascending frequency order. The candidate extensions of an item include all the items that are after it in the ascending frequency order. Let i_1 and i_2 be two items in $cand\_ext(X)$. Item i_1 is before i_2 in the ordering if $sup(X \cup \{i_1\})$ is smaller than $sup(X \cup \{i_2\})$, and item i_2 is a candidate extension of $X \cup \{i_1\}$. The motivation behind dynamic item reordering is to increase the effectiveness of the superset frequency pruning technique. The superset frequency pruning can be applied when $X \cup cand\_ext(X)$ is frequent. It is therefore desirable to make many Xs satisfy this condition. A good heuristic for accomplishing this is to force the most frequent items to be the candidate extensions of all other items because items with high frequency are more likely to be part of long frequent itemsets.

Besides the above two pruning techniques, Max-Miner also uses a technique that can often determine when a new candidate itemset is frequent before accessing the database. The idea is to use information gathered during previous database passes to compute a good lower-bound on the number of transactions that contain the itemset.

The Max-Miner algorithm uses the breadth-first search order to explore the search space, which makes it not very efficient on dense datasets. DepthProject [1], MAFIA [4], GenMax [5] and AFOPT-Max [8] use the depth-first search strategy to traverse the search space. The depth-first search strategy is capable of finding long patterns first, which makes the superset frequency pruning technique more effective. These algorithms differ mainly in their support counting technique. Both DepthProject and MAFIA assume that the dataset fits in the main memory. At any point in the search, DepthProject maintains the projected transaction sets for some of the nodes on the path from the root to the node currently being processed, where a projected transaction of a node contains only the candidate extensions of the node. It is possible that a projected transaction is empty, in this case, the projected transaction is discarded. Since the projected database is substantially smaller than the original database both in terms of the number of transactions and the number of items, the process of finding the support counts is speeded up substantially. DepthProject also uses a bucketing technique to speed up the support counting. MAFIA and GenMax use the vertical mining technique, that is, each itemset is associated with a tid (transaction id) bitmap, and support counting is performed by tid bitmap join. MAFIA uses another pruning technique called parent equivalence pruning (PEP), which is essentially to remove frequent non-closed itemsets. GenMax[5] proposes a progressive focusing technique to improve the efficiency of superset searching. AFOPT-Max uses a prefix-tree structure to store projected transactions, which can make the lookahead pruning technique be performed more efficiently.

Foundations

In practice, mining maximal patterns is much cheaper than mining the complete set of frequent itemsets. However, the worst-case time complexity of maximal pattern mining is the same as mining all frequent patterns. Yang [11] studies the complexity of the maximal pattern mining problem and proves that the problem of counting the number of distinct maximal frequent itemsets in a transaction database, given an arbitrary support threshold, is #P-complete, thereby providing strong theoretical evidence that the problem of mining maximal frequent itemsets is NP-hard.

The concept of maximal patterns has been extended to other similar data mining problems dealing with complex data structures. Yang et al. [12] devise an algorithm that combines statistical sampling and a technique called border collapsing to discover long sequential patterns with sufficiently high confidence in a noisy environment. Xiao et al. [10] propose an algorithm to mine maximal frequent subtrees from a database of unordered labeled trees.

Key Applications

Maximal pattern mining is applicable to dense domains where extracting all frequent patterns is not feasible. It can also be used as a preprocessing step to improve the efficiency of frequent pattern mining and to decide appropriate thresholds for frequent pattern mining and association rule mining.

Mean Reciprocal Rank

Nick Craswell
Microsoft Research Cambridge, Cambridge, UK

Synonyms

MRR; Mean Reciprocal Rank of the First Relevant Document; MRR1

Definition

The Reciprocal Rank (RR) information retrieval measure calculates the reciprocal of the rank at which the first relevant document was retrieved. RR is 1 if a relevant document was retrieved at rank 1, if not it is 0.5 if a relevant document was retrieved at rank 2 and so on. When averaged across queries, the measure is called the Mean Reciprocal Rank (MRR).

Key Points

Mean Reciprocal Rank is associated with a user model where the user only wishes to see one relevant document. Assuming that the user will look down the ranking until a relevant document is found, and that document is at rank n, then the precision of the set they view is 1/n, which is also the reciprocal rank measure. For this reason, MRR is equivalent to Mean Average Precision in cases where each query has precisely one relevant document. MRR is not a shallow measure, in that its value changes whenever the required document is moved, although the change is much larger when moving from rank 1 to rank 2 (change is 0.5) compared to moving from rank 100 to 1,000 (change of 0.009).

MRR is an appropriate measure for known item search, where the user is trying to find a document that he either has seen before or knows to exist. This is called *navigational search* in the case of web search. In a case where there are multiple copies of the required document, or otherwise a set of relevant documents that are substitutes, MRR can still be applied based on the first copy.

Numerical fact

Definition

A *measure* is a numerical property of a multidimensional *cube*, e.g., sales price, coupled with an aggregation formula, e.g., SUM. It captures numerical information to be used for aggregate computations.

Key Points

As an example, a three-dimensional cube for capturing sales may have a Product *dimension* P, a Time dimension T, and a Store dimension S, capturing the product sold, the time of sale, and the store it was sold in, for each sale, respectively. The cube has two measures: DollarSales and ItemSales, capturing the sales price and the number of items sold, respectively. ItemSales can be viewed as a function: ItemSales: $Dom(P) \times Dom(T) \times Dom(S) \mapsto \mathbb{N}_0$ that given a certain combination of dimension values returns the total number of items sold for that combination. If a dimension value corresponds to a higher level in the dimension *hierarchy*, e.g., a product group or even *all* products, the result is an aggregation of several lower-level measure values.

In a multidimensional database, measures generally represent the properties of the chosen facts that the users want to study, e.g., with the purpose of optimizing them. Measures then take on different values for different combinations of dimension values. The property and formula are chosen such that the value of a measure is meaningful for all combinations of aggregation levels. The formula is defined in the metadata and thus not stored redundantly with the data. Although most multidimensional data models have measures, some do not. In these, dimension values are also used for computations, thus obviating the need for measures, but at the expense of some user-friendliness [2].

It is important to distinguish three classes of measures, namely *additive*, *semi-additive*, and *non-additive* measures, as these behave quite differently in computations. Additive measure values can be combined meaningfully along any dimension. For example, it makes sense to add the total sales over Product, Store, and Time, as this causes no overlap among the real-world phenomena that caused the individual values. Semi-additive measure values cannot be combined along one or more of the dimensions, most often the Time dimension. Semi-additive measures generally occur for so-called "snapshot" facts. For example, it does not make sense to sum inventory levels across time, as the same inventory item, e.g., a specific product item, may be counted several times, but it is meaningful to sum inventory levels across products and stores. Non-additive measure values cannot be combined along any dimension, usually because of the chosen formula. For example, this occurs when averages for lower-level values cannot be combined into averages for higher-level values. The additivity of measures is related to the so-called "type" of the measure (Flow, Stock or Value-Per-Unit).

Mediation

Cesare Pautasso

Definition

Mediation is the process of reconciling differences to reach an agreement between different parties. In databases, the goal of mediation is to compute a common view over multiple, distinct, and heterogeneous sources of data. In software architecture, a component plays the role of mediator if it achieves interoperability by decoupling heterogeneous component having mismatching interfaces. Protocol mediation enables the exchange of information between autonomous endpoints that use incompatible communication protocols.

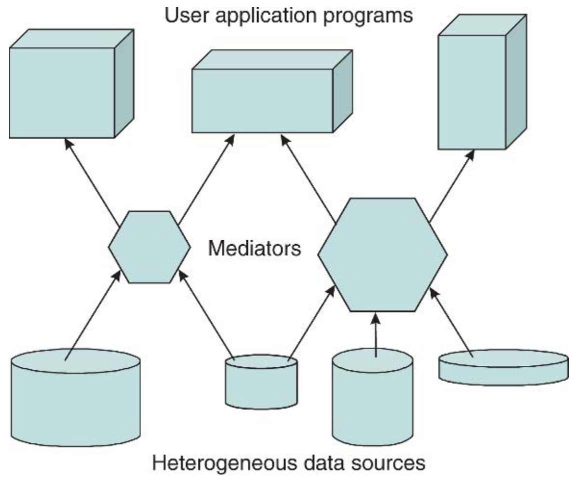
Mediation middleware helps applications deal with heterogeneity. By hiding the multiplicity and the complexity of the underlying systems, it transforms a one-to-many interaction (the application communicating with multiple data sources) into a simpler, one-to-one interaction (the application communicates with the mediator) and shifts the complexity of handling the communication with multiple, heterogeneous parties into a reusable component: the mediator.

Historical Background

In the context of information systems, the concept of mediation has been introduced by Gio Wiederhold in 1992 as the organizing principle for the interoperation of heterogeneous software components and data sources [8]. Mediation is performed by *a layer of intelligent middleware services in information systems, linking data resources and application programs* [9]. Programs need to consume information of multiple data resources and mediators offer them a solution to deal with representation and abstraction problems and exchange objects across multiple, heterogeneous information sources [5]. In the original vision, mediators were seen as independently developed, reusable software modules exploiting expert knowledge about the data to create aggregated information for application programs found at a higher level of abstraction. As shown in Fig. 1, queries from applications are translated by mediators into sub-queries sent out to the different data sources. The various sub-answers are then collected, integrated and returned by the mediator as a single answer to the application.

Foundations

Mediation techniques help to deal with the integration of heterogeneous and incompatible systems. A good understanding of the nature of the problem of dealing with heterogeneity helps to determine when and how mediation should be applied [6]. Conflicts requiring mediation may be found at the level of specific data elements (or messages) to be exchanged or at the level of schema (or interface metadata) definitions. Data values may be stored with multiple representations (syntactic mismatches) or the same representation may be interpreted in different ways (semantic mismatches). Data units (e.g., centimeters versus inches) are also a significant source of conflicts and potential bugs if they are not correctly accounted for when performing data fusion. Identification mismatches are due to the use of locally unique key identifiers that need to be reconciled when tuples from different databases are joined. At the schema level, conflicts involve mismatches in the naming of corresponding elements ("Customer" versus "Client" table); conflicts in the structure ("Street, Number, Zip, City" versus "Address") and granularity ("Purchase Order" versus "Order Line Item") of corresponding data types.



Mediation. Figure 1. Mediation architecture.

It is important to address such mismatches and conflicts at both data and schema levels. To do so, typical mediation middleware tools provide support for operations such as:

1. Selection, filtering, and aggregation of data
2. Data type, encoding and format conversion
3. Join, comparison, and fusion of data originating from multiple data sources
4. Resolution of conflicts between inconsistent sources
5. Multiplexing and demultiplexing over different channels
6. Lookup-based data translation
7. View materialization and caching of intermediate results

Mediator components can be developed using both imperative and declarative programming languages. Automatic schema matching techniques and algorithms that can be applied to support the development of mediators [7].

Mediation can be provided according to two styles:

- Standard-Based Mediation. The mediator transforms each of the incompatible interfaces to comply with a standardized interface that features the least common denominator between all representations. In order for two parties to communicate, this style requires performing two back-to-back transformations (to the standard representation and from the standard representation), thus introduces a larger performance overhead. However, in terms of development cost and maintainability of the mediator, providing support for a new interface only requires introducing one additional transformation in the mediator (assuming that the new interface can be funneled through the standard one).

- Point-to-Point Mediation. The mediator directly maps each pair of incompatible interfaces. This way, the performance overhead is minimized as only one transformation is required as data is exchanged between two parties. Also, there is no need to define a standardized representation, which may be a difficult task in some cases. However, this style should be applied to mediate between a limited (and fixed) set of interfaces only. The complexity of maintaining this kind of mediator does not scale: adding support for a new interface requires to introduce *n* additional mappings in the mediator (one for each existing interface).

Key Applications

Mediation plays a prominent role in applications that require integrating data and functionality originally provided by separate systems (especially in database federation and data integration [10]). For example, a mediator performing currency conversion makes it possible to compare prices of products on sale in different markets. Likewise, mediation is needed to build a country-wide census database out of local databases maintained by different cities, if these have been created independently based on different data models and schemas.

In the context of Service-Oriented Architectures, the role of mediator is associated with the communication bus (or Enterprise Service Bus). Through the bus, services exchange messages without being aware that messages may be transformed while in transit to reconcile differences between service interfaces. Such transformations may be based on context and semantics metadata [4]. Mediation is one of the main features of the Web Services Modeling Framework [1], which applies it to address heterogeneity going beyond traditional data mappings. Also mediators for Business Logic (to compensate between different message ordering constraints found in the public processes of service) and Message Exchange Protocols (for translation between different transport protocols, e.g., to provide reliable and secure message delivery) are introduced in the framework.

In object-oriented design, the *mediator behavioral pattern* has been applied to decouple multiple collaborating objects [3, p. 273]. Instead of having the objects depend on each other and partitioning the interaction logic among them, a mediator object is introduced. It contains and centralizes some potentially complex interaction logic. All objects only refer to the mediator and interact through it. This pattern has also been named *mapper* in the context of enterprise application architecture [2]. Similar to the other applications of mediation, also in this case the interfaces and the overall interactions are simplified thanks to the mediator. However, the price of employing an additional layer of indirection between the elements of a system must be paid.

Membership Query

Mirella M. Moro
The Federal University of Rio Grande do Sol,
Porte Alegre, Brazil

Synonyms

Equality query; Equality selection

Definition

Consider a relation R whose schema contains some attribute A taking values over a domain D. A *membership query* retrieves all tuples in R with $A = x$ ($x \in D$).

Key Points

A membership query effectively checks membership in a set (relation). As such, it can be implemented using either a hash-based index (built on the attribute(s) involved in the query) or a B+-tree. If a hashing scheme is used, each indexed value is placed on an appropriate hash bucket. Then all records that satisfy $A = x$ are located on the bucket responsible for value x. If A is a numeric attribute (and can thus be indexed using an order-preserving access method like a B+-tree) the membership query is a special case of a range query where the range interval *[low, high]* is reduced to a single value (*low* = *high* = x).

Memory Hierarchy

Stefan Manegold
CWI, Amsterdam, The Netherlands

Synonyms

Hierarchical memory system

Definition

A Hierarchical Memory System – or Memory Hierarchy for short – is an economical solution to provide computer programs with (virtually) unlimited fast memory, taking advantage of locality and cost-performance of memory technology. Computer storage and memory hardware – from disk drives to DRAM main memory to SRAM CPU caches – shares the limitation that as they became faster, they become more expensive (per capacity), and thus smaller. Consequently, memory hierarchies are organized into several levels, starting from huge and inexpensive but slow disk systems to DRAM main memory and SRAM CPU caches (both off and on chip) to registers in the CPU core. Each level closer to the CPU is faster but smaller than the next level one step down in the hierarchy. Memory hierarchies exploit the principle of locality, i.e., the property that computer programs do not access all their code and data uniformly, but rather focus on referencing only small fractions for given periods of time. Consequently, during each period of time, only the fraction currently referenced – also called hot-set, locality-set, or working-set – needs to be present in the fastest memory level, while the remaining data and code can stay in slower levels. In general, all data in one level is also found in all (slower but larger) memory levels below it.

Historical Background

A three-level memory hierarchy, consisting of (i) the CPU's registers, (ii) DRAM main-memory as primary storage and (iii) secondary storage, has been in use since the introduction of drums and then disk drives as secondary storage. In this memory hierarchy, the decision of which data are loaded into a higher level at what time (and written back in case it is modified) is completely under software control. Application programs determine when to load data from secondary to primary memory, and compilers determine when to load data from main memory into CPU registers.

With the introduction of virtual memory around 1960 [10] application software – and in particular their programmers – are provided with uniformly addressable memory larger than physical memory. The operating system takes care of loading the references portion of data into main memory, automating page transfers, and hence relieving programmers from this task. In the late 1960s, the discovery of the locality principle [7] led to the invention of working sets [6] that exploit locality properties to predict data references, and enabled the design of page replacement algorithms that make virtual memory work efficiently and reliably in multiprogramming environments. Since then, virtual memory has become an inherent feature of operating systems. In contrast to many other application programs, a database management system usually does not rely on the operating system's generic virtual memory management, only. Instead, it implements its own buffer pool, exploiting domain specific knowledge to implement application-specific replacement algorithms.

Until the 1980s, the three-level memory hierarchy has been the state-of-the art, mainly because main memory is considered fast enough to serve the CPU – or better, the CPU were "slow enough." Since then, a continuously growing performance gap develops between CPU and main memory. With the chip integration technology following Moore's Law [12], i.e., doubling the number of transistors per chip area roughly every 1.5 years, the performance has grown exponentially, due to increasing clock-speeds, increasing inherent parallelism, or both. Advanced manufacturing techniques has grown the capacity and – thanks to even wider and faster system buses – their data transfer bandwidth of main memory similarly. Memory access latency, however, has lagged behind, demonstrating at most a slight linear improvement.

To bridge this performance gap, in the 1980's hardware designers started to extend the memory hierarchy by adding small (and expensive) but fast SRAM cache memories between the CPU and main memory. Initially, a single cache level is added, either located on the system board between CPU and main memory, or integrated on the CPU chip. With advancing integration and manufacturing techniques, more levels are added. Nowadays, two to three cache levels integrated on the CPU chip represent the most common configuration.

The main difference between cache memories and the original three levels of the memory hierarchy is that their contents are completely controlled by hardware logic. Relying on the locality principle, carefully turned replacement algorithms (usually variations of LRU), decide when data are loaded into or evicted from which cache level. While ensuring transparent use and easy portability, this approach leaves programs virtually without means to explicitly control the content of CPU caches. In modern systems, software prefetching commands have been introduced to provide programs with limited control to (pre-)load data into caches without actually accessing it.

The scientific computing and algorithm communities – both usually focusing on compute-intensive tasks on memory-based data sets – quickly realized that they have to make the algorithms and data structures *cache-conscious* to exploit the performance potentials of ever faster CPU and CPU caches effectively and efficiently.

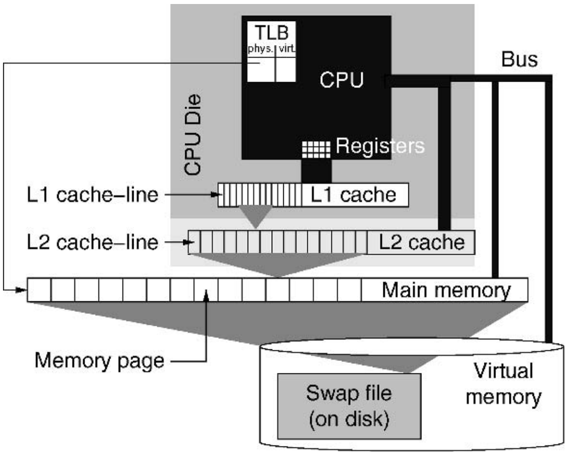
The database world initially ignored the new hardware developments, assuming that optimizing disk access (I/O) is still the key to high performance execution of data-intensive tasks on large disk-based data sets. First proposals of cache-conscious database algorithms occurred in the mid 1990s [14]. It was not until the end of the 20th century that the database community realized that memory access has become a severe bottleneck also for database query processing performance, taking up to 90% of the execution time [4,5]. In the last decade, the development of hardware-aware database technology from system architectures over data structures to query processing algorithms has become a very active and recognized research area [1–3,13].

Foundations

Memory- and Cache-Architectures

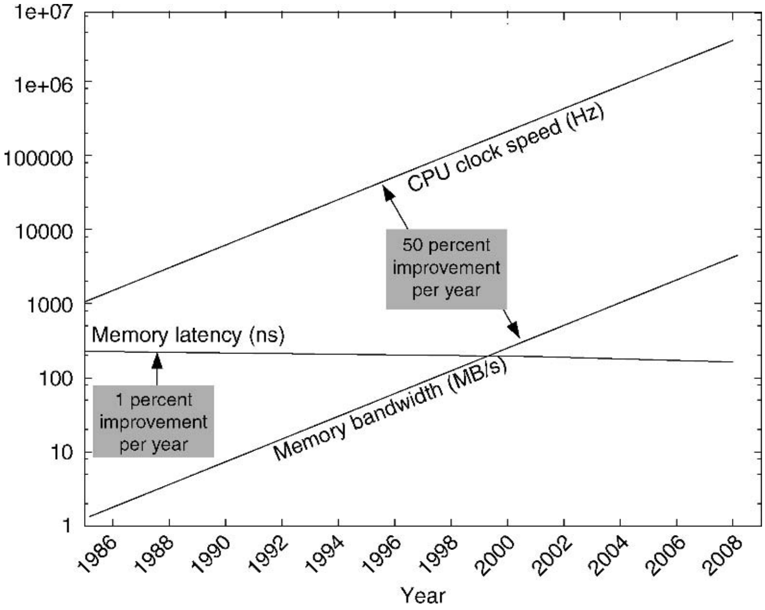
Modern computer architectures have a *hierarchical memory system*, as depicted in Fig. 1. The main memory on the system board consists of *DRAM* (*Dynamic Random Access Memory*) chips. While CPU speeds are increasing rapidly, DRAM access latency has hardly progressed over time. To narrow the exponentially growing performance gap between CPU speed and memory latency (cf., Fig. 2), *cache memories* have been introduced, consisting of fast but expensive *SRAM* (*Static Random Access Memory*) chips. SRAM cells are usually made-up of six transistors per memory bit, and hence, they consume a rather large area on the chips. DRAM cells require a single transistor and a small capacitor to store a single bit. Thus, DRAMs can store much more data than SRAMs of equal (physical) size. But due to some current leakage, the capacitor in DRAMs get discharged over time, and have to be recharged (*refreshed*) periodically to keep their information. These refreshes slow down access.

The fundamental principle of all cache architectures is "*reference locality*," i.e., the assumption that at any time the CPU, thus the program, repeatedly accesses only a limited amount of data (i.e., memory) that fits in the cache. Only the first access is "slow," as the data have to be loaded from main memory. This is called a *compulsory cache miss* (see below). Subsequent accesses (to the same data or memory addresses) are then "fast", as the data are then available in the cache. This is called a *cache hit*. The fraction of memory accesses that can be fulfilled from the cache is called *cache hit rate*; analogously, the fraction of memory accesses that cannot be fulfilled from the cache is called *cache miss rate*.



Memory Hierarchy. Figure 1. Hierarchical memory architecture.

Cache memories are often organized in *multiple cascading levels* between the main memory and the CPU. As they become faster, but smaller, the closer they are to the CPU. Originally, there was one level (typically 64 KB to 512 KB) of cache memory located on the system board. As the chip manufacturing processes improved, a small cache of about 4 KB to 16 KB was integrated on the CPU's die itself, allowing much faster access. The on-board cache is typically not replaced by the on-chip cache, but rather both make up a cache hierarchy, with the one on chip called *first level* (*L1*) cache and the one on board called *second level* (*L2*) cache. Over time, the L2 cache has also been integrated on the CPU's die (e.g., with Intel's Pentium III "Coppermine," or AMD's Athlon "Thunderbird"). On PC systems, the on-board cache has since disappeared, keeping two cache levels. On other platforms, e.g., workstations based on Compaq's (formerly DEC's)



Memory Hierarchy. Figure 2. Trends in CPU and DRAM speed.

Alpha CPU, the on-board cache is kept as *third level* (*L3*) cache, next to the two levels on the die. Most recent multi-core CPUs usually have a private L1 cache of 16 KB to 64 KB per core. The L2 cache is also integrated on the CPU's die. L2 configuration vary between one private L2 per core to one single L2 that is shared among all cores. On Intel's Core 2 Quad, for instance, each of the two L2 caches is shared by two of the four cores. Typical L2 sizes are in the order of 1 MB to 8 MB.

To simplify presentation, the remainder of this entry assumes a typical system with two cache levels (L1 and L2). However, the discussion can easily be generalized to an arbitrary number of cascading cache levels in a straightforward way.

In practice, caches memories do not only cache the data used by an application, but also the program itself, more accurately, the instructions that are currently being executed. With respect to caching, there is one major difference between data and program. Usually, a program must not be modified while it is running, i.e., the caches may be read-only. Data, however, requires caches that also allow modification of the cached data. Therefore, almost all systems nowadays implement two separate L1 caches, a read-only one for instructions and a read-write one for data. The L2 cache, however, is usually a single "unified" read-write cache used for both instructions and data.

Caches are characterized by three major parameters: Capacity (C), Line Size (Z), and Associativity (A):

Capacity (C) A cache's capacity defines its total size in bytes. Typical cache sizes range from 8 KB to 8 MB.

Line Size (Z) Caches are organized in *cache lines*, which represent the smallest unit of transfer between adjacent cache levels. Whenever a cache miss occurs, a complete cache line (i.e., multiple consecutive words) is loaded from the next cache level or from main memory, transferring all bits in the cache line in parallel over a wide bus. This exploits spatial locality, increasing the chances of cache hits for future references to data that are "close to" the reference that caused a cache miss. Typical cache line sizes range from 16 bytes to 256 bytes. Dividing the cache capacity by the cache line size yields the *number of available cache lines* in the cache: $\# = C/Z$.

Associativity (A) To which cache line the memory is loaded depends on the memory address and on the cache's *associativity*. An *A-way set associative* cache allows loading a line in A different positions. If $A > 1$, some *cache replacement* policy chooses one from among the A candidates. *Least Recently Used* (*LRU*) is the most common replacement algorithm. In case $A = 1$, the cache is called *directly-mapped*. This organization causes the least (virtually no) overhead in determining the cache line candidate. However, it also offers the least flexibility and may cause a lot of *conflict misses* (see below). The other extreme case is a *fully associative* cache. Here, each memory address can be loaded to any line in the cache ($A = \#$). This avoids conflict misses, and only *capacity misses* (see below) occur as the cache capacity is exceeded. However, determining the cache line candidate in this strategy causes a relatively high overhead that increases with the cache size. Hence, it is feasible for only smaller caches. Current PCs and workstations typically implement two-way to eight-way set associative caches.

With multiple cache levels, two types are distinguished: inclusive and exclusive caches. With *inclusive caches*, all data stored in L1 is also stored in L2. As data are loaded from memory, they are stored in all cache levels. Whenever a cache line needs to be replaced in L1 (because a mapping conflict occurs or as the capacity is exceeded), its original content can simply be discarded as another copy of that data still remains in the (usually larger) L2. The new content is then loaded from where it is found (either L2 or main memory). The total capacity of an inclusive cache hierarchy is hence determined by the largest level. With *exclusive caches*, all cached data are stored in exactly one cache level. As data are loaded from memory, they get stored only in the L1 cache. When a cache lines needs to be replaced in L1, its original content is first written back to L2. If the new content is then found in L2, it is moved from L2 to L1, otherwise, it is copied from main memory to L1. Compared to inclusive cache hierarchies, exclusive cache hierarchies virtually extend the cache size, as the total capacity becomes the sum of all levels. However, the "swap" of cache lines between adjacent cache levels in case of a cache miss also causes more "traffic" on the bus and hence increases the cache miss latency.

Cache misses can be classified into the following disjoint types [9]:

Compulsory The very first reference to a cache line always causes a cache miss, which is hence classified as a compulsory miss, i.e., an unavoidable miss (even) in an infinite cache. The number of compulsory misses obviously depends only on the data volume and the cache line size.

Capacity A reference that misses in a fully associative cache is classified as a capacity miss because the finite sized cache is unable to hold all the referenced data. Capacity misses can be minimized by increasing the temporal and spatial locality of references in the algorithm. Increasing cache size also reduces the capacity misses because it captures more locality.

Conflict A reference that hits in a fully associative cache but misses in an *A*-way set associative cache is classified as a conflict miss. This is because even though the cache is large enough to hold all the recently accessed data, its associativity constraints force some of the required data out of the cache prematurely. For instance, alternately accessing just two memory addresses that "happen to be" mapped to the same cache line will cause a conflict cache miss with each access. Conflict misses are the hardest to remove because they occur due to address conflicts in the data structure layout and are specific to a cache size and associativity. Data structures would, in general, have to be remapped to minimize conflicting addresses. Increasing the associativity of a cache will decrease the conflict misses.

Coherence Only in case of multi-processor or multi-core systems with private per processor/core high-level caches but shared lower-level caches and/or main memory, the following can occur. If two or more cores access the same data item, it will be loaded in each private cache. If one core than modifies this data item in its private cache, the other copies are invalidated and cannot server futures references. Instead, to ensure cache coherence, a cache miss occurs, and the modified data item has to be loaded from the cache that holds the most up-to-date copy.

Memory Access Costs

In general, memory access costs are characterized by the following three aspects:

Latency Latency is the time span that passes after issuing a data access request until the requested data is available in the CPU. In hierarchical memory systems, the latency increases with the distance from the CPU. Accessing data that are already available in the L1 cache causes *L1 access latency* (λ_{L1}), which is typically rather small (one or two CPU cycles). In case the requested data are not found in L1, an *L1 miss* occurs, additionally delaying the data access by *L2 access latency* (λ_{L2}) for accessing the L2 cache. Analogously, if the data are not yet available in L2, an *L2 miss* occurs, further delaying the access by *memory access latency* (λ_{Mem}) to finally load the data from main memory. Hence, the total latency to access data that are in neither cache is $\lambda_{Mem} + \lambda_{L2} + \lambda_{L1}$. As L1 accesses cannot be avoided, L1 access latency is often assumed to be included in the pure CPU costs, leaving only memory access latency and L2 access latency as explicit memory access costs. As mentioned above, all current hardware actually transfers multiple consecutive words, i.e., a complete cache line, during this time.

When a CPU requests data from a certain memory address, modern DRAM chips supply not only the requested data, but also the data from subsequent addresses. The data are then available without additional address request. This feature is called *Extended Data Output* (EDO). Anticipating sequential memory access, EDO reduces the effective latency. Hence, two types of latency for memory access need to be distinguished. *Sequential access latency* (λ^s) occurs with sequential memory access, exploiting the EDO feature. With random memory access, EDO does not speed up memory access. Thus, *random access latency* (λ^r) is usually higher than sequential access latency.

Bandwidth Bandwidth is a metric for the data volume (in megabytes) that can be transferred between CPU and main memory per second. Bandwidth usually decreases with the distance from the CPU, i.e., between L1 and L2 more data can be transferred per time than between L2 and main memory. The different bandwidths are referred to as *L2 access bandwidth* (β_{L2}) and *memory access bandwidth* (β_{Mem}), respectively. In conventional hardware, the memory bandwidth used to be simply the cache line size divided by the memory latency. Modern multiprocessor systems typically provide excess bandwidth capacity $\beta' \geq \beta$. To exploit this, caches need to be *non-blocking*, i.e., they need to allow more than one outstanding memory load at a time, and the CPU has to be able to issue subsequent load requests while waiting for the first one(s) to be resolved. Further, the access pattern needs to be sequential, in order to exploit the EDO feature as described above.

Indicating its dependency on sequential access, the excess bandwidth is referred to as *sequential access bandwidth* ($\beta^s = \beta'$). The respective *sequential access latency* is defined as $\lambda^s = Z/\beta^s$. For *random access latency* as described above, the respective *random access bandwidth* is defined as $\beta^r = Z/\lambda^r$.

On some architectures, there is a difference between read and write bandwidth, but this difference tends to be small.

Address Translation For data access, logical virtual memory addresses used by application code have to be translated to physical page addresses in the main memory of the computer. In modern CPUs, a *Translation Lookaside Buffer* (*TLB*) is used as a cache for physical page addresses, holding the translation for the most recently used pages (typically 64). If a logical address is found in the TLB, the translation has no additional costs. Otherwise, a *TLB miss* occurs. The more pages an application uses (which also depends on the often configurable size of the memory pages), the higher the probability of TLB misses.

The actual *TLB miss latency* (l_{TLB}) depends on whether a system handles a TLB miss in hardware or in software. With software-handled TLB, TLB miss latency can be up to an order of magnitude larger than with hardware-handled TLB. Hardware-handled TLB fetches the translation from a fixed memory structure that is just filled by the operating system. Software-handled TLB leaves the translation method entirely to the operating system, but requires trapping to a routine in the operating system kernel on each TLB miss. Depending on the implementation and hardware architecture, TLB misses can therefore be more costly than a main-memory access. Moreover, as address translation often requires accessing some memory structure, this can in turn trigger additional memory cache misses.

TLBs can be treated similar to memory caches, using the memory page size as their cache line size, and calculating their (virtual) capacity as *number_of _entries* × *page_size*. TLBs are usually fully associative. Like caches, TLBs can be organized in multiple cascading levels.

For TLBs, there is no difference between sequential and random access latency. Further, bandwidth is irrelevant for TLBs, because a TLB miss does not cause any data transfer.

Unified Hardware Model

Summarizing the above discussion, one can describe a computer's memory hardware as a cascading hierarchy of *N* levels of caches (including TLBs) [11]. An index $i \in \{1,...,N\}$ added to the parameters described above identifies to the respective value of a specific level. The relation between access latency and access bandwidth then becomes $\lambda_{i+1} = Z_i/\beta_{i+1}$. Exploiting the dualism that an access to level $i + 1$ is caused a miss on level i allows some simplification of the notation. Introducing the *miss latency* $l_i = \lambda_{i+1}$ and the respective *miss bandwidth* $b_i = \beta_{i+1}$ yields $l_i = Z_i/b_i$. Each cache level is characterized by the parameters given in Table 1. Costs for L1 cache accesses are assumed to be included in the CPU costs, i.e., λ_1 and β_1 are not used and hence undefined.

Manegold developed a system independent C program called *Calibrator* to measure these parameters on any computer hardware.

Key Applications

In the last decade, the database community has done much research on modifying existing and developing new database technology (system architecture, data

Memory Hierarchy. Table 1. Characteristic parameters per cache level ($i \in \{1,..., N\}$)[2]

Description	Unit	Symbol
Cache name (level)	–	L*i*
Cache capacity	[bytes]	C_i
Cache block size	[bytes]	Z_i
Number of cache lines	–	$\#_i = C_i/Z_i$
Cache associativity	–	A_i
Sequential access		
Access bandwidth	[bytes/ns]	β^S_{i+1}
Access latency	[ns]	$\lambda^s{}_{i+1} = Z_i/\beta^S_{i+1}$
Miss latency	[ns]	$l_i^s = \lambda^S_{i+1}$
Miss bandwidth	[bytes/ns]	$b_i^s = \beta^S_{i+1}$
Random access		
Access latency	[ns]	$\lambda^r{}_{i+1}$
Access bandwidth	[bytes/ns]	$\beta^r{}_{i+1} = Z_i/\lambda^r_{i+1}$
Miss bandwidth	[bytes/ns]	$b_i^r = \beta^r_{i+1}$
Miss latency	[ns]	$l_i^r = \lambda^r_{i+1}$

structures, query processing algorithms) to exploit the characteristics of the extended memory hierarchy efficiently and effectively, improving query evaluation performance up to orders of magnitude.

Memory Locality

Stefan Manegold
CWI, Amsterdam, The Netherlands

Synonyms

Principle of locality; Locality principle; Locality of reference

Definition

Locality refers to the phenomenon that computer programs — or computational processes in general — do not access all of their data items uniformly and independently, but rather in a clustered and/or dependent/correlated manner. Some data items are accessed more often than others, repeated accesses to the same data item occur in bursts, and related items are usually accessed together, concurrently or within a short time interval.

There are two types of locality:

1. *Temporal locality* means that accesses to the same data item are grouped in time, i.e., multiple accesses to the same data item occur in rather short time intervals compared to rather long time periods where the same data item is not accessed. Hence, temporal locality is the concept that a data item that is referenced by a program at one point in time will be referenced again sometime in the near future.
2. *Spatial locality* means that data items that are stored physically close to each other tend to be accessed together. Hence spatial locality is the concept that likelihood of referencing a data item by a program is higher if a data item near it has been referenced recently.

Locality belongs to the most fundamental principles of computer science.

Key Point

The discovery of the locality principle dates back to the 1960s. Denning's pioneering work on working-set memory management exploits the locality principle to avoid thrashing of virtual memory systems high levels of multiprogramming [2,3]. Today, this is the key to making virtual memory systems work reliably and efficiently.

In particular, with modern hierarchical memory architectures, exploiting and increasing locality in algorithms and data structures is the key to achieving high performance.

Increased temporal locality ensures that once a data item is referenced, and hence loaded into a fast high-level memory (e.g., cache), all subsequent references occur in short succession while the data item is still available in the cache. Ideally, this data item will not be required, again, once it is evicted from the fast high-level memory.

Data transfer between adjacent levels of hierarchical memory systems does not happen per byte but with larger granularities, e.g., pages of multiple KB or even MB at a time between disk and main memory, cache lines of tens to hundreds of bytes between main memory and CPU cache. *Increased spatial locality* ensures that all data bytes/items that are loaded with each transfer are indeed useful for the program.

Database system architecture exploits and increases locality in numerous ways. Key examples for increased temporal locality are, for instance partitioned join algorithms, where iterating over small partition of the outer relation increases temporal locality of repeated access to the inner relation [5,4]. In fact, smaller partitions of the inner relation also increased spatial locality. Examples of spatial locality range from clustered indices over tuned page layouts such as PAX [1] to the decision between column-stores and row-stores to optimal support of column-major (OLAP) of row-major (OLTP) workloads.

Merkle Trees

Barbara Carminati
University of Insubria, Varese, Italy

Synonyms

Merkle hash trees; Hash trees; Authentication trees

Definition

Merkle trees are data structures devised to authenticate, with a unique signature, a set of messages, by at the same time making an intended verifier able to verify authenticity of a single message without the disclosure of the other messages. In particular, given a set of messages $M = \{m_1,\ldots,m_n\}$, the Merkle tree created with them is a binary tree whose leaves contain the hash value of each message m in M, whereas internal nodes contain the concatenation of the hash values corresponding to its children.

Key Point

A Merkle tree is a data structure introduced by Merkle in 1979 [1] to improve the Lamport-Diffie one-time signature scheme [2]. In this digital signature scheme, keys can be used to sign, at most, one message. This implies that for each signed message a new public key has to be generated and published. As consequence, Lamport-Diffie one-time digital signature scheme requires publishing a large amount of data. To overcome this drawback, in [1] Merkle proposed a tree-structure, called *authentication tree*, with the aim of authenticating a large number of public keys to be used in one-time signature scheme.

In general, Merkle trees can be exploited to authenticate with a unique signature a set of messages by, at the same, time making an intended verifier able to authenticate a single message without the disclosure of the other messages. Given a set of messages $M = \{m_1,...,m_n\}$, the corresponding Merkle tree is computed by means of the following bottom-up recursive computation: at the beginning, for each different message $m \in M$, a different leaf containing the hash value of m is inserted into the tree; then, for each internal node, the value associated with it is equal to $h(h_l||h_r)$, where $h_l||h_r$ denotes the concatenation of the hash values corresponding to the left and right children nodes, and $h()$ is an hash function. The root node of the resulting binary hash tree is the digest of all the messages, and thus it can be digitally signed by using a standard signature technique. The main benefit of this method is that a user is able to validate the signature by having a subset of messages, providing him/her with a set of additional hash values corresponding to missing messages. Indeed, these additional hash values, together with the provided set of original messages, make a user able to locally re-build the binary tree and, therefore, to validate the signature generated on its root. Consider, for instance, the following set of messages $M = \{m_1, m_2, m_3, m_4\}$. The Merkle tree created with them is a complete binary tree with height of two. More precisely, according to the recursive computation, the root value of the Merkle tree is equal to $h(hr_l||hr_r)$, where hr_l is its left children with value $h(h(m_1)||h(m_2))$, whereas hr_r is its right children with value $h(h(m_3)||h(m_4))$. Assume, now, that a user receives only messages m_1 and m_2. To make him/her able to validate the signature, he/she must be provided also with hash value hr_r. Indeed, by having m_1 and m_2 messages, the user is able to calculate hr_l. Then, using hr_r and hr_l he/she can compute the hash value of the root, and thus verify the signature.

Message Authentication Codes

Marina Blanton
University of Notre Dame, Notre Dame, IN, USA

Synonyms

MAC; Message integrity codes

Definition

A *message authentication code* (MAC) is a short fixed-length value which is used to authenticate a message. A MAC algorithm can be viewed as a hash function that takes as input two functionally distinct values: a secret key and a message. The output of a MAC algorithm is a short string computed in such a way that it is infeasible to produce the same output on the message without the knowledge of the key. Thus, the MAC value protects both the *integrity* and *authenticity* of a message by allowing the entity in possession of the secret key to detect any changes to the message content.

Key Points

While MAC functions can be viewed as keyed cryptographic hash functions, they have specific security requirements for authentication purposes. More precisely, an attacker who does not have access to the secret key and has not seen the MAC value for a specific message before should not be able to compute that value. MAC functions use symmetric techniques (i.e., the same key is used to create and verify a MAC) and thus are different from digital signatures where the signing and verification keys differ. Practical MAC algorithms can be constructed from cryptographic hash functions (for example, HMAC) or from block ciphers (for example, CBC-MAC and others).

Synonyms

Message-oriented middleware (MOM); Message-oriented systems; Messaging systems; Queuing systems

Definition

A message is an information sent by a sender process to a receiver process. A message queue is a mechanism that allows a sender process and a receiver process to exchange messages. The sender posts a message in the queue, and the receiver retrieves the message from the queue. A message queuing system provides a means to build distributed systems, where distributed processes communicate through messages exchanged via queues.

Key Points

A message queuing system provides several facilities, such as creating messages, creating queues, initializing sender and receiver processes, and providing a means to send and receive messages.

First of all, a message queuing system provides a facility to build a message and fill it with data. Properties may be associated with a message, such as the message size, the message expiration time and the message priority.

A message queuing system also provides facilities to create a queue and, optionally, to associate parameters with a queue, such as the queue length (i.e., the maximum number of messages a queue may hold), the queue topics (i.e., the types of messages the queues may contain), etc.

The senders and receivers of messages may communicate in a synchronous way or in an asynchronous way. With a synchronous communication protocol, a receiver waits for a message from a sender, i.e., it blocks until the message arrives. Whereas with an asynchronous communication protocol, the receiver continues executing and is notified of the reception of a message when this one arrives.

Furthermore, the destination of a message may be specified either explicitly or implicitly. In the explicit mode, the sender specifies the queue to which the message is sent. While in the implicit mode, the sender specifies a topic to which a message is sent, and the message queuing system is responsible of automatically finding the queues that correspond to that topic before sending the message to these queues.

Several message queuing systems are proposed, some are proprietary and others are open source. Oracle proposes Advanced Queuing for Oracle databases [3], Skype has Skytools PgQ for PostgreSQL databases [5], IBM provides WebSphere MQ, Microsoft has MSMQ [1], and Sun Microsystems defines Java Message Service (JMS) as a specification of a Java standard for message queuing systems [6]. Open source message queuing systems include ActiveMQ [7], JBoss Messaging [2], and JORAM [4].

Metadata Interchange Specification

Wei Tang
Teradata Corporation, El Segundo, CA, USA

Synonyms

MDIS

Definition

Metadata Interchange Specification (MDIS) is a standard proposed by the Metadata Coalition (MDC) for defining metadata.

Key Points

Metadata Coalition (MDC) was an organization of database and data warehouse venders founded in October 1995. Its aim was to define a tactical set of standard specifications for the access and interchange of meta-data between software tools.

In July 1996, Metadata Interchange Specification (MDIS) 1.0 was officially ratified by MDC.

The MDIS Version 1.0 specification represents Coalition member input and recommendations collected and synthesized by the Coalition's technical subcommittee which included representatives from Business Objects, ETI, IBM, Platinum Technology, Price Waterhouse, Prism Solutions, R&O and SAS Institute. The latest version of MDIS is 1.1, which was published in August 1997.

The Metadata Interchange Specification draws a distinction between:

- The Application Metamodel – the tables, etc., used to "hold" the metadata for schemas, etc., for a particular application; for example, the set of tables used to store metadata in Composer may differ significantly from those used by the Bachman Data Analyst.
- The Metadata Metamodel – the set of objects that the MDIS can be used to describe. These represent the information that is common (i.e., represented) by one or more classes of tools, such as data discovery tools, data extraction tools, replication tools, user query tools, database servers, etc. The metadata metamodel should be:
  - Independent of any application metamodel.
  - Character-based so as to be hardware/platform-independent.

- Fully qualified so that the definition of each object is uniquely identified.

There are two basic aspects of the specification:

1. Those that pertain to the semantics and syntax used to represent the metadata to be exchanged. These items are those that are typically found in a specifications document.
2. Those that pertain to some framework in which the specification will be used. This second set of items is two file-based semaphores that are used by the specification's import and export functions to help the user of the specification control consistency.

MDIS consists of a metamodel, which defines the syntax and semantics of the metadata to be exchanged, as well as the specification of a framework for supporting an actual MDIS implementation. The MDIS Metamodel is a hierarchically structured, semantic database model that's defined by a tag language. The metamodel consists of a number of generic, semantic constructs, such as Element, Record, View, Dimension, Level, and Subschema, plus a Relationship entity that can be used in the specification of associations between arbitrary source and target constructs. The MDIS metamodel may be extended through the use of named properties that are understood to be tool-specific and not defined within MDIS. Interchange is accomplished via an ASCII file representation of an instance of this metamodel. Although support for an API is mentioned in the specification, no API definition is provided.

The MDIS Access Framework specifies several fairly general mechanisms that support the interchange of metamodel instances. The Tool and Configuration Profiles define semaphores that ensure consistent, bidirectional metadata exchange between tools. The MDIS Profile defines a number of system parameters (environment variables) that would be necessary in the definition of an MDIS deployment. Finally, Import and Export functions are exposed by the framework as the primary file interchange mechanisms for use by tools.

MDIS 1.1 was planned to be incorporated with Microsoft's Open Information Model (OIM) when Microsoft joined the MDC in December 1998. MDC decided later that MDIS be superseded by OIM. In 2000, the Metadata Coalition merged with the Object Management Group (OMG). OMG has worked on integrating OIM into its Common Warehouse Model (CWM) in order to provide a single standard for modeling meta-data in data warehouses. MDC, MDIS, and OIM are no longer in existence today (as independent entities).

Meta Data Repository

Christoph Quix
RWTH Aachen University, Aachen, Germany

Synonyms

Meta data base; Meta data manager; Meta data management system; Meta data registry

Definition

A meta data repository (MDR) is a component which manages meta data. In the context of database systems, one example of meta data is information about the database schema, i.e., a description of the data. In addition, MDRs can manage information about the processes which create, use, or update the data, the hardware components that host these processes or the database system, or other (human) resources which make use of the data [6]. As meta data is also data, meta data repositories offer the same functionality for meta data as database management systems (DBMS) for data, e.g., queries, updates, transactions, access control.

Moreover, as meta data is semantically rich data, MDRs often employ object-oriented data models as the basis for the definition of meta data. MDRs should also offer predefined meta models for different types of meta data, so that the user is able to store meta data directly, without defining a meta model in advance.

Another task for a meta data repository is the integration of meta data from various sources into a comprehensive meta data model.

Historical Background

The first components that managed meta data in the context of database systems were dictionary systems which were integrated into the database management systems (DBMS) [12]. These dictionaries were already part of early DBMS products, such as IDMS or IBM IMS. For example, the integrated data dictionary (IDD) of IDMS was a separate database inside the IDMS which was used to maintain meta data of products in the IDMS family [11]. It could be extended also to maintain other types of meta data.

The relational database systems developed in the 1980s also had integrated dictionary systems (also known as system catalogs) to maintain definitions about tables, views, columns, etc. These dictionaries were mainly used by the DBMS itself, but they could be also queried by users and other applications to retrieve information about the contents of a database.

In the 1980s, ANSI started to develop a standard for Information Resource Dictionary Systems (IRDS) which was later adopted by ISO [6]. The standard defined the content, structure, and functionality of an IRDS. The main requirements stated by the IRDS standard are the availability of data modeling facilities, extensibility (i.e., the possibility to add new data types), and the provision of standard DBMS functionality such as query and reporting facilities, integrity and constraint management, and access control.

With the growing need for integrated information systems, stand-alone meta data repository systems became more popular in the 1990s. In contrast to the integrated repositories in DBMS products, a stand-alone MDR was able to manage meta data from different systems. The requirement for meta data integration was especially important for data warehouses, where data that was managed by independent, heterogeneous systems should be integrated into a common data store with a uniformed data model. The availability of meta data of the data sources was a prerequisite for data integration. In this context, some companies tried to build enterprise wide meta data repositories which were supposed to manage all meta data that is available in the enterprise. Such an ambitious goal was hard to achieve, and often, the return-of-investment of such a system was not as high as expected [5]. Therefore, the MDR market was significantly reduced at the end of the 1990s.

Since 2000, two trends for meta data repositories gained importance: community-focused repositories and federated repositories [5]. Communicty-focused repositories are employed in communities (within a company), which share a common interest, such as data warehousing or enterprise application integration. In these communities, the main problem of interoperability of meta data tools could be solved by dedicated bridging technologies, because of the limited scope of the meta data. With the rising importance of service oriented architecture (SOA), MDR needed again to address a broader scope of meta data. Therefore, federated solutions for MDRs are considered to be a solution for the meta data integration problem. In a federated MDR, there are still several MDRs for different communities but federated queries across several MDRs are enabled [5].

Foundations

Requirements

Requirements for MDRs were stated in the IRDS standard [6], in [2], and in [1]:

1. *Dynamic extensibility.* The MDR should provide easy functionalities for the extension of the built-in data models.
2. *Management of objects and relationships.* Objects and relationships between objects should be managed by the MDR.
3. *Notification.* An operation on a specific object in the MDR might trigger other operations on the same or different objects. Therefore, the MDR must be able to notify applications which are interested in certain events. In addition, the invocation

of methods inside the MDR (based on other events) should be also possible.

4. *Version management*. Versioning of meta data is required to track the evolution of a meta data object. It is also important to know which versions of two objects were active at a specific time. It might be also necessary to maintain relationships between older and newer versions of an object.
5. *Configuration management*. A configuration is a set of meta data objects which belong together in respect of content, e.g., they all describe the state of one component. The MDR should be able to manage a configuration as one group. Configurations can be also versioned.
6. *Integrity constraints*. The MDR must provide a language for the definition of integrity constraints on meta data, and enforce the compliance of the meta data with these constraints.
7. *Query and reporting functionality*. To retrieve meta data from the repository, the MDR needs to offer a query language. In addition, user-configurable reports should be also supported.
8. *User access*. If the MDR can be accessed directly by end-users or administrators, the MDR needs to support: a browsing facility for meta data, so that users can navigate through the metadata; an access control, so that users see or update only meta data which they are allowed to; a sophisticated user interface if the users are also allowed to update the meta data, so that the integrity of the MDR is maintained.
9. *Interoperability*. To enable interoperability with other tools and repositories, the MDR should support standards for meta data exchange (such as XMI) and offer an API (application program interface).

Architecture

There are several MDRs already available (see "Systems" section below), each having its own unique architecture. However, by abstracting from these concrete architectures, several components which are common for all MDRs can be identified:

1. *Repository*. The repository component is the internal data store of the MDR and therefore the core of the MDR. As MDRs have to provide similar functionality for meta data as DBMS for data, the repository is often implemented on top of a DBMS.
2. *Meta data manager*. The meta data manager acts as the controller of the repository. As all accesses to the repository should go through the meta data manager, it provides an interface for external applications. Using this interface, applications can store, update, and query meta data.
3. *Models*. A MDR needs to come with already predefined meta models (or information models) which can be directly employed by the users of the MDR to store meta data. If the user has to define its own meta models, the effort to get the MDR running might be too high for the application. Nevertheless, it should be possible to extend the existing models for the specific requirements of the applications that use the MDR.
4. *User interface*. As described above, a MDR can be also accessed by users, which are either end-users using the data or processes described in the MDR, or administrators controlling the system of which the MDR is a part. The user interface can consist of a query facility, a meta data browser, an administrator interface, and an interface to update the meta data.

As mentioned above, a current trend for MDRs is the idea of a federated MDR. This changes the standard architecture described before: the repository component in a federated MDR is not one single data store, the meta data can be distributed across several independent and heterogeneous components. In a federated MDR architecture, the meta data could be stored in files, databases, or managed by specific applications. This increases the complexity of the meta data manager significantly, as meta data queries have to be transformed into queries of the individual systems holding the meta data.

Systems

There are several MDRs available in the market. They can be classified as stand-alone MDRs, repositories integrated into larger software platforms, open source systems and research prototypes.

The market for stand-alone MDRs is changing frequently as companies specialized on MDRs are being acquired by other companies. The current products for separate meta data management solutions are, for example, *ASG Rochade*, *Adaptive Metadata Manager*, and *Advantage Repository*. These products came mainly from the data management area (especially used as MDRs in data warehouse systems), but are now also addressing other areas such as enterprise application integration and service-oriented architectures. Other systems, such as *Logidex* from *LogicLibrary* or *BEA AquaLogic Registry Repository*, have been originally developed as meta data systems for service-oriented architectures.

As mentioned above, large software companies are also addressing the meta data challenges in their software or technology platforms. For example, *IBM* has an integrated MDR in their information integration framework.

There are also a few open source systems which can be used as MDR. Two examples are *Repository in a Box* and *XMDR*. In the research community, *ConceptBase* [9] is a MDR which has been used in several research projects. ConceptBase provides a very flexible data model which can be used for any kind of meta data structure.

Key Applications

There are various application areas for MDRs, basically in all areas in which the management of meta data is necessary. The most important applications for MDRs are situations in which meta data from different sources has to be integrated in one repository. This goes usually beyond the capabilities of builtin MDRs, i.e., repositories which are integrated with other software components.

Data integration in general is an application area in which MDRs play a central role. If data has to be integrated from heterogeneous systems, the description of this data is required to enable the integration. Data warehouse systems [8] are an example for an architecture of integrated data management in which the role of MDRs has been defined explicitely.

In the context of data warehouse systems, also the problem of data quality has been discussed [10,7]. Meta data is often the basis for data quality measurements, e.g., meta data describes the provenance, the age, the semantics of data. Therefore, MDRs are important components for data quality projects.

A MDR can also be used as a resource for structured documentation about IT systems. In addition to the "usual" meta data artefacts such as models and mappings for data integration, also a documentation of the employed systems and their architecture in an organization is useful.

As discussed before, service-oriented architecture (SOA) are becoming an important concept for software development. As a system based on a SOA is a distributed and often heterogeneous system, the management of meta data in a SOA is also important. Therefore, a MDR is often also a component in a SOA.

Another application area for MDRs might the management of meta data on the web, such as RDF or OWL ontologies. However, the web is build on the idea of decentralized data management which is in conflict with the concept of a central, integrated repository for all kind of meta data. Nevertheless, MDRs can be useful to manage the meta data at a specific site, e.g., the ontologies which are offered by that site and their mappings to other ontologies.

Future Directions

The integration of meta data will remain to be a challenge, however the meta data will be integrated, either materialized in a repository, federated with a virtual integration system, or some combination of these. With the rising importance of web applications, service-oriented architectures and similar concepts, it can be expected that more loosely coupled MDRs with a federated integration become more successful. Existing or upcoming meta data standards, such as such as CWM (common warehouse metamodel) and XMI (XML metadata interchange), might simplify the task, but the integration of meta data will remain a problem. Another trend is the integration of MDR into larger software platforms as it is done (or planned) by the major software vendors.

Meta data integration and new architectures for MDRs are also interesting questions for the research community: How can such systems be built, that enable the integrated querying of various meta data sources? Which lessons can be applied for meta data that have already been learned at the data level? Other research questions for MDRs and meta data management are addressed in model management [3,4] which investigates formal methods for working with data models. The challenge for MDRs here is to provide generic structures for the representation of models and mappings.

Synonyms

MOF

Definition

The Meta Object Facility (MOF) is an OMG metamodeling and metadata repository standard. It is an extensible model driven integration framework for defining, manipulating and integrating metadata and data in a platform independent manner. MOF-based standards are in use for integrating tools, applications and data [1].

Key Points

MOF was developed as a response to a request for proposal (RFP), issued by the OMG Analysis and Design Task Force, for Metadata repository facility (http://www.omg.org/cgi-bin/doc?cf/96-05-02). The purpose of the facility was to support the creation, manipulation, and interchange of meta models.

MOF provides a metadata management framework, and a set of metadata services to enable the development and interoperability of model and metadata driven systems. The MOF metadata framework is typically depicted as a four-layer architecture as shown in Table 1:

The MOF specification has three core parts:

1. The specification of the MOF Model
   a. The MOF's built-in meta-metamodel, the "abstract language" for defining MOF metamodels
2. The MOF IDL Mapping
   a. A standard set of templates that map an MOF metamodel onto a corresponding set of CORBA IDL interfaces
3. The MOF's interfaces
   a. The set of IDL interfaces for the CORBA objects that represent an MOF metamodel

The OMG adopted the MOF version 1.0 in November 1997. The most recent revision of MOF, 2.0, was adopted in January 2006 and based on the following OMG specifications:

- MOF 1.4 Specification – MOF 2.0 is a major revision of the MOF 1.4 Specification. MOF 2.0 addresses issues deferred to MOF 2.0 by the MOF 1.4 RTF.

Meta Object Facility. Table 1. OMG's Metadata Architecture

Meta-level	MOF terms	Examples
M3	Meta-metamodel	The "MOF Model"
M2	Metamodel, meta-metadata	UML Metamodel, CWM Metamodel
M1	Model, metadata	UML models, CWM metadata
M0	Object, data	Modeled systems, Warehouse data

- UML 2.0 Infrastructure Convenience Document: ptc/04-10-14 – MOF 2.0 reuses a subset of the UML 2.0 Infrastructure Library packages.
- MOF 2.0 XMI Convenience document: ptc/04-06-11 – Defines the XML mapping requirements for MOF 2.0 and UML 2.0.

The MOF 2 Model is made up of two main packages, Essential MOF (EMOF) and Complete MOF (CMOF).

1. The EMOF Model merges the Basic package from UML2 and merges the Reflection, Identifiers, and Extension capability packages to provide services for discovering, manipulating, identifying, and extending metadata.
2. The CMOF Model is the metamodel used to specify other metamodels such as UML2. It is built from EMOF and the Core:Constructs of UML 2. The Model package does not define any classes of its own. Rather, it merges packages with its extensions that together define basic metamodeling capabilities.

Examples of metadata driven systems that use MOF include modeling and development tools, data warehouse systems, metadata repositories etc. A number of technologies standardized by OMG, including UML, MOF, CWM, SPEM, XMI, and various UML profiles, use MOF and MOF derived technologies (specifically XMI and more recently JMI which are mappings of MOF to XML and Java respectively) for metadata-driven interchange and metadata manipulation. MOF mappings from MOF to W3C XML and XSD are specified in the XMI (ISO/IEC 19503) specification. Mappings from MOF to Java are in the JMI (Java Metadata Interchange) specification defined by the Java Community Process.

Note that MOF 2.0 is closely related to UML 2.0. MOF 2.0 specification integrates and reuses the complementary UML 2.0 Infrastructure submission to provide a more consistent modeling and metadata framework for OMG's Model Driven Architecture. UML 2.0 provides the modeling framework and notation, MOF 2.0 provides the metadata management framework and metadata services.

MOF was also incorporated into an ISO/IEC (the International Organization for Standardization/the International Electrotechnical Commission) standard (19502:2005) in November 2005. The standard defines a metamodel (defined using the MOF), a set of interfaces (defined using ODP IDL – ITU-T Recommendation X.920 (1997) | ISO/IEC 14750:1999), that can be used to define and manipulate a set of interoperable metamodels and their corresponding models (including the Unified Modeling Language metamodel – ISO/IEC 19501:2005, the MOF meta-metamodel, as well as future standard technologies that will be specified using metamodels). It also defines the mapping from MOF to ODP IDL (ITU rec X920|ISO 14750).

In conclusion, the MOF provides the infrastructure for implementing design and reuse repositories, application development tool frameworks, etc. The MOF specifies precise mapping rules that enable the CORBA interfaces for metamodels to be generated automatically, thus encouraging consistency in manipulating metadata in all phases of the distributed application development cycle.

Metadata

Manfred A. Jeusfeld
Tilburg University, Tilburg, The Netherlands

Definition

Metadata is data linked to some data item, i.e., metadata is data about data. The metadata of a data item specifies how the data item was created, in which context it can be used, how its was transformed, or how it can be interpreted or processed. The earliest use of metadata are bibliographic records about books, such as the author of the book. In principle, any type of data item can have metadata attached to it. The type of the data item itself can be metadata and determines which other metadata fields may be attached to the data item.

Key Points

The purpose of metadata is to provide contextual information for a data item. It may be used hy humans to determine the usability of a data item. Likewise, computer programs can read the metadata in order to guide the processing of a data item. Metadata can be included in the data item (e.g., the date and location of a photography) or it may be stored apart of the data item. In the latter case, the data item requires being identifiable. In databases, metadata fields can be represented next to data fields, virtually blurring the distinction between metadata and data.

Metadata is mostly used in domains where the structure of the data item is rather complex. Metadata typically has a simple structure such as name/value pairs. Applications domains are word processing, multi-media processing, system design, data warehouses, data quality management, and others. The common characteristic of these domains is the presence of many data items of the same type, which need to be managed according to some criteria. Metadata allows providing the necessary information to check these criteria. In the semantic web, metadata can be represented in RDF and related formalisms such as the Dublin Core.

There is no limitation on the size of metadata attached to data items. It can be that the size of metadata exceeds the size of the data item itself. For example, the complete change history of a document is metadata of the document.

The schema of a database can be interpreted as metadata about the database. It specifies the type of the data items stored in the database. Likewise, a metamodel can be interpreted as metadata about schemas (or models).

Definition

ISO/IEC-11179 [10] is an international standard that documents the standardization and registration of metadata to make data understandable and shareable. This standardization and registration allows for easier locating, retrieving, and transmitting data from disparate databases. The standard defines the how metadata are conceptually modeled and how they are shared among parties, but does not define how data is physically represented as bits and bytes. The standard consists of six parts. Part 1 [5] provides a high-level overview of the standard and defines the basic element of a metadata registry – a data element. Part 2 [7] defines the procedures for registering classification schemes and classifying administered items in a metadata registry (MDR). Part 3 [4] specifies the structure of an MDR. Part 4 [6] specifies requirements and recommendations for constructing definitions for data and metadata. Part 5 [8] defines how administered items are named and identified. Part 6 [9] defines how administered items are registered and assigned an identifier.

Historical Background

The first edition of the standard was published by the Technical Committee ISO/IEC JTC1, Information Technology Subcommittee 32, Data Management and Interchange, starting in 1994 and completed in 2000. The second edition was started in 2004 and was completed in 2005. The second edition cancels and replaces the first edition of the standard.

Foundations

Metadata is data that describes other data. A metadata registry is a database of metadata. The database allows for the registration of metadata, which enables the identification, provenance tracking, and quality monitoring of metadata. Identification is accomplished by assigning a unique identifier to each object registered in the registry. Provenance details the source of the metadata and the object described. Monitoring quality ensures that the metadata accomplishes its designed task. An MDR also manages the semantics of data, so that data can be re-used and interchanged. An MDR is organized so that application designers can determine whether a suitable object described in the MDR already exists so that it may be reused instead of developing a new object.

Part 1: Framework

Part 1 introduces the building blocks of the MDR standard: data elements, value domains, data element concepts, conceptual domains, and classification schemes. An MDR is organized as a collection of concepts, which are mental constructs created by a unique combination of characteristics. A concept system is a set of concepts with relations among them. One such concept system that classifies objects is a classification scheme. A classification scheme is organized with some specified structure and is designed for assigning objects to concepts defined within it.

The basic construct in a metadata registry is the data element. A data element consists of a data element concept and a representation. A data element concept (DEC) is a concept that can be represented as a data element described independently of any particular representation. The representation of a data element consists of a value domain, a data-type, units of measure, and a representation class. A data element concept may consist of an object class, which is a set of abstractions in the real world that can be identified with explicit boundaries, and a property, which is a characteristic common to all members of an object class. A value domain is a set of permissible values. Each value domain is a member of the extension of a concept known as the conceptual domain. A conceptual domain is a set of value meanings, which are the associated meanings to values.

An MDR contains metadata describing data constructs. Registering a metadata item makes it a registry item. If the registry item is subject to administration, it is called an administered item. An ISO/IEC 11179 MDR consists of two levels: the conceptual level and the representational level. The conceptual level contains the classes for the data element concept and conceptual domain. The representational level contains classes for data element and value domain.

Part 2: Classification

Part 2 provides a conceptual model for managing concept systems used as classification schemes. Associating an object with a concept from a classification scheme provides additional understanding of the object, comparative information across similar objects, an understanding of an object within the context of a subject matter field, and the ability to identify differences of meaning between similar objects.

Classification schemes are registered in an MDR by recording their attributes, such as those regarding its designation, definition, classification scheme, administration record, reference document, submission, stewardship, registration authority, and registrar.

Part 2 also defines the mechanism for classifying an administered item, which is the assignment of a concept to an object. Objects can also be linked together by relationships linking concepts in the concept system.

Part 3: Registry Metamodel and Basic Attributes

Part 3 describes the basic attributes that are required to describe metadata items and the structure for a metadata registry. The standard uses a metamodel to describe the structure of an MDR. A metamodel is a model that describes other models. The registry metamodel is specified as a conceptual data model, which describes how relevant information is structured in the real world, and is expressed in the Unified Modeling Language [13].

The registry model is divided into six regions:

- **The administration and identification region:** supports the administrative aspects of administered items in the MDR. This region manages the identification and registration of items submitted to the registry, organizations that have submitted and/or are responsible for items in the registry, supporting documentation, and relationships among administered items. An administered item can be a classification scheme, a conceptual domain, context for an administered item, a data element, a data element concept, an object class, a property, a representation class, and a value domain. An administered item is associated with an administration record, which records administrative information about the administered item in the registry.
- **The naming and definition region:** manages the names and definitions of administered items and the contexts for names. Each administered item is named and defined within one or more contexts. A context defines the scope within which the data has meaning, such as a business domain, a subject area, an information system, a data model, or standards document.
- **The classification region:** manages the registration and administration of classification schemes and their constituent classification scheme items. It is also used to classify administered items.
- **The data element concepts region:** maintains information on the concepts upon which the data elements are developed, primarily focusing on semantics.
- **The conceptual and value domain region:** administrates the conceptual domains and value domains.
- **The data element region:** administrates data elements, which provide the formal representations for some information (e.g., a fact, observation, etc.) about an object. Data elements are reusable and shareable representations of data element concepts.

Part 4: Formulation of Data Definitions

Part 4 specifies the requirements and recommendations for constructing data and metadata definitions. A data definition must be stated in the singular. It also must be a descriptive phrase, containing only commonly understood abbreviations, that state what the concept is (as opposed to what the concept is not). A data definition must also be expressed without embedding definitions of other data. The standard also recommends that a data definition should be concise, precise, and unambiguous when stating the essential meaning of the concept. Additionally, a data definition should be self-contained and be expressed without embedding rationale, functional usage, or procedural information, circular reasoning. Terminology and consistent logical structure for related definitions should also be used.

Part 5: Naming and Identification Principles

Part 5 defines the naming and identification of the data element concept, the conceptual domain, data element, and value domain. Each administered item has a unique data identifier within the register of a Registration Authority (RA), which is the organization responsible for an MDR. The international registration data identifier (IRDI) uniquely identifies an administered item globally and consists of a registration authority identifier (RAI), data identifier (DI), and version identifier (VI).

Each administered item has at least one name within a registry of an RA. Each name for an administered item is specified within a context. A naming convention can be used for formulating names. A naming convention may address the scope of the naming convention and the authority that establishes the name. A naming convention may additionally address semantic, syntactic, lexical, and uniqueness rules. Semantic rules govern the existence of the source and content of the terms in a name. Syntactic rules govern the required term order. Lexical rules govern term lists, name length, character set, and language. Uniqueness rules determine whether or not names must be unique.

Part 6: Registration

Part 6 specifies how administered items are registered and assigned an IRDI. Metadata in the MDR is also associated with a registration status, which is a designation of the level of registration or quality of the administered item. There are two types of status categories: lifecycle and documentation. The lifecycle registration status categories address the development and progression of the metadata and the preferences of usage of the administered item. The documentation registration status categories are used when there is no further development in the quality of metadata or use of the administered item.

Each RA establishes its own procedures for the necessary activities of its MDR. Some activities include the submission, progression, harmonization, modification, retirement, and administration of administered items.

Key Applications

The standardization that ISO/IEC 11179 provides enables for the easy sharing of data. For example, many organizations exchange data between computer systems using data integration technologies. In data warehousing schemes, completed transactions must be regularly transferred to separate data warehouses. Exchanges of data can be accomplished more easily if data is defined precisely so that automatic methods can be employed. By having a repository of metadata that describes data, application designers can reuse and share data between computer systems, making the sharing of data easier. ISO/IEC 11179 also simplifies data manipulation by software by enabling the manipulation of data based on characteristics described by the metadata in the registry. This also allows for the development of a data representation model for CASE tools and repositories [3].

There are several organizations that have developed MDRs that comply with ISO/IEC 11179, such as the Australian Institute of Health and Welfare [1], the US Department of Justice [14], the US Environmental Protection Agency [15], the Minnesota Department of Education [11], and the Minnesota Department of Revenue [12]. Currently, there is also an MDR available developed by Data Foundations [2].

Synonyms

Meta model

Definition

A metamodel is a model that consists of statements about models. Hence, a metamodel is also a model but its universe of discourse is a set of models, namely those models that are of interest to the creator of the metamodel. In the context of information systems, a metamodel contains statements about the constructs used in models about information systems. The statements in a metamodel can define the constructs or can express true and desired properties of the constructs. Like models are abstractions of some reality, metamodels are abstractions of models. The continuation of the abstraction leads to meta metamodels, being models of metamodels containing statements about metamodels. Metamodeling is the activity of designing metamodels (and metametamodels). Metamodeling is applied to design new modeling languages and to extend existing modeling languages.

A second sense of the term metamodel is the specification of the generation of mathematical models, in particular sets of mathematical equations that describe some reality.

Historical Background

One of the earliest metamodels is the definition of the binary data model of Abrial [1]. Abrial distinguished three abstraction levels: the data level of a database, the schema of the database (model), and the category level (metamodel).

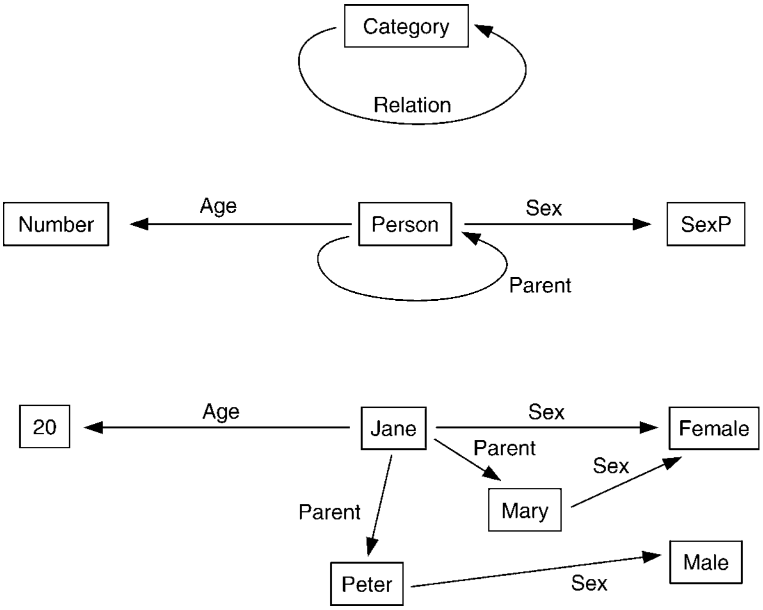
The metamodel defining the binary data model consists of the construct `Category` and the construct `relation`. Abrial interpreted the abstraction between the levels as classification. For example, `Jane` is classified to `Person` and `Person` is classified to `Category`. A similar classification holds for the relations.

In the 1980s, the use of metamodels became so widespread that an ISO standard, the Information Resource Dictionary Standard [2], was defined. It extended Abrial's view by a fourth level, i.e., by metametamodels. In the late 1990s, the Object Management Group (OMG) [5] consolidated and standardized the terminology of metamodels. They distinguished the levels M_0 (information), M_1 (model), M_2 (metamodel), and M_3 (metametamodel). The M_3 level is under control of OMG. It defined four basic constructs (classes, associations, data types, and packages). The M_2 level is used to define modeling languages such as UML, IDL, and so forth.

Besides the standardization efforts, there were several metamodeling languages developed from the 1990s onwards that mostly adopted the four-level approach. Examples is the Telos language and the GOPPR language of MetaEdit+ [9].

Foundations

Meta models in computer science and related domains are mainly used to facilitate conceptual modeling, to define constructs of the conceptual modeling languages, to specify constraints on the use of constructs, and to encode the similarities of different models (and metamodels). As conceptual modeling is about representing concepts, an element of a metamodel is



Metamodel. Figure 1. Abrial's definition of the binary data model.

also a concept say *meta concept*, being interpreted by all entities that are defined or constrained by the meta concept. For example, the meta concept `EntityType` is a construct of the Entity-Relationship Diagramming language. It is interpreted by all possible entity types of all possible entity relationship diagrams. Essentially, `EntityType` is the name of a set that has all possible entity types as elements. A problem with this set-view is that it immediately introduces sets of sets (=concepts in metamodels) and sets of sets of sets (concepts of metametamodels). To overcome this complexity, metamodels were originally only investigated as level-pairs: (metametamodel vs. metamodel), (metamodel vs. model), (model vs. data). First a metametamodel is developed. Then, a metamodel or several metamodels are expressed as instances of the metametamodel, then models are expressed in terms of the metamodels. The lowest level (M_0 in MOF) is typically not expressed in conceptual modeling since it is about data or actual activities of some application domain. The pair-wise approach allows to keep the set-oriented semantics or other forms of semantics specification relying on distinguishing a concept from its instances.

The set-oriented semantics is mirrored by a logical interpretation, in which concepts are represented by unary predicates and relations and attributes are represented by binary predicates. For example, `EntityType (Employee)` is the fact expressing that `Employee` (model level) is classified to `EntityType` (metamodel level). A fact `Employee(Jane)` would then express that `Jane` (data level) is an instance of `Employee`. If one restricts to just two consecutive levels, predicate symbols can be distinguished from constant symbols. In other words, the underlying logic is a first order logic. Scaling the semantics to more than two levels would move the logic to higher order.

One can avoid higher order semantics by introducing a binary predicate `In(x,c)` where `x` is some concept of some modeling level M_i and `c` is a concept of the next higher modeling level M_{i+1}. This framework allows to represent the facts `In(Employee,EntityType)` and `In(Jane,EntityType)` without leaving first order logic.

The specific choice of the underlying semantics for metamodels determines to which degree a metamodel can express the intended meaning of the concepts included in a metamodel. In UML, the semantics of the UML constructs are defined in a metamodel using OCL (object constraint language [6]). Current metamodeling tools dominantly use cardinality constraints as means to constrain the semantics of metamodel concepts. Constraints exceeding cardinalities have to be expressed in OCL or script languages.

The second sense of metamodels, the generation of mathematical equations to describe some reality, is for example used by Bailey and Basili [3] to develop a formal framework for understanding real world phenomena in the domain of software engineering.

Key Applications

Meta models became a popular technique at the end of the 1990s. The current specification of UML is supporting metamodeling in order to extend the capabilities of the language and to adapt it to specific modeling domains. Tools supporting metamodeling are among others MetaEdit+ [9], ConceptBase [4] and Aris [7]. The MetaEdit+ tool claims to accelerate system development by orders of magnitude since the concepts of a metamodel can be linked to parameterized program code.

Future Directions

An open problem of metamodels is their utility. If a metamodel is represented as a UML class diagram, then it does list the allowed constructs but it does not explain how to use it in a meaningful way, i.e., to represent models in terms of the metamodel. Conceptual modeling textbooks motivate constructs by examples and discuss scenarios in which certain constructs are usable. This pragmatic level is neglected by metamodels.

Meta models should be seen as part of the larger model-driven architecture framework. That framework (also defined by OMG) is based on the assumption that system development is essentially a series of model transformations. The design of system development methods is then the combination of metamodeling and the specification of suitable model transformations.

The relationship between metamodels (or metametamodel) with ontologies is not yet well understood. Ontologies rely on two levels of abstraction: the concepts defined in the ontology and the real world objects being the interpretations of the concepts. Apparently, an ontology makes no difference between a model level concept like `Employee` and a metamodel level concept like `EntityType`. See also [8] for a discussion.

Federated search engine

Definition

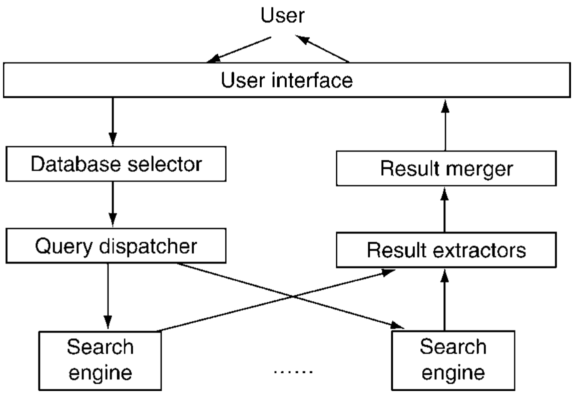
Metasearch is to utilize multiple other search systems (called *component search systems*) to perform simultaneous search. A metasearch engine is a search system that enables metasearch. To perform a basic metasearch, a user query is sent to multiple existing search engines by the metasearch engine; when the search results returned from the search engines are received by the metasearch engine, they are merged into a single ranked list and the merged list is presented to the user. Key issues include how to pass user queries to other search engines, how to identify correct search results from the result pages returned from search engines, and how to merge the results from different search sources. More sophisticated metasearch engines also perform *search engine selection* (also referred to as *database selection*), i.e., identify the search engines that are most appropriate for a query and send the query to only these search engines. To identify appropriate search engines to use for a query requires estimating the usefulness of each search engine with respect to the query based on some usefulness measure.

Historical Background

The earliest Web-based metasearch engine is probably the MetaCrawler system [12] that became operational in June 1995. (The MetaCrawler's website (www.metacrawler.com) says the system was first developed in 1994.) Motivations for metasearch include (i) increased search coverage because a metasearch engine effectively combines the coverage of all component search engines, (ii) improved convenience for users because a metasearch engine allows users to get information from multiple sources with one query submission and the metasearch engine hides the differences in query formats of different search engines from the users, and (iii) better retrieval effectiveness because the result merging component can naturally incorporate the voting mechanism, i.e., results that are highly ranked by multiple search engines are more likely to be relevant than those that are returned by only one of them. Over the last thirteen years, many metasearch engines have been developed and deployed on the Web. Most of them are built on top of a small number of popular general-purpose search engines but there are also metasearch engines that are connected to more specialized search engines (e.g., medical/health search engines) and some are connected to over one thousand search engines.

Even the earliest metasearch engines tackled the issues of search result extraction and result merging. Result merging is one of the most fundamental components in metasearch, and as a result, it has received a lot of attention in the metasearch and distributed information retrieval (DIR) communities and a wide range of solutions has been proposed to achieve effective result merging. Since different search engines may index a different set of web pages and some search engines are better than others for queries in different subject areas, it is important to identify the appropriate search engines for each user query. The importance of search engine selection was realized early in metasearch research and many approaches have been proposed to address this issue. A survey on some earlier result merging and search engine selection techniques can be found in [11].

Most metasearch engines are built on top of other search engines without explicit cooperation from these search engines. As a result, creating these metasearch engines requires a connection program and an extraction program (wrapper) for each component search engine. The former is needed to pass the query from the metasearch engine to the search engine and receive search results returned from the search engine, and the latter is used to extract the search result records from the result pages returned from the search engine. While the programs may not be difficult to produce by an experienced programmer, maintaining their validity can be a serious problem as they can become obsolete when the used search engines change their connection parameters and/or result display format. In addition, for applications that need to connect to hundreds or thousands of search engines, it can be very expensive and time-consuming to produce and maintain these programs. As a result, in recent years, automatic wrapper generation techniques have received much attention. Figure 1 shows a basic architecture of a typical metasearch engine.



Metasearch Engines. Figure 1. Metasearch engine component architecture.

Foundations

Result Merging

Result merging is to combine the search results returned from multiple search engines into a single ranked list. Early search engines often associated a numerical matching score (similarity score) to each retrieved search result and the result merging algorithms at that time were designed to "normalize" the scores returned from different search engines into values within a common range with the goal to make them more comparable. Normalized scores will then be used to re-rank all the search results. When matching scores are not available, the ranks of the search results from component search engines can be aggregated using voting-based techniques (e.g., Borda Count [1]). Score normalization and rank aggregation may also take into consideration the estimated usefulness of each selected search engine with respect to the query, which is obtained during the search engine selection step. For example, the normalized score of a result can be weighted by the usefulness score of the search engine that returned the result. This increases the chance for the results from more useful search engines to be ranked higher.

Another result merging technique is to download all returned documents from their local servers and compute their matching scores using a common similarity function employed by the metasearch engine. The results will then be ranked based on these scores. For example, the Inquirus metasearch engine employs this approach [7]. The advantage of this approach is that it provides a uniform way to compute ranking scores so the resulted ranking makes more sense. Its main drawback is the longer response time due to the delay caused by downloading the documents and analyzing them on the fly. Most modern search engines display the title of each retrieved result together with a short summary called *snippet*. The title and snippet of a result can often provide good clues on whether or not the result is relevant to a query. As a result, result merging algorithms that rely on titles and snippets have been proposed recently (e.g., [9]). When titles and snippets are used to perform the merging, a matching score of each result with the query can be computed based on several factors such as the number of unique query terms that appear in the title/snippet and the proximity of the query terms in the title/snippet.

It is possible that the same result is retrieved from multiple search engines. Such results are more likely to be relevant to the query based on the observation that different ranking algorithms tend to retrieve the same set of relevant results but different sets of irrelevant results [8]. To help rank these results higher in the merged list, the ranking scores of these results from different search engines can be added up to produce the final score for the result. The search results are then ranked in descending order of the final scores.

Search Engine Selection

To enable search engine selection, some information that can represent the contents of the documents of each component search engine needs to be collected first. Such information for a search engine is called the *representative* of the search engine. The representatives of all search engines used by the metasearch engine are collected in advance and are stored with the metasearch engine. During search engine selection for a given query, search engines are ranked based on how well their representatives match with the query. Different search engine selection techniques have been proposed and they often use different types of representatives. A simple representative of a search engine may contain only a few selected key words or a short description. This type of representative is usually produced manually by someone familiar with the contents of the search engine but it can also be automatically generated. As this type of representatives provides only a general description of the contents of search engines, the accuracy of using such representatives for search engine selection is usually low. More elaborate representatives consist of detailed statistical information for each term in each search engine. In [14], the *document frequency* of each term in each search engine is used to compute the *cue validity variance* of each query term, which measures the skew of the distribution of the query term across all component search engines, to help rank search engines for each query. In [3], the *document frequency* and *collection frequency* of each term (the latter is the number of component search engines that contain the term) are used to represent each search engine. In [10], the *adjusted maximum normalized weight* of each term across all documents in a search engine is used to represent a search engine. For a given term *t* and a search engine *S*, the adjusted maximum normalized weight of *t* is computed as follows: compute the normalized weight of *t* in every document (i.e., the term frequency weight of *t* divided by the length of the document) in *S*, find the maximum value among these weights, and multiply this maximum weight by the global *idf* weight of *t* across all component search engines. In [13], the notion of optimal search engine ranking is proposed based on the objective of retrieving the *m* most similar (relevant) documents with respect to a given query Q from across all component search engines: *n* search engines are said to be optimally ranked with order [S_1, S_2,...,S_n] if for any integer *m*, an integer *k* can be found such that the *m* most similar documents are contained in [S_1,...,S_k] and each of these *k* search engines contain at least one of the *m* most similar documents. It is shown in [13] that a necessary and sufficient condition for the component search engines to be optimally ranked is to order the search engines in descending order of the similarity of the most similar document with respect to Q in each search engine. Different techniques have been proposed to estimate the similarity of the most similar document with respect to a given query and a given search engine [10,13]. Since it is impractical to find out all the terms that appear in some pages in a search engine, an approximate vocabulary of terms for a search engine can be used. Such an approximate vocabulary can be obtained from pages retrieved from the search engine using probe queries [2].

There are also techniques that create search engine representatives by learning from the search results of past queries. Essentially such type of representatives is the knowledge indicating the past performance of a search engine with respect to different queries. In the Savvy Search metasearch engine [4], for each component search engine *S*, a weight is maintained for every term that has appeared in previous queries. After each query *Q* is evaluated, the weight of each term in the representative that appears in *Q* is increased or decreased depending on whether or not *S* returns useful results. Over time, if a term for *S* has a large positive (negative) weight, then *S* is considered to have responded well (poorly) to the term in the past. For a new query received by the metasearch engine, the weights of the query terms in the representatives of different search engines are aggregated to rank the search engines. In the ProFusion metasearch engine [5], training queries are used to find out how well each search engine responds to queries in different categories. The knowledge learned about each search engine from training queries is used to select search engines for each user query and the knowledge is continuously updated based on the user's reaction to the search result, i.e., whether or not a particular retrieved result is clicked by the user.

Automatic Search Engine Connection

The search interfaces of most search engines are implemented using the HTML *form* tag with a query textbox. In most cases, the form tag of a search engine contains all information needed to make the connection to the search engine, i.e., sending queries and receiving search results, via a program. Such information includes the name and the location of the program (i.e., the search engine server) that evaluates user queries, the network connection method (i.e., the HTTP request method, usually GET or POST), and the name associated with the query textbox that is used to save the query string. The form tag of each search engine interface is usually pre-processed to extract the information needed for program connection and the extracted information is saved at the metasearch engine. The existence of Javascript in the form tag usually makes extracting the connection information more difficult. After the metasearch engine receives a query and a particular search engine, among possibly other search engines, is selected to evaluate this query, the query is assigned to the name of the query textbox of the search engine and sent to the server of the search engine using the HTTP request method supported by the search engine. After the query is evaluated by the search engine, one or more result pages containing the search results are returned to the metasearch engine for further processing.

Automatic Search Result Extraction

A result page returned by a search engine is a dynamically generated HTML page. In addition to the search result records for a query, a result page usually also contains some unwanted information/links such as advertisements and sponsored links. It is important to correctly extract the search result records on each result page. A typical search result record corresponds to a retrieved document and it usually contains the URL and the title of the page as well as a short summary (snippet) of the document. Since different search engines produce result pages in different format, a separate result extraction program (also called *extraction wrapper*) needs to be generated for each search engine. Automatic wrapper generation for search engines has received a lot of attention in recent years and different techniques have been proposed. Most of them analyze the source HTML files of the result pages as text strings or tag trees (DOM trees) to find the repeating patterns of the search record records. A survey that contains some of the earlier extraction techniques can be found in [6]. Some more recent works also utilize certain visual information on result pages to help identify result patterns (e.g., [15]).

Key Applications

The main application of metasearch is to support search. It can be an effective mechanism to search both surface web and deep web data sources. By providing a common search interface over multiple search engines, metasearch eliminates users' burden to search multiple sources separately. When a metasearch engine employs certain special component search engines, it can support interesting special applications. For example, for a large organization with many branches (e.g., a university system may have many campuses), if each branch has its own search engine, then a metasearch engine connecting to all branch search engines becomes an organization-wide search engine. As another example, if a metasearch engine is created over multiple e-commerce search engines selling the same type of product, then a comparison-shopping system can be created. Of course, for comparison-shopping applications, a different type of result merging is needed, such as listing different search results that correspond to the same product in non-descending order of the prices.

Future Directions

Component search engines employed by a metasearch engine may change their connection parameters and result display format anytime. These changes can make the affected search engines un-usable in the metasearch engine unless the corresponding connection programs and result extraction wrappers are changed accordingly. How to monitor the changes of search engines and make the corresponding changes in the metasearch engine automatically and timely is an area that needs urgent attention from metasearch engine researchers and developers.

Most of today's metasearch engines employ only a small number of general-purpose search engines. Building large-scale metasearch engines using numerous specialized search engines is another area that deserves more attention. The current largest metasearch engine is a news metasearch engine called AllInOneNews (www.allinonenews.com). This metasearch engine currently connects to about 1,800 news search engines. Challenges arising from building very large-scale metasearch engines include automatic generation and maintenance of high quality search engine representatives needed for efficient and effective search engine selection, and highly automated techniques to add search engines into metasearch engines and to adapt to changes of search engines.

Metric Space

Pavel Zezula, Michal Batko, Vlastislav Dohnal
Masaryk University, Brno, Czech Republic

Synonyms

Distance space

Definition

In mathematics, a metric space is a pair $M = (D, d)$, where D is a domain of objects (or objects' *keys* or *indexed descriptors*) and d is a total (distance) function. The properties of the function $d : D \times D \mapsto R$, sometimes called the metric space postulates, are typically characterized as:

(p1)	$\forall x, y \in D, d(x, y) \geq 0$	non-negativity,
(p2)	$\forall x, y \in D, d(x, y) = d(y, x)$	symmetry,
(p3)	$\forall x \in D, d(x, x) = 0$	reflexivity,
(p4)	$\forall x, y \in D, x \neq y \Rightarrow d(x, y) > 0$	positiveness,
(p5)	$\forall x, y, z \in D, d(x, z) \leq d(x, y) + d(y, z)$	triangle inequality.

Key Points

Modifying or even abandoning some of the metric function properties leads to interesting concepts that can better suit the reality in many situations. A *pseudo-metric* function does not satisfy the positiveness property (p4), i.e., there can be pairs of different objects that have zero distance. However, these functions can be transformed to the standard metric by regarding any pair of objects with zero distance as a single object. If the symmetry property (p2) does not hold, the function is called a *quasi-metric*. For example, a car-driving distance in a city where one-way streets exist is a quasi-metric. The following equation allows to transform a quasi-metric into a standard metric: $d_{sym}(x, y) = d_{asym}(x, y) + d_{asym}(y, x)$. By tightening the triangle inequality property (p5) to $\forall x, y, z \in D$, $d(x, z) \leq \max\{d(x, y), d(y, z)\}$, an *ultra-metric* also called *super-metric* is obtained. The geometric characterization of the ultra-metric requires every triangle to have at least two sides of equal length, i.e., to be isosceles. A metric space M is bounded if there exists a number r, such that $d(x, y) \leq r$ for any $x, y \in D$. More details about metric functions can be found in [3].

Microdata

Josep Domingo-Ferrer
Universitat Rovira i Virgili, Tarragona, Catalonia

Synonyms

Individual data

Definition

A *microdata* file V with s respondents and t attributes is an $s \times t$ matrix where V_{ij} is the value of attribute j for respondent i. Attributes can be numerical (e.g., age, salary) or categorical (e.g., gender, job).

Key Points

The attributes in a microdata set can be classified in four categories which are not necessarily disjoint [1,2]:

1. *Identifiers*. These are attributes that *unambiguously* identify the respondent. Examples are the passport number, social security number, name-surname, etc.
2. *Quasi-identifiers or key attributes*. These are attributes which identify the respondent with some degree of ambiguity. (Nonetheless, a combination of quasi-identifiers may provide unambiguous identification.) Examples are address, gender, age, telephone number, etc.
3. *Confidential outcome attributes*. These are attributes which contain sensitive information on the respondent. Examples are salary, religion, political affiliation, health condition, etc.
4. *Non-confidential outcome attributes*. Those attributes which do not fall in any of the categories above.

Microaggregation

JOSEP DOMINGO-FERRER
Universitat Rovira i Virgili, Tarragona, Catalonia

Definition

Microaggregation is a family of masking methods for statistical disclosure control of numerical microdata (although variants for categorical data exist). The rationale behind microaggregation is that confidentiality rules in use allow publication of microdata sets if records correspond to groups of k or more individuals, where no individual dominates (i.e., contributes too much to) the group and k is a threshold value. Strict application of such confidentiality rules leads to replacing individual values with values computed on small aggregates (microaggregates) prior to publication. This is the basic principle of microaggregation.

To obtain microaggregates in a microdata set with n records, these are combined to form g groups of size at least k. For each attribute, the average value over each group is computed and is used to replace each of the original averaged values. Groups are formed using a criterion of maximal similarity. Once the procedure has been completed, the resulting (modified) records can be published.

The optimal k-partition (from the information loss point of view) is defined to be the one that maximizes within-group homogeneity. The higher the within-group homogeneity, the lower the information loss, since microaggregation replaces values in a group by the group centroid. The sum of squares criterion is common to measure homogeneity in clustering. The within-groups sum of squares SSE is defined as

$$SSE = \sum_{i=1}^{g} \sum_{j=1}^{n_i} (x_{ij} - \bar{x}_i)'(x_{ij} - \bar{x}_i)$$

The lower SSE, the higher the within-group homogeneity. Thus, in terms of sums of squares, the optimal k-partition is the one that minimizes SSE.

Key Points

For a microdata set consisting of p attributes, these can be microaggregated together or partitioned into several groups of attributes. Also the way to form groups may vary. Several taxonomies are possible to classify the microaggregation algorithms in the literature: (i) fixed group size vs. variable group size; (ii) exact optimal (only for the univariate case vs. heuristic microaggregation; (iii) continuous vs. categorical microaggregation.

To illustrate, a heuristic algorithm called MDAV (maximum distance to average vector, by Domingo-Ferrer, Mateo-Sanz and Torra) is next given for multivariate fixed group size microaggregation on unprojected continuous data. MDAV has been implemented in the μ-Argus package:

1. Compute the average record $\bar{x}$ of all records in the dataset. Consider the most distant record x_r to the average record $\bar{x}$ (using the squared Euclidean distance).
2. Find the most distant record x_s from the record x_r considered in the previous step.
3. Form two groups around x_r and x_s, respectively. One group contains x_r and the $k - 1$ records closest to x_r. The other group contains x_s and the $k - 1$ records closest to x_s.
4. If there are at least $3k$ records which do not belong to any of the two groups formed in Step 3, go to Step 1 taking as new dataset the previous dataset minus the groups formed in the last instance of Step 3.
5. If there are between $3k - 1$ and $2k$ records which do not belong to any of the two groups formed in Step 3: (i) compute the average record $\bar{x}$ of the remaining records; (ii) find the most distant record x_r from $\bar{x}$; (iii) form a group containing x_r and the $k - 1$ records closest to x_r; (iv) form another group containing the rest of records. Exit the Algorithm.
6. If there are less than $2k$ records which do not belong to the groups formed in Step 3, form a new group with those records and exit the Algorithm.

The above algorithm can be applied independently to each group of attributes resulting from partitioning the set of attributes in the dataset. Microaggregation can be used to achieve k-anonymity.

Jeffrey Xu Yu[3]
[1]University of Alberta, Edmonton, AB, Canada
[2]INRIA Saday, Orsay, Cedex, France
[3]The Chinese University of Hong Kong, Hong Kong, China

Definition

A micro-benchmark is an experimental tool that studies a given aspect (e.g., performance, resource consumption) of XML processing tool. The studied aspect is called the target of the micro-benchmark. A micro-benchmark includes a parametric measure and guidelines, explaining which data and/or operation parameters may impact the target, and suggesting value ranges for these parameters.

Key Points

Micro-benchmarks help capture the behavior of an XML processing system on a given operation, as a result of varying one given parameter. In other words, the goal of a micro-benchmark is to study the *precise* effect of a given system feature or aspect *in isolation*.

Micro-benchmarks were first introduced for object-oriented databases [2]. An XML benchmark sharing some micro-benchmark features is the Michigan benchmark [3]. The MemBeR project [1], developed jointly by researchers at INRIA Futurs, the University of Amsterdam, and University of Antwerpen provides a comprehensive repository of micro-benchmarks for XML.

Unlike application benchmarks, micro-benchmarks do not directly help determining which XML processing system is most appropriate for a given task. Rather, they are helpful in assessing particular modules, algorithms and techniques present inside an XML processing tool. Micro-benchmarks are therefore typically very useful to system developers.

Microdata Rounding

Josep Domingo-Ferrer
Universitat Rovira i Virgili, Tarragona, Catalonia

Synonyms

Rounding

Definition

Microdata rounding is a family of masking methods for statistical disclosure control of numerical microdata; a similar principle can be used to protect tabular data. Rounding replaces original values of attributes with rounded values. For a given attribute X_i, rounded values are chosen among a set of rounding points defining a *rounding set* (often the multiples of a given base value).

Key Points

In a multivariate original dataset, rounding is usually performed one attribute at a time (*univariate* rounding); however, multivariate rounding is also possible [1,2]. The operating principle of rounding makes it suitable for continuous data.

Middleware Support for Database Replication and Caching

Emmanuel Cecchet
EPFL, Lausanne, Switzerland

Definition

Database replication is a technique that aims at providing higher availability and performance than a single RDBMS. A database replication middleware implements a number of replication algorithms on top of existing RDBMS. Features provided by the replication middleware include load balancing, caching, and fault tolerance.

Historical Background

Database replication is a well-known mechanism for performance scaling and availability of databases across a wide range of requirements. Limitations of 2-phase commit and synchronous replication have been pointed out early on by Gray et al. [7]. Since then, research on middleware-based replication addresses these issues and tries to provide solutions for better performance and availability while maintaining consistency guarantees for applications.

Foundations

Database replication is a wide area of research that encompasses multiple architectures and possible designs. This entry does not address in-core database replication, where the replication algorithms are implemented inside the database engine. Instead, it focuses on middleware-based replication, where the replication logic is implemented in a set of middleware components, outside the database engine.

Shared Disk Versus Shared Nothing

Two main architecture designs can be chosen for database replication. *Shared disk* replication is mostly used by in-core implementations, where replicas share the data storage, such as, a SAN (Storage Area Network). Middleware-based replication usually uses a *shared nothing* architecture, where each replica has its own local storage. This allows disk IOs to be distributed among replicas and prevents the storage from being a Single Point of Failure (SPOF).

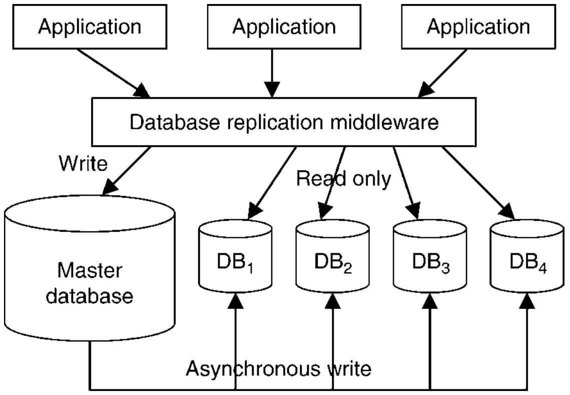
Master/Slave Versus Multi-Master

Database replication is often used as a way to scale up performance. Such efforts are typically targeted at increasing read performance or at increasing write performance; increasing both simultaneously is difficult.

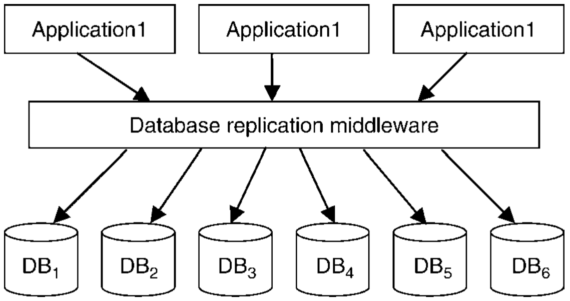
Master-slave replication, depicted in Fig. 1, is popular because it improves read performance. This setup is frequently used in e-commerce applications, with slave databases dedicated to product catalog browsing, while the master performs all catalog updates.

In this scenario, read-only content is accessed on the slave nodes and updates are sent to the master. If the application can tolerate loose consistency, any data can be read at any time from the slaves given a freshness guarantee. As long as the master node can handle all updates, the system can scale linearly simply by adding slave nodes.

Multi-master replication, as shown on Fig. 2, allows each replica that owns a full copy of the database to serve both read and write requests. The replicated system then behaves as a centralized database which theoretically does not require any application modifications. However, replicas need to synchronize to agree on a serializable execution order of transactions so that each replica executes update transactions in the same order. Also, concurrent transactions might



Middleware Support for Database Replication and Caching. Figure 1. Master/slave scale-out scenario.

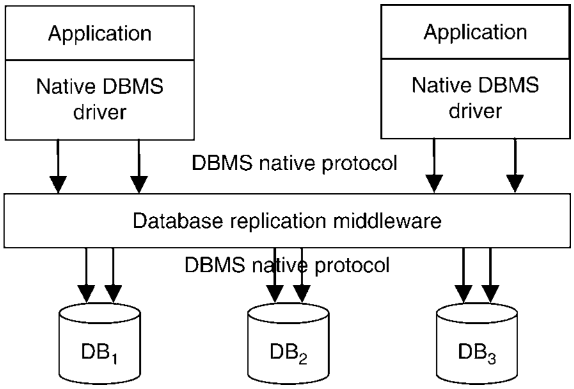


Middleware Support for Database Replication and Caching. Figure 2. Multi-Master database replication.

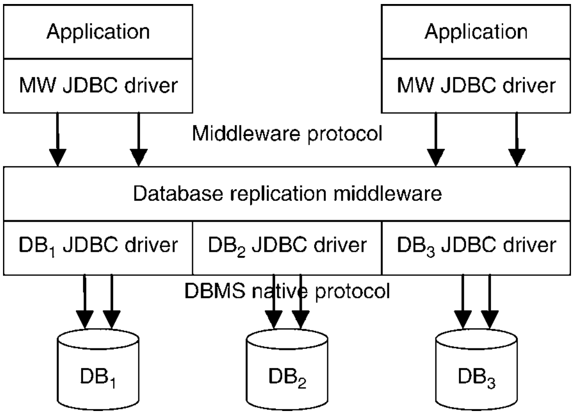
conflict leading to aborts and limiting the system scalability [7]. Even though real applications generally avoid conflicting transactions, significant efforts are spent to optimize for this problem in middleware replication research. However, the volume of update transactions remains the limiting performance factor for such systems.

Middleware Design

The replication middleware has to intercept client requests to process them and run them through the replication algorithm. A first technique consists of keeping existing database drivers and to intercept queries at the database protocol level as show on Fig. 3. This has the significant advantage to not have to re-implement database drivers but the database protocol specification must be available, which is not always the case for commercial databases. Moreover, this design requires multi-protocol implementations and bridges to support heterogeneous clusters.



Middleware Support for Database Replication and Caching. Figure 3. Query interception at the DBMS protocol level.



Middleware Support for Database Replication and Caching. Figure 4. Query interception in JDBC-based replication.

Another technique provides the application with a replacement driver that can communicate with the replication middleware and that is API compatible with the original driver so that application changes are not required. Figure 4 shows an example of a middleware that intercepts queries at the JDBC level. The client application uses the middleware JDBC driver, and the middleware uses the database native JDBC driver to access the replicas. The middleware driver typically adds functionality such as load balancing and failover that is usually not present in standalone database drivers. This is a popular approach introduced by C-JDBC [3] (now Sequoia [9]) and used in other prototypes like Tashkent [5] and Ganymed [8].

Concurrency Control

In replicated database systems, each replica runs Snapshot Isolation (SI) as its local concurrency control and the replicated system provides Generalized Snapshot Isolation (GSI) to the clients.

Snapshot isolation (SI) is a multi-version database concurrency control algorithm for centralized databases. In snapshot isolation, when a transaction begins it receives a logical copy, called snapshot, of the database for the duration of the transaction. This snapshot is the most recent version of the committed state of the database. Once assigned, the snapshot is unaffected by (i.e., isolated from) concurrently running transactions. When an update transaction commits, it produces a new version of the database.

Many database vendors use SI, e.g., PostgreSQL, Oracle and Microsoft SQL Server. SI is weaker than serializability but in practice many applications run serializably under SI including the widely used database benchmarks TPC-C and TPC-W. SI has attractive performance properties. Most notably, read-only transactions do not block or abort-they do not need read-locks, and they do not cause update transactions to block or abort.

Generalized Snapshot Isolation (GSI) extends SI to replicated databases such that the performance properties of SI in a centralized setting are maintained in a replicated setting. In addition, workloads that are serializable under SI are also serializable under GSI.

Informally, a replica using GSI works as follows. When a transaction starts, the replica assigns its latest snapshot to the transaction. All read and write operations of a transaction, e.g., the SELECT, UPDATE, INSERT and DELETE SQL statements, are executed locally on the replica. At commit, the replica extracts the transaction writeset. If the writeset is empty (i.e., it is a read-only transaction), the transaction commits immediately. Otherwise, certification is performed to detect write-write conflicts among update transactions in the system. If no conflict is found, then the transaction commits, otherwise it aborts.

Certification results in total order on the commits of update transactions. Since committing an update transaction creates a new version (snapshot) of the database, the total order defines the sequence of snapshots the database goes through. Therefore, processing update transactions proceeds as follows: When a replica receives update transaction T, it executes T against a snapshot. At commit, the certification service receives the writeset of T and the version of the assigned snapshot. If certification is successful, the replica applies writesets of concurrent update transactions that committed before T in the order determined during certification and then commits T. Certification is a stateful service because it maintains recent committed writesets and their versions.

Statement Replication Versus Transaction Replication

Multi-master replication can be implemented either by multicasting every update statement (statement replication) or by capturing transaction writesets (the set of data *W* updated by a transaction *T*, such that applying *W* onto a replica is equivalent to executing *T* on it) and propagating them after certification (transaction replication). Both approaches have different performance/availability tradeoffs.

Statement-based replication requires that the execution of an update statement produces the same result on each replica. However, many SQL statements may produce different results on every replica if they are not processed before execution. This requires macros related to timing or random numbers to be preprocessed for a deterministic execution cluster-wide. Moreover, stored procedures or user-defined functions must have a deterministic behavior to prevent replicas from diverging in content. The advantage of statement-based replication is that it can replicate any kind of SQL statement including DDL (Data Definition Language) queries that alters the database schema or requests that modify non-persistent objects such as environment variables, sequences or temporary tables.

Transaction replication relies on writeset extraction that is usually implemented using triggers. This requires declaring additional triggers on every database table. This can become complex if the database already uses triggers, materialized views or temporary tables. Writeset extraction does not capture changes such as auto-incremented keys, sequence values or environment variable updates. Queries altering such database structures change the replica they execute on and can result in cluster divergence. Moreover, most of these data structures cannot be rolled back (for instance, an auto-incremented key or sequence number incremented in a transaction is not decremented at rollback time).

With statement replication, all replicas execute write transactions simultaneously in the same serializable order, whereas transaction replication executes update transaction at only one replica and propagates the transaction writeset to other replicas only after certification at commit time. Therefore, transaction replication usually offers better performance over statement replication as long as the writeset extraction and certification mechanisms are efficient. Statement replication offers a better infrastructure for failover during a transaction since each replica has a copy of every transactional context. With transaction replication, the failure of the replica executing the transaction will systematically abort the transaction and force the transaction to retry.

High Availability

High availability is often synonymous with little downtime. Such downtime can be either planned or unplanned, depending on whether it occurs under the control of the administrator or not. Planned downtime is incurred during most software and hardware maintenance operations, while unplanned downtime can strike at any time and is caused by foreseeable and unforeseeable failures (hardware failures, software bugs, human error, etc.).

A system's availability is the ratio of its uptime to total time. In practice, it is computed as the ratio between the expected time of continuous operation between failures to total time, or

$$\begin{aligned} Availability &= \frac{MTTF}{MTTF + MTTR} \Rightarrow Unavailability \\ &= \frac{MTTR}{MTTF + MTTR} \approx \frac{MTTR}{MTTF} \end{aligned}$$

where MTTF is Mean Time To Failure and MTTR is Mean Time To Repair. Since MTTF >> MTTR, one can approximate unavailability (ratio of downtime to total time) as MTTR/MTTF.

The goal of replication together with failover/failback is to reduce MTTR, and thus reduce unavailability. Failover is the ability for users of a database node to be switched over to another database node containing a replica of the data whenever the node they were connected to has failed. Failback happens when the original replica comes back from its failure and users are re-allocated to that replica.

A replicated database built for availability must eliminate any single point of failure (SPOF). This means that the middleware components (load balancer, certifier...) must also be replicated. Group communication libraries are used to synchronize the state of the different components. Total order is usually required by replication protocols to ensure a serializable execution order.

Several database drivers or connection pools offer automatic reconnection when a failure is detected. This technique only offers session failover but not failover of the transactional context. Sequoia [9] (the continuation of the C-JDBC project) provides transparent failover without losing transactional context. Failover code is available in the middleware to handle a database failure and additional code is available in the middleware driver running in the application to handle a middleware failure. A fully transparent failover requires consistently replicated state kept at all components, and is more easily achieved using statement-based rather than transaction-based replication. In the latter case, the transaction is only played at a single replica; if the replica fails, the entire transaction has to be replayed at another replica, which cannot succeed without the cooperation of the application.

Load Balancing

Load balancing aims at dispatching user requests or transactions to the replica that can provide consistent data with the lowest latency. Load balancer design is tightly coupled with the replication strategy implemented. Static strategies such as round-robin or even weighted-round-robin are usually not well adapted to the dynamic nature of transactional workloads. Algorithms taking into account replica resource usage such as LPRF (Least Pending Request First) perform much better. With additional information on transaction working set, it is also possible to optimize load balancing to improve in-memory request execution such as MALB (Memory-Aware Load Balancing) used in Tashkent+ [6]. More information on load balancing can be found in [1].

Caching

To reduce request execution time, the middleware can provide multiple caches. C-JDBC [3] provides three different caches. The parsing cache stores the results of query parsing so that a query that is executed several times is parsed only once. The metadata cache records all ResultSet metadata such as column names and types associated with a query result.

These caches work with query skeletons found in PreparedStatements used by application servers. A query skeleton is a query where all variable fields are replaced with question marks and filled at runtime with a specific API. An example of a query skeleton is "SELECT * FROM t WHERE x=?". In this example, a parsing or metadata cache hit will occur for any value of x.

The query result cache is used to store the ResultSet associated with each query. The query result cache reduces the request response time as well as the load on the database replicas. By default, the cache provides strong consistency. In other words, C-JDBC invalidates cache entries that may contain stale data as a result of an update query. Cache consistency may be relaxed using user-defined rules. The results of queries that can accept stale data can be kept in the cache for a time specified by a staleness limit, even though subsequent update queries may have rendered the cached entry inconsistent.

Different cache invalidation granularities are available ranging from database-wide invalidation to table-based or column-based invalidation. An extra optimization concerns queries that select a unique row based on a primary key. These queries are often issued by application servers using JDO (Java Data Objects) or EJB (Enterprise Java Beans) technologies. These entries are never invalidated on inserts since a newly inserted row will always have a different primary key value and therefore will not affect this kind of cache entries. Moreover, update or delete operations on these entries can be easily performed in the cache.

Key Applications

Middleware-based database replication is currently used in many e-Commerce production environments that require both high availability and performance scalability. Many open problems remain on the integration of databases with replication middleware, failure detection and transparent failover/failback, autonomic management and software upgrades.

Future Directions

Current research trends explore autonomic behavior for replicated databases [4] to automate all management operations such as provisioning, tuning, failure repair and recovery. Heterogeneous clustering is also used in the context of satellites databases [8] to scale legacy databases with open source databases. Partial replication is studied in conjunction with WAN (Wide Area Network) replication for global applications spanning over multiple datacenters distributed on different continents. A summary of the remaining gaps between the theory and practice of middleware-based replication can be found in [2].

Middleware Support for Precise Failure Semantics

Vivien Quéma
CNRS, INRIA, Saint-Ismier Cedex, France

Definition

Providing support for precise failure semantics requires defining an appropriate correctness criterion for replicated action execution of a replication algorithm. Such a correctness criterion allows formally verifying that a sequence of actions is executed correctly. In the context of replication, a sequence of actions executed is correctly if their side-effect appears to have happened exactly-once.

Historical Background

Reasoning about the behavior of concurrent programs has been an active research area during the past decades. Of particular interest in this area are the works on linearizability, a consistency criterion for concurrent objects [4], and on serializability, a consistency criterion for concurrent transactions [5]. These two criteria facilitate certain kinds of formal reasoning by transforming assertions about complex concurrent behavior into assertions about simpler sequential behavior. Moreover, these consistency criteria are local properties: the correctness of individual objects or services is used to reason about system-level correctness. Recently, Frølund and Guerraoui introduced x-ability [2] (exactly-once ability), a correctness criterion for replicated services. X-ability is independent of particular replication algorithms. Although they facilitate reasoning in similar ways, there are fundamental differences between x-ability on one hand and serializability [5] and linearizability [4] on the other. X-ability has safety as well as liveness aspects to it whereas serializability and linearizability are safety conditions only. X-ability is a theory of distribution and partial failures where serializability and linearizability are theories of concurrency. X-ability does not specify correctness for concurrent invocations of a replicated service. More precisely, x-ability states constraints about the concurrency among replicas in the context of a given request (intra-request concurrency), but ignores the concurrency that originates from different requests (inter-request concurrency). This entry gives a precise description of the x-ability theory.

Foundations

Frølund and Guerraoui proposed x-ability [2] (exactly-once ability), a correctness criterion for replicated services. X-ability is independent of particular replication algorithms. The main idea behind x-ability is to consider a replicated service correct if it provides the illusion of a single, fault-tolerant entity. More precisely, an x-able service must satisfy a contract with its clients as well as a contract with third-party entities. In terms of clients, a service must provide idempotent, non-blocking request processing. Moreover, it must deliver replies that are consistent with its invocation history. The side-effect of a service, on third-party entities, must obey exactly-once semantics. X-ability is a local property: replicated services can be specified and implemented independently, and later composed in the implementation of more complex replicated services.

To model side-effects, x-ability is based on the notion of action execution. Actions are executed correctly (i.e., are *x-able*) if their side-effect *appears* to have happened *exactly-once*. The side-effect of actions can be the modification of a shared state or the invocation of another (replicated or non-replicated) service. X-ability represents the execution of actions as event histories and defines the notion of "appears to have happened exactly-once" in terms of history equivalence: an event history h is x-able if it is equivalent to a history h' obtained under failure-free conditions. Being defined relative to failure-free executions, x-ability encompasses both safety and liveness. It is a safety property because it states that certain partial histories must not occur. It is also a liveness property since it enforces guarantees about what must occur. History equivalence is defined relatively to the execution of two particular kinds of actions, namely *idempotent* and *undoable* actions:

- The side-effect of a history with n incarnations of an idempotent action is equivalent to a history with a single incarnation. For example, writing a particular value to a data object is an idempotent action.
- An undoable action is similar to a transaction: its side-effect can be cancelled up to a certain point (the commit point), after which the side-effect is permanent. Thus, the side-effect of a history with a cancelled action is equivalent to the side-effect of a history with no action at all.

System Model

The replicated service is implemented by a set of replicas. The functionality of the service is captured by a *state machine*. Each replica has its own copy of the state machine. A state machine exports a number of *actions*. An action takes an input value and produces an output value. In addition, an action may modify the internal state of its state machine and it may communicate with external entities. A client can invoke a replica's state machine by sending a request to the replica. A request contains the name of an action and an input value for the action. When it receives a request, a replica invokes its state machine based on the values in the request. If no failures occur, the replica returns the action's output value to the client. The execution of an action may fail or the replica executing the action may fail. If the action fails, it returns an exception (or error) value as the execution result. Formally speaking, action names are modeled as elements of a set `Action` (referred to using the letter a). The set `Value` contains the input and output values associated with actions. Furthermore, two sets, `Request` and `Result`, are defined as follows: `Request`$=$(`Action` $\times$ `Value`) and `Result`$=$`Value`. This signifies that a request is simply a pair that contains an action name and an input value (noted "(a, v)" for a request with action name a and value v).

The actions performed by state machines are represented by *events*. More precisely, the x-ability theory considers two kinds of events: start events to represent the invocation of a state-machine action by a process, and completion events to represent the successful completion of a state-machine action: a process receives a non-exception value back from the state machine. The causal and temporal relationship between action execution and event observation is subject to the following axioms: (i) an action's start event cannot be observed unless the action is invoked, (ii) an action's completion event cannot be observed before its start event, and (iii) if an action returns successfully, then its start and completion events have been observed. Events are modeled as elements of the set `Event`. Events are structured values with the following structure: $e ::= S(a,\ iv) \ \mid \ C(a,\ ov)$. The event $S(a,\ iv)$ captures the start of executing the action a with iv as argument. The event $C(a, ov)$ captures the completion of executing the action a, and ov is the output value produced by the action.

A sequence of events form a *history*. The notion of a sequence captures the total order in which events are observed. Histories are modeled as elements of the set `History`. Histories are structured values as defined by the following syntax: $h \ ::= \ \Lambda \ \mid \ e_1 ... e_n \ \mid h_1 \ \bullet ... \bullet \ h_n$. The symbol Λ denotes the empty history – a history with no events. The history $e_1 ... e_n$ contains the events e_1 through e_n. The history $h_1 \ \bullet ... \bullet \ h_n$ is the concatenation of histories h_1 through h_n. The semantics of concatenating histories is to concatenate the corresponding event sequences. An action a *appears* with input value iv in a history h (noted $(a, iv) \in h$) if h contains a start event produced by the execution of a on iv.

To capture structural properties of histories, the x-ability theory defines the notion of history *patterns*. Formally speaking, patterns are elements of the set `Pattern` (referred to using the letter p). The abstract syntax for patterns is depicted in Fig. 1. A simple pattern sp matches single-action histories. The pattern

$$\begin{aligned} sp \ &::= \ [a,\ iv,\ ov] \mid ?\,[a,\ iv,\ ov] \\ p \ &::= \ sp \mid sp_1 \|_h \, sp_2 \end{aligned}$$

Middleware Support for Precise Failure Semantics. Figure 1. Abstract syntax for history patterns.

$[a, iv, ov]$ matches a history that contains the events from a failure-free execution of an action a. The value iv is the input to a and ov is the output from a. The pattern $?[a, iv, ov]$ matches a history in which a may have failed. A matching history may be the empty history, it may contain a start event only, or it may contain both the start and completion event of a. The pattern $sp_1 \parallel h\ sp_2$ matches a history h' that contains an interleaving of three sub-histories h_1, h_2, and h, where h_1 matches sp_1, h_2 matches sp_2, and h is an arbitrary history. The interleaving is constrained as follows: the first event in h_1 must also be the first event in h' and the last event in h_2 must also be the last event in h'.

X-ability defines *pattern matching* as a relation $\triangleright$ between elements of the set `History` and elements of the set `Pattern`. In other words, $\triangleright$ is a subset of `History` $\times$ `Pattern` (the set of all pairs from `History` and `Pattern`). Pattern matching rules are shown in Fig.2. A history that matches a simple pattern contains at most two events. X-ability defines two operators on such histories: `first` and `second` (see Fig.3). The `first` operator returns the first element in a history, if any, and Λ otherwise. The `second` operator returns the second element in a history of length two, the only element in a history of length one, and the empty history otherwise.

X-Able Histories

To be fault-tolerant, a replicated service must be prepared to invoke the same action multiple times until the action executes successfully. To provide replication transparency, the service must have exactly-once semantics relative to its environment – the service must maintain the illusion that the action was executed once only. In short, an x-able history is a history that maintains the illusion of exactly-once but possibly contains multiple incarnations of the same action. The rest of this section describes how the x-ability theory defines the notion of x-able history.

The x-ability theory defines a *history reduction* relation, $\Rightarrow$, on histories as follows: if $h \Rightarrow h'$, then the execution that produced h has the same side-effect as an execution that produced h'. Essentially, a history is x-able if it can be reduced, under $\Rightarrow$, to a history that could arise from a system that does not fail. Two particular types of actions are considered: `idempotent` and `undoable`. The corresponding sets are called Idempotent and Undoable. The set

$$(1)\qquad \triangleright \subseteq (\mathtt{History} \times \mathtt{Pattern})$$

$$(2)\qquad S(a, iv)C(a, ov) \triangleright [a, iv, ov]$$

$$(3)\qquad \Lambda \triangleright ?[a, iv, ov]$$

$$(4)\qquad S(a, iv) \triangleright ?[a, iv, ov]$$

$$(5)\qquad S(a, iv)C(a, ov) \triangleright ?[a, iv, ov]$$

$$(6)\qquad \frac{h_1 \triangleright sp_1 \quad h_2 \triangleright sp_2}{(h_1 \bullet h \bullet h_2) \triangleright (sp_1 \|_h sp_2)}$$

$$(7)\qquad \frac{h_1 \triangleright sp_1 \quad h_2 \triangleright sp_2}{(\mathrm{first}(h_1) \bullet h_3 \bullet \mathrm{second}(h_1) \bullet h_4 \bullet \mathrm{first}(h_2) \bullet h_5 \bullet \mathrm{second}(h_2)) \triangleright (sp_1 \|_{h_3 \bullet h_4 \bullet h_5}\ sp_2)}$$

$$(8)\qquad \frac{h_1 \triangleright sp_1 \quad h_2 \triangleright sp_2}{(\mathrm{first}(h_1) \bullet h_3 \bullet \mathrm{first}(h_2) \bullet h_4 \bullet \mathrm{second}(h_1) \bullet h_5 \bullet \mathrm{second}(h_2)) \triangleright (sp_1 \|_{h_3 \bullet h_4 \bullet h_5}\ sp_2)}$$

Middleware Support for Precise Failure Semantics. Figure 2. Pattern matching rules.

$$\begin{array}{rrcl@{\qquad}rcl}
(9) & \mathrm{first}(\Lambda) & = & \Lambda & \mathrm{first}(e_1 e_2) & = & e_1 \\
(10) & \mathrm{first}(e) & = & e & \mathrm{second}(\Lambda) & = & \Lambda \\
(11) & \mathrm{second}(e) & = & e & \mathrm{second}(e_1 e_2) & = & e_2
\end{array}$$

Middleware Support for Precise Failure Semantics. Figure 3. The definition of first and second.

`Idempotent` contains the names of idempotent actions. The notation a^i indicates that the action a is idempotent. The set `Undoable` contains names of undoable actions. The notation a^u indicates that an action a is undoable. An undoable action, a^u, has two associated actions: a cancellation action, a^{-1}, and a commit action, a^c. The commit and cancellation actions for an action a^u take the same arguments as a^u, and they return the value nil. Moreover, cancellation and commit actions are idempotent.

Figure 4 defines the⇒operator in terms of idempotent and undoable actions. The first inference rule (13) defines ⇒ as a transitive relation. The second rule (14) captures the semantics of idempotent actions. If a history contains a successfully executed idempotent action a^i, then the events from a previous attempt to execute a^i can be removed. The third rule (15) is concerned with cancellation of undoable actions. Intuitively, if an undoable action is successfully cancelled, then its side-effect can be removed. The fourth rule (16) states that commit actions are idempotent.

The x-ability theory defines a *failure-free history* as a history that could have been produced by a failure-free execution of a single state-machine action. To define the notion of failure-free history, the x-ability theory relies on the definition of a function, called eventsof, which returns the failure-free history associated with an action and its values.

$$\begin{aligned}\texttt{eventsof}(a^u,\ iv,\ ov)\ &= S(a^u, iv)C(a^u, ov)\\ &\quad S(a^c,\ iv)C(a^c, \text{nil})\end{aligned} \tag{17}$$

$$\texttt{eventsof}(a^i)\ =\ S(a^i, iv)C(a^i, ov) \tag{18}$$

Due to non-determinism, there are multiple failure-free histories which are possible for a given action a and a given input value iv. The set of all possible histories, $\texttt{FailureFree}_{(a,iv)}$, is defined as follows:

$$\begin{aligned}\texttt{FailureFree}_{(a,iv)}\ &= \{h \in \texttt{History}\,|\,\exists\, ov \in\\ &\qquad \texttt{Result} : \texttt{h} = \texttt{eventsof}\\ &\qquad (a, iv, ov)\}\end{aligned} \tag{19}$$

An *x-able history* is defined as a history that can be reduced to a failure-free history. Formally speaking, an x-able history is one that satisfies the predicate x-able on histories:

$$\begin{aligned}&\texttt{X-4able}_{(a,iv)}(h)\ =\\ &\begin{cases}\texttt{true} & \text{if } \exists\, h' \in \texttt{FailureFree}_{(a,\,iv)} : h \Rightarrow h'\\ \texttt{false} & \text{otherwise}\end{cases}\end{aligned} \tag{20}$$

This definition of x-able histories applies to single-action histories, that is, a history that arises from a particular request. This reflects the fact that x-ability only specifies correctness relative to distribution and failures, it does not specify correctness for the concurrent processing of multiple requests from different clients.

Client-Service Consistency

The x-ability theory formalizes the relationship between clients and services. More precisely, the reply value given to a client in response to a request must be the value returned from the server-side state machine when the service processes the request. Moreover, the service is not allowed to invent requests. The server-side history is used to define the constraints for requests and replies. This history contains a request value as part of start events and reply values as part of

$$\Rightarrow\ \subseteq (\texttt{History} \times \texttt{History}) \tag{12}$$

$$\frac{h_1 \Rightarrow h_2 \quad h_2 \Rightarrow h_3}{h_1 \Rightarrow h_3} \tag{13}$$

$$\frac{h \triangleright (?[a^i, iv, ov] \,\|_{h'}\, [a^i, iv, ov])}{h_1 \bullet h \bullet h_2 \Rightarrow h_1 \bullet h' \bullet (S(a^i, iv)C(a^i, ov)) \bullet h_2} \tag{14}$$

$$\frac{h \triangleright (?[a^u, iv, ov] \,\|_{h'}\, [a^{-1}, iv, \text{nil}]) \quad (a^u, iv) \notin h_1 \quad (a^c, iv) \notin h'}{h_1 \bullet h \bullet h_2 \Rightarrow h_1 \bullet h' \bullet h_2} \tag{15}$$

$$\frac{h \triangleright (?[a^c, iv, \text{nil}] \,\|_{h'}\, [a^c, iv, \text{nil}]) \quad (a^u, iv) \notin h'}{h_1 \bullet h \bullet h_2 \Rightarrow h_1 \bullet h' \bullet (S(a^c, iv)C(a^c, \text{nil}) \bullet h_2} \tag{16}$$

Middleware Support for Precise Failure Semantics. Figure 4. Definition of history reduction.

completion events. The x-ability theory introduces the notion of *history signature*, which captures the client-side information (request and result) that is legal relative to a given server-side history. Because of non-determinism and server-side retry, a history can have multiple signatures. The set of signatures is defined by the following inference rules:

$$\frac{h \Rightarrow S(a^u, iv)C(a^u, ov)S(a^c, iv)C(a^c, \text{nil})}{(a, iv, ov) \in \texttt{signature}(h)} \tag{21}$$

$$\frac{h \Rightarrow S\left(a^i, iv\right)C\left(a^i, ov\right)}{(a, iv, ov) \in \texttt{signature}(h)} \tag{22}$$

If a client submits a sequence of requests, one after the other, later requests should be processed in the context of earlier requests. To prevent a service from forgetting the effect of previous requests, the x-ability theory assumes the existence of a set `PossibleReply` that contains the possible reply values for a given request. To capture the history-sensitive nature of the set of possible replies, PossibleReply is defined in the context of a request sequence $R_1 ... R_n$. The interpretation of `PossibleReply` in the context of a sequence is the set of possible replies to request R_n after the state machine has executed the requests $R_1 ... R_{n-1}$ one after the other. Thus, the set is written as follows: $\texttt{PossibleReply}_{(R_1 ... R_n)}$.

X-Able Services

The x-ability theory provides a formal specification of replication that is independent of a particular replication protocol. Formally speaking, a replicated service consists of a server-side state machine S and a client-side action *submit*. The state machine captures the functionality of the service. It is executed by a set of server processes $s_1 ... s_n$ that each have a copy of S. The action *submit* can be used by any process p to invoke the service. The action takes a value in the domain `Request` and, when executed, produces a value in the domain `Result`. Correctness is specified relative to a single client C. Thus, the considered system consists of the processes $s_1 ... s_n$ and C only. The client submits one request at a time, and the service is x-able if the following conditions hold:

- R1. The action *submit* is idempotent.
- R2. The client C will eventually be able to execute *submit* successfully.
- R3. If the client submits a request (a, iv), then the server-side history for (a, iv) is either empty or it satisfies $\texttt{x-able}_{(a,iv)}$.
- R4. If the client receives a reply ov in response to a request (a, iv), and if the server-side history for executing this request is h, then $(a, iv, ov) \in \texttt{signature}(h)$.
- R5. If the client successfully submits a sequence of requests, $R_1 ... R_n$, and receives the reply R' in response to R_n, then R' is in $\texttt{PossibleReply}_{(R_1 ... R_n)}$.

The first two requirements (R1 and R2) are concerned with the contract between a service and its clients. Clients use the action *submit* to invoke the service. Because *submit* is idempotent, clients can repeatedly invoke the service without concern for duplicating side-effects. The second requirement (R2) is a liveness property. The action *submit* is not allowed to fail an infinite number of times. The requirement also makes a service non-blocking in the sense that *submit* is guaranteed to eventually return a value. The third requirement (R3) deals with the server-side side-effect of executing a request. The resulting server-side history must be x-able, that is, it must be equivalent (under history reduction) to a failure-free history. The fourth requirement (R4) forces an algorithm to preserve consistency between the client-side view (request and reply) and the server-side view (the side-effect). This requirement, prevents the *submit* action from inventing reply values. It also prevents the service from inventing request values. The fifth requirement (R5) forces the service to correctly maintain S's state, if any. The server-side history must be equivalent to a failure-free execution of the sequence $R_1 ... R_n$. But since R_1 may result in a transformation of S's state, the actions executed for R_2 may depend on this state transformation. So, a replication algorithm must ensure that the state resulting from R_1 is used as a context for executing R_2. The replication algorithm cannot assume that R_1 did not update the state of S, or that the state update is immaterial to the processing of R_2.

Key Applications

A key application of the x-ability theory is the design transactions protocols for three-tier applications. Such applications encompass three layers: human users interact with front-end clients (e.g., browsers), middle-tier application servers (e.g., Web servers) contain the business logic of the application, and perform transactions against back-end databases. Three-tier applications usually rely on replication and transaction-processing techniques. It has been defined in [1,3] the notion of the Exactly-Once Transaction (e-Transaction) abstraction: an abstraction that encompasses both safety and liveness properties in three-tier environments and ensures end-to-end reliability.

Mining of Chemical Data

Xifeng Yan

IBM T. J. Watson Research Center, Hawthorne,
NY, USA

Definition

Given a set of chemical compounds, chemical data mining is to characterize the compounds present in the data set and apply a variety of mining methods to discover relationships between the compounds and their biological and chemical activities.

Historical Background

In 1969, Hansch [6] introduced quantitative structure-activity relationship (QSAR) analysis which attempts to correlate physicochemical or structural properties of compounds with biological and chemical activities. These physicochemical and structural properties are determined empirically or by computational methods. QSAR prefers vectorial mappings of compounds, which are usually coded by existing physicochemical and structural fingerprints. Dehaspe et al. [3] applied inductive logic programming to predict chemical carcinogenicity by mining frequent substructures in chemical datasets, which identifies new structural fingerprints so that QSAR could build comprehensive analytical models.

Foundations

Chemical compounds are unstructured data with no explicit vector representation. For chemical compounds, various similarity measures are defined, which could be classified into three categories: (i) physicochemical property-based, e.g., toxicity and weight; (ii) structure-based; and (iii) feature-based. The structure-based similarity measure directly compares the topology of two chemical compounds, e.g., maximum common subgraph, graph edit distance, and graph kernel. As for the feature-based similarity measure, each graph is represented as a feature vector, $\mathbf{x} = [x_1, x_2,\ldots,x_n]$, where x_i is the value of feature f_i. A feature could be physicochemical or structural. The similarity between two graphs is measured by the similarity between their feature vectors. Bunke and Shearer [1] used maximum common subgraph to measure structure similarity. Given two graphs G and G', if P is the maximum common subgraph of G and G', then the structure similarity between G and G' is defined by

$$\frac{2|E(P)|}{|E(G)| + |E(G')|},$$

where $E(G)$ is the edge set of G.

Kashima et al. [7] introduced marginalized kernels between labeled graphs,

$$K(G, G') = \sum_{h} \sum_{h'} K_z(z, z')p(h|G)p(h'|G'),$$

where $z = [G,h]$ and $K_z(z,z')$ is the joint kernel over z. The hidden variable h is a path generated by random walks and the joint kernel K_z is defined as a kernel between these paths. Other sophisticated graph kernels are also available. For example, Fröhlich et al. [5]

proposed optimal assignment kernels for attributed molecular graphs, which compute an optimal assignment from the atoms of one molecule to those of another one, including local structures and neighborhood information.

The structure-based similarity measure can serve general chemical data mining such as chemical structure classification and clustering. The implicit definition of feature space makes it hard to interpret, and hard to adapt to many powerful data management and analytical tools such as R-tree and support vector machine. An alternative approach is to mine the most interesting features from chemical data directly, such as patterns that are discriminative between compounds with different chemical activities. Figure 1 depicts the pipeline of this approach built on features discovered by a mining process.

The feature-based mining framework includes three steps: (i) mine patterns/features from chemical data, (ii) select discriminative or significant features, and (iii) perform advanced mining. The first step is the process of finding and extracting useful features from raw datasets. One kind of features used in data mining is frequent substructures, the common structures that occur in many compounds. Formally, given a graph dataset $D = \{G_1,G_2,\ldots,G_n\}$ and a minimum frequency threshold θ, frequent substructures are subgraphs that are contained by at least $\theta|D|$ graphs in D. A set of graph pattern mining algorithms are available for mining frequent substructures, including SUBDUE, Warmr, AGM, gSpan, FSG, MoFa/MoSS, FFSM, Gaston, and so on. Generally, for mining graph patterns measured by an objective function F, there are two related mining tasks: (i) enumeration task, find all of subgraphs g such that $F(g)$ is no less than a threshold; and (ii) optimization task, find a subgraph g^* such that

$$g^* = \text{argmax}_g F(g).$$

The enumeration task might encounter the exponential number of patterns as the traditional frequent substructure mining does. To resolve this issue, one may rank patterns according to their objective score and select patterns with the highest value. The feature-based mining framework finds many key applications in chemical data mining including, but not limited to, chemical graph search, classification and clustering.

Chemical graph search aims to find graphs that contain a specific query structure. It is inefficient to scan the whole database and check each graph. Yan et al. [9] applied the feature-based mining framework to support fast search using frequent substructures selected by the following criterion. Let substructures $f_1,f_2,\ldots,f_n$ be selected features. Given a new substructure x, the selectivity power of x can be measured by

$$1 - Pr(x|f_{\varphi_1},\ldots,f_{\varphi_m}), f_{\varphi_i} \subseteq x, 1 \le \varphi_i \le n.$$

which shows the absence probability of x given the presence of $f_{\varphi_1},\ldots,f_{\varphi_m}$ in a graph. When the selectivity is high, substructure x is a good candidate to index.

In addition to molecule search, chemical data classification and clustering could also benefit from graph patterns. A typical setting of molecule classification is to induce a mapping $h(\mathbf{g}) : \mathcal{G} \rightarrow \{\pm 1\}$ from the training samples $D = \{\mathbf{g}_i, y_i\}^n{}_{i=1}$, where $\mathbf{g}_i \in \mathcal{G}$ is a labeled graph and $y_i \in \{\pm 1\}$ is the class label. Feature-based classification models were proposed in [8,4]. In these models, graphs are first transformed to vectors using discriminative substructures, which are then processed by standard classification methods.

the bioassay records for anti-cancer screen tests with different cancer cell lines. Each dataset belongs to a certain type of cancer screen with the outcome active or inactive. These bioassays are experimented to identify the chemical compounds that display the desired and reproducible behavior against cancers. Chemical compound classification is to computationally predict the activity of untested compounds given the bioassay data. This process can replace or supplement the physical assay techniques. Furthermore, it could also identify substructures that are critical to specific biological or chemical activities.

The following experiment demonstrates the effectiveness of graph kernel method [7,5] (optimal assignment kernel, OA) and pattern-based classification [8,4] (PA), both of which show good accuracy. From the PubChem screen tests, 11 bioassay datasets are displayed. Since the active class is very rare (around 5%) in these datasets, 500 active compounds and 2,000 inactive compounds are randomly sampled from each dataset for performance evaluation. The classification accuracy is evaluated with 5-fold cross validation. For both methods, the same implementation of support vector machine, LIBSVM [2], with parameter C selected from $[2^{-5}, 2^5]$, is used. Table 1 shows AUC by OA and PA. The area under the ROC curve (AUC) is a measure of the model accuracy, in the range of [0,1]. A perfect model will have an area of one. As shown in Table 1, PA achieves comparable results with OA. A detailed examination shows that PA is able to discover substructures that determine the activity of compounds, without domain knowledge.

Mobile Database

Ouri Wolfson
University of Illinois at Chicago, Chicago, IL, USA

Definition

A mobile database is a database that resides on a mobile device such as a PDA, a smart phone, or a laptop. Such devices are often limited in resources such as memory, computing power, and battery power.

Key Points

Due to device limitations, a mobile database is often much smaller than its counterpart residing on servers and mainframes. A mobile database is managed by a Database Management System (DBMS). Again, due to resource constraints, such a system often has limited functionality compared to a full blown database management system. For example, mobile databases are single user systems, and therefore a concurrency control mechanism is not required. Other DBMS components such as query processing and recovery may also be limited.

Queries to the mobile database are usually posed by the user of the mobile device. Updates of the database may originate from the user, or from a central server, or directly from other mobile devices. Updates from the server are communicated wirelessly. Such communication takes place either via a point-to-point connection between the mobile device (the client) and the server, or via broadcasting by the server [Acharya S., Franklin M., and Zdonik S, 1995, Dissemination-based Data Delivery Using Broadcast Disks, Personal Communications]. Direct updates from other mobile devices may use short-range wireless communication protocols such as Bluetooth or Wifi [1].

Synonyms

Handhelds interfaces; Navigation system interfaces

Definition

Mobile interfaces are interfaces specifically designed for little portable electronic devices (handhelds), like cellular phones, personal digital assistants (PDAs), and pagers. Mobile interfaces provide means to execute complex activities on highly constrained devices, characterized by small screens, low computing power, and limited input/output (I/O) capabilities. While this term is mainly used to refer to interfaces for classical Web applications, like email and Web browsing it should be intended in a broader sense, encompassing all Web and non-Web applications that run on little mobile equipments (e.g., GPS navigation systems).

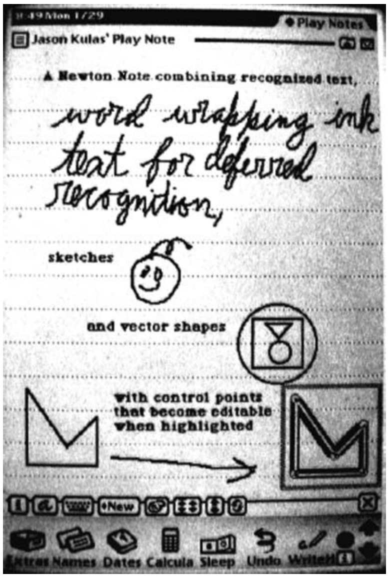
Historical Background

Mobile interfaces came up with the proliferation of cellular phones through the 1980s. At that time, the notion of mobile interface was very primitive and the offered services were very simple: handling lists of contacts, usually limited to <name, phone-number>

pairs, starting/answering a phone call, writing short text, setting phone preferences (volume, light, ring tone, etc.). Even in this restricted scenario, the vendors had to deal with challenging issues, posed by the very limited early cellular phones capabilities, in terms of screen dimension and resolution, limited computing power, and I/O capabilities. No standards were around and different, unrelated solutions were adopted. The most used interaction strategy was to mimic the typical hierarchical computer menus with very poor results: the user was (and still is) forced to access functions and services through a series of boring menus. The main reason of failure is that while PCs can present to the user a complete list of all possible choices mobile phones can show a small number of options at time (usually one), forcing the user to remember the paths to the commands. That results in a very large number of key presses, errors, and mental overwhelming: many of the advantages of the conventional menus are lost [12].

For about ten years the unique available portable devices were mainly cellular phones; from 1993 to 1998 Apple Computer (now Apple Inc.) marketed the "Apple Newton," the first line of PDAs, personal digital assistants, a term introduced on January 7, 1992 by John Sculley at the Consumer Electronics Show in Las Vegas, Nevada, referring to the Apple Newton. The Apple's official name for the PDA was "MessagePad" and it was based on the ARM 610 RISC processor using a dedicated operating system (Newton OS, an allusion to Isaac Newton's apple); however, the word Newton was popularly used to refer to the device and its software. The new device was characterized by a wider touchable monochromatic screen (366 × 240) with retro illumination (only for the top version). The increased computational power and the larger screen allowed for very innovative interaction techniques (for a portable device): icons, simulated touchable QWERTY keyboard, and handwriting recognition (called Calligrapher). Moreover, the user was allowed to turn the screen horizontally ("landscape") as well as vertically ("portrait") preserving the handwriting recognition functionality (see Fig. 1).

Even the data management was quite innovative: programs were able to convert and share data (e.g., the calendar was able to refer to names in the address book or to convert a note into an appointment). Finally all the devices were equipped with a built in infrared and an expansion port for connecting to a modem or Ethernet. Disregarding the color absence and the limited device connectivity, the Palm Newton functionalities were quite similar to the ones of modern PDAs!



A Newton Note combining recognized text,

and vector shapes

with control points that become editable when highlighted

Mobile Interfaces. Figure 1. A screenshot from Apple Newton.

In spite of the innovative interface and capabilities, the product was not a successful one. The main reasons were the poor handwriting recognition accuracy, the high price, and the non comfortable size (it did not fit in a regular pocket). Still, the pioneering Apple ideas were captured by other vendors and many similar devices were around in the next years. Among them, the Palm series with the PalmOS operative system and the Graffiti handwriting recognition system conquered (in 1999) about 80% of the world market, mostly for the effective handwriting system and for the availability of a huge amount of third part software. On February 2000 Palm marketed the PalmIIIc, the first color PDA. Concerning the interface it is worth noting the different Graffiti philosophy: instead of allowing the user to write in his/her own style it forced the user to learn a set of pen strokes for each character (see Fig. 2). This narrowed the possibility for erroneous input, although memorization of the stroke patterns did increase the learning curve for the user. Some studies demonstrated that even if the error rate with Graffiti was higher than using the virtual keyboard (19.3 vs. 4.1%), users prefer Graffiti, because its usage is more natural.

Mobile Interfaces. Figure 2. The PalmOS Graffiti.

As soon as the hardware made it possible a deeper integration between PDA and cellular phones started: phones were equipped with larger screen and complex applications (smartphones), while PDA included phone hardware. Moreover, the so called pager devices, mainly intended for on the way email, came up. In 2004, smartphones were outselling PDAs for the first time. Nowadays, the difference between these three categories in term of capabilities and interface is very little. The main consequence of this integration is that all these devices allow for Internet access (through GPRS or WI-FI) and it is very likely that in the next future there will be more people accessing the Internet via mobile devices (phones, PDA, etc) than via conventional PCs. According to this issue many researchers are now dealing with the problem of designing friendly interface for accessing Internet through portable devices.

Foundations

The research effort concerning mobile interfaces followed two main paths: designing interface for a specific application running on a specific device (e.g., the agenda interface of a specific cellular phone) or designing web based applications that can be deployed on multiple devices (e.g., a web browser working on different PDAs and cellular phones).

Mobile Interface for Specific Devices

The problem of dealing with little screen is not new. Much literature from the 1980s and early 1990s, written even before the Web, deals with user interfaces on small screens. At that time the focus was on first generation cash dispensing ATMs, electronic typewriters and photocopiers. All of these systems could display only a limited number of text lines to communicate with the user. Research looked into the impact of reduced screen size on comprehension [3], reading rate [4], and interaction [12]. This research is still valid and has new relevance to mobile Web devices [8].

The availability of graphic display and the diffusion of navigation system raised the issue of interacting with graphics and maps [6]. Moreover, the increasing usage of such systems while driving a car posed several new issues concerning distracting factors and security [1].

Multi Target Applications

In this case, research deals with techniques able to support the design of applications that run on several devices that present different interaction capabilities (e.g., small/large screens, keyboard/keypad input, etc.). In order to address this issue, researchers have adopted two main approaches:

1. Designing applications in order to let them run on different platforms
2. Adapting existing systems in order to render them usable on platform that were not originally included as service provider (e.g., standard web sites)

In the first approach the solution is offered at design time, that is, the designer explicitly knows that the system will run on multiple devices. Some research exists that follows this approach and the key issues consist in giving models, methods, and tools to support the designer in the creation of multi-device applications and in offering techniques and algorithms to generate the final interface at run time for the specific device utilized. In [10], a tool for support is presented together with a well defined development life cycle: the designer starts from abstract tasks definition and upon it designs the interface in abstract. The final interfaces are statically generated at design time by following suggestions offered by the system and further refined in order to accommodate specific details. Puerta et al. in [5] propose a similar framework, defining a model to design user interfaces in abstract as well, but their work envisions also adaptive techniques to produce the final user interface. A central mediator agent is responsible for translating the abstract specification of the user interface, according to a description of device's characteristics, into the final interface. Fundamental questions arising from this kind of research are what kind of models should be employed to specify abstract interaction elements and what strategies/techniques can permit an effective translation of abstract models into real interfaces.

The second approach is the one that attempts to bring existing systems, typically web sites, to small screen devices by means of some sort of adaptation/filtering. Among them, the WAP forum (www.wapforum.org) defined a protocol that enables Web-like services on little, portable devices. The interface uses a card metaphor and the designers claim that it is highly appropriate and usable. However, Nielson [11] raised doubts about its effectiveness. A similar proposal is i-mode, developed by the dominant Japanese carrier NTT DoCoMo, and widely used in Japan. Moreover, the World Wide Web Consortium (W3C) is also developing a framework that will enable Web content to be accessed on a diverse range of devices [13]. This framework will allow a document to exist in multiple variants, each variant specifying the type of support needed by the browser to display its contents. Device capabilities and user preferences will also be captured. The information about documents, devices and users will be used to automatically adapt a Web page to best suit the device and user.

Key Applications

Users of mobile interfaces are growing at high speed. According to IDC's Worldwide Quarterly Mobile Phone Tracker (www.idc.com), worldwide mobile phone shipments rose 19.1% year over year and increased sequentially 8.8% in 2005 to reach 208.3 million units. While unconnected PDA's are a declining segment, the emerging navigator market is still increasing about 10 million cars guided by navigation systems, 43 million dedicated portable navigators, and 16 millions smart phones based navigators forecasted for 2010 (www.strategyanalytics.net).

These figures make clear the importance of mobile interfaces in the coming years.

Future Directions

There are some emerging issues that will likely affect the behavior and structure of mobile interfaces:

- Search versus menu browsing. Several proposals relies on the idea that, in order to start an action, it is better to search it (i.e., to write down the command name) instead of browsing boring menus [9,7].
- Multimodal interaction. When the hardware allows it, mobile interfaces can exploit multimodal input/output (e.g., voice commands, likely together with the aforementioned search strategy).
- Context and user modeling. Some proposal describe interfaces that can adapt themselves according to the user preferences and the context [2], e.g., an interface for browsing tourist information presents a user with list of vegetarian restaurants at walking distance, according to the user location, discovered through the integrated GPS device, knowing that the user is vegetarian and that s/he is currently walking.

These research issues could greatly improve the mobile interfaces in the next years.

Synonyms

MSN data management; Mobile wireless sensor network data management

Definition

Mobile Sensor Network (MSN) Data Management refers to a collection of centralized and distributed algorithms, architectures and systems to handle (store, process and analyze) the immense amount of spatio-temporal data that is cooperatively generated by collections of sensing devices that move in space over time.

Formally, given a set of n homogenous or heterogeneous mobile sensors $\{s_1, s_2,...,s_n\}$ that are capable of acquiring m physical attributes $\{a_1, a_2,...,a_m\}$ from their environment at every discrete time instance t (i.e., datahas a temporal dimension), an implicit or explicit mechanism that enables each s_i $(i \leq n)$ to move in some multi-dimensional Euclidean space (i.e., data has one or more spatial dimensions), MSN Data Management provides the foundation to handle spatio-temporal data in the form $(s_i, t, x, [y, z,]a_1[,...,a_m])$, where x, y, z defines three possible spatial dimensions and the bracket expression "[ ]" denotes the optional arguments in the tuple definition. In a more general perspective, MSN Data Management deals with algorithms, architectures and systems for in-network and out-of-network query processing, access methods, storage, data modeling, data warehousing, data movement and data mining.

Historical Background

The improvements in hardware design along with the wide availability of economically viable embedded sensor systems have enabled scientists to acquire environmental conditions at extremely high resolutions. Early approaches to monitor the physical world were primarily composed of passive sensing devices, such as those utilized in wired weather monitoring infrastructures, that could transmit their readings to more powerful processing units for storage and analysis. The evolution of passive sensing devices has been succeeded by the development of *Stationary Wireless Sensor Networks (Stationary WSNs)*. These are composed of many tiny computers, often no bigger than a coin or a credit card, that feature a low frequency processor, some flash memory for storage, a radio for short-range wireless communication, on-chip sensors and an energy source such as AA batteries or solar panels. Applications of stationary WSNs have emerged in many domains ranging from environmental monitoring [15] to seismic and structural monitoring as well as industry manufacturing.

The transfer of information in such networks is conducted without electrical conductors (i.e., wires) using technologies such as radio frequency (RF), infrared light, acoustic energy and others, as the mobility aspect inherently hinders the deployment of any technology that physically connects nodes with wires. Since communication is the most energy demanding factor in such networks, data management researchers have primarily focused on the development of energy-conscious algorithms and techniques.

In particular, declarative approaches such as TinyDB [9] and Cougar [16] perform a combination of in-network aggregation and filtering in order to reduce the energy consumption while conveying data to the *querying node (sink)*. Additionally, approaches such as TiNA [13] and MINT Views [17] take into account intelligent in-network data reduction techniques to further reduce the consumption of energy. *Data Centric Routing* approaches, such as directed diffusion [8], establish low-latency paths between the sink and the sensors in order to reduce the cost of communication. *Data Centric Storage* [14] schemes organize data with the same attribute (e.g., humidity readings) on the same node in the network in order to offer efficient location and retrieval of sensor data.

The evolution of stationary WSNs in conjunction with the advances made by the distributed robotics and low power embedded systems communities have led to a new class of *Mobile (and Wireless) Sensor Networks (MSNs)* that can be utilized for land [3,5,10], ocean exploration [11], air monitoring [1], automobile applications [7,6], Habitant Monitoring [12] and a wide range of other scenarios. MSNs have a similar architecture to their stationary counterparts, thus are governed by the same energy and processing limitations, but are supplemented with implicit or explicit mechanisms that enable these devices to move in space (e.g., motor or sea/air current) over time. Additionally, MSN devices might derive their coordinates through absolute (e.g., dedicated Geographic Positioning System hardware) or relative means (e.g., *localization techniques*, which enable sensing devices to derive their coordinates using the signal strength, time difference of arrival or angle of arrival). There are several classes of MSNs which can coarsely be structured into the following classes: (i) highly mobile, which contains scenarios in which devices move at high velocities such as cars, human with cell phones, airplanes, and others; (ii) mostly static, which contains scenarios in which devices move at low velocities such as monitoring sensors in a shop floor with moving robots; and (iii) hybrid, which contains both classes such as an airplane that has sensors installed on inside and outside.

Foundations

The unique characteristics of MSNs create novel data management opportunities and challenges that have not been addressed in other contexts including those of mobile databases and stationary WSNs. In order to realize the advantages of such networks, researchers have to re-examine existing data management and data processing approaches in order to consider sensor and user mobility; develop new approaches that consider the impact of mobility and capture its trade-offs. Finally, MSN data management researchers are challenged with structuring these networks as huge distributed databases whose edges consist of numerous "receptors" (e.g., RFID readers or sensor networks) and internal nodes form a pyramid scheme for (in-network) aggregation and (pipelined) data stream processing.

There are numerous advantages of MSNs over their stationary counterparts. In particular, MSNs offer: (i) *dynamic network coverage*, by reaching areas that have not been adequately sampled; (ii) *data routing repair*, by replacing failed routing nodes and by calibrating the operation of the network; (iii) *data muling*, by collecting and disseminating data/readings from stationary nodes out of range; (iv) *staged data stream processing*, by conducting in-network processing of continuous and ad-hoc queries; and (v) *user access points*, by enabling connection to handheld and other mobile devices that are out of range from the communication infrastructure.

These advantages enable a wide range of new applications whose data management requirements go beyond those of stationary WSNs. In particular, MSN system software is required to handle: (i) *the past*, by recording and providing access to history data; (ii) *the present*, by providing access to current readings of sensor data; (iii) *the future*, by generating predictions; (iv) *distributed spatio-temporal data*, by providing new means of distributed data storage, indexing and querying of spatio-temporal data repositories; (v) *data uncertainty*, by providing new means of handling real world signals that are inherently uncertain; (vi) *self-configurability*, by withstanding "harsh" real-life environments; and (vii) *data and service mash-ups*, by enabling other innovative applications that build on top of existing data and services.

In light of the above characteristics, the most predominant data management challenges that have prevailed in the context of MSNs include:

In-Network Storage: The absence of a stationary network structure in MSNs makes continuous data acquisition to some sink point a non-intuitive task (e.g., mobile nodes might be out of communication range from the sink). In particular, the absence of an always accessible sink mandates that acquisition has to be succeeded by in-network storage of the acquired events so that these events can later be retrieved by the user. Mobile devices usually utilize flash memory as opposed to magnetic disks, which are not shock-resistant and thus are not appropriate for a mobile setting. Consequently, a major challenge in MSNs is to extend local storage structures and access methods in order to provide efficient access to the data stored on the local flash media of a sensor device while traditional database research has mainly focused on issues related to magnetic disks.

Flexible and Expressive Query Types: In a traditional database management system, there is a single correct answer to a given query on a given database instance. When querying MSNs the situation is notably different as there are many more degrees of freedom and the underlying querying engine needs to be guided regarding which alternative execution strategy is the right one, typically on the basis of target answer quality and resource availability. In this context, there are additional relevant parameters that include: (i) *Resolution:* physical sensor data can be observed at multiple resolutions along space and time dimensions; (ii) *Confidence:* more often than not, correctness of query results can be specified only in probabilistic terms due to the inherent uncertainty in the sensor hardware and the modeling process; (iii) *Alternative models:* in some cases, several alternative models apply to a single scenario. Each alternative typically represents a different point in the efficiency (resource consumption) and effectiveness (result quality) spectrum, thereby allowing a tradeoff between these two metrics on the basis of application-level expectations. The prime challenge is to define new declarative query languages that make use of these new parameters while allowing a highly flexible and optimizable implementation. Additionally, approximate query processing with controlled result accuracy becomes vital for dynamic mobile environments with varying node velocities, changing data traffic patterns, information redundancy, uncertainty, and inevitable flexible load shedding techniques. Finally, in order to have an efficient and optimized implementation of query types, MSNs will need to consider cross-layer optimization since all layers of the data stack are involved in query execution.

Efficient Query Routing Trees: Query routing and resolution in stationary WSNs is typically founded on some type of query routing tree that provides each sensor with a path over which answers can be transmitted to the sink. In a MSN, such a query routing tree can neither be constructed in an efficient manner nor be maintained efficiently as the network topology is transient. The dynamic nature of the underlying physical network tremendously complicates the interchange of information between nodes during the resolution of a query. In particular, it is known that sensing devices tend to power-down their transceiver (transmitter-receiver) during periods of inactivity in order to conserve energy [2]. While stationary WSNs define transceiver scheduling approaches, such as those defined in TAG [9], Cougar [16] and MicroPulse [1], in order to enable accurate transceiver allocation schemes, such approaches are not suitable for mobile settings in which a sensor is not aware of its designated parent node in the query tree hierarchy. Consequently, nodes are not able to agree on rendezvous time-points on which data interchange can occur.

Purpose-Driven Data Reduction: The amount of data generated from MSNs can be overwhelming. Consequently, a main challenge is to provide data reduction techniques which will be tuned to the semantics of the target application. Furthermore, data reduction must take into account the entire spectrum of uses, ranging from real-time to off-line, supporting both snapshot and continuous queries that take advantage of designated optimization opportunities (e.g., multi-query) especially targeted for mobile environments. Finally, it must also consider the inherently dynamic aspects of these environments and the possibility of in-network data reduction (e.g., in-network aggregation).

Perimeter Construction and Swarm-Like Behavior: In many types of MSNs, new events are more prevalent at the periphery of the network (e.g., water detection and contamination detection) rather than uniformly throughout the network (which is more typically for applications like fire detection). This creates the necessity to construct the perimeter of a MSN in an online and distributed manner. Additionally, many types of MSNs are expected to feature a swarm-like behavior (The term *Swarm (or Flock)* refers to a group of objects that exhibit a polarized, non-colliding and aggregate motion.). For instance, consider a MSN design that consists of several rovers that are deployed as a swarm in order to detect events of interest (e.g., the presence of water) [18]. The swarm might collaboratively collect spatio-temporal events of interest and store them in the swarm until an operator requests them. In order to increase the availability of the detected answers, in the presence of unpredictable failures, individual rovers can perform replication of detected events to neighboring nodes. That creates challenges in data aggregation, data fusion and data storage that have not yet been addressed.

Enforcement of Security, Privacy and Trust: Frequent node migrations and disconnections in MSNs, as well as resource constraints raise severe concerns with respect to security, privacy and trust. Additionally, the cost of traditional secure data dissemination approaches (e.g., using encryption) may be prohibitively high in volatile mobile environments. As such, research on encryption-free data dissemination strategies becomes very relevant here. This includes strategies to deliver separate and under-defined data shares, secure multiparty computation and advanced information recovery techniques.

Context-Awareness and Self-Everything: Providing a useful level of situational awareness in an unobtrusive way is crucial to the success of any application utilizing MSNs as this can be used to improve functionality by including preferences from the users but can also be used to improve performance (e.g., better network routing decisions if the exact topology is known). Note that context is often obvious in stationary WSN deployments (i.e., a specific sensor is always in the same location) but in the context of a MSN additional data management measures need to be taken into account in order to enable this parameter. Additionally, it is crucial for them to be "plug-and-play" and self-everything (i.e., self-configurable and self-adaptive) as application deployment of sensors in the field is famously hard, even without the mobility aspect which is introducing additional challenges. Finally, a crucial parameter is that of being adaptive both in how to deal with the system issues (i.e., how to adapt from failures in network connectivity) and also with user-interface/application issues (i.e., how to adapt the application when the context changes).

Key Applications

MSN Data Management algorithms, architectures and systems will play a significant role in the development of future applications in a wide range of disciplines including the following:

Environmental and Habitant Monitoring: A large class of MSN applications have already emerged in the context of environmental and habitant monitoring systems. Consider an ocean monitoring environment that consists of *n* independent surface drifters floating on the sea surface and equipped with either acoustic or radio communication capabilities. The operator of such a MSN might seek to answer queries of the type: "*Has the MSN identified an area of contamination and where exactly?*". The MSN architecture circumvents the peculiarities of individual sensors, is less prone to failures and is potentially much cheaper. Similar applications have also emerged with MSNs of car robots, such as CotsBots [3], Robomotes [5] or Millibots [10], and MSNs of Unmanned Aerial Vehicles (UAVs), such as SensorFlock [1], in which devices can fly autonomously based on complex interactions with their peers. One final challenging application in this class is that of detecting a phenomenon that itself is mobile, for example a brush fire which is being carried around by high winds.

Intelligent Transportation Systems: Sensing systems have been utilized over the years in order to better manage traffic with the ultimate goal of reducing accidents and minimizing the time and the energy (gasoline) wasted while staying idle in traffic. Since cars are already equipped with a wide range of sensors, the generated information can be shared in a vehicle-to-vehicle network. For example the ABS system can detect when the road is slippery or when the driver is hitting the brakes thus this information can be broadcasted to the surrounding cars but also to the many cars back and forth, as needed, in order to make sure that everybody can safely stop with current weather conditions and car speeds.

Medical Applications: This class includes applications that monitor humans in order to improve living conditions and in order to define early warning systems that identify when human life is at risk. For instance, Nike+ is an example for monitoring the health of a group of runners that have simple sensing devices embedded in their running shoes. Such an application would require embedded storage and retrieval techniques in order to administer the local amounts of data. Applications in support of the elderly and those needing constant supervision (e.g., due to chronic diseases like diabetes, allergies, etc.) are another example in which MSN data management techniques will play an important role. Wellness applications could also be envisioned, where a health "dose" of exercise is administered according to ones needs and capabilities. Another area are systems to protect soldiers on the battlefield. SPARTNET has recently developed wearable physiological sensor systems that collect, organize and interpret data on the health status of soldiers in order to improve situational and medical awareness during field trainings. Such systems could be augmented with functionality of detecting and reporting threats that are either derived from individual signals (e.g., when a soldiers personal health monitor shows erratic life-signals) and from correlated signals that are derived from multiple sensors/soldiers (e.g., by recognizing when a small group of soldiers is deviating away from the expected formation). Finally, disaster and emergency management are another prime area where MSN data management techniques will play a major impact.

Location-Based Services and the Sensor Web: The last group of challenging motivating applications is that of real-time location-based services, for example a service that can report whether there are any available parking spaces or a service that can keep track of buses moving and report how delayed a certain bus is. Many of these services become more powerful with the integration of data from the *Sensor Web* (i.e., live sensor data) with the *Web* (i.e., static content available online) and the *Deep-web* (i.e., data that is stored in a database, but are accessible through a web page or a web service).

Model Management

Christoph Quix
RWTH Aachen University, Aachen, Germany

Definition

Model management comprises technologies and mechanisms to support the integration, transformation, evolution, and matching of models. It aims at supporting metadata-intensive applications such as database design, data integration, and data warehousing. To achieve this goal, a model management system has to provide definitions for *models* (i.e., schemas represented in some metamodel), *mappings* (i.e., relationships between different models), and *operators* (i.e., operations that manipulate models and mappings). Model management has become more and more important, since the interoperability and/or integration of heterogeneous information systems is a frequent requirement of organizations. Some important operations in model management are *Merge* (integration of two models), *Match* (creating a mapping between two models), and *ModelGen* (transforming a model given in one modeling language into a corresponding model in a different modeling language).

The current understanding of model management has been defined in [4] and focuses mainly on (but is not limited to) the management of *data* models. Most of the problems mentioned before have been already addressed separately and for specific applications. The goal now is to build a model management system (MMS) which unifies the previous approaches by providing a set of *generic* structures representing models and mappings, and the definition of *generic* operations on these structures. Such a system could then be used by an application to solve model management tasks.

Historical Background

Model management, as it is understood today, has been defined by Bernstein et al. [4]. In the 1980s, the term “model management” was used in the context of decision support systems, but this refered mainly to mathematical models. Dolk [7] stated first the requirement for a theory for models similar to the relational database theory. Such a theory should include formal definitions of models and operations on models and could be used as a basis for the implementation of a model management system. This work was based on a draft of the *Information Resource Dictionary System* (IRDS) standard (ISO/IEC 10027:1990) which was accepted in 1990. The IRDS standard clarified the terminology of modeling systems and defined a framework structure for such systems as a four-level hierarchy: at the lowest level reside data instances which are described by a model (or schema) on the next higher level. This model is expressed in some modeling language (or metamodel) which is located at the third level. The highest level contains a metametamodel which can be used to define metamodels.

The new definition of model management in 2000 [4] integrated the research efforts of several previously loosely coupled areas. Therefore, research in model management did not start from scratch, rather it could build already on many results such as schema integration [3], or model transformation [1]. The main contribution of [4] was the definition of operations (such as Match, Merge, Compose) which a model management system should offer. Furthermore, it was required that models and mappings are considered as first class objects and that operations should address them as a whole and not only one model element at a time.

Since the vision of model management has been stated, research diverted into the areas of schema matching [14], model transformation [1], generic metamodels [10], schema integration [3], and the definition and composition of mappings [8]. Each of these areas will be summarized briefly in the next section.

Recently, research on model management has been summarized in [5]. It was also emphasized that more expressive mapping languages are required than proposed in the original vision of model management. Model management systems should also include a component in which the mappings can be executed.

Foundations

Schema Matching

Schema matching is the task of identifying a set of correspondences (also called a morphism or a mapping) between schema elements. Many aspects have to be considered during the process of matching, such as data values, element names, constraint information, structure information, domain knowledge, cardinality relationships, and so on. All this information is useful in understanding the semantics of a schema, but it can be a very time consuming problem to collect this information. Therefore, automatic methods are required for schema matching.

A multitude of methods have been proposed for schema matching [14] using different types of information to identify similar elements. The following categories of schema matchers are frequently used:

- Element-Level Matchers take only the information of one schema element separately into account. These can either use linguistic information (name of the element) or constraint information (data type, key constraints).
- Structure-Level Matchers use graph matching approaches to measure the similarity of the structures implied the schema.
- Instance-Level Matchers use also data instances to match schema elements. If the instance sets of two elements are similar, or have a similar value distribution, this might indicate a similarity of the schema elements.
- Machine-Learning Matchers use either instance data or previously identified matches as training data for a machine-learning system. Based on this training data, the system should then detect similar matches in new schema matching problems.

It has been agreed that no single method can solve the schema matching problem in general. Therefore, matching frameworks have been developed which are able to combine multiple individual matching methods to achieve a better result.

Model Transformation

Model transformation (also called *ModelGen*) is the task of transforming a given model M in some particular modeling language into a corresponding model M' in some other modeling language. A classical example for such a transformation is the transformation of an entity-relationship model into a relational database schema. In general, the transformation cannot guarantee that all semantic information of M is still present in the resulting model M' as the target modeling language might have limited expressivity.

Whereas transformation of models between different modeling languages is a frequent task, it has up to now mainly been adressed in specialized settings which map from one particular metamodel to another fixed metamodel. Recent approaches for generic model transformations are based on generic model representations and use a rule-based system to transform a generic representation of the original model into a different model in the generic metamodel. As a side effect, these approaches generate also instance-level mappings which are able to transform data conforming to the original model into data of the generated model.

Another important application area of model transformation is MDA (Model Driven Architecture). The MDA concept is based on the transformation of abstract, conceptual models into more concrete implementation-oriented models.

Generic Metamodel

A generic representation of models is a prerequisite for building a model management system. Without a generic representation, model operations would have to be implemented for each modeling language that should be supported by the system. Especially for the task of model transformation, a generic representation of models is advantageous as the necessary transformations have just to be implemented for the generic representation.

Such a generic representation is called a *generic metamodel*. A generic metamodel should be able to represent models originally represented in different metamodels (or modeling languages) in a generic way without loosing detailed information about the semantics of the model.

First implementations of model management systems used rather simple graph representations of models, e.g., Rondo [13]. Although the graph-based approach might allow an efficient implementation of operations which do not rely on a detailed representation of the models (such as schema matching), it is more difficult to implement more complex operations (such as model transformation or schema integration).

Schema integration approaches used rather abstract generic metamodels. More detailed generic metamodels have been used for model transformation. In [1], the authors describe a metamodel consisting of "superclasses" of the modeling constructs in the native metamodels. The transition between this internal representation and a native metamodel is described as a set of patterns. This induces the concept of a *supermodel* which is the union of patterns defined for any supported native metamodel.

A detailed generic metamodel called *GeRoMe* (Generic Role based Metamodel) is proposed in [10].

GeRoMe employs the *role based* modeling approach in which an object is regarded as playing roles in collaborations with other objects. This allows to describe the properties of model elements as accurately as possible while using only metaclasses and roles from a relatively small set. Therefore, *GeRoMe* provides a generic, yet detailed representation of data models originally represented in different metamodels.

Schema Integration

In model management, the *Merge* operator addresses the problem of schema integration, i.e., generating a merged model given two input models and a mapping between them. The merged model should contain all the information contained in the input models and the mapping. In this context, a mapping is not just a simple set of correspondences between model elements; it might have itself a complex structure and is therefore often regarded also as a *mapping model*. A mapping model is necessary because the models to be merged also have complex structures, which usually do not correspond to each other; the mapping model then acts as a "bridge" to connect these heterogeneous structures.

These structural heterogeneities are one class of conflicts which have to be solved in schema integration. Other types of conflicts are semantic conflicts (model elements describe overlapping sets of objects), descriptive conflicts (the same elements are described by different sets of properties; this includes also name conflicts), and heterogeneity conflicts (models are described in different modeling languages) [15]. The resolution of these conflicts is the main problem in schema integration.

The problem of schema integration has been addressed for various metamodels, such as variants of the ER metamodel [15] or generic metamodels.

Mappings

Depending on the application area, such as data translation, query translation or model merging, schema mappings come in different flavors. One can distinguish between correspondences, also called morphisms, extensional and intensional mappings. Correspondences usually do not have a formal semantics but only state informally that the respective model elements are similar. Morphisms are often – as the result of a schema matching operation [14] – the starting point for specifying more formal mappings. Intensional mappings are usually used for schema integration (see above) and are based on the *possible* instances of a schema. In contrast to intensional mappings, extensional mappings refer to the actual instances of a schema.

Extensional mappings are defined as local-as-view (LAV), global-as-view (GAV), source-to-target tuple generating dependencies (s-t tgds), [12], second order tuple generating dependencies (SO tgds) [8], or similar formalisms. Each of these classes has certain advantages and disadvantages when it comes to properties such as composability, invertibility or execution of the mappings.

Composition is an important sub-problem when dealing with extensional mappings. In general, the problem of composing mappings has the following definition: given a mapping M_{12} from model S_1 to model S_2, and a mapping M_{23} from model S_2 to model S_3, derive a mapping M_{13} from model S_1 to model S_3 that is equivalent to the successive application of M_{12} and M_{23} [8].

Fagin et al. [8] explored the properties of the composition of schema mappings specified by a finite set of s-t tgds. They proved that the language of s-t tgds is not closed under composition. To ameliorate the problem, they introduced the class of SO tgds which are closed under composition.

Model Management Systems

In the recent years, several prototype systems related to model management have been developed. Many of them focus only on some particular aspects of model management whereas only a few try to address a broader range of model management operators. The systems Rondo [13] and GeRoMeSuite [11] aim at providing a complete set of model management operators and are not restricted to particular modeling languages. Clio [9] focuses especially on mappings between XML and relational databases, the generation, and composition of these mappings. COMA++ [2] provides schema matching functionality.

Key Applications

Model management can be applied in scenarios, in which the management of complex data models is necessary. For example, data warehouses (DWs) are one application area for model management systems [6]. For integrating a new data source into the DW, a *Match* operator could be used to identify the similarities between the source schema and the DW schema. If the DW schema has not yet been created, a *Merge* operator can be used to generate it from several source schemas. The composition of mappings can be used after a source schema *S* has been evolved to a new version *S*′: if a mapping from *S*′ to *S* is known (either given by the schema evolution operation, or computed by a *Match* operator), one can compose this mapping with the original mapping between the source schema *S* and the integrated schema *T* to get a mapping from the new version of the source schema *S*′ to the integrated schema *T*.

Such applications of model management operators are also possible for other integrated information systems. For example, web services or e-business systems often have to take a message in XML format and store it in some relational data store for further processing. To implement this data transformation, a mapping between the XML schema and the schema of the relational database has to be defined. Such tasks are already supported by commercial products (e.g., Microsoft BizTalk, Altova MapForce). These products already use some model management operators (e.g., simple *Match* operators to simplify the task of mapping definition), but could further benefit from more powerful techniques for mapping generation. Clio started as a research prototype for mapping generation between XML and relational schemas, results have now been integrated into the IBM Information Integration platform.

Another application area for model management is the design and development of software applications. Model transformation is an inherent problem in software development, models have to be transformed into new metamodels, and then interoperability between the original model and the transformed model has to be implemented. A classical example is the transformation of an object-oriented data model of an application to a relational database schema, for which data access objects later have to be implemented to enable the synchronization between the data in the database and in the application. Such tasks are supported by frameworks (e.g., ADO.NET Entity Framework or the Entity Beans in Java 2 Enterprise Edition).

Future Directions

Mappings will become more and more important for MMS in the future [5]. The initial vision of model management, which considered mappings as rather simple correspondences attached with some complex expressions which contain the semantics of the mapping, was too limited. Mappings are in practice very complex and therefore, a rich mapping language is required in a MMS. The MMS must also be able to reason about the mappings. Furthermore, the MMS should not only enable the definition of a mapping, but support also its application; for example, using it for the integration of two schemas or for data transformation between two data stores. In addition, complex processes involving mappings (such as ETL process in data warehouses) have also to be considered.

Approximate querying; Model-driven data acquisition

Definition

The data generated by sensor networks or other distributed measurement infrastructures is typically incomplete, imprecise, and often erroneous, such that it is not an accurate representation of physical reality. To map raw sensor readings onto physical reality, a mathematical description, a *model*, of the underlying system or process is required to complement the sensor data. Models can help provide more robust interpretations of sensor readings: by accounting for spatial or temporal biases in the observed data, by identifying sensors that are providing faulty data, by extrapolating the values of missing sensor data, or by inferring hidden variables that may not be directly observable. Models also offer a principled approach to predict future states of a system. Finally, since models incorporate spatio-temporal correlations in the environment (which tend to be very strong in many monitoring applications), they lead to significantly more energy-efficient query execution – by exploiting such attribute correlations, it is often possible to use a small set of observations to provide approximations of the values of a large number of attributes.

Model-based querying over a sensor network consists of two components: (i) identifying and/or building a model for a given sensor network, and (ii) executing declarative queries against a sensor network that has been augmented with such a model (these steps may happen serially or concurrently). The queries may be on future or hidden states of the system, and are posed in a declarative SQL-like language. Since the cost of acquiring sensor readings from the sensor nodes is the dominant cost in these scenarios, the optimization goal typically is to minimize the total data acquisition cost.

Historical Background

Statistical and probabilistic models have been a mainstay in the scientific and engineering communities for a long time, and are commonly used for a variety of reasons, from simple pre-processing tasks for removing noise (e.g., using Kalman Filters) to complex analysis tasks for prediction purposes (e.g., to predict weather or traffic flow). Standard books on machine learning and statistics should be consulted for more details (e.g., Cowell [3], Russell and Norvig [14]).

The first work to combine models, declarative SQL-like queries and live data acquisition in sensor networks was the BBQ System [7,6]. The authors proposed a general architecture for model-based querying, and posed the optimization problem of selecting the best sensor readings to acquire to satisfy a user query (which can be seen as a generalization of the *value of information problem* [14]). The authors proposed several algorithms for solving this optimization problem; they also evaluated the approach on a several real-world sensor network datasets, and demonstrated that model-based querying can provide high-fidelity representation of the real phenomena and leads to significant performance gains versus traditional data acquisition techniques. Several works since then have considerably expanded upon the basic idea, including development of sophisticated algorithms for data acquisition [12,13], more complex query types [15], and integration into a relational database system [8,11].

The querying aspect of this problem has many similarities to the problem of approximate query processing in database systems, which often uses model-like *synopses*. For example, the AQUA project [1] proposed a number of sampling-based synopses that can provide approximate answers to a variety of queries using a fraction of the total data in a database. As with BBQ, such answers typically include tight bounds on the correctness of answers. AQUA, however, is designed to work in an environment where it is possible to generate an independent random sample of data (something that is quite tricky to do in sensor networks, as losses are correlated and communicating random samples may require the participation of a large part of the network). AQUA also does not exploit correlations, which means that it lacks the *predictive* power of representations based on probabilistic models. Deshpande et al. [4] and Getoor et al. [9] proposed exploiting data correlations through use of graphical modeling techniques for approximate query processing, but, unlike BBQ, neither provide any guarantees on the answers returned. Furthermore, the optimization goal of approximate query processing is typically not to minimize the data acquisition cost, rather it is minimizing the size of the synopsis, while maintaining reasonable accuracy.

Foundations

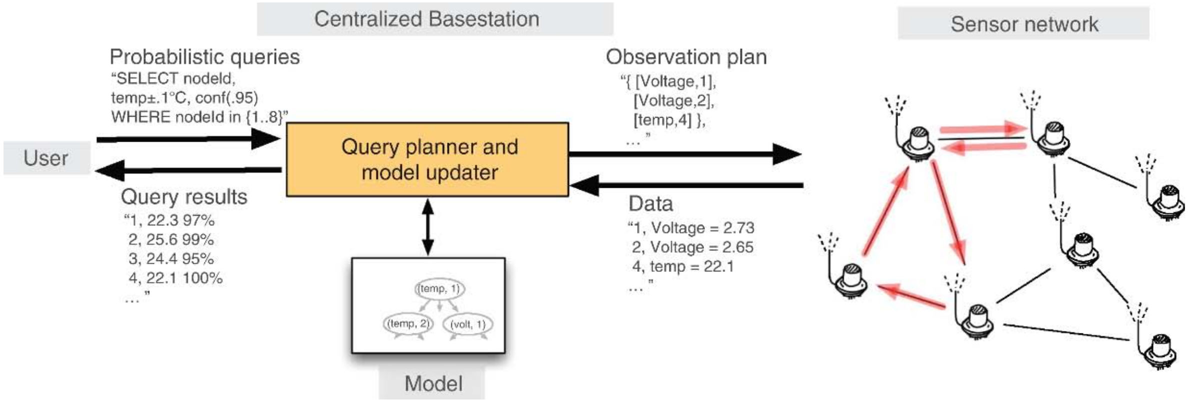
Figure 1 shows the most common architecture of a model-based querying system (adapted from the architecture of the BBQ system). The model itself is located at a centralized, Internet-connected basestation, which also interacts with the user. The user may issue either continuous or ad hoc queries against the sensor network, using a declarative SQL-like language. The key module in this architecture is the *query planner and model updater*, which is in charge of maintaining the model and answering the user queries (possibly by acquiring more data from the underlying sensor network). The following sections elaborate on the various components of such a system.

Model

A model is essentially a simplified representation of the underlying system or the process, and describes how various attributes of the system interact with each other, and how they evolve over time. Hence, the exact form of the model is heavily dependent on the system being modeled, and an astounding range of models have been developed over the years for different environments. For ease of exposition, the rest of this entry focuses on a dynamic model similar to the one used in the BBQ system.

Let $X_1,\ldots,X_n$ denote the (n) attributes of interest in the sensor network. Further, let X_i^t denote the value of X_i at time t (assuming that time is discrete). At any time t, a subset of these attributes may be observed and communicated to the basestation; here, the observations at time t are denoted by $\mathbf{o}^t$ (note that hidden variables can never be observed). The attributes typically correspond to the properties being monitored by the sensor nodes (e.g., *temperature* on sensor number 5, *voltage* on sensor number 8). However, more generally, they may be *hidden variables* that are of interest, but cannot be directly observed. For example, it may be useful to model and query a hidden boolean variable that denotes whether a sensor is faulty [11] – the value of this variable can be inferred using the model and the actual observations from the sensor.

The model encodes the spatial and temporal relationships between these attributes of interest. At any time t, the model provides us with a posterior *probability density function* (pdf), $p(X_1^t,\ldots,X_n^t|\mathbf{o}^{1\ldots(t-1)})$, assigning a probability for each possible assignment to the attributes at time t given the observations



Model-based Querying in Sensor Networks. Figure 1. Architecture of a model-based querying system (adapted from BBQ [7,6]).

made so far. Such a joint distribution can capture all the spatial correlations between the attributes; more compact representations like Bayesian networks can be used instead as well.

To model the temporal correlations, it is common to make a *Markov* assumption; given the values of *all* attributes at time *t*, one assumes that the values of the attributes at time $t + 1$ are independent of those for any time earlier than *t*. This assumption leads to a simple model for a dynamic system where the dynamics are summarized by a conditional density called the *transition model*, $p(X_1^{t+1},\ldots,X_n^{t+1}|X_1^t,\ldots,X_n^t)$. Using a transition model, one can compute $p(X_1^{t+1},\ldots,X_n^{t+1}|\mathbf{o}^{1\ldots t})$ from $p(X_1^t,\ldots,X_n^t|\mathbf{o}^{1\ldots t})$ using standard probabilistic procedures. Different transition models may be used for different time periods (e.g., hour of day, day of week, season, etc.) to model the differences in the way the attributes evolve at different times.

Learning the model. Typically in probabilistic modeling, a *class* of models is chosen (usually with input from a *domain expert*), and learning techniques are then used to pick the best model in the class. Model parameters are typically learned from training data, but can also be directly inferred if the behavior of the underlying physical process is well-understood. In BBQ, the model was learned from historical data, which consisted of readings from all of the monitored attributes over some period of time.

Updating the model. Given the formulation above, model updates are fairly straightforward. When a new set of observations arrives (say $\mathbf{o}^t$), it can be incorporated into the model by conditioning on the observations to compute new distributions (i.e., by computing $p(X_1^t,\ldots,X_n^t|\mathbf{o}^{1\ldots t})$ from $p(X_1^t,\ldots,X_n^t|\mathbf{o}^{1\ldots(t-1)})$. Similarly, as time advances, the transition model is used to compute the new distribution for time $t + 1$ (i.e., $p(X_1^{t+1},\ldots,X_n^{t+1}|\mathbf{o}^{1\ldots t})$ is computed from $p(X_1^t,\ldots,X_n^t|\mathbf{o}^{1\ldots t})$ and $p(X_1^{t+1},\ldots,X_n^{t+1}|X_1^t\ldots X_n^t)$).

Query Planning and Execution

User queries are typically posed in a declarative SQL-like language that may be augmented with constructs that allow users to specify the approximation that the user is willing to tolerate, and the desired confidence in the answer. For example, the user may ask the system to report the temperature readings at all sensors within ± 0.5, with confidence 95%. For many applications (e.g., building temperature control), such approximate answers may be more than sufficient. Tolerance for such approximations along with the correlations encoded by the model can lead to significant energy savings in answering such queries.

Answering queries probabilistically based on a pdf over the query attributes is conceptually straightforward; to illustrate this process, consider two types of queries (here, assume that all queries are posed over attributes $X_1^t,\ldots,X_n^t$, and the corresponding pdf is given by $P(X_1^t,\ldots,X_n^t)$):

Value query. A value query [6] computes an approximation of the values of the attributes to within $\pm\,\varepsilon$ of the true value, with confidence at least $1 - \delta$. Answering such a query involves computing the expected value of each of the attribute, μ_i^t, using standard probability theory. These μ_i^t's will be the reported values. The pdf can then be used again to compute the probability that X_i^t is within ε from the mean, $P(X_i^t \in [\mu_i^t - \varepsilon, \mu_i^t + \varepsilon])$. If all of these probabilities meet or exceed user specified confidence threshold, then the requested readings can be directly reported as the means μ_i^t. If the model's confidence is too low, additional readings must be acquired before answering the query (see below).

Max query. Consider an *entity* version of this query [2] where the user wants to know the identity of the sensor reporting the maximum value. A naive approach to answering this query is to compute, for each sensor, the probability that its value is the maximum. If the maximum of these probabilities is above $1 - \delta$, then an answer can be returned immediately; otherwise, more readings must be acquired. Although conceptually simple, computing the probability that a given sensor is reporting the maximum value is non-trivial, and requires complex integration that may be computationally infeasible [15].

If the model is not able to provide sufficient confidence in the answer, the system must acquire more readings from the sensor network, to bring the model's confidence up to the user specified threshold. Suppose the system observes a set of attributes $\mathcal{O} \subset \{X_1,\ldots,X_n\}$. After incorporating these observations into the model and recomputing the answer, typically the confidence in the (new) answer will be higher (this is not always true). The new confidence will typically depend on the actual observed values. Let $R(\mathcal{O})$ denote the *expected* confidence in the answer after observing

$\mathcal{O}$. Then, the optimization problem of deciding which attributes to observe can be stated as follows:

$$\begin{aligned} &\text{minimize}_{\mathcal{O}\subseteq\{1,\ldots,n\}} && C(\mathcal{O}),\\ &\text{such that} && R(\mathcal{O}) \geq 1-\delta. \end{aligned} \tag{1}$$

where $C(\mathcal{O})$ denotes the *data acquisition cost* of observing the values of attributes in $\mathcal{O}$.

This optimization problem combines three problems that are known to be intractable, making it very hard to solve it in general:

1. Answering queries using a pdf: as mentioned above, this can involve complex numerical integration even for simple queries such as max.
2. hoosing the minimum set of sensor readings to acquire to satisfy the query (this is similar to the classic *value of information problem* [14,12,15,10]).
3. Finding the optimal way to collect a required set of sensor readings from the sensor network that minimizes the total communication cost. Meliou et al. [13] present several approximation algorithms for this NP-Hard problem.

Example

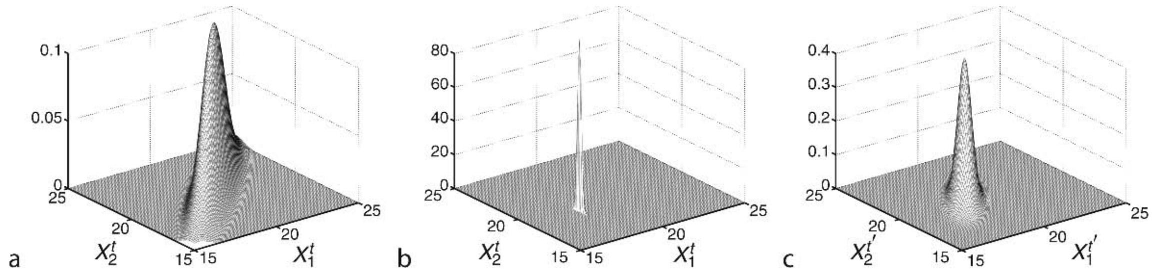
Figure 2 illustrates the query answering process using a simple example, where the model takes the form of time-varying *bivariate Gaussian (normal)* distribution over two attributes, X_1 and X_2. This was the basic model used in the BBQ system. A bivariate Gaussian is the natural extension of the familiar unidimensional normal probability density function (pdf), known as the "bell curve". Just as with its one-dimensional counterpart, a bivariate Gaussian can be expressed as a function of two parameters: a length-2 vector of means, μ, and a 2 × 2 matrix of covariances, Σ. Figure 2a shows a three-dimensional rendering of a Gaussian over the two attributes at time t, X_1^t and $\mathrm{X}_2^{\mathrm{t}}$ the z axis represents the *joint density* that $X_2^t = x$ and $\mathrm{X}_1^{\mathrm{t}} = \mathrm{y}$).

Now, consider a *value query* over this model, posed at time t, which asks for the values of X_1^t and X_2^t, within $\pm\,\epsilon$, with confidence $1-\delta$. The reported values in this case would be the means (μ), and the confidence can be computed easily using Σ (details can be found in [6]). Considering the high initial covariance, it is unlikely that the Gaussian in Figure 2a can achieve the required confidence. Suppose the system decides to observe $X_1{}^t$. Figure 2b shows the result of incorporating this observation into the model. Note that not only does the spread of $X_1{}^t$ reduces to near zero, because of the high correlation between $X_1{}^t$ and $X_2{}^t$, the variance of $X_2{}^t$ also reduces dramatically, allowing the system to answer the query with required confidence.

Then, after some time has passed, the belief about the values of X_1 and X_2 (at time $t' > t$) will be "spread out", again providing a high-variance Gaussian over two attributes, although both the mean and variance may have shifted from their initial values, as shown in Fig. 2c.

Key Applications

Model-based querying systems like BBQ, that exploit statistical modeling techniques and optimize the utilization of a network of resource constrained devices could have significant impact in a number of application domains, ranging from control and automation in buildings [16] to highway traffic monitoring. Integrating a model into the data acquisition process can significantly improve data quality and reduce data



Model-based Querying in Sensor Networks. Figure 2. Example of Gaussians: (a) 3D plot of a 2D Gaussian with high covariance; (b) the resulting Gaussian after a particular value of X_1^t has been observed (because of measurement noise, there might still be some uncertainty about the true value of X_1^t); (c) the uncertainty about X_1 and X_2 increases as time advances to t'.

uncertainty. The ability to query over missing, future or hidden states of the system will prove essential in many applications where sensor failures are common (e.g., highway traffic monitoring) or where direct observation of the variables of interest is not feasible. Finally, model-based querying has the potential to significantly reduce the cost of data acquisition, and thus can improve the life of a resource-constrained measurement infrastructure (e.g., battery-powered wireless sensor networks) manyfold.

Future Directions

Model-based querying is a new and exciting research area with many open challenges that are bound to become more important with the increasingly widespread use of models for managing sensor data. The two most important challenges are dealing with a wide variety of models that may be used in practice, and designing algorithms for query processing and data acquisition; these are discussed briefly below:

Model selection and training. The choice of model affects many aspects of model-based querying, most importantly the accuracy of the answers and the confidence bounds that can be provided with them. The problem of selecting the right model class has been widely studied [3,14] but can be difficult in some applications. Furthermore, developing a new system for each different model is not feasible. Ideally, using a new model should involve little to no effort on the part of user. Given a large variety of models that may be applicable in various different scenarios, this may turn out to be a tremendous challenge.

Algorithms for query answering and data acquisition. Irrespective of the model selected, when and how to acquire data in response to a user query raises many hard research challenges. As discussed above, this problem combines three very hard problems, and designing general-purpose algorithms that can work across the spectrum of different possible model remains an open problem.

See Deshpande et al. [5] for a more elaborate discussion of the challenges in model-based querying.

Monotone Constraints

Carson Kai-Sang Leung
University of Manitoba, Winnipeg, MB, Canada

Synonyms

Monotonic constraints

Definition

A constraint C is *monotone* if and only if for all itemsets S and S':

$$\text{if } S \supseteq S' \text{ and } S \text{ violates } C, \text{ then } S' \text{ violates } C.$$

Key Points

Monotone constraints [1–3] possess the following property. If an itemset S violates a monotone constraint C, then any of its subsets also violates C. Equivalently, all supersets of an itemset satisfying a monotone constraint C also satisfy C (i.e., C is upward closed). By exploiting this property, monotone constraints can be used for reducing computation in frequent itemset mining with constraints. As frequent itemset mining with constraints aims to find frequent itemsets that satisfy the constraints, if an itemset S satisfies a monotone constraint C, no further constraint checking needs to be applied to any superset of S because all supersets of S are guaranteed to satisfy C. Examples of monotone constraints include $min(S.Price) \leq \$30$, which expresses that the minimum price of all items in an itemset S is at most \$30. Note that, if the minimum price of all items in S is at most \$30, adding more items to S would not increase its minimum price (i.e., supersets of S would also satisfy such a monotone constraint).

Moving Object

RALF HARTMUT GÜTING
University of Hagen, Hagen, Germany

Synonyms

Time dependent geometry

Definition

A moving object is essentially a time dependent geometry. Moving objects are the entities represented and queried in moving objects databases.

Key Points

The term emphasizes the fact that geometries may change continuously (whereas earlier work on spatio-temporal databases allowed only discrete changes, e.g., of land parcels). One can distinguish between moving objects for which only the time dependent position is of interest and those for which also shape and extent are relevant and may change over time. The first can be characterized as *moving points*, the second as *moving regions*. For example, moving points could represent people, vehicles (such as cars, trucks, ships or air planes), or animals. Moving regions could be hurricanes, forest fires, spread of epidemic diseases etc. Moving point data may be captured by GPS devices or RFID tags; moving region data may result from processing sequences of satellite images, for example. Moving points and moving regions can be made available as data types in suitable type systems; such a design can be found in [1]. Such an environment may have further "moving" data types (e.g., *moving lines*).

Synonyms

Spatio-temporal databases; trajectory databases

Definition

Moving objects database systems provide concepts in their data model and data structures in the implementation to represent moving objects, i.e., continuously changing geometries. Two important abstractions are *moving point*, representing an entity for which only the time dependent position is of interest, and *moving region*, representing an entity for which also the time dependent shape and extent is relevant. Examples of moving points are cars, trucks, air planes, ships, mobile phone users, RFID equipped goods, or polar bears; examples of moving regions are forest fires, deforestation of the Amazon rain forest, oil spills in the sea, armies, epidemic diseases, hurricanes, and so forth.

There are two flavors of such databases. The first represents information about a set of currently moving objects. Basically one is interested in efficiently maintaining their location information and asking queries about the current and expected near future positions and relationships between objects. In this case, no information about histories of movement is kept. This is sometimes also called a *tracking database*.

The second represents complete histories of movements. The goal in the design of query languages for moving objects is to be able to ask any kind of questions about such movements, perform analyses, derive information, in a way as simple and elegant as possible. The underlying system must support efficient execution of such analyses. This view is associated with the term *moving objects database*, sometimes also called *trajectory database*.

Historical Background

The field of moving objects databases came into being in the late 1990s mainly by two parallel developments. First, a model was developed [11,16,17] that allows one to keep track in a database of a set of time dependent locations, e.g., to represent vehicles. The authors observed that one should store in a database not the locations directly, which would require high update rates, but rather a motion vector, representing an object's expected position over time. An update to the database is needed only when the deviation between the expected position and the real position exceeds some threshold. At the same time this concept introduces an inherent, but bounded uncertainty about an object's real location. The model was formalized introducing the concept of a *dynamic attribute*. This is an attribute of a normal data type which changes implicitly over time. This implies that results of queries over such attributes also change implicitly over time. A related query language FTL (future temporal logic) was introduced that allows one to specify time dependent relationships between expected positions of moving objects.

Second, the European project CHOROCHRONOS set out to integrate concepts from spatial and temporal databases. In this case, one represents in a database time-dependent geometries of various kinds such as points, lines, or regions. Earlier work on spatio-temporal databases had generally admitted only discrete changes. This restriction was dropped and continuously changing geometries were considered. A model was developed based on the idea of *spatio-temporal data types* to represent histories of continuously changing geometries [2,4–6]. The model offers data types such as *moving point* or *moving region* together with a comprehensive set of operations. For example, there are operations to compute the projection of a moving point into the plane, yielding a *line* value, or to compute the distance between a moving point and a moving region, returning a time dependent real number, or *moving real*, for short. Such data types can be embedded into a DBMS data model as attribute types and can be implemented as an extension package.

A second approach to data modeling for moving object histories was pursued in CHOROCHRONOS. Here the constraint model was applied to the representation of moving objects [10] and a prototype called Dedale was implemented. Constraint databases can represent geometries in *n*-dimensional spaces; since moving objects exist in 3D (2D + time) or 4D (3D + time) spaces, they can be handled by this approach. Several researchers outside CHOROCHRONOS also contributed to the development of constraint-based models for moving objects.

Foundations

Modeling and Querying Current Movement (Tracking)

Consider first moving objects databases for current and near future movement, or tracking databases. Sets of moving entities might be taxi-cabs in a city, trucks of a logistics company, or military vehicles in a military application. Possible queries might be:

- Retrieve the three free cabs closest to Cottle Road 52 (a passenger request position).
- Which trucks are within 10 km of truck T70 (which needs assistance)?
- Retrieve the friendly helicopters that will arrive in the valley within the next 15 min and then stay in the valley for at least 10 min.

Statically, the positions of a fleet of taxi-cabs, for example, could be easily represented in a relation

```
taxi-cabs(id: int, pos: point)
```

Unfortunately this representation needs frequent updates to keep the deviation between real position and position in the database small. This is not feasible for large sets of moving objects.

The MOST (moving objects spatio-temporal) data model [11,16], discussed in this section, stores instead of absolute positions a motion vector which represents a position as a linear function of time. This defines an expected position for a moving object. The distance between the expected position and the real position is called the *deviation*. Furthermore, a *distance threshold* is introduced and a kind of contract between a moving object and the database server managing its position is assumed. The contract requires that the moving object observes the deviation and sends an update to the server when it exceeds the threshold. Hence the threshold establishes a bound on the *uncertainty* about an object's real position.

A fundamental new concept in the MOST model is that of a *dynamic attribute*. Each attribute of an object class is classified to be either static or dynamic. A dynamic attribute is of a standard data type (e.g., *int*, *real*) within the DBMS conceptual model, but changes its value automatically over time. This means that queries involving such attributes also have time dependent results, even if time is not mentioned in the query and no updates to the database occur.

The MOST model assumes that time advances in discrete steps, so-called clock ticks. Hence time can be represented by integer values. For a data type to be eligible for use in a dynamic attribute, it is necessary that the type has a value 0 and an addition operation. This holds for numeric types but can be extended to types like *point*. A dynamic attribute A of type T is then internally represented by three subattributes $A.value$, $A.updatetime$, and $A.function$, where $A.value$ is of type T, $A.updatetime$ is a time value, and $A.function$ is a function f: $int \rightarrow T$ such that at time $t = 0$, $f(t) = 0$. The semantics of this representation is called the value of A at time t and defined as

$$value(A, t) = A.value + A.function(t - A.updatetime) \quad for\ t \geq A.updatetime$$

When attribute A is mentioned in a query, its dynamic value $value(A, t)$ is meant.

With dynamic attributes, for each clock tick one obtains a new state of the database, even without explicit updates. Such a sequence of states is called a database history. With each explicit update, all subsequent states change so that one obtains a new database history. One can now define different types of queries:

- An *instantaneous query* issued at a time t_0 is evaluated once on the database history starting at time $t_{0.}$
- A *continuous query* issued at time t_0 is (conceptually) reevaluated for each clock tick. Hence it is evaluated once on the database history starting at time t_0, then on the history starting at t_1, then on... t_2, and so forth.

Of course, reevaluating a continuous query on each clock tick is not feasible. Instead, the evaluation algorithm for such queries is executed only once and returns a time dependent result, in the form of a set of tuples with associated time stamps. A reevaluation is only necessary when explicit updates occur.

The query language associated with the MOST model is called FTL (future temporal logic). Here are a few example queries formulated in FTL.

1. Which trucks are within 10 km of truck T70?
```
RETRIEVE t
FROM trucks t, trucks s
WHERE s.id = ’T70’ ∧ dist(s, t) <= 10
```
   Here nothing special happens, yet, the result is time dependent.
2. Retrieve the helicopters that will arrive in the valley within the next 15 min and then stay in the valley for at least 10 min.
```
RETRIEVE h
FROM helicopters h
WHERE eventually_within_15
   (inside(h, Valley) ∧
   always_for_10 (inside(h, Valley)))
```
   Here *Valley* is a polygon object.

The general form of a query in FTL is
```
RETRIEVE <target-list> FROM <object
classes> WHERE <FTL-formula>
```
FTL formulas may contain special time dependent constructs, in particular:

- If f and g are formulas, then f **until** g and **nexttime** f are formulas

Informally, the meaning is that for a given database state s, f **until** g holds if there exists a future state s' on the database history such that g holds in state s' and for all states from s up to s', f holds. Similarly, **nexttime** f holds in state s_{i+1} if f holds in state s_i. Based on such temporal operators one can define bounded temporal operators like **eventually_within_c** g or **always_for_c** g as they occur in the second example query.

Modeling and Querying History of Movement

Now consider the problem of representing complete histories of movement in a database. The scope is also extended from point objects to more complex geometrical shapes.

The idea of the approach [4] presented in the following is to introduce spatio-temporal data types that encapsulate time dependent geometries with suitable operations. For moving objects, point and region appear to be most relevant, leading to data types *moving point* and *moving region*, respectively. The *moving point* type (*mpoint* for short) can represent entities such as vehicles, people, or animals moving around whereas the *moving region* type (*mregion*) can represent hurricanes, forest fires, armies, or flocks of animals, for example. Geometrically, values of spatio-temporal data types are embedded into a 3D space (2D + time) if objects move in the 2D plane, or in a 4D space if movement in the 3D space is modeled. Hence, a moving point and a moving region can be visualized as shown in Fig. 1

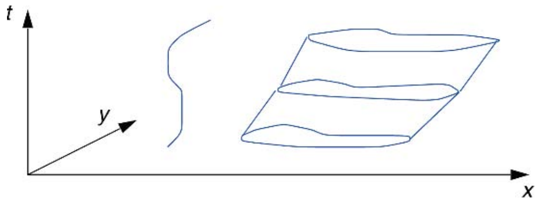
Data types may be embedded in the role of attribute types into a DBMS data model. For example, in a relational setting, there may be relations to represent the movements of air planes or storms:

```
flight (id: string, from: string, to:
  string, route: mpoint)
weather (id: string, kind: string,
  area: mregion)
```

The data types include suitable operations such as:

intersection: *mpoint* × *mregion* → *mpoint*
trajectory: *mpoint* → *line*
deftime: *mpoint* → *periods*
length: *line* → *real*

One discovers quickly that in addition to the main types of interest, *mpoint* and *mregion*, related spatial and temporal as well as other time-dependent types are needed. The operations above have the following meaning: **Intersection** returns the part of a moving point whenever it lies inside a moving region, which is a moving point (*mpoint*) again. **Trajectory** projects a moving point into the plane, yielding a *line* value (a curve in the 2D space). **Deftime** returns the set of time intervals when a moving point is defined, of a data type called *periods*. **Length** returns the length of a *line* value.



Moving Objects Databases and Tracking. Figure 1. A moving point and a moving region.

Given such operations, one may formulate queries:

"Find all flights from Düsseldorf that are longer than 5,000 km."

```
select id
from flights
where from = 'DUS' and length
  (trajectory (route)) > 5000
```

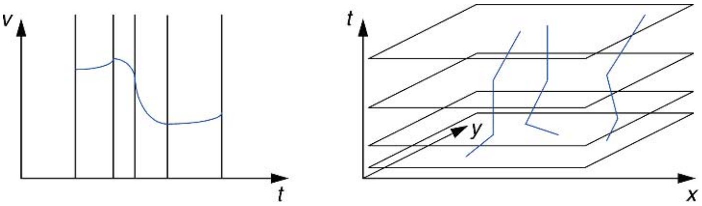
"At what times was flight BA488 within the snow storm with id S16?"

```
select deftime(intersection
  (f.route, w.area))
from flights as f, weather as w
where f.id = 'BA488' and w.id = 'S16'
```

Reference [4] develops the basic idea, discusses the distinction between *abstract models* (using infinite sets, and describing e.g., a moving region as a function from time into region values) and *discrete models* (selecting a suitable finite representation, e.g., describing a moving region as a polyhedron in the 3D space), and clarifies several fundamental questions related to this approach. A system of related data types and operations for moving objects is carefully defined in [6], emphasizing genericity, closure, and consistency. The semantics of these types is defined at the abstract level.

Implementation is based on the discrete model proposed in [5] using algorithms for the operations studied in [2]. The discrete model uses the so-called *sliced representation* as illustrated in Fig. 2. A temporal function value is represented as a time-ordered sequence of *units* where each unit has an associated time interval, and time intervals of different units are disjoint. Each unit is capable of representing a piece of the moving object by a "simple" function. Simple functions are linear functions for moving points or regions, and quadratic polynomials (or square roots of such) for moving reals, for example.

Within a database system, an extension module (data blade, cartridge, extender, etc.) can be provided offering implementations of such types and operations. The sliced representation is basically stored in an array of units. (It is a bit more complicated in case of variable size units as for a moving region, for example.) Because values of moving object types can be large and complex, the DBMS must provide suitable storage techniques for managing large objects. A large



Moving Objects Databases and Tracking. Figure 2. Sliced representation of a *moving*(*real*) and a *moving*(*points*) value.

part of this design has been implemented prototypically in the SECONDO extensible DBMS [1] which is available for download (see URL below).

Related Issues

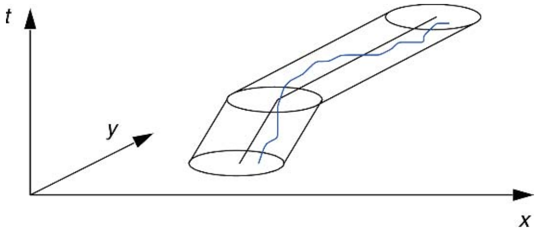
In this short closing section some issues related to moving objects databases are briefly discussed.

Uncertainty Locations of moving objects are most often captured using GPS devices at certain instants of time. This introduces an inherent uncertainty already for the sampled positions (due to some inaccuracy of the GPS device) and in particular for the periods of time between measurements [9]. Bounded uncertainty is also introduced due to a contract between location server and moving object, as discussed above. The MOST model includes concepts to deal with this uncertainty in querying [16,17]. For history of movement, one can consider uncertain trajectories based on an uncertainty threshold, resulting in a shape of a kind of slanted cylinder (Fig. 3). It is only known that the real position is somewhere inside this volume. Based on this model, Trajcevski et al. [15] have defined a set of predicates between a trajectory and a region in space taking uncertainty and aggregation over time into account.

Movement in Networks Whereas the basic case is free movement in the Euclidean plane, it is obvious that vehicles usually move on transport networks. There is a branch of research on network-constrained movement (e.g., [7,13]); there is also work on indexing network based movements. For network based movement, captured GPS positions have to be mapped to the transportation network; this is called map matching.

Spatio-Temporal Indexing A lot of research exists on indexing movement, both for expected near future movement and for history movement.

Query Processing for Continuous/Location Based Queries Continuous queries for moving objects have



Moving Objects Databases and Tracking. Figure 3. Geometry of an uncertain trajectory.

been studied in depth, for example, maintaining the result of nearest neighbor or range queries both for moving query and moving data objects (e.g., [12,14], see continuous monitoring of spatial queries).

Spatiotemporal Aggregation and Selectivity Estimation Another subfield of research in moving objects databases considers the problem of computing precisely or estimating the numbers of moving objects within certain areas in space and time – hence, of computing aggregates. For example, various index structures have been proposed to compute efficiently such aggregates. This is also related to the problem of performing selectivity estimation for spatio-temporal query processing.

Key Applications

Databases for querying current and near future movement like the MOST model described, are the foundation for location-based services. Service providers can keep track of the positions of mobile users and notify them of upcoming service offers even some time ahead. For example, gas stations, hotels, shopping centres, sightseeing spots, or hospitals in case of an emergency might be interesting services for car travelers.

Several applications need to keep track of the current positions of a large collection of moving objects, for example, logistics companies, parcel delivery services, taxi fleet management, public transport systems, air traffic control. Marine mammals or other animals are traced in biological applications. Obviously, the military is also interested in keeping track of fighting units in battlefield management.

Database systems for querying history of movement are needed for more complex analyses of recorded movements. For example, in air traffic control one may go back in time to any particular instant or period to analyze dangerous situations or even accidents. Logistics companies may analyze the paths taken by their delivery vehicles to determine whether optimizations are possible. Public transport systems in a city may be analyzed to understand reachability of any place in the city at different periods of the day. Movements of animals may be analyzed in biological studies. Historical modeling may represent movements of people or tribes and actually animate and query such movements over the centuries.

The data model of such systems offers not only moving point entities but also moving regions. Hence also developments of areas on the surface of the earth may be modeled and analyzed like the deforestation of the Amazon rain forest, the Ozone hole, development of forest fires or oil spills over time, and so forth.

Future Directions

Recent research in databases has often addressed specific query types like continuous range queries or nearest neighbor queries, and then focused on designing efficient algorithms for them. An integration of the many specific query types into complete language designs as presented in this entry is still lacking. Uncertainty may be treated more completely also in the approaches for querying history of movement. A seemless query language for querying past, present, and near future would also be desirable.

A text book covering the topics presented in this article in more detail is [8].

Experimental Results

Running times for queries of the BerlinMOD benchmark (see below), evaluated in the SECONDO system, can be found in [3].

Data Sets

A collection of links to data sets with real spatio-temporal data, partially assembled within the CHOROCHRONOS project mentioned above can be found at

http://dke.cti.gr/people/pfoser/data.html

Recently a benchmark data set is available, the so-called BerlinMOD benchmark [3]. It is based on a simulation of the movements of 2,000 people's vehicles in the city of Berlin, observed over 1 month (at scale factor 1). The benchmark contains a number of test queries. Test data are generated by the SECONDO system. The benchmark can be found and the relevant resources downloaded at

http://dna.fernuni-hagen.de/secondo/BerlinMOD/Berlin MOD.html

See also real and synthetic test data sets; this entry should include links to further test data generators.

Multidimensional Data Formats

Amarnath Gupta
University of California San Diego, La Jolla, CA, USA

Definition

The term "multidimensional data" is used in two different ways in data management. In the first sense, it refers to data aggregates created by different groupings of relational data for on-line analytical processing. In the second sense, the term refers to data that can be described as arrays over heterogeneous data types together with metadata to describe them.

Example: HDF (Hierarchical Data Format) and NetCDF (network Common Data Form) are well known multidimensional data formats used in scientific applications.

Key Points

The goal of a multidimensional data format is to enable random access to very large, very complex, heterogeneous data, such that the data is self describing, sharable, compact, extendible, and archivable. For example, a composite of 900 files from a seismic simulation has been organized in HDF5 format to create a terabyte-sized dataset. One can mix tables, images, small metadata, streams of data from instruments, and structured grids all in the same HDF file. While multidimensional file formats are very flexible, they present the challenge of storing such large datasets and providing concurrent, random access to any part of the data required by user queries. Design of novel index structures over these formats is an area of active research.

Synonyms

Dimensional modeling; Star schema modeling

Definition

Multidimensional modeling is the process of modeling the data in a universe of discourse using the modeling constructs provided by a multidimensional data model. Briefly, multidimensional models categorize data as being either *facts* with associated numerical *measures*, or as being *dimensions* that characterize the facts and are mostly textual. For example, in a retail business, *products* are sold to *customers* at certain *times* in certain *amounts* and at certain *prices*. A typical fact would be a *purchase*. Typical measures would be the amount and price of the purchase. Typical dimensions would be the location of the purchase, the type of product being purchased, and the time of the purchase. Queries then aggregate measure values over ranges of dimension values to produce results such as the total sales per month and product type.

Historical Background

Multidimensional databases do not have their origin in database technology, but stem from multidimensional matrix algebra, which has been used for (manual) data analyses since the late nineteenth century. During the late 1960s, two companies, IRI and Comshare, independently began the development of systems that later turned into multidimensional database systems. The IRI Express tool became very popular in the marketing analysis area in the late 1970s and early 1980s; it later turned into a market-leading OLAP tool and was acquired by Oracle. Concurrently, the Comshare system developed into System W, which was heavily used for financial planning, analysis, and reporting during the 1980s.

A concurrent development started in the early 1980s in the area of so-called *statistical data management* which focused on modeling and managing statistical data [1], initially within social science contexts such as census data. Many important concepts of multidimensional modeling such as *summarizability* (ensuring correct aggregate query results for complex data) have their roots in this area. An overview is found in [14].

In 1991, Arbor was formed with the specific purpose of creating "a multiuser, multidimensional database server," which resulted in the Essbase system. Arbor, now Hyperion, later licensed a basic version of Essbase to IBM for integration into DB2. It was Arbor and Codd who in 1993 coined the term OLAP [2].

Another significant development in the early 1990s was the advent of large *data warehouses* [6] for storing and analyzing massive amounts of enterprise data. Data warehouses are typically based on relational *star schemas* or *snowflake schemas*, an approach to implementing multidimensional databases using relational database technology. The 1996 version of [6] popularized the use of star schema modeling for data warehouses.

From the mid 1990s and beyond, the introduction of the "data cube" operator [4] sparked a considerable research interest in the field of modeling multidimensional databases for use in data warehouses and *on-line analytical processing* (OLAP).

In 1998, Microsoft shipped its MS OLAP Server, the first multidimensional system aimed at the mass market. This has lead to the current situation where multidimensional systems are increasingly becoming commodity products that are shipped at no extra cost together with leading relational database systems.

A more in-depth coverage of the history of multidimensional databases is available in the literature [16]. Surveys of multidimensional data models can also be found in the literature [12,17].

Foundations

First, an overview of the concept of a multidimensional *cube* is given, then dimensions, facts, and measures are covered in turn.

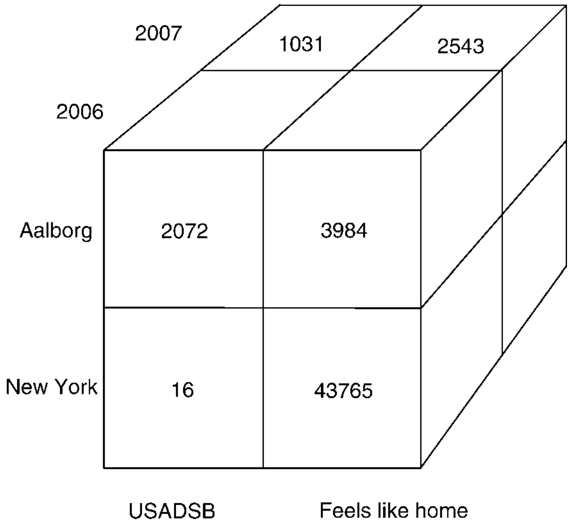
Data Cubes

Data cubes provide true multidimensionality. They generalize spreadsheets to any number of dimensions. In addition, hierarchies in dimensions and formulas are first-class, built-in concepts, meaning that these are supported without duplicating their definitions. A collection of related cubes is commonly referred to as a *multidimensional database* or a *multidimensional data warehouse*.

A dimensional cube for, e.g., CD sales can be obtained by including additional dimensions apart from just the album and the city where the album was sold. The most pertinent example of an additional dimension is a time dimension, but it is also possible to include other dimensions, e.g., an artist dimension that describes the artists associated with albums. In a cube, the combinations of a dimension value from each dimension define the *cells* of the cube. The actual sales counts are stored in the corresponding cells.

In a cube, dimensions are first-class concepts with associated domains, meaning that the addition of new dimension values is easily handled. Although the term "cube" implies three dimensions, a cube can have any number of dimensions. It turns out that most real-world cubes have 4–12 dimensions [6,16]. Although there is no theoretical limit to the number of dimensions, current tools often experience performance problems when the number of dimensions is more than 10–15. To better suggest the high number of dimensions, the term "hypercube" is often used instead of "cube."

Figure 1 illustrates a three-dimensional cube based on the number of CD sales of two particular albums in Aalborg, Denmark, and New York, USA, for 2006 and 2007. The cube then contains sales counts for two cities, two albums, and two years. Depending on the specific application, a highly varying percentage of the cells in a cube are non-empty, meaning that cubes range from *sparse* to *dense*. Cubes tend to become increasingly sparse with increasing dimensionality and with increasingly finer granularities of the dimension values.



Multidimensional Modeling. Figure 1. Sales data cube.

A non-empty cell is called a *fact*. The example has a fact for each combination of time, album, and city where at least one sale was made. A fact has associated with it a number of *measures*. These are numerical values that "live" within the cells. In our case, there is only one measure, the sales count.

Generally, only two or three dimensions may be viewed at the same time, although for low-cardinality dimensions, up to four dimensions can be shown by nesting one dimension within another on the axes. Thus, the dimensionality of a cube is reduced at query time by *projecting* it down to two or three dimensions via *aggregation* of the measure values across the projected-out dimensions. For example, if the user wants to view just sales by City and Time, she aggregates over the entire dimension that characterizes the sales by Album for each combination of City and Time.

An important goal of multidimensional modeling is to "provide as much context as possible for the facts" [6]. The concept of *dimension* is the central means of providing this context. One consequence of this is a different view on *data redundancy* than in relational databases. In multidimensional databases, controlled redundancy is generally considered appropriate, as long as it considerably increases the information value of the data. One reason to allow redundancy is that multidimensional data is often *derived* from other data sources, e.g., data from a transactional relational system, rather than being "born" as multidimensional data, meaning that updates can more easily be handled [6]. However, there is usually no redundancy in the facts, only in the dimensions.

Having introduced the cube, its principal elements, dimensions, facts, and measures, are now described in more detail.

Dimensions

The notion of a dimension is an essential and distinguishing concept for multidimensional databases. Dimensions are used for two purposes: the *selection* of data and the *grouping* of data at a desired level of detail.

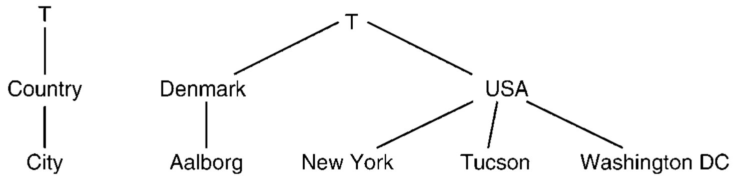
A dimension is organized into a containment-like *hierarchy* composed of a number of *levels*, each of which represents a level of detail that is of interest to the analyses to be performed. The instances of the dimension are typically called *dimension values*. Each such value belongs to a particular level.

In some cases, it is advantageous for a dimension to have *multiple hierarchies* defined on it. For example, a Time dimension may have hierarchies for both *Fiscal Year* and *Calendar Year* defined on it. Multiple hierarchies share one or more common lowest level(s), e.g., Day and Month, and then group these into multiple levels higher up, e.g., Fiscal Quarter and Calendar Quarter to allow for easy reference to several ways of grouping. Most multidimensional models allow multiple hierarchies. A dimension hierarchy is defined in the metadata of the cube, or the metadata of the multidimensional database, if dimensions can be shared.

In Fig. 2, the schema and instances of a sample *Location* dimension capturing the cities where CDs are sold are shown. The Location dimension has three levels, the City level being the lowest. City level values are grouped into *Country* level values, i.e., countries. For example, Aalborg is in Denmark. The ⊤ ("top") level represents *all* of the dimension, i.e., every dimension value is part of the ⊤ ("top") value.

In some multidimensional models, a level may have associated with it a number of *level properties* that are used to hold simple, non-hierarchical information. For example, the duration of an album can be a level property in the Album level of the Music dimension. This information could also be captured using an extra Duration dimension. Using the level property has the effect of not increasing the dimensionality of the cube.

Unlike the linear spaces used in matrix algebra, there is typically no ordering and/or distance metric on the dimension values in multidimensional models. Rather, the only ordering is the containment of



Multidimensional Modeling. Figure 2. Schema and instance for the location dimension.

lower-level values in higher-level values. However, for some dimensions, e.g., the Time dimension, an ordering of the dimension values is available and is used for calculating cumulative information such as "total sales in year to date."

Most models require dimension hierarchies to form *balanced trees*. This means that the dimension hierarchy must have uniform height everywhere, e.g., all departments, even small ones, must be subdivided into project groups. Additionally, direct links between dimension values can only go between immediate parent-child levels, and not jump two or more levels. For example, all cities are first grouped into states and then into countries, cities cannot be grouped directly under countries (as is the case in Denmark which has no states). Finally, each non-top value has precisely one parent, e.g., a product must belong to exactly one product group. Below, the relaxation of these constraints is discussed.

Facts

Facts are the objects that represent the *subject* of the desired analyses, i.e., the interesting "thing," or event or process, that is to be analyzed to better understand its behavior.

In most multidimensional data models, the facts are *implicitly* defined by their combination of dimension values. If a non-empty cell exists for a particular combination, a fact exists; otherwise, no fact exists. (Some other models treat facts as first-class objects with a separate identity [12].) Next, most multidimensional models require that each fact be mapped to precisely one dimension value at the lowest level in each dimension. Other models relax this requirement [12].

A fact has a certain *granularity*, determined by the levels from which its combination of dimension values are drawn. For example, the fact granularity in our example cube is "Year by Album by City." Granularities consisting of higher-level or lower-level dimension levels than a given granularity, e.g., "Year by Album Genre by City" or "Day by Album by City" for our example, are said to be *coarser* or *finer* than the given granularity, respectively.

It is commonplace to distinguish among three kinds of facts: *event* facts, *state* facts, and *cumulative snapshot* facts [6]. Event facts (at least at the finest granularity) typically model *events in the real world*, meaning that a unique instance, e.g., a particular sale of a given (particular physical instance of a) product in a given store at a given time, of the overall real-world process that is captured, e.g., sales for a supermarket chain, is represented by one fact. Examples of event facts include sales, clicks on web pages, and movement of goods in and out of (real) warehouses (flow).

A snapshot fact models the *state* of a given process at a given point in time. Typical examples of snapshot facts include the inventory levels in stores and warehouses, and the number of users using a web site. For snapshot facts, the same physical object, e.g., a specific physical instance of a can of beans on a shelf, with which the captured real-world process, e.g., inventory management, is concerned, may be "measured" at several time points, meaning that data related to that particular physical object will occur in several facts at different time points. This is unlike event facts, where a specific physical object such as a particular instance of a can of beans can only be sold once, and will thus only occur in one fact.

Cumulative snapshot facts are used to handle information about *a process up to a certain point in time*. For example, the total sales in the year to date may be considered as a fact. Then the total sales up to and including the current month this year can be easily compared to the figure for the corresponding month last year.

Often, all three types of facts can be found in a given data warehouse, as they support complementary classes of analyses. Indeed, the same base data, e.g., the movement of goods in a (real) warehouse, may often find its way into three cubes of different types, e.g., warehouse flow, warehouse inventory, and warehouse flow in year-to-date.

Measures

A *measure* has two components: a *numerical property* of a fact, e.g., the sales price or profit, and a *formula* (most often a simple aggregation function such as SUM) that can be used to combine several measure values into one. In a multidimensional database, measures generally represent the properties of the chosen facts that the users want to study, e.g., with the purpose of optimizing them.

Measures then take on different values for different combinations of dimension values. The property and formula are chosen such that the value of a measure is meaningful for all combinations of aggregation levels. The formula is defined in the metadata and thus not replicated as in the spreadsheet example. Most multidimensional data models provide the built-in concept of measures, but a few models do not. In these models, dimension values are used for computations instead [12].

It is important to distinguish among three classes of measures, namely *additive*, *semi-additive*, and *non-additive* measures, as these behave quite differently in computations.

Additive measure values can be summed meaningfully along any dimension. For example, it makes sense to add the total sales over Album, Location, and Time, as this causes no overlap among the real-world phenomena that caused the individual values. Additive measures occur for any kind of fact.

Semi-additive measure values cannot be summed along one or more of the dimensions, most often the Time dimension. Semi-additive measures generally occur when the fact is of type snapshot or cumulative snapshot. For example, it does not make sense to sum inventory levels across time, as the same inventory item, e.g., a specific physical instance of an album, may be counted several times, but it is meaningful to sum inventory levels across albums and stores.

Non-additive measure values cannot be summed along any dimension, usually because of the chosen formula. For example, this occurs when averages for lower-level values cannot be summed into averages for higher-level values. Non-additive measures can occur for any kind of fact.

The Modeling Process

Now, the process to be carried out when doing multidimensional modeling is covered. One difference from "ordinary" data modeling is that the multidimensional modeler should not try to include all the available data and all their relationships in the model, but only those parts which are essential "drivers" of the business. Another difference is that redundancy may be ok (in a few, well-chosen places) if introducing redundancy makes the model more intuitive for the user. For example, time-related information may be stored in both a Calendar time dimension and a Fiscal Year time dimension, or specific customer info may be present both in a person-oriented Customer dimension or a group-oriented Demographics dimension.

Kimball [6,5] advocates a four-step process when doing multidimensional modeling.

1. Choose the business process(es) to model
2. Choose the grain of the business process
3. Choose the dimensions
4. Choose the measures

Step 1 refers to the facts that not all business processes may be equally important for the business. For example, in a supermarket, there are business processes for *sales* and *purchases*, but the sales process is probably the one with the largest potential for increasing profits, and should thus be prioritized. Step 2 says that data should be captured at the right grain, or granularity, compared to the analysis needs. For example, "individual sales items" may be captured, or perhaps (slightly aggregated) "total sales per product per store per day" may be precise enough, enabling performance and storage gains. Step 3 then goes on to refine the schema of each part of the grain into a complete dimension with levels and attributes. For the example above, a Store, a Product, and a Time dimension are specified. Finally, Step 4 chooses the numerical measures to capture for each combination of dimension values, for example dollar sales, unit sales, dollar cost, profit, etc.

When doing multidimensional modeling "in the large" for many types of data (many cubes) and several user groups, the most important task is to ensure that analysis results are comparable across cubes, i.e., that the cubes are somehow "compatible." This is ensured by (as far as possible) picking dimensions and measures from a set of common so-called "conformed" dimensions and measures [6,5] rather than "re-definining" the same concept, e.g., product, each time it occurs in a new context. New cubes can then be put onto the common "DW bus" [5] and used together. This sounds easier than it is, since it often requires quite a struggle with different parts of an organisation to define for example a common Product dimension that can be used by everyone.

Complex Multidimensional Modeling

Multidimensional data modeling is not always as simple as described above. A complexity that is almost always present is that of handling *change* in the dimension values. Kimball [6,5] calls this the problem of *slowly changing dimensions*. For example, customer addresses, product category names, and the way products are categorized may change over time. This must be handled to ensure correct results both for current and historical data. Kimball advises three types of slowly changing dimensions: Type 1 (overwrite previous value with current value), Type 2 (keep versions of dimension rows), and Type 3 (keep previous and current value in different columns). Finally, the concept of *minidimensions* [6] advocates the separation of relatively static information (customer name, etc.) and dynamic information (income, number of kids, etc.) into separate dimensions.

The traditional multidimensional data models and implementation techniques assume that the data being modeled is quite regular. Specifically, it is typically assumed that all facts map (directly) to dimension values at the lowest levels of the dimensions and only to one value in each dimension. Further, it is assumed that the dimension hierarchies are simply balanced trees. In many cases, this is adequate to support the desired applications satisfactorily. However, situations occur where these assumptions fail.

In such situations, the support offered by "standard" multidimensional models and systems is inadequate, and more advanced concepts and techniques are called for. Now, the impact of irregular hierarchies on the performance enhancing technique known as partial, or practical, pre-computation, is reviewed.

Complex multidimensional data are problematic as they are not summarizable. Intuitively, data is *summarizable* if the results of higher-level aggregates can be derived from the results of lower-level aggregates. Without summarizability, users will either get wrong query results, if they base them on lower-level results, or the system cannot use pre-computed lower-level results to compute higher-level results. When it is no longer possible to pre-compute, store, and subsequently reuse lower-level results for the computation of higher-level results, aggregates must instead be calculated directly from base data, which leads to considerable increases in computational costs.

It has been shown that summarizability requires that aggregate functions be distributive and that the ordering of dimension values be *strict*, *onto*, and *covering* [12, 7]. Informally, a dimension hierarchy is *strict* if no dimension value has more than one (direct) parent, *onto* if the hierarchy is balanced, and *covering* if no containment path skips a level. Intuitively, this means that dimension hierarchies must be balanced trees. If this is not the case, some lower-level values will be either double-counted or not counted when reusing intermediate query results.

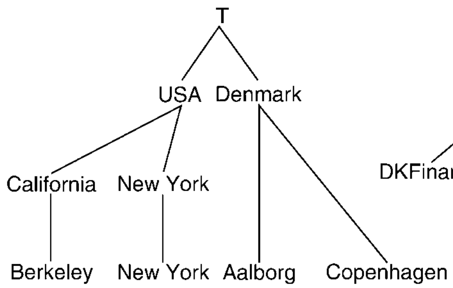
Figure 3 contains two dimension hierarchies: a Location hierarchy including a State level, and the hierarchy for the Organization dimension for some company. The hierarchy to the left is *non-covering*, as Denmark has no states. If aggregates at the State level are pre-computed, there will be no values for Aalborg and Copenhagen, meaning that facts mapped to these cities will not be counted when computing country totals.

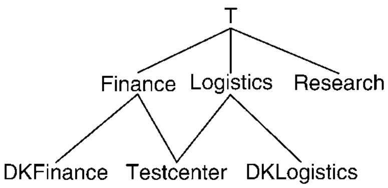
To the right in figure 3, the hierarchy is non-onto because the Research department has no further subdivision. If aggregates are materialized at the lowest level, facts mapping directly to the Research department will not be counted. The hierarchy is also non-strict as the TestCenter is shared between Finance and Logistics. If aggregates are materialized at the middle level, data for TestCenter will be counted twice, for both Finance and Logistics, which is, in fact, what is desired at this level. However, this means that data will be double-counted if these aggregates are then combined into the grand total.

Several design solutions exist that aims to solve the problems associated with irregular hierarchies by altering the dimension schemas or hierarchies [8,11].

Key Applications

Multidimensional data models have three important application areas within data analysis. First, multidimensional models are used in *data warehousing*. Briefly, a data warehouse is a large repository of





Multidimensional Modeling. Figure 3. Irregular dimensions.

integrated data obtained from several sources in an enterprise for the specific purpose of data analysis. Typically, this data is modeled as being multidimensional, as this offers good support for data analyses.

Second, multidimensional models lie at the core of *on-line analytical processing* (OLAP) systems. Such systems provide fast answers to queries that aggregate large amounts of so-called detail data to find overall trends, and they present the results in a multidimensional fashion. Consequently, a multidimensional data organization has proven to be particularly well suited for OLAP. The widely acknowledged "OLAP Report" company [15] provides an "acid test" for OLAP by defining OLAP as "fast analysis of shared multidimensional information" (FASMI). In this definition, "Fast" refers to the expectation of response times that are within a few seconds, "Analysis" refers to the need for easy-to-use support for business logic and statistical analyses, "Shared" suggests a need for security mechanisms and concurrency control for multiple users, "Multidimensional" refers to the expectation that a data model with hierarchical dimensions is used, and "Information" suggests that the system must be able to manage all the required data and derived information.

Third, multidimensional data are increasingly becoming the basis for *data mining*, where the aim is to (semi-) automatically discover unknown knowledge in large databases. Indeed, it turns out that multidimensionally organized data are also particularly well suited for the queries posed by data mining tools.

Future Directions

A pressing need for multidimensional modeling is the aspect of standardization, i.e., agreeing on a common data model, a graphical notation for it, and support by tools. Also, better integration between ordinary "operational modeling" and multidimensional modeling is needed. Another future research line is the modeling of important system aspects such as security, quality, requirements, evolution, and interoperability [13]. This will be extended to also cover the modeling of business intelligence applications such as data mining, patterns, *extraction-transformation-loading* (ETL), *what-if analysis*, and business process modeling [13]. Finally, an important line of research will cover the modeling of more (complex) types of data, including integrating multidimensional data with text data, semi-structured/XML/web data and spatial/spatio-temporal/mobile data [9].

MDS

Definition

Multidimensional scaling (MDS) is a mathematical dimension reduction technique that best preserves the inter-point distances by analyzing gram matrix. Given any two points p_i and p_j in a dataset P, MSD aims to minimize the following objective function:

$$Error = \sum [d(p_i, p_j) - d'(p_i, p_j)]^2$$

Where $d(p_i, p_j)$ and $d'(p_i, p_j)$represent the distance between points p_i and p_j in original space and the lower dimensional subspace respectively.

Key Points

Multidimensional scaling (MDS) is a set of related statistical techniques often used in data visualisation and analysis for exploring similarities or dissimilarities in data. An MDS algorithm starts with a matrix of point-point (dis)similarities, then assigns a location of each point in a low-dimensional space. The points are arranged in this subspace so that the distances between pairs of points have their original distance maximally retained. MDS is a generic term that includes many different specific types. These types can be classified according to whether the data are qualitative (called nonmetric MDS) or quantitative (metric MDS). The number of (dis)similarity matrices and the nature of the MDS model can also classify MDS types. This classification yields classical MDS (one matrix, unweighted model), replicated MDS (several matrices, unweighted model), and weighted MDS (several matrices, weighted model) [1,2].

MDS applications include scientific visualisation and data mining in fields such as cognitive science, information science, psychophysics, psychometrics, marketing and ecology [2].

Multi-Level Recovery and the ARIES Algorithm

Gerhard Weikum
Max-Planck Institute for Informatics, Saarbrücken, Germany

Definition

In contrast to basic database recovery with page-level logging and redo/undo passes, *multi-level recovery* is needed whenever the database system uses fine-grained concurrency control, such as index-key locking or operation-based "semantic" conflict testing, or when log records describe composite operations that are not guaranteed to be atomic by single page writes (as a consequence of concurrency control or for other reasons). Advanced methods perform logging and recovery at multiple levels like pages and data objects (records, index entries, etc.). Page-level recovery is needed to ensure the atomicity and applicability of higher-level operations, and also for efficient redo. Higher-level recovery is needed to perform correct undo for composite operations of loser transactions. In addition, logged actions at all levels must be testable at recovery-time, by embedding extra information in database pages, typically using log sequence numbers (LSNs), and appropriate logging of recovery steps. A highly optimized instantiation of these principles is the *ARIES algorithm* (Algorithms for Recovery and Isolation Exploiting Semantics) [8,7], the de facto standard solution for industrial-strength database systems. Its salient features are: very fast, potentially parallelizable or selective, redo for high availability; use of LSNs and compensation log records (CLRs) for tracking recovery progress; full-fledged support for crash and media recovery; suitability for all kinds of semantic concurrency control methods.

Historical Background

Crash recovery for composite operations on database records and indexes has first been addressed by [3], but that solution required heavy-weight check pointing (based on shadow storage) and was fairly inefficient. Some commercial engines developed various techniques to overcome these problems while supporting fine-grained concurrency control, but there is very little public literature on such system internals [1,2,4]. The ARIES algorithm was the first comprehensive solution [8] and has become the state-of-the-art method for industrial-strength recovery [7]. In parallel to and independently of the ARIES papers, research on multi-level recovery developed general principles and a systematic framework [9,10,6]. The textbook [11] discusses both the general framework and the ARIES algorithm in great detail. A correctness proof for the ARIES algorithm is given in [5].

Foundations

Basic database recovery methods log page modifications during normal operation. During the restart after a system crash (i.e., soft failure of the server with all disks intact), a three-phase recovery procedure is performed with an analysis pass, a redo pass, and an undo pass over the log file. This is appropriate when the database system uses page locking or some other page-granularity concurrency control. Such locking guarantees that all updates of loser transactions (i.e., uncommitted transactions that require undo) that are in conflict with updates of winner transactions (i.e., committed transactions that may require redo) follow the winners' updates in the log file. However, with fine-grained locking or some form of semantic concurrency control (e.g., exploiting commutative operations on hot-spot objects), this invariant does no longer hold and thus necessitates more advanced recovery algorithms.

As an example, consider the following execution history of two transactions t1 and t2 that insert various database records, with time proceeding from left to right and c2 denoting a successful commit of t2:

$$insert1(x) \quad insert1(y) \quad crash \quad insert2(z) \quad c2$$

The insertions may appear to be single operations, but they are not atomic from the system viewpoint. In fact, each of them may require multiple page writes to maintain indexes and other storage structures. For example, the following history of page writes may result from the above execution:

$$w1(p)\ w1(q)\ w1(s)\ w1(r)\ w1(p)\ w1(q)\ crash$$
$$w2(p)\ w2(s)\ c2$$

Here, p would be a data page into which all three records x, y, z are inserted, and q and s may be leaf pages of the same B + -tree index. For simplicity, the history does not show any read accesses like accesses for descending the tree. It may happen that the index update on behalf of record x triggers a leaf split of page q with a newly allocated page s and a corresponding update to the parent page r. The subsequent record operations may then access the new pages or the old page q, depending on where their corresponding keys now reside. This is a very normal situation for a database system, and it is perfectly admissible from a concurrency control viewpoint, because there are no (high-level) conflicts between the three insert operations. The system may have to use additional short-term locks or latches on pages to implement a multi-level concurrency control method, but this is very normal as well.

If the standard page-level recovery were applied to this situation, it would first redo (if necessary) all page writes of winner transaction t2 and then undo all page writes of loser transaction t1, using before-images of pages or byte-range-oriented log records. This would lead to two kinds of problems:

- Redoing the page write w2(s) may be logically flawed and lead to an inconsistent index state if the effects of the preceding leaf split are not properly reflected in page s. But it is indeed possible that the loser updates w1(q) and w1(s) were not written to disk before the crash, and no redo would be performed for them.
- If all index updates were fully recovered and correctly captured in the database by the time the undo recovery for t1 takes place, undoing the write w1(s) of page s would restore the page as of the time before t1 started, thus accidentally – and incorrectly – eliminating also the index update of the winner transaction t2.

If, on the other hand, the logging and recovery procedures were changed so that only record- and index-level operations are captured and redone or undone, one would run into a third problem:

- If the system crashed in the middle of a high-level operation, say in between the w1(q) and the w1(s) steps, the database may be left in an inconsistent state with partial effects of an operation. Such a database would not be recoverable as all logged operations could face a state that they cannot properly interpret.

These problems show the need for multi-level recovery; the solution must meet the following requirements:

- *Operation atomicity:* High-level operations that comprise multiple page writes must be guaranteed to appear atomic (i.e., have an all-or-nothing impact on the database).
- *High-level undo:* Operations of loser transactions must, in full generality, be undone by means of inverse operations at the same level of abstraction. For example, the insertion of an index key must be undone by performing a delete operation on that key, not by restoring the before-images of the underlying pages (and neither by corresponding byte-range modifications).
- *Testable operations:* Before invoking a high-level operation for undoing or redoing the effect of a prior operation, it must be tested whether the effects of the prior operation are indeed present (as they may have been lost by the crash or already undone/redone in a recovery procedure that was interrupted by another crash). This testability is crucial for handling non-idempotent operations.
- *Efficient redo:* As the restart time and thus the unavailability of the system is usually dominated by the redo pass, it is crucial that the redo actions are performed as efficiently as possible. This strongly suggests performing redo in terms of page writes rather than re-executing high-level operations.

Multi-level recovery methods address these requirements in the following way:

- For *proper undo*, both page-level writes and higher-level operations are logged. The page-level log records guarantee that high-level operations can always be made to appear atomic. The high-level log records guarantee that undo can be performed by means of inverse operations. During the undo of a high-level operation, page-level logging is again enabled. This way, the first two requirements are satisfied.
- For *testable operations*, when the recovery procedure undoes a (high-level) operation, both the resulting page writes and a marker for the inverse operation itself are logged. The latter kind of log record is referred to as a compensation log record (CLR). In addition, the standard technique of maintaining log sequence numbers (LSNs) in the headers of modified pages, as a form of virtual time stamping, is used to be able to compare a log record to the state of a page and decide whether the logged action should be undone/redone or disregarded.
- For *efficient redo*, although redoing high-level operations may add to the repertoire of recovery actions, it is much more desirable to perform all redo steps in terms of page writes. This can leverage all kinds of acceleration techniques that have been developed for more conventional, page-level recovery like asynchronous check pointing and dirty-pages bookkeeping, smart scheduling of page reads from the database disk, parallelized per-page redo, and selective redo for pages with very high availability demands.
- Further considerations on the redo pass lead to the *repeating-history principle* [8]: rather than aiming to redo only winner updates or at least as few loser updates as possible, it is much simpler to redo all

logged page writes regardless of their transaction status, thus effectively reconstructing the database as of the time of the crash.

All these principles together result in the following algorithmic template for multi-level recovery:

- Analysis pass for determining loser transactions.
- Redo pass by repeating history in terms of logged page writes.
- Undo pass for loser transactions, with page-level undo for incomplete high-level operations and high-level undo for complete (and possibly just redone) high-level operations. Logging at both levels is enabled during the undo pass, thus creating new log records: page-write log records during the operation's execution, and undo information for the entire operation at the very end, thus also marking the completion of the operation.

For all steps, *idempotence* is ensured by two means: for page writes the standard comparison of page-header LSN versus log-record LSN is performed; for high-level operations, only undo idempotence is a potential issue, and this is guaranteed by the fact that the preceding redo pass always repeats history so that all completely repeated operations need subsequently be undone by definition.

The *ARIES algorithm* is an integrated and highly optimized instantiation of these principles, with various additional features. Its recovery procedure performs three passes over the log: analysis, repeating-history redo, and undo. The analysis pass mostly follows standard recovery methods; the redo pass has been discussed above; the undo pass uses additional techniques based on the use of *compensation log records (CLRs)*. The following undo-relevant log records are produced by ARIES:

- During normal operation, page writes are logged in a way that they can be redone or undone (whichever is needed later), and each high-level operation is logged for undo purposes following all page-write log records that were produced during the operation's execution. The high-level log records have a backward pointer that points to the preceding high-level action of the same transaction, thus allowing the recovery manager to skip the operation's logged page writes.
- During the undo pass, when undoing a page write, a CLR is written with a backward pointer to the log record that precedes the undo page write within the same transaction. When undoing a high-level operation, normal page-write log records are written during the execution of the inverse operation, and a CLR for the entire high-level operation is written at the end. That CLR again has a backward pointer to its preceding high-level action, skipping its own page writes.

With these preparations, the undo procedure itself is rather straightforward. For each loser transaction, it locates the most recent log record and then follows the backward chain of log records. Whenever a CLR is encountered, this tells the recovery manager that the undo of the corresponding action is already completed (either already during normal operation or by the preceding redo pass) and the log record should thus be disregarded. Page-write log records are relevant for incomplete high-level operations; otherwise high-level log records determine the undo logic.

This undo procedure of the ARIES algorithm has a number of great benefits:

- It handles high-level undo in a correct and efficient way, thus allowing *fine-grained and semantic concurrency control.*
- It handles *nested rollbacks* in a correct and efficient way. These are situations where a transaction rollback is interrupted by a crash and later considered for undo or when the undo pass after a server crash is interrupted by a second crash. In all these situations, it is guaranteed that the amount of recovery work stays bounded, regardless of how many "nested" crashes might occur during recovery. This is important for high availability.
- For *media recovery*, restoring the database after disk failures, an analogous but even more severe situation arises. As media recovery always starts with a backup copy of the database and then repeats the history of a potentially very long archive log, rollbacks or undo steps for (soft) system crashes that happened long ago would interfere with log truncation and become performance showstoppers with pre-ARIES recovery methods. The way ARIES generates redo log records for undo actions and CLRs for progress tracking, media recovery is as fast as possible, which is crucial for availability.

For the example scenario given above, ARIES would create the following log records during normal operation, denoted in the form *LSN:action*. Note that log records 5 and 8 will only be used for undo purposes (if necessary). Further note that the example happens to show page-level log records for the second insert operation of t1 but no high-level log record. This may occur because of the crash happening before the high-level log record was flushed to the log disk.

$$1 : w1(p)\ 2 : w1(q)\ 3 : w1(s)\ 4 : w1(r)$$

$$5 : insert1(x)\ 6 : w2(p)\ 7 : w2(s)\ 8 : insert2(z)$$

$$9 : w1(p)\ 10 : w1(q)\ 11 : c2$$

During recovery, the redo pass processes log records 1, 2, 3, 4, 6, 7, 9, and 10. Subsequently the undo pass processes log records 10, 9, and 5 (in this – chronologically reverse – order). As it does so, it will create the following new log records, with CLRs denoted in the form *LSN:action→UndoNextLSN* with UndoNextLSN being the LSN of the log record to which the CLR has a backward pointer.

$$12 : w1(q) \rightarrow 9\ 13 : w1(p) \rightarrow 5\ 14 : w1(s)$$

$$15 : w1(p)\ 16 : delete1(x) \rightarrow 0$$

If the system crashed again immediately after the completion of the delete1(x) undo step, the redo pass would repeat the page writes with LSNs 12, 13, 14, and 15 (in addition to all writes with LSNs 1 through 11 that may need redo again). This means that all effects of t1 have been properly removed. The subsequent undo pass would then encounter the CLR 16, but its backward pointer immediately tells the recovery manager that it can skip all log records of transaction t1 as t1 had already been completely undone before the second crash.

If the system crashed again after the action with LSN 14 (a page write issued on behalf of the high-level undo of insert1(x)), the redo pass would repeat the page writes with LSNs 12, 13, and 14, thus effectively removing all effects of insert1(y) but only some partial effects of insert1(x). The subsequent undo pass would start with LSN 14, undo it and create a new CLR, and then encounter LSN 13, which points to LSN 5 which in turn is the next logged action to undo.

In general, ARIES can be implemented with very low overhead, and it is compatible with other optimizations in the storage engine of a database system: flexible free space management, flexible buffer management, acceleration techniques for the redo pass, and many more. For *high availability*, the redo pass of both crash and media recovery can be parallelized or performed selectively for most important page sets; media recovery efficiently works also with fuzzy backups without ever quiescing the system. For *index management*, extensions of ARIES have been developed that optimize the locking, logging, and recovery of index keys in B + -trees. Finally, there are also extensions of ARIES for the special requirements of *shared-disk clusters* with automated fail-over procedures and very high availability.

Future Directions

The ARIES algorithm is a mature and comprehensive solution that can be readily adopted for most data management systems. A salient property of the multi-level recovery framework is that it can be generalized to arbitrary kinds of composite operations (with deeper and flexible nestings). All the ARIES techniques for efficient repeating-history redo are directly applicable, and the undo procedures need to be extended to handle a conceptual stack of undo log records and corresponding CLRs – with the stack actually being embedded in the linear log. This generalization is of potential interest for modern applications like composite Web services or enterprise-level middleware with integrated recovery.

Multilevel Secure Database Management System

BHAVANI THURAISINGHAM
University of Texas at Dallas, Richardson, TX, USA

Synonyms

Secure database systems; Trusted database systems

Definition

Many of the developments in the 1980s and 1990s in database security were on multi-level secure database management systems (MLS/DBMS). These systems were also called trusted database management systems (TDBMS). In a MLS/DBMS, users are cleared at different clearance levels such as Unclassified, Confidential, Secret and TopSecret. Data is assigned different sensitivity levels such as Unclassified, Confidential, Secret, and TopSecret. It is generally assumed that these security levels form a partially ordered lattice. For example, Unclassified < Confidential < Secret < TopSecret. Partial ordering comes from having different compartments. For example, Secret Compartment A may be incomparable to Secret Compartment B.

Historical Background

MLS/DBMSs have evolved from the developments in multilevel secure operating systems such as MULTICS and SCOMP (see for example [4]) and the developments in database systems. Few developments were reported in the late 1970s on MLS/DBMSs. However, during this time there were many developments in discretionary security, such as access control for System R and INGRES as well as many efforts on statistical database security. Then there was a major initiative by the Air Force and a summer study was convened. This summer study marks a significant milestone in the development of MLS/DBMSs [2].

The early developments in MLS/DBMSs influenced the Air Force Summer Study a great deal. Notable among these efforts are the Hinke-Schaefer approach to operating system providing mandatory security, the Ph.D. Thesis of Deborah Downs at UCLA (University of California at Los Angeles), the IP Sharp Model developed in Canada and the Naval Surveillance Model developed at the MITRE Corporation. The Hinke Schaefer approach [3] essentially developed a way to host MLS/DBMSs on top of the MULTICS MLS operating system. The system was based on the relational system and the idea was to partition the relation based on attributes and store the attributes in different files at different levels. The operating system would then control access to the files. The early efforts showed a lot of promise to designing and developing MLS/DBMSs. As a result, the Air Force started a major initiative, which resulted in the summer study of 1982

Since the summer study, several efforts were reported throughout the 1980s. Many of the efforts were based on the relational data model. At the end of that decade, the National Computer Security Center started a major effort to interpret the Trusted Computer Systems Evaluation Criteria for database systems [7]. This interpretation was called the Trusted Database Interpretation [8]. In the 1990s research focused on non-relational systems including MLS object database systems and deductive database systems. Work was also carried out on multilevel secure distributed database systems. Challenging research problems such as multilevel data models, inference problem and secure transaction processing were being investigated. Several commercial products began to emerge. Since the late 1990s, while the interest in MLS/DBMSs began to decline a little, efforts are still under way to examine multilevel security for emerging data management technologies. A detailed discussion of many of the developments with significant references are given in [5].

Foundations

Many of the developments were based on the relational model. The early systems were based on the Integrity

Lock approach developed at the MITRE Corporation. Two prototypes were designed and developed. One used the MISTRESS relational database system and the other used the INGRES relational database system. Around 1985 TRW designed and developed a MLS/DBMS called ASD and this system was designed to be hosted on ASOS (the Army Secure Operating System). The approaches were based on the Trusted Subject based architecture. Later on TRW developed some extensions to ASD and the system was called ASD Views where access was granted on views (GARV88). Two of the notable systems designed in the late 1980s were the SeaView system by SRI International and LOCK Data Views system by Honeywell. These two efforts were funded by the then Rome Air Development Center and the goal was to focus on the longer term approaches proposed by the Summer Study. Both efforts influenced the commercial developments a great deal. Three other efforts worth mentioning are the SINTRA system developed by the Naval Research Laboratory, the SWORD system developed by the then Defense Research Agency and funded by the Ministry of Defense in the United Kingdom and the SDDBMS effort by Unisys. The SINTRA system was based on the distributed architecture proposed by the Air Force Summer Study. The SWORD system proposed some alternatives to the SeaView and LOCK Data Views data models. While the initial planning for these systems began in the late 1980s, the designs were actually developed in the early 1990s. The SDDBMS effort was funded by the Air Force Rome Laboratory and investigated both the partitioned and replicated approaches to designing an MLS/DBMS.

Around l987, the Rome Air Development Center (now known as Air Force Research Laboratory in Rome) funded an effort to design an MLS/DBMS based on the Entity Relationship (ER) model. The ER model was initially developed in 1976 by Peter Chen and since then it has been used extensively to model applications. The goal of the security effort carried out by Gajnak and his colleagues was to explore security properties for the ER model as well as to explore the use of secure ER models to design DBMSs. The effort produced MLS ER models that have since been used to model secure applications. Furthermore variations of this model have been used to explore the inference problem by Burns, Thuraisingham and Smith. However, there does not appear to have been any efforts undertaken on designing MLS/DBMSs based on the ER model. In summary, the ER approach has contributed extensively toward designing MLS applications.

During the late 1980s, efforts began on designing MLS/DBMSs based on object models. Notable among these efforts is the one by Keefe, Tsai and Thuraisingham who designed the SODA model by Keefe and his colleagues. Later Thuraisingham designed the SORION and SO2 models. These models extended models such as ORION and O2 with security properties. Around 1990 Millen and Lunt produced an object model for secure knowledge base systems. Jajodia and Kogan developed a message-passing model in 1990. Finally MITRE designed a model called UFOS. Designs of MLS/DBMSs were also produced based on the various models. The designs essentially followed the designs proposed for MLS/DBMSs based on the relational model. However with the object model, one had to secure complex objects as well as handle secure method execution. While research progressed on designing MLS/DBMSs based on objects, there were also efforts on using object models for designing secure applications. Notable efforts were those by Sell and Thuraisingham. Today with the development of UML (Unified Modeling Language) there are efforts to design secure applications based on UML.

Around 1989 work began at MITRE on the design and development of multilevel secure distributed database systems (MLS/DDBMS). Prototypes connecting MLS/DBMSs at different sites were also developed. Work was then directed toward designing and developing MLS heterogeneous distributed database systems. These efforts focused on connecting multiple MLS/DBMSs, which are heterogeneous in nature. Research was also carried out on MLS federated databases by Thuraisingham and Rubinovitz.

In the late 1970 and throughout the 1980s there were many efforts on designing and developing logic-based database systems. These systems were called deductive databases. While investigating the inference problem, multilevel secure deductive database systems were designed. These systems were based on a logic called NTML (Non monotonic Typed Multilevel Logic) designed by Thuraisingham at MITRE. NTML essentially provides the reasoning capability across security levels, which are non-monotonic in nature. Essentially, it incorporates constructs to reason about the applications at different security levels. A Prolog language based on NTML, which is called NTML-Prolog, was also designed. Both reasoning with the Closed World

Assumption as well as with the Open World Assumption were investigated. Due to the fact that there was limited success with logic programming and the Japanese Fifth Generation Project, deductive systems are being used only for a few applications. If such applications are to be multilevel secure, then systems such as those based on NTML will be needed. Nevertheless there is use for NTML on handling problems such as the inference problem. Note that presently the integration of NTML-like logic with descriptive logics for secure semantic webs is being explored.

Researchers have identified several hard problems. The most notable hard problem is the Inference problem. Inference problem is the process of posing queries and deducing sensitive information form the legitimate responses received. Many efforts have been discussed in the literature to handle the inference problem First of all, Thuraisingham proved that the general inference problem was unsolvable [6] and this effort was stated by Dr. John Campbell of the National Security Agency as one of the significant developments in database security in [1]. Then Thuraisingham explored the use of security constraints and conceptual structures to handle various types of inferences. Note that the aggregation problem is a special case of the inference problem where collections of data elements are sensitive while the individual data elements are Unclassified. Another hard problem is secure transaction processing. Many efforts have been reported on reducing covert channels when processing transactions in MLS/DBMSs including the work of Jajodia, Bertino and Atluri among others. A third challenging problem is developing a multilevel secure relational data model. Various proposals have been developed including those by Jajodia and Sandhu, the Sea View model by Denning and her colleagues and the LOCK Data Views model by Honeywell. SWORD developed by Wiseman also proposed its own model. The problem is due to the fact that different users have different views of the same element. If multiple values are used to represent the same entity then the integrity of databases is violated. However, if what is called polyinstantiation is not enforced, then there is a potential for signaling channels. This is still an open problem.

Key Applications

The department of defense was the major funding agency for multilevel secure database management systems. The applications are mainly in the defense and intelligence area. However many of the concepts can be used to design systems that have multiple labels, privacy levels or roles. Therefore these systems can also be used to a limited extent for non-defense applications including healthcare and financial applications.

Future Directions

As technologies emerge, one can examine multilevel security issues for these emerging technologies. For example, as object database systems emerged in the 1980s, multilevel security for object databases began to be explored. Today there are many new technologies including data warehousing, e-commerce systems, multimedia systems, real-time systems and the web and digital libraries. Only a limited number of efforts have been reported on investigating multilevel security for the emerging data management systems. This is partly due to the fact the even for relational systems, there are hard problems to solve with respect to multilevel security. As the system becomes more complex, developing high assurance multilevel systems becomes an enormous challenge. For example, how can one develop usable multilevel secure systems say for digital libraries and e-commerce systems? How can one get acceptable performance? How does one verify huge systems such as the World Wide Web? At present, there is still a lot to do with respect to discretionary security for such emerging systems. As progress is made with assurance technologies and if there is a need for multilevel security for such emerging technologies, then research initiatives will commence for these areas.

Multilevel Transactions and Object-Model Transactions

Gerhard Weikum
Max-Planck Institute for Informatics, Saarbrücken, Germany

Synonyms

Layered transactions; Open nested transactions

Definition

Multilevel transactions are a variant of nested transactions where nodes in a transaction tree correspond to executions of operations at particular levels of abstraction in a layered system architecture. The edges in a tree represent the implementation of an operation by a sequence (or partial ordering) or operations at the next lower level. An example instantiation of this model are transactions with record and index-key accesses as high-level operations which are in turn implemented by reads and writes of database pages as low-level operations. The model allows reasoning about the correctness of concurrent executions at different levels, aiming for serializability at the top level: equivalence to a sequential execution of the transaction roots. This way, semantic properties of operations, like different forms of commutativity, can be exploited for higher concurrency, and correctness proofs for the corresponding protocols can be derived. Likewise, multilevel transactions provide a framework for structuring recovery methods and reasoning about their correctness.

Multilevel transactions have wide applications outside of database engines as well. For example, transactional properties can be provided by middleware application servers, layered on top of a database system. A generalization of this approach is the notion of object-model transactions, also known as open nested transactions (trees where the nodes correspond to arbitrary method invocations). In contrast to multilevel transactions, there is no layering constraint anymore, and arbitrary caller-callee relations among objects of abstract data types can be expressed. This provides a model for reasoning about transactional guarantees in composite web services, and for structuring the design and run-time architecture of web-service-based applications.

Historical Background

Object-model transactions have been around for thirty years, going back to the work of Bjork and Davies on “spheres of control” [2]. The first work that made these concepts explicit and gave formal definitions is by Beeri et al. [1]. Parallel work on the important special case of multilevel transactions has been done by Moss et al. [7] and Weikum et al. [13,11]. The textbook [14] gives a detailed account of both conceptual and practical aspects. A broader perspective of extended transaction models is given by [9]. More recently, the concept of object-model transactions has received considerable attention also for long-running workflows (e.g., [10,15]) and transactional memory (e.g., [8]).

On the system side, multilevel transaction protocols have been employed for concurrency control and recovery in various products and prototypes [3,5,6,12]. Typically, the layered structure of the protocols is only implicit; a suite of additional smart implementation techniques is used for integrated, highly efficient code. An example for concurrency control is transaction-duration locking for index-manager operations combined with operation-duration latching. Examples for recovery are the ARIES family of algorithms by Mohan et al. [6] and the MLR algorithm by Lomet [5].

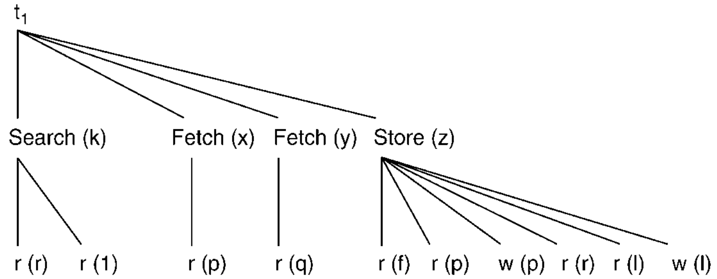
Foundations

Multilevel and object-model transactions are best understood in an object model where operations are invoked on arbitrary objects. This allows exploiting “semantic” properties of the invoked operations for the sake of improved performance. This model also captures situations where an operation on an object invokes other operations on the same or other objects. Often the implementation of an object and its operations requires calling operations of some lower-level types of objects.

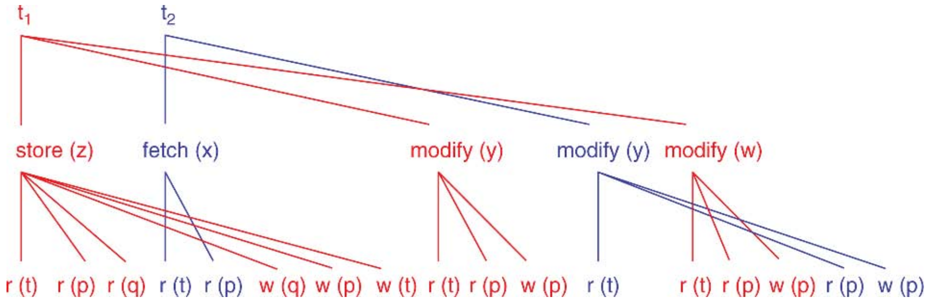
For example, operations at the access layer of a database system, such as index searches, need to invoke page oriented operations at the storage layer underneath. Similar invocation hierarchies may exist among a collection of business objects that are made available as abstract data type (ADT) instances within a data server or an application server, e.g., a “shopping cart” or a “bank account” object type along with operations like deposit, withdraw, get_balance, get_history, compute_interests, etc. The following figure depicts an example of a transaction execution against an object model scenario that refers to the internal layers of a database system.

The figure shows a transaction, labeled t1, which performs, during its execution, (i) an SQL Select command to retrieve all records from a database that satisfy a certain attribute-value condition, and, after inspecting the result set, (ii) an SQL command to insert a record for a new record with this attribute value. Since SQL commands are translated into query execution plans already at compile time, the operations invoked at run time refer to an internal level of index and record accesses. The Select command is executed by first issuing a Search operation with some key k on an index that returns the RIDs (i.e., addresses) of the result records. Next, these records, referred to as x and y in the figure, are fetched by dereferencing their RIDs. The Search operation in turn invokes operations at the underlying storage layer: read and write operations on pages. First the root of a B+ tree is read, labeled as page r in the figure, which points to a leaf page, labeled l, that contains the relevant RID list for key k. The subsequent Fetch operations to access the two result records x and y by their RIDs, require only one page access each to pages p and q, respectively. Finally, the SQL Insert command is executed as a Store operation, storing the new record and also maintaining the index. This involves first reading a metadata page, labeled f that holds free space information in order to find a page p with sufficient empty space. Then that page is read and subsequently written after the new record z has been placed in the page. Finally, the RID of the new record z is added to the RID list of the key k in the index. This requires reading the B+ tree root page r, reading the proper leaf page l, and finally writing page l after the addition of the new RID.

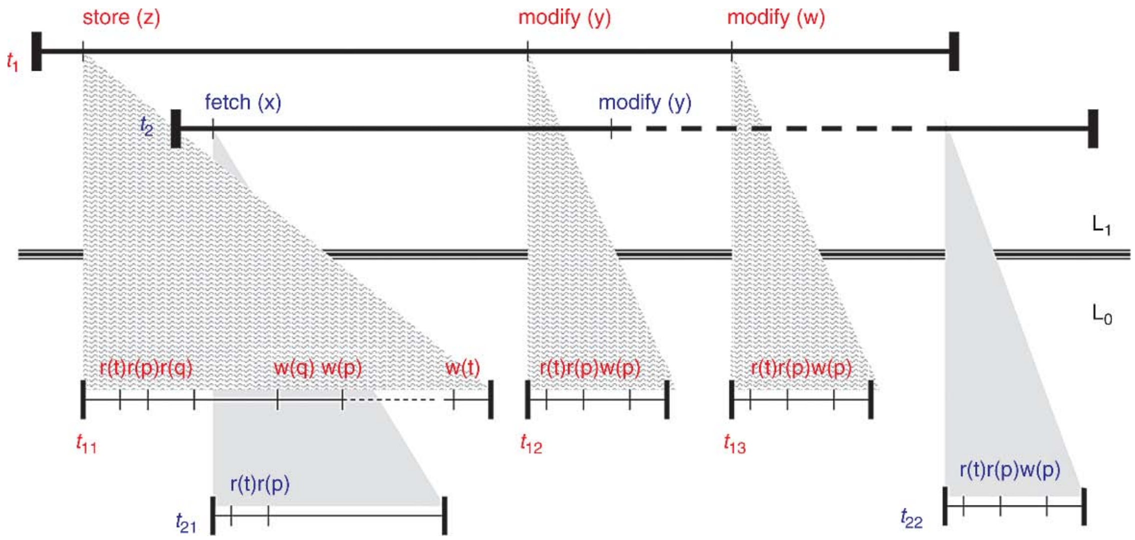
This entire execution is represented in a graphical, compact form, by connecting the calling operation and the called operation with an arc when operations invoke other operations. As a convention, the caller is



Multilevel Transactions and Object-Model Transactions. Figure 1. Example of a multilevel transaction.



Multilevel Transactions and Object-Model Transactions. Figure 2. Example of a multilevel schedule.



Multilevel Transactions and Object-Model Transactions. Figure 3. Concurrent execution of multilevel schedules with a multilevel locking protocol.

always placed closer to the top of the picture than the callee. Furthermore, the order in which operations are invoked is represented by placing them in "chronological" order from left to right, which suffices for illustration purposes.

More formally, a ***multilevel transaction tree*** is defined as a partially ordered labeled tree with node labels being operation invocations and the leaf nodes denoting elementary (i.e., indivisible) read and write operations. Moreover, the tree must be perfectly balanced with all leaves having the same distance from the root; this constraint is dropped for the more general case of ***object-model transactions (open nested transactions)***. Finally, a constraint is imposed on conflicting leaf nodes to be totally ordered so that no concurrent write-write or read-write pair of operations is possible on the same elementary object; for all other cases partial orders are allowed. It is important to note that transaction trees model executions and not programs. Thus, node labels are method names along with concrete input parameter values (and possibly even output parameter values if these are exploited in the reasoning about concurrency); edges denote the dynamic calling structure and not a static hierarchy.

A ***concurrent execution of several transaction trees***, referred to as a multilevel schedule, is essentially an interleaved forest of the individual transaction trees. This is illustrated in the figure below, for two transactions with record-level and page-level operations, in the same spirit as the previous example but with some simplifications. Like before, the ordering of operations is indicated by drawing the leaf nodes in their execution order from left to right (assuming total ordering of leaves for simplicity). As the caller-callee relationship in transaction trees is captured by vertical or diagonal arcs, the crossing of such arcs indicates that two (non-leaf) operations are concurrent. In the figure the two transactions t1 and t2 are concurrent, and also the store and fetch operations execute concurrently and the same holds for the last two modify operations.

To reason about the correctness of such interleavings, it is first necessary to define the ordering of non-leaf operations: node o1 precedes o2 in the execution, o1 < o2, if all leaf-level descendants of o1 precede all leaf-level descendants of o2. The forest of labeled trees and this execution order < define a ***multilevel schedule***, more generally, a schedule of transaction trees.

Following the standard argumentation about serializability for conventional, "flat" transactions, the goal for a correct schedule is to show that the execution is equivalent to a sequential one based on a notion of ***conflicting versus non-conflicting operations***. Usually, ***commutativity*** properties of operations are the basis for defining conflict relations. In the example, this suggests that store and fetch operations on different objects as well as pairs of modify operations on different objects are non-conflicting (even if their implementations write the same page). Thus, their observed execution order could be changed, by swapping adjacent operations, without changing the overall effect of the schedule. But applying this principle to, for example, the store and fetch operations in the above schedule does not work because these two nodes are composite operations (i.e., non-leaf nodes) and executed concurrently among themselves. To disentangle the concurrency between these operations, one needs to reason about the execution ordering of their children, and in an actual system, one would need a ***lower-level concurrency control*** mechanism that treats the two operations as ***subtransactions***. The goal of this disentangling, the counterpart to serial schedules in conventional concurrency control theory, are ***isolated subtrees*** for the two operations. A subtree rooted at node o is isolated if there is a total ordering among all its leaf-level descendants and o either precedes or follows all other operations o' that are not among its descendants (o < o' or o' < o). Once a subtree is isolated, the fact that its root is a composite operation is no longer important, and it is possible, for reasoning about equivalent executions, to ***reduce an isolated subtree*** to its root alone. This argument abstracts from the lower-level executions, as they are now (shown to be equivalent to) sequential.

Putting everything together, the above considerations lead to three rules for transforming a multilevel schedule into equivalent and abstracted executions, ideally leading to a sequential execution of the transaction roots:

- *Commutativity rule:* The order of two ordered leaf operations p and q with, say, the order p < q, can be reversed provided that
  - both are isolated, adjacent in that there is no other operation r with p < r < q, and commutative,
  - the operations belong to different transactions, and
  - the operations p and q do not have ancestors, say p' and q', respectively, which are non-commutative and totally ordered (in the order p' < q').
- *Ordering rule:* Two unordered leaf operations p and q can be (arbitrarily) ordered, i.e., assuming either p < q or q < p, if they are commutative.
- *Tree pruning rule:* An isolated subtree can be pruned and replaced by its root.

A schedule that, by applying the above rules, can be transformed into a sequential execution of the transaction roots is called ***tree-reducible*** or ***multilevel serializable***. Note that this notion of multilevel serializability is much more liberal than the conventional notion of read-write-oriented serializability. The example schedule shown above is not serializable at the leaf level of read and write operations (i.e., if one ignored the level of search, fetch, store, and modify operations and simply connected all leaves directly to the roots), but these seemingly non-serializable effects on the low-level storage structures are irrelevant as long as they are properly handled within the scope of their parent operations and new transactions access the data through the higher-level operations like search, fetch, store, and modify.

The example schedule depicted above is multilevel serializable. It can be reduced as follows. First the two reads of the fetch(x) operation are commuted with their left-hand neighbors so that fetch(x) completely precedes store(z); analogously the r(t) step of modify (y) is commuted with its right-hand neighbors, the children of modify(w), so that modify(w) completely precedes modify(y). This establishes a serial order of the record-level operations, all of them now being isolated subtrees. This enables the application of the pruning rule to remove all page-level operations. Next, the fetch(x) operation of t2 is commuted with t1's store(z), modify(y), and modify(w) operations all the way to the right, producing an order where all of t1's operations precede all of t2's operations. This turns t1 and t2 into isolated subtrees. Finally, pruning the operations of t1 and t2 produces the sequential order of the transaction roots: t1 < t2.

The transformation rules do not directly lead to an efficient concurrency control protocol. Rather their purpose is to prove the correctness of protocols. But for the case of a layered system, the way the example was handled points towards a practically viable protocol. The key is to consider pairs of adjacent levels and apply the transformation rules in a bottom-up manner. So first, the commutativity and ordering rules are used to establish a sequential execution of the parent nodes of the leaf-level nodes, then these isolated parents are reduced. Then, with the lowest level removed, this procedure is iterated through the levels until the roots of the entire transaction trees are isolated. This proof strategy can be directly turned into a protocol by enforcing conventional order-preserving conflict-serializability (OPCSR) for each pair of adjacent levels. Any protocol for OPCSR can be used, and even different protocols for different level pairs are possible. The most widely used protocol, two-phase locking, is often a natural choice, and then forms the following ***multilevel locking protocol***:

- *Lock acquisition rule:* When an operation f(x) is issued, an f-mode lock on x needs to be acquired before the operation can start its execution.
- *Lock release rule:* Once a lock originally acquired by an operation f(x) with parent o (an operation at the next higher level) is released, no other descendant of o is allowed to acquire any locks.
- *Subtransaction rule:* At the termination of an operation o, all locks that have been acquired for descendants of o are released, thus treating o as a committed subtransaction. Note that the o-lock for o itself is still kept – until the parent of o terminates. The releasing of lower-level locks at the end of a subtransaction is the origin of the name "open nested transaction".

A possible execution of the example schedule under this multilevel locking protocol is shown in the figure below (with levels L1 and L0 referring to the record and page layer in a database engine, and t_{ij} denoting the jth subtransaction of transaction t_i).

The example shows that, despite many page-level conflicts, high concurrency is possible by exploiting the finer granularity and richer semantics of record-level operations. These benefits are even more pronounced for index-key operations. For this case, highly optimized special-purpose protocols like ARIES Key-Value Locking have been developed. One important optimization for both record and index operations is that the subtransactions may use light-weight latching instead of full-fledged locks.

Another use case with wide applicability are operations on counters, such as increment and decrement or conditional variants on lower-bounded or upper-bounded counters. Such objects and operations are common in reservation systems, inventory control, financial trading, and so on. The relaxed (but not universal) commutativity properties of the operations can be leveraged for very high concurrency even if operations access the same object. Again, special implementation techniques like escrow locking have been developed for these settings. When counter operations have a composite nature, e.g., by automatically triggering updates on other objects, then the special commutativity techniques need to be embedded in a multilevel transaction framework.

A complication that arises from all these high-concurrency settings is that undo recovery (for transaction abort and to wipe out effects of incomplete transactions after a crash) can no longer be implemented merely by restoring prior page versions. Instead, adequately implemented forms of inverse operations need to be executed. Together with the composite nature of operations, this necessitates a form of multilevel recovery.

Most of the outlined principles and algorithms apply to the general case of object-model transactions as well. However, the absence of a layering does incur some extra difficulties, which are beyond the scope of this entry. The algorithms for fully general object-model transactions are explained in detail in the textbook [14].

Future Directions

Multilevel transactions have originally been developed in the database system context, but their usage and potential benefits are by no means limited to database management. So not surprisingly, object-model transactions and related concepts are being explored in the operating systems and programming languages community. Recent trends include, for example, enhancing the Java language with a notion of atomic blocks that can be defined for methods of arbitrary classes. This could largely simplify the management of concurrent threads with shared objects, and potentially also the handling of failures and other exceptions. The runtime environment could be based on an extended form of software transactional memory [8].

Another important trend is to enhance composite web services with transactional properties. Again, object-model transactions is a particularly intriguing paradigm because of its flexibility in allowing application-specific methods for providing atomicity, isolation, and persistence. Adapting and extending transactional concepts for web services and combining them with other aspects of service-oriented computing is the subject of ongoing research [15].

Multimodal data

Definition

Multimedia in principle means data of more than one medium. It usually refers to data representing multiple types of medium to capture information and experiences related to objects and events. Commonly used forms of data are numbers, alphanumeric, text, images, audio, and video. In common usage, people refer a data set as multimedia only when time-dependent data such as audio and video are involved.

Historical Background

In early stages of computing, the major applications were scientific computations. In these applications, computers dealt with numbers and were programmed to carry out a sequence of calculations to solve a scientific problem. As people realized power of computing, new applications started emerging. Alphanumeric data was the next type of data to be used in different applications. In early days, these applications were mostly related to businesses. These applications were mostly to store large volumes of data to find desired information from this data set. These applications were the motivation of the development of current database technology.

Text is a special case of alphanumeric data. In text, there is a large string of alphanumeric data that humans associate with written language. Text has been the basis of written human communication and has become one of the most common data form. Most of the information and communication among humans takes place in text.

Next data type to start appearing on computers was images. Images started in many applications where they needed to be analyzed as well as in applications where computers were used to create and display images. Image processing and computer vision emerged as fields dealing with image analysis and understanding while computer graphics emerged as a field dealing with creation and display of images. Images were initially represented in two ways: a list of lines (called vectors) and a 2-dimensional array of intensity values. The second method has now become the most common method of representing images. Images represent a more complex data type because people perceive not the data, which is really a large collection of intensity values, but what the data represents. In computer generated images, the semantics of the pixels is determined and is known at the creation time. In all other images, the semantics must be determined. Computer vision researchers have been developing tools to automatically determine this semantics and have made progress. However, segmenting an image to determine objects in it has been a difficult problem and in general remains an unsolved problem.

Audio data represents variation of a signal over time. Signal processing deals with many types of signals, but due to its closeness to human perception, audio became an important signal type. Unlike regular numerical, alphanumerical, and image data, audio is time-varying or time dependent data. Like images, the numbers have semantics only when they are rendered, in this case using a speaker, to a human. Both images and audio are a collection of numbers that have strong semantics associated with them. This semantics can be associated only by segmenting the data and identifying each segment. Video is next in this sequence of semantic richness. Video is a time-dependent sequence of images synchronized with audio. This means that it brings with it enormous volume of data and richness of semantics.

In late 1980s, people started using the term multimedia to denote combination of text, audio, and video. This gained popularity because the technology had advanced enough to combine these media to articulate thoughts, messages, and stories using appropriate combination of these components and present them easily on computers, save them on CDs, and transmit and receive them using compression/decompression and streaming technologies. By the year 2000, multimedia had become a common data form on computers and Internet.

Foundations

Multimedia data is fundamentally different than the data traditional databases normally manage. Some fundamental differences in multimedia data are discussed here by considering several aspects.

Types and Semantics

The data in early generation databases was either a number or a string of characters. Each data item usually represented value of an attribute. These attribute had clear and explicit semantics in the applications that used the data.

Multimedia data may be considered to be composed of numbers or strings. So an image may be viewed as a two dimensional array of integers. In multimedia applications, however, the semantics is not defined and used at the level of such basic types as in traditional applications. An image is usually considered an image that contains certain objects that are characterized by regions in the image. The relationships among these regions should also be captured. Depending on the context and an application, the semantics associated with an image may change and may need to be represented differently. Similarly an audio file may be viewed as a collection of phonemes rather than just integer values at a time instant representing sound energy. Video is a synchronized combination of audio and images. But if a video is considered just a combination of separate sound energy and images, then the semantics of video is lost. The semantics of video is due to synchronized combination of its components rather than individual elements.

Multimedia types cannot be considered simply by considering its atomic components. One must consider whole data. The data types and the semantics of multimedia data are the result of the "multi" and are not present in single (mono) medium that may be part of the whole data.

Gestalt philosophy is in action in multimedia data: the whole is bigger than the sum of its parts.

Sequence and Order

Many components of multimedia data are measurements using some sensors. These sensors measure some attribute of physical world. These measurements represent the attribute at a point in space at a particular time. The semantics of the data is intimately tied to the space and time underlying the data. The data is usually organized in the time sequence as it is acquired over some predefined spatial ordering of its acquisition using multiple sensors covering the space of interest.

Multimedia data could be archived data or live data. Archived data is the one that was acquired and stored and hence comes from a server. Live data is presented as it is being acquired. Live data is increasingly being used in many applications.

Size

Multimedia data is voluminous. Audio, Images, and video are much larger in size than alphanumeric data and text. Usually the size of traditional data can be measured in bytes to Kilobytes. Images usually, even the regular amateur photographs run into Megabytes and video easily runs into Gigabytes to Terabytes. Due to the size of the multimedia data, it is usually stored and transmitted in compressed form. For analysis and use of the data, it must be usually decompressed.

Meta data plays a significant role in the analysis of multimedia data and is commonly stored as part of the dataset. Metadata can be of two types: about context or about content. Contextual metadata is about the situation of the real world and the parameters of devices used in acquiring the data. Content related metadata is obtained either thru analysis of the data or by human annotation or interpretation of data.

Many different standards have evolved for compression of multimedia data and association and storage of metadata. Usually these standards related to the medium and are developed by international standards body. Some commonly used standards are JPEG for images, MP3 for audio, and MPEG for video.

Accessing Multimedia Data

Each multimedia data is usually large and represents measurements acquired using a sensor over space and time. Even an image is acquired at a location at a particular time and also contains measurements performed in space using an array of pixel. Each pixel represents measurements related to a particular point in three-dimensional space. Each image or audio video is usually represented as a separate file. This file may contain raw measurements in original form or in compressed form and may also contain associated metadata such as in EXIF data for photos acquired using digital cameras.

Multimedia data representing a measurement is usually represented as one file. In databases such data is usually represented as a pointer to the file, as a BLOB, or the name of the file.

In most current applications, multimedia data is accessed based on the metadata. All queries are formed based on metadata and then the correct file is retrieved and presented. The granularity at which multimedia data is accessed is at the level of file. Text search became so useful when it was applied to documents by analyzing and indexing all areas of a document. This content analysis and indexing based on content within a file will be very useful in multimedia data also. Research in content analysis of multimedia documents for content-based retrieval is an active research area currently.

Presentation

Multimedia data must be presented to a user by sending it to appropriate devices. Audio must be sent to speakers and images and video should also be displayed using special display programs. Displaying raw data in a file is not useful to users. In most cases, before displaying the data, it must be decompressed.

Considering large files and copyright issues, many times multimedia data is not transferred to users for storage, users are allowed to see or listen it only once each time a display request is made. Such playback of data is commonly called streaming of data and is commonly used with video. In streaming, the data from server is sent to a client only for displaying it once. This is also used in the context of live data also.

Key Applications

Computing at one time was mostly numeric, then it became alphanumeric. Now it is multimedia. Almost all applications in computing now deal with multimedia data. In a sense, the term multimedia was a good term to use in the last decade, but now it is a redundant term. In early days of computing there were two types of computing: analog and digital. Slowly all computing became digital. Now no body normally uses the term digital computing because all computing is digital. In the same way all computing ranging from scientific to entertainment will use multimedia data and hence the term multimedia data or multimedia computing will shed "multimedia" and simply become data and computing.

Future Directions

Multimedia data has already become ubiquitous. With the increasing popularity of mobile phones with camera, digital cameras, and falling prices of sensors of different kinds multimedia data is becoming as widespread as alphanumeric data. Considering the current trend and human dependence on sensory data, it is likely that soon multimedia data will become more common than the traditional alphanumeric data. In terms of volume, multimedia data already may be far ahead of alphanumeric data.

Most of the current techniques which deal with multimedia data have two major limitations: first they mostly rely on metadata for access and they treat each type, such as images, audio, and video, as a separate type and hence create silos. What is required is dealing with all data, alphanumeric as well as different types of multimedia, as the data related to some physical objects or situations. This unified approach will treat all data in a unified manner and will not distinguish between media. Each media will be considered only as a source helping understand an object or a situation.

Multimedia Data Buffering

Jeffrey Xu Yu
Chinese University of Hong Kong, Hong Kong, China

Definition

Multimedia data are large in size and reside on disks. When users retrieve large multimedia data, in-memory buffers are used to reduce the number of disk I/Os, since memory is significantly faster than disk. The problem to be studied is to efficiently make use of buffers in the multimedia system to reduce the number of I/Os in order to get a better performance when multiple users are retrieving multiple multimedia data simultaneously. Existing works on multimedia data buffering focus on either the replacement algorithms to lower the number of cache misses or the buffer sharing algorithms when many simultaneous clients reference the same data item in memory.

Historical Background

Early works on multimedia data buffering focus on replacement algorithms to reduce the number of cache misses. Although in the traditional database systems, a number of different buffer replacement algorithms, such as the least recently used (LRU) and most recently used (MRU) algorithms are used to approximate the performance behavior of the optimal buffer replacement algorithm [1,2,6,8,15]. They do not reduce disk I/O significantly when they are used in a multimedia database system. Many new buffer replacement algorithms are proposed to save as much of the reserved disk bandwidth for continuous media data as possible. In [5], the effects of various buffer replacement algorithms on the number of glitches experienced by clients are studied. In [9], the authors introduce two buffer replacement algorithms, namely, the basic replacement algorithm (BASIC) and the distance-based replacement algorithm (DISTANCE), for multimedia database systems, which have a much better performance in comparison with LRU and MRU schema.

In terms of buffer sharing, a simple buffer replacement strategy may miss some opportunities to share memory buffers [14]. A straightforward use of LRU or LRU-k [6,8] is shown to be inadequate [7]. Bridging [3,4,10–12] as a new technique is studied to facilitate data sharing in memory, but it can degrade the system performance. In [13], the authors observe that an uncontrolled buffer sharing scheme may reduce system performance, and introduce the Controlled Buffer Sharing (CBS), which can trade memory for disk bandwidth in order to minimize cost per stream.

Foundations

Buffer Replacement

Assume that each buffer in the buffer space of a system is of the same size and is tagged as either free or used. All the free buffers are kept in a free buffer pool. In order to meet the rate requirement for clients, the system must pre-fetch the required data block from disks into the buffer space, so that the required piece of data is already in the buffer space before being read. In each service cycle, the system first moves the buffers containing data blocks that were already consumed in the last service cycle to the free buffer pool, then determines which data block need to be pre-fetched from disk to the buffer next. If the block is not in the buffer space, then it allocates buffers, from the set of free buffers for the block and issues disk I/O to retrieve the needed data block from disk into the allocated buffers. The algorithm to decide which of the buffers should be allocated is referred to as the buffer replacement algorithm. Several general replacement algorithms are listed below, which are widely used in database management systems. (i) LRU: when a buffer is to be allocated, the buffer containing the block that is used least recently is selected. (ii) MRU: when a buffer is to be allocated, the buffer containing the block that is used most recently is selected. (iii) Optimal: when a buffer is to be allocated, the buffer containing the block that will not be referenced for the longest period of time is selected. Since arrival, pause, resume and jump time when playing an object are unknown in advance, the optimal algorithm can only be implemented for simulation studies.

For the multimedia database systems, the commonly used LRU and MRU algorithms may not reduce disk I/O significantly. Two buffer replacement algorithms are proposed. They are the basic replacement algorithm (BASIC) and the distance-based replacement algorithm (DISTANCE).

The BASIC Buffer Replacement Algorithm The main idea behind the BASIC buffer replacement algorithm [9] is as follows. It is possible to estimate the duration by assuming each client will remain its consumption rate for a long period, even though it is difficult to decide which block will not be referenced for the longest period of time. It assumes that clients continue to consume data at the specified rate they are accessing the blocks. When there is a new request to allocate a buffer, the BASIC algorithm selects the buffer containing the block that will not be accessed for the longest period of time. If there are several such buffers, the algorithm will select the block with the highest offset-rate ratio (the ratio of offset/rate) to be replaced. The BASIC algorithm may reduce the miss ratio to nearly optimal, but it requires to sort clients and free buffers in the increasing order of their offset, which make the overhead of the BASIC algorithm very high. The DISTANCE algorithm is proposed to handle the overhead.

The DISTANCE Buffer Replacement Algorithm The main idea behind the DISTANCE buffer replacement algorithm is based on distance between clients [9]. Suppose that there are clients, c_1,c_2,..., accessing the same media data, M. Assume that each client, c_i, is accessing the M at a certain position of M, denoted as $p_i(M)$, and the data block on disk starting from $p_i(M)$ is kept in a buffer, B_i. Let all clients that are accessing the same media data M be sorted in order, c_1,c_2,.... Here, c_i is accessing M ahead of c_j if $i < j$, or in other words, $p_i(M) > p_j(M)$, because c_i has already accessed $p_j(M)$ and is now accessing $p_i(M)$. The distance between c_i and its next c_{i+1} is denoted as $dist_i$ which is equal to $p_i(M) - p_{i+1}(M)$. Note that the distance d_i is a value associated with the client c_i. Suppose all clients c_1,c_2,..., are accessing their blocks in the buffers in the current cycle. They all need to move ahead and access the next data blocks. The question becomes which buffer they are accessing in the current cycle needs to be freed if the buffer is full. In brief, the buffers consumed by a client, c_i, will be kept longer if the next client, c_{i+1}, will need them shortly (small distance $dist_i$). The buffers consumed by a client, c_j, will be freed earlier if the next client, c_{j+1}, does not need to access the data block $p_j(M)$, that c_j has just accessed, shortly (large distance $dist_j$). The DISTANCE algorithm frees buffers consumed by clients in the previous cycle in the decreasing order of clients' $dist_i$. In other words, when a new buffer needs to be allocated and there are no free buffers, a buffer consumed by a client, which will not be accessed by its next client shortly, based on the distance between clients, will be selected as a victim to be freed.

The DISTANCE algorithm can be implemented by dynamically maintaining a client list which is ordered in the decreasing order of clients' $dist_i$. The overhead is lower than the BASIC algorithm.

Table 1 shows the comparison of overhead and cache misses of different buffer replacement algorithms, n_B is the number of buffers used.

Buffer Sharing

Consider buffer sharing, where cached data can be shared among all the clients. A naive approach is to use LRU or LRU-k, which is shown to be inadequate to efficiently share data. An example is given in Fig. 1. There are two displays, D_1 and D_2, and both reference different blocks of the same clip. With LRU as a global buffer pool replacement policy, the blocks accessed by D_1 may be discarded before D_2 needs to access.

Bridging [3,4,10–12] as a technique is to form a bridge between the data blocks staged by two different clients referencing the same clip, which enables them to share memory and use one disk stream. As shown in Fig. 2, two displays D_1 and D_2 are supported using a single disk stream. The distance between D_1 and D_2 is 5. With the bridging technique, it holds the intermediate data pages between D_1 and D_2 in the buffer pool, and does not swap these pages out from the buffer pool. However, as analyzed in [11,12], a potential problem is that a simple bridging may possibly exhaust the available buffer space, which will have great impacts on the system performance.

A Controlled Buffer Sharing (CBS) technique is proposed in [13], which increases disk bandwidth using memory in order to achieve two objectives, namely, minimization of cost per simultaneous stream, and balancing memory and disk utilization. The latter considers that unlimited memory consumption may in fact degrade the system performance. The framework of CBS is shown in Fig. 3. The framework consists of three components: a configuration planner, a system generator, and a buffer management technique. The configuration planner determines the amount of required buffer and disk bandwidth in support of a prespecified performance objective. The system generator simply acts as a multiplier. The first two components

are applied off-line to determine the system size. The buffer management technique controls the memory consumption at run time.

In the CBS framework, a distance threshold, d_t, is used to capture the cost of memory and disk bandwidth and control the number of pinned buffer blocks between two adjacent displays that access the same clip. As shown in Fig. 4, suppose $d_t = 5$, D_1 and D_2 can share one disk stream because their distance is below the specified threshold, while D_3 and D_4 cannot share one disk stream because their distance exceeds the threshold.

Key Applications

Buffering is widely used in retrieving and playing multimedia data, especially for network continuous media applications, where multiple users may need to display multiple medias simultaneously.

Multimedia Data Indexing

Paolo Ciaccia
University of Bologna, Bologna, Italy

Synonyms

MM indexing

Definition

Multimedia (MM) data indexing refers to the problem of preprocessing a database of MM objects so that they can be efficiently searched for on the basis of their content. Due to the nature of MM data, indexing solutions are needed to efficiently support *similarity queries*, where the similarity of two objects is usually defined by some expert of the domain and can vary depending on the specific application. Peculiar features of MM indexing are the intrinsic high-dimensional nature of the data to be organized, and the complexity of similarity criteria that are used to compare objects. Both aspects are therefore to be considered for designing efficient indexing solutions.

Historical Background

Earlier approaches to the problem of MM data indexing date back to the beginning of 1990s, when it became apparent the need of efficiently supporting queries on large collections of non-standard data types, such as images and time series. Representing the content of such data is typically done by automatically extracting some low-level features (e.g., the color distribution of a still image), so that the problem of finding objects similar to a given reference one is transformed into the one of looking for similar features. Although, at that time, many solutions from the pattern recognition field were available for this problem, they were mainly concerned with the *effectiveness* issue (which features to consider and how to compare them), thus almost disregarding *efficiency* aspects.

The issue of making similarity query processing scalable to large databases was first considered in systems like QBIC [6] for the indexing of color images and by more focused approaches such as the one described by Jagadish in [8] for indexing shapes. Not surprisingly, these solution adopted index methods available at that time that had been developed for the case of low-dimensional spatial databases, such as R-trees and Grid files. The peculiarity of MM data then originated a flourishing brand new stream of research, which resulted in many indexes explicitly addressing the problems of high-dimensional features and complex similarity criteria.

Foundations

Figure 1 illustrates the typical scenario to be dealt with for indexing multimedia data. The first step, *feature extraction*, is concerned with the problem of highlighting those relevant features, f_i, of an object o_i on which content-based search wants to be performed. In the figure, this is the shape of the image subject (a cheetah). The second step, *feature approximation*, is optional and aims to obtain a more compact representation, af_i, of f_i that can be inserted into a suitable index structure (third step). It has to be remarked that, while feature extraction is needed to define which are the relevant aspects of objects on which the search has to focus on, feature approximation is mainly motivated by feasibility and efficiency reasons. This is because it might not be possible to directly index non-approximate features and/or indexing approximate features might result in a better performance of the search algorithms.

Consider a collection $O = \{o_1, o_2, ..., o_n\}$ of MM objects with corresponding features $F = \{f_1, f_2, ... f_n\}$ and approximate features $AF = \{af_1, af_2, ... af_n\}$. In order to compare features, a *distance function* d is typically set up, where $d(f_i, f_j)$ measures how dissimilar are the feature values of objects o_i and o_j. Given a reference object q (the *query point*), a range query with radius $\in$, also called an $\in$-similarity query, will return all the objects $o_i \in O$ such that $d(f_i, f(q)) \leq \in$, whereas a k-nearest neighbor query (k-NN) will return the k objects in O whose features are closest to those of q.

A simple yet remarkable result due to Agrawal, Faloutsos, and Swami [1], and now popularly known as the lower-bounding lemma, provides the basis for exactly solving queries by means of an index that organizes approximate features:

The lower-bounding lemma. Let I be an index that organizes the set of approximate features $AF = \{af_1, af_2, ... af_n\}$ and that compares such features using an *approximate distance* d_{appr}. If, for any pair of objects, it is $d_{appr}(af_i, af_j) \leq d(f_i, f_j)$, then the result of a range query obtained from I is guaranteed to contain the exact result, i.e., no false dismissals are present.

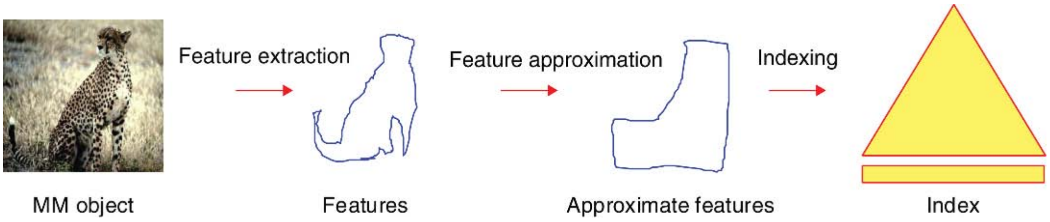
The result easily follows from the observation that, since d_{appr} lower bounds d by hypothesis, $d(f_i, f(q)) \leq \in$ implies $d_{appr}(af_i, af(q)) \leq \in$. The lower-bounding lemma guarantees that querying the index with a search radius equal to $\in$ will return a result set that contains all the objects whose non-approximate features satisfy the query constraint.

Filter & Refine

When indexing is based on an approximate distance, a two-step *filter & refine* process is therefore needed, in which the role of the index is to filter out many irrelevant objects. The so-resulting candidate objects then need to be verified by using the actual distance d. The lower-bounding lemma is also the key for solving k-NN queries using a multi-step query processing approach.

The effectiveness of the filter & refine approach depends on two contrasting requirements:

1. The approximate distance function d_{appr} should be a tight approximation of d, in order to minimize the number of false hits, i.e., those objects that do not satisfy the query constraint yet the index is not able to discard them. These are exactly those objects o_i for which both $d_{appr}(af_i, af(q)) \leq \in$ and $d(f_i, f(q)) > \in$ hold.



Multimedia Data Indexing. Figure 1. The multimedia data indexing scenario.

2. At the same time, d_{appr} should be relatively cheap to compute as compared to d, in order to avoid wasting much time in the filter phase.

The literature on MM indexing abounds of examples showing how to derive effective approximations for complex distance functions. For instance, the QBIC system compares color images using a quadratic form distance function, $d_A^2(f_i, f_j) = (f_i - f_j)A(f_i - f_j)^T = \sum_{k=1}^{D} \sum_{l=1}^{D} a_{k,l}(f_{i,k} - f_{j,k})(f_{i,l} - f_{j,l})$, where $A = (a_{k,l})$ is a color-to-color similarity matrix and features are color histograms. Evaluating d_A has complexity $O(D^2)$, which becomes too costly even for moderately large values of D, the number of bins in the color histograms. In [6] it is demonstrated that using as approximate features the average RGB color of an image, which is a three-dimensional vector, and comparing average colors using the Euclidean distance, i.e., $d_{avg}^2(af_i, af_j) = \sum_{k \in \{R,G,B\}}(af_{i,k} - af_{j,k})^2$, leads to derive that $d_{avg}^2 \leq {d_A}^2/\lambda_1$, where λ_1 is the smallest eigenvalue of matrix A. Then, the lower-bounding lemma guarantees that querying an index built on average colors with a range query of radius $\epsilon/\sqrt{\lambda_1}$ will not lead to any false dismissal.

As another relevant example, consider the problem of comparing feature vectors that represent time-varying signals. A distance function more robust than the Euclidean one to misalignments on the time domain is the dynamic time warping (DTW) distance. However, evaluating DTW has a complexity $O(D^2)$, which is untenable for long time series. In [9] Keogh introduces an effective lower-bounding function for the DTW distance. In essence, the idea is to construct an *envelope*, $Env(q)$, around the query time series q, after that an Euclidean-like distance between $Env(q)$ and a stored sequence f_i can be computed in $O(D)$ time.

The Need for Approximate Features

As anticipated, there are several reasons for which approximate features might have to be considered. First, in many relevant cases the features of a MM object are represented through a high-dimensional vector, $f_i = (f_{i,1}, f_{i,2}, \ldots, f_{i,D})$, with D of the order of the hundreds or even thousands. At such high dimensions it is known that the performance of multidimensional indexes rapidly deteriorates, becoming either comparable to, or even worse than, that of a sequential scan. This phenomenon, known as the dimensionality curse, inhibits any approach based on a direct indexing of feature values. Besides ad hoc solutions, such as those above described, one might consider using some dimensionality reduction technique that projects feature vectors onto a (much) lower D'-dimensional space, $D' \ll D$, and then indexing the so-obtained D'-dimensional feature vectors. The effectiveness of such techniques however is highly variable, being dependent on the actual data distribution.

Another practical reason that could motivate the use of approximate features is the mismatch between the type of the features and the one natively supported by the index. As a simple example, consider an index implementation that only manages entries of an arbitrary, but fixed, size, and that objects to be indexed are regions of pixels described by their boundaries. Clearly, boundary descriptions have different sizes, depending on the shape of the region. In this case a possible solution would be to use a *conservative approximation* of boundaries, like minimum bounding rectangles.

Finally, it might also be the case that, although in principle actual feature values could be stored in the index, the distance function to be used on them cannot be supported by the index organization. A remarkable example is the DTW distance: since DTW is *not* a true metric, in that it does not satisfy the triangle inequality, no multidimensional index can directly process queries with such a distance function.

Metric Indexing

When features are not vectors and/or the distance function is not the Euclidean distance or some other (possibly weighted) L_p norm, coordinate-based spatial indexes cannot be used. There are many cases in which this situation shows up. For instance, in region-based image retrieval (RBIR), each image is first automatically segmented into a set of homogeneous regions, each of them being represented by a vector of low-level features (usually encoding color and texture information). Thus, each f_i is a *set of vectors* and as such cannot be indexed by a spatial index. As a further example, *graphs* representing, say, spatially located objects with their relationships cannot be directly supported by a coordinate-based index. In cases like these, one could consider using a metric index, such as the M-tree [5]. A metric index just requires the distance function d used to compare feature values to be a metric, i.e., a positive and symmetric function that also satisfies the triangle inequality: $d(f_i, f_j) \leq d(f_i, f_k) + d(f_k, f_j)$ $\forall f_i, f_j, f_k$. Although there is nowadays a large number of metric indexes available [14], as demonstrated in [3] all of them are based on the common principle of organizing the indexed features into a set of equivalence classes and then discarding some of these classes by exploiting the triangle inequality. For instance, in the case of the M-tree each class corresponds to the set of feature values stored into a same leaf of the tree. Triangle inequality can also be applied to save some distance computations while searching the index, which turns out to be particularly relevant in the case of computationally demanding distance functions (a common case with MM data). This was first shown for the M-tree, in which distances between each feature value and its parent in the index tree are precomputed and stored in the tree. The idea is quite general and effective, an obvious tradeoff existing between the amount of extra information stored in the tree and the benefit this has on pruning the search space. Along this direction, Skopal and Hoksza propose the M*-tree [12], a variant of the M-tree in which each entry in a node also includes its NN in that node, i.e., the *NN-graph* of the features in each node is maintained.

A common objection to metric indexes is that they are bound to use only a specific distance function, namely the one with which the index is built. Along the direction of increasing flexibility, Ciaccia and Patella [4] introduce the QIC-M-tree, which is an extension of the M-tree able to support queries with any distance function d_Q from the same "family" of the distance d_I used to build the tree. On the condition that there exists a *scaling factor* $S_{d_I \to d_Q}$ such that $d_I(f_i, f_j) \leq S_{d_I \to d_Q} d_Q(f_i, f_j)$ holds (i.e., d_I lower bounds d_Q up to a constant factor), the lower-bounding lemma applies, and the index can answer queries based on d_Q. A similar idea allows the QIC-M-tree to use also a "cheap" approximate distance d_C as a filter before computing the "costly" d_I and d_Q functions.

Ad Hoc Solutions

The availability of general purpose metric indexes does not rule out the possibility of deriving better, more specialized solutions for the problem at hand. For instance, the STRG-Index [10] is a specialized structure for indexing spatio-temporal graphs arising from the modelling of video sequences. Consider a video segment with N frames. Each frame is first segmented into a set of homogeneous color regions, each of which becomes a node in the region adjacency graph (RAG) of that frame, with edges connecting spatially adjacent regions. Node attributes (such as size, color, and location) are then defined, and the same is done for edges (in which case attributes such as the distance and the orientation between the centroids of connected regions can be used). Since a node representing a region can span multiple frames, nodes in consecutive RAGs can be connected to represent temporal aspects. The resulting graph is called spatio-temporal region graph (STRG). The STRG is then decomposed into a set of object graphs (OGs) and background graphs (BGs), and clusters of OGs are obtained for the purpose of indexing. Since the distance function used for comparing OGs (the so-called extended graph edit distance (EGED)) is a metric, any metric index could be used. The ad hoc STRG-Index proposed in [10] is a three-level metric tree, where the root node contains entries for the BGs, the intermediate level stores clusters of OGs, and individual OGs are inserted into the leaf level.

Extensions of available indexes might be also required as a consequence of feature approximation. An example is found in [13], where the problem of providing rotation-invariant retrieval of shapes under the Euclidean (L_2) distance is considered. After converting a shape boundary into a time series $f_i = (f_{i,1}, f_{i,2}, \ldots, f_{i,D})$ (this is quite a common way to represent shapes, see e.g., [2]), a discrete fourier transform (DFT) is applied to obtain a representation of f_i in the frequency domain. Due to Parseval's theorem, the DFT transformation preserves the Euclidean distance [1]. To obtain invariance to rotation, only the magnitude of DFT coefficient is retained. The so-resulting vectors F_i are then compressed by keeping only the k ($k \ll D$) coefficients with the highest magnitude (together with their position in the original vector) plus an error term $\in F_i$ given by the square root of the sum of the squares of dropped coefficients. This information allows a tight lower bound to be derived on the actual rotation-invariant Euclidean distance between f_i and a query shape q. For indexing, a variation of the VP-tree is introduced, which allows compressed features to be stored and searched.

Key Applications

Any application dealing with massive amounts of multimedia data requires effective indexing solutions for efficiently supporting similarity queries. This is further motivated by the complexity of distance functions that are of interest for multimedia data.

Future Directions

All the above indexing techniques and methods assume (at least) that the distance function is a metric. An interesting problem is to devise indexing methods for non-metric distance functions that do not rely on the lower-bounding lemma. The work of Skopal [11] on *semimetrics* appears to be a relevant step on this direction. In the same spirit, Goial, Lifshits and Schütse [7] study how to avoid turning the *similarity* search problem into a *distance*-based one, which in several cases might not yield a metric. Working directly with similarities is however more complex, since there is no analogue of the triangle inequality property for similarity values. Let $rank_y(x)$ be the rank of object x with respect to object y (i.e., x is the NN of y if $rank_y(x) = 1$). Then, [7] introduces the concept of *disorder constant DC*, the smallest value for which the *disorder inequality* $rank_y(x) \leq DC(rank_z(x) + rank_z(y))$ holds $\forall x, y, z$ in the given dataset, and describes algorithms for NN search based on this idea. Making this approach practical for large MM databases remains an open problem.

Multimedia Data Querying

K. Selcuk Candan[1], Maria Luisa Sapino[2]
[1]Arizona State University, Tempe, AZ, USA
[2]University of Turin, Turin, Italy

Definition

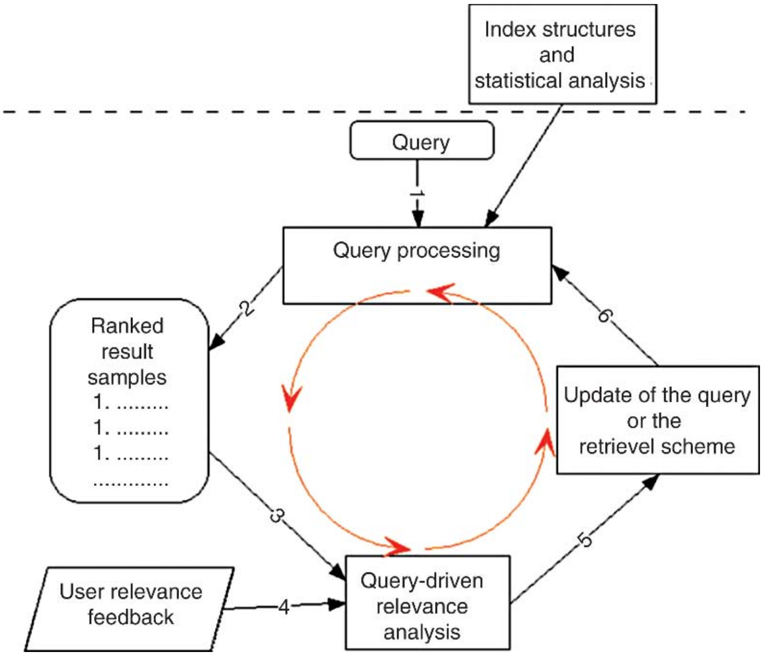
One common characteristic of multimedia systems is the *uncertainty or imprecision of the data.* The models that can capture the imprecise and statistical nature of multimedia data and query processing are fuzzy and probabilistic in nature. Therefore multimedia data query evaluation requires fuzzy and probabilistic data and query models as well as appropriate query processing mechanisms. Probabilistic models rely on the premise that the sources of imprecision in data and query processing are inherently statistical and thus they commit onto probabilistic evaluation. Fuzzy models are more flexible and allow various different semantics, each applicable under different system requirements to be selected for query evaluation.

Historical Background

Due to the possibly redundant ways to sense the environment, the alternative ways to process, filter, and fuse multimedia data, and the subjectivity involved in the interpretation of data and query results, multimedia data quality is inherently imprecise:

- *Feature extraction algorithms that form the basis of content-based multimedia data querying are generally imprecise.* For example, high error rate is encountered in motion capture data due to the multitude of environmental factors involved, including camera and object speed. Especially for video/ audio/ motion streams, data extracted through feature extraction modules are only *statistically* accurate and may be based on the frame rate or the position of the video camera related to the observed object.
- *It is rare that a multimedia querying system relies on exact object matching.* Instead, in many cases, multimedia databases leverage similarities between feature vectors to identify data objects that are similar to the query. In many cases, it is also necessary to account for s*emantic similarities* between associated annotations and *partial matches,* where objects in the result satisfy some of the requirements in the query, but fail to satisfy all query conditions.
- *Imprecision can also be due to the available index structures which are imperfect.* Due to the sheer size of the data, many systems rely on clustering and classification algorithms for pruning during query processing.
- *Query formulation methods are not able to capture user's subjective intention perfectly.* For example, in Query by Example (QBE), which features, feature value ranges, feature combinations, or which similarity notions are to be used for processing is left to the system to figure out through feature significance analysis, user preferences, relevance feedback (Fig. 1), and/or collaborative filtering techniques, which are largely statistical and probabilistic in nature.

In many multimedia querying systems, more than one of these reasons coexist and, consequently, the system must take them into consideration collectively. Figure 2 provides an example query (in an SQL-like syntax used by the SEMCOG system [10]) which brings together imprecise and exact predicates. Processing this query



Multimedia Data Querying. Figure 1. Multimedia query processing usually requires the semantic gap between what is stored in the database and how the user interprets the query and the data to be bridged through a relevance feedback cycle. This process itself is usually statistical in nature and, consequently, introduces probabilistic imprecision in the results.

Multimedia Data Querying. Figure 2. A sample multimedia query with imprecise and exact predicates.

requires assessment of different sources of imprecision and merging them into a single value. Traditional databases are not able to deal with imprecision since they are based on Boolean logic: predicates are treated as propositional functions, which return either *true* or *false*. A naive way to process queries is to transform imprecision into *true* or *false* by mapping values less than a cut-off to *false* and the remainder to *true*. With this naïve approach, partial results can be quickly refuted or validated based on their relationships to the cut-off. User provided cut-offs can also be leveraged for *filtering*, while maintaining the imprecision value of the results for further processing. In general, however, cut-off based early pruning leads to misses of relevant results. This leads to the need for data models and query evaluation mechanisms, which can take into account imprecision in the evaluation of the query criteria. In particular, the data and query models cannot be propositional in nature.

Foundations

Assessments of the degrees of imprecisions in multimedia data can take different forms. For example, if the data is generated through a sensor/operator with a quantifiable quality rate (for instance a function of the available sensor power), then a scalar-valued assessment of imprecision may be applicable. This is similar to the (so called type-1) fuzzy predicates, which (unlike propositional functions which return *true* or *false*) return a membership value to a fuzzy set. *In this simplest case, the quality assessment of a given object, o, is modeled as a value* $0 \leq qa(o) \leq 1$. A more general quality assessment model would take into account the uncertainties in the assessments themselves. These type of predicates, where sets have grades of membership that are themselves fuzzy, are referred to as type-2 fuzzy predicates. For example the assessment of a given object o can be modeled as a normal distribution of qualities, $qa(o) = No(qo, \xi o)$, where qo is the expected quality and ξo is the variance. Although the type-2 model can be more general and use different probability distributions, this specific model (using the normal distribution) is a generally applicable sampling-related imprecision as it relies on the well-known *central limit theorem*, which states that the average of the samples tends to be normally distributed, even when the distribution from which the average is computed is not normally distributed. Note that, in general, such complex statistical assessments of data precision can be hard to obtain. A compromise between the above two models represents the range of possible qualities of an object with a lower- and an upper-bound. In this case, *given an object o, its quality assessment,* $qa(o)$ *is modeled as a pair* $<qo_{low}, qo_{high}>$, *where* $0 \leq qo_{low} \leq qo_{high} \leq 1$.

Fuzzy data and query models for multimedia querying are based on the fuzzy set theory and fuzzy logic introduced by Zadeh in mid 1960s [14]. A fuzzy set, *F*, with domain *D* is defined using a membership function, $F: D \rightarrow [0,1]$. A fuzzy predicate, then, corresponds to a fuzzy set: instead of returning *true(1)* or *false(0)* values as in propositional functions, fuzzy predicates return the corresponding membership values (or scores). Fuzzy clauses combine fuzzy predicates and fuzzy logical operators into complex fuzzy statements. Like the predicates, the fuzzy clauses also have associated scores. The meaning of a fuzzy clause (i.e., the score it has, given the constituent predicate scores) depends on the semantics chosen for the fuzzy logical operators, *not* ($\neg$), *and* ($\wedge$), and *or* ($\vee$).

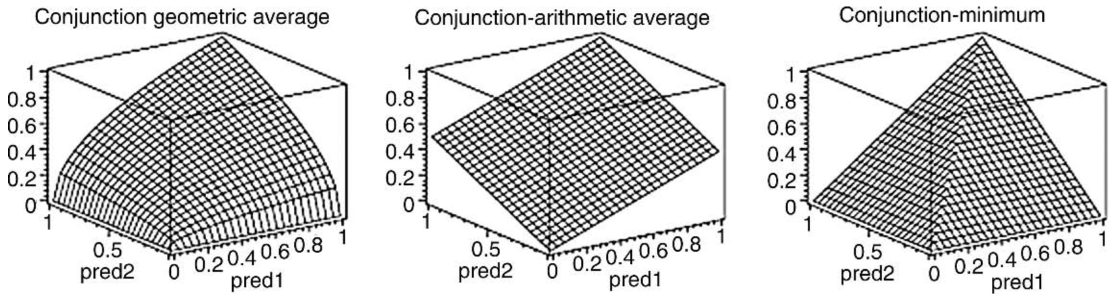
Table 1 shows popular *min* and *product* fuzzy semantics used in multimedia querying. These two semantics (along with some others) have the property that binary conjunction and disjunction operators are triangular-norms (t-norms) and triangular-conorms (t-conorms). Intuitively, t-norm functions reflect the (boundary, commutativity, monotonicity, and associativity) properties of the corresponding Boolean operations. Although the property of capturing Boolean semantics is desirable in many applications of fuzzy logic, for multimedia querying, this is not always the case [3]. For instance, the partial match requirements invalidate the boundary conditions. Monotonicity can be too weak a condition for multimedia query processing. In many cases, according to real-world and artificial nearest-neighbor workloads, the highest-scoring predicates are interesting and the rest is not interesting. This implies that the *min* semantics, which gives the highest importance on the lowest scoring predicate, may not be suitable for real workloads. Other fuzzy semantics used in multimedia systems include arithmetic and geometric average semantics. Figure 3 visualizes the behavior of the fuzzy conjunction operator under different fuzzy semantics. It is well established that the only fuzzy semantics which preserves logical equivalence of statements (involving conjunction and disjunction) and is also monotonic is the *min* semantics. This, and the query processing efficiency it enables due to its simplicity, make it a popular choice despite its shortcomings.

Processing multimedia queries, like the one depicted in Fig. 2, under a fuzzy system requires extending query languages and query processors with fuzzy semantics. Many commercial database management systems include fuzzy extensions that are suitable for multimedia applications. Relational databases can be extended to capture fuzzy data in various different ways. In *tuple-level approaches,* the schema of each fuzzy relation is extended to include one or more attributes, each representing the degrees of imprecision of the tuples in the relation with respect to a different interpretation of the tuples. In these systems, the relational algebra operators (such as select, project, join, union, difference) are also extended to apply the selected fuzzy semantics to the tuple scores. In the *attribute-level approaches*, the degrees of uncertainty are associated individually to the attribute values. Especially when the imprecisions in the various attributes of a multimedia object are due to different reasons, attribute level approaches are more applicable due to their finer granularity. Furthermore, since each attribute can be treated as a fuzzy predicate on the multimedia object, query evaluation within these models can benefit more naturally from fuzzy logic evaluation schemes.

Processing these queries, on the other hand, requires significant extensions to the underlying database engines. For example, the underlying relational concepts, such as functional dependencies and normalization, need to be extended to cope with fuzziness in the stored data. In particular, in multimedia

Multimedia Data Querying. Table 1. Fuzzy *min* and *product* semantics for logic operators: $\mu_i\ (x)$ stands for the score of the predicate P_i on x

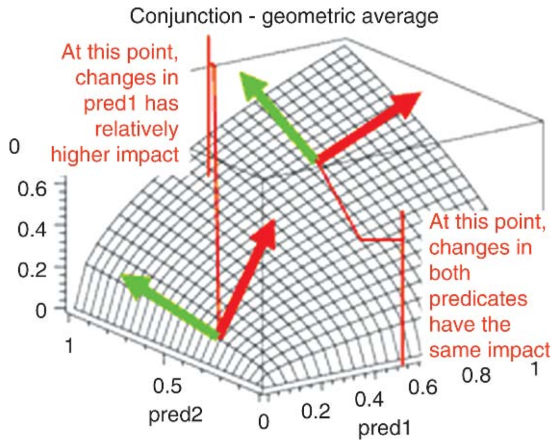
Min semantics	Product semantics
$\mu_{P_i \wedge P_j}(x) = min\{\mu_\imath(x), \mu_j(x)\}$	$\mu_{P_i \wedge P_j}(x) = \frac{\mu_\imath(x) \times \mu_j(x)}{max\{\mu_\imath(x), \mu_j(x), \alpha\}} \qquad \alpha \in [0, 1]$
$\mu_{P_i \wedge P_j}(x) = max\{\mu_\imath(x), \mu_j(x)\}$	$\mu_{P_i \vee P_j}(x) = \frac{\mu_\imath(x)+\mu_j(x)-\mu_\imath(x)\times\mu_j(x)-min\{\mu_\imath(x),\mu_j(x),1-\alpha\}}{max\{1-\mu_i(x),1-\mu_j(x),\alpha\}}$
$\mu_{\neg P_i}(x) = 1 - \mu_i(x)$	$\mu_{\neg P_i}(x) = 1 - \mu_i(x)$



Multimedia Data Querying. Figure 3. Visual representations of various binary fuzzy conjunction semantics: The horizontal axes correspond to the values between 0 and 1 for the two input conjuncts and the vertical axis represents the resulting scores according to the corresponding function.

databases, users are usually interested in a result set which is ranked according to a ranking criterion which is generally user dependent (Fig. 1). Adali et al. [1] introduces a similarity algebra which brings together relational operators and results of multiple similarity implementations in a uniform language. Other algebraic treatments of fuzzy multimedia queries, relying on finer granularity attribute-based models, include the *FNF*^{2} *algebra* [5]. When the requirement for exact matches is removed, the result space becomes significantly large, and thus, the query engine cannot rely on any processing scheme which would need to touch or enumerate all solutions. Consequently, query processing schemes would need to generate results as progressively (in decreasing order of relevance) as possible. Fagin [7] proposes ranked query evaluation algorithms, which assume that individual sources can progressively output sorted results and also enable random access. These algorithms also assume that the query has a monotone combined scoring function. Candan et al. [4] presents *approximate* ranked query processing techniques for cases where not all sub-queries are able to return ordered results. In turn, Fagin et al. [8] recognizes that there may be cases where random accesses are impossible and presents algorithms under monotonicity assumption to enumerate top-*k* objects without accessing all the data. These augment *monotonicity* with an *upper bound* principle, which enables bounding of the maximum possible score of a partial result. Qi et al. [13] establishes an alternative, *sum-max monotonicity* property and shows how to leverage this for developing a self-punctuating, horizon-based ranked join (HR-Join) operator for cases when the more strict monotonicity property does not hold. Top-*k* querying can also be viewed as a *k*-constrained optimization problem, where the goal function includes both a Boolean constraint characterizing the data of interest and a quantifying function which acts as the numeric optimization target [15]. Adali et al. [2] and Li et al. [11] extend the relational algebra to support ranking as a first-class construct. Li et al. [11] also presents a pipelined and incremental execution model of ranking query plans.

A particular challenge in multimedia querying is that (as shown in Fig. 1) the underlying query processing scheme needs to adapt to the specific needs and preferences of individual users. Due to its flexibility, the fuzzy model enables various mechanisms of adaptation. First of all, if user's feedback focuses on a particular attribute in the query, the way the fuzzy score of the corresponding predicate is computed can change based on the feedback. Secondly, the semantics of the fuzzy logic operator can be adapted based on the feedback of the user. A third mechanism through which user's feedback can be taken into account is to enrich the merge function, used for merging the fuzzy scores, with weights that regulate the impacts of the individual predicates. Fagin proposed a generic weighting mechanism that can be used for any fuzzy merge function [7]. The mechanism ensures that (a) the result is a continuous function of the weights (as long as the original merge function is continuous), (b) sub-queries with zero weight can be dropped without affecting the rest of the query, and (c) if all weights are equal, then the result is equal to the original, not-weighted merge function. Candan and Li [3], on the other hand, argued that the relative importance of predicates in a merge function should be measured in terms of the overall impacts changes in the scores that the individual predicates would have on the overall score (Fig. 4). Consequently, the relative importance of predicates can vary based on the scores the individual predicates take and the corresponding partial derivatives. A more direct mechanism to capture the user feedback is to modify the partial derivatives of the scoring functions appropriately. While the generic scheme presented by Fagin [7] would satisfy this for some merge functions, such as the arithmetic average, it would fail to capture this requirement for others, such as the commonly used product semantics.



Multimedia Data Querying. Figure 4. The relative impact of the predicates in a scoring function can vary based on the scores of the individual predicates.

Unlike the fuzzy models, which can capture a large spectrum of application requirements, probabilistic approaches to data and query modeling are applicable only to those cases where the source of imprecision is of statistical nature. These cases include probabilistic noise in data collection, sampling (over time, space, or population members) during data capture or processing, randomized and probabilistic algorithms (such Markov chains and Bayesian networks) used in media processing and pattern detection, and probabilistic consideration of relevance feedback. Dalvi and Suciu [6], for example, associates a value between 0 and 1 to each tuple in a given relation: the value expresses to probability with which a given tuple belongs to the relation. By extending SQL and the underlying relational algebra with probabilistic semantics and a theory of belief, the authors provide a probabilistic semantics for query processing with uncertain matches.

A general simplifying assumption in many probabilistic models is that the individual attributes (and the corresponding predicates) are independent of each other: consequently, the probability of a conjunction can be computed as the product of the probabilities of the conjuncts; i.e., under these conditions, the probabilistic model corresponds to the fuzzy product semantics. However, the independence assumption does not always hold (in fact, it rarely holds). Lakshmanan et al. [9] presents a probabilistic relational data model, an algebra, and aggregate operators that capture various types of interdependencies, including independence, mutual exclusion, as well as positive, negative, and conditional correlation.

While the simplest probabilistic models associate a single value between 0 and 1 to each attribute or tuple, more complete models represent the score in the form of an interval of possible values or more generally in terms of a probability distribution describing the possible values for the attribute or the tuple. Consequently, these models are able to capture more realistic scenarios, where the imprecision in data collection and processing prevents the system to compute the exact *quality* of the individual media objects, but (based on the domain knowledge) can associate probability distributions to them. Note that relaxing the independence assumption or extending the model to capture non-singular probability distributions both necessitate changes in the underlying rank evaluation algorithms.

Other non-relational probabilistic models for multimedia querying includes Markov chains and Bayesian networks. A stochastic process is said to be Markovian if the conditional probability distribution of the future states depends only on the present. A Markov chain is a discrete-time stochastic process which is conditionally independent of the past states. A random walk on a graph, $G(V,E)$, is a Markov chain whose state at any time is described by a vertex of G and the transition probability is distributed equally among all outgoing edges. The transition probability distribution in the corresponding Markov model can be represented as a matrix, where the (i, j)'th element of this matrix, T_{ij}, describes the probability that, given that the current state is i, the process will be in state j in the next time unit; i.e., the n-step transition probabilities can be computed as the n'th power of the transition matrix. Markovian models are used heavily for linkage analysis in supporting queries over web, multimedia, and social network data with graphical representations.

A Bayesian network is another graphical probabilistic model used especially for representing probabilistic relationships between variables (e.g., objects, properties of the objects, or beliefs about the properties of the objects) [12]. In a Bayesian network nodes represent variables and edges between the nodes represent the relationships between the probability distributions of the corresponding variables. Consequently, once they are fully specified, Bayesian networks can be used for answering probabilistic queries given certain observations. However, in many cases, both the structure as well as the parameters of the network have to be learned through iterative and sampling-based heuristics, such as expectation maximization (EM), and Markov Chain Monte Carlo (MCMC) algorithms. Hidden Markov models (HMMs), where some of the states are hidden (i.e., unknown), but variables that depend on these states are observable, are Bayesian networks used commonly in many machine-learning based multimedia pattern recognition applications. This involves training (i.e., given a sequence of observations, learning the parameters of the underlying HMM) and pattern recognition (i.e., given the parameters of an HMM, finding the most likely sequence of states that would produce a given output).

Key Applications

Applications of multimedia querying include personal and public photo/media collections, personal information management systems, digital libraries, on-line and print advertisement, digital entertainment, communications, long-distance collaborative systems, surveillance, security and alert detection, military, environmental monitoring, ambient and ubiquitous systems that provide real-time personalized services to humans, improved accessibility to blind and elderly, rehabilitation of patients through visual and haptic feedback, and interactive performing arts.

Future Directions

While most of the existing work in this area focused on content-based and object-based query processing, future directions in multimedia querying will involve understanding of how media objects affect users and how do they fit into users experiences in the real world. These require better understanding of underlying psychological and cognitive processes in human media processing. Ambient media-rich systems which collect and feed in diverse media from environmentally embedded sensors necessitate novel ways of continuous and distributed media processing and fusion schemes. Intelligent schemes to choose the right objects to process are needed to scale query processing workflows to the immense influx of real-time media data. In a similar manner, collaborative-filtering based query processing schemes that can help overcoming the semantic gap between media and users' experiences will help the multimedia databases scale to Internet-scale media indexing and querying.

Multimedia Data Storage

Jeffrey Xu Yu
Chinese University of Hong Kong, Hong Kong, China

Definition

Data storage management, as one of the important functions in database management systems, is to manage data on disk in an efficient way to support data retrieval and data update. Multimedia data storage management is to manage continuous media data (audio/video) on disk. The uniqueness of multimedia data storage management is, in a multiuser environment, how to arrange the data storage to support a continuous retrieval of large continuous media data from disk to be displayed on screen, at a pre-specified rate, without any disruptions, which is also called hiccup-free display.

Historical Background

In a multimedia environment, the continuous media needs to be retrieved and displayed continuously. As magnetic disks are used as the mass storage device for multimedia data, zoning is one approach to increase the storage capacity of magnetic disks. Here, zones of a disk drive are different regions of the disk drive that usually have different transfer rates. A number of studies have investigated techniques to support a hiccup-free display of continuous media (video/audio) using magnetic disk drives with a single zone [1,2,9,10] in the early 1990s. These studies assume a fixed transfer rate for a disk drive. These techniques can be possibly adopted to design a multi-zone disk system, but such a multi-zone disk system is then forced to use the minimum transfer rate of the zones for the entire disk, in order to guarantee a continuous display of continuous media objects. Such an approach is called Min-Z-tfr.

In the late 1990s and early 2000s, many new techniques are proposed to deal with the storage of continuous media in multi-zone disks [4,5]. In [4], VARB and FIXB are proposed to place media objects on the multi-zone disks. VARB and FIXB techniques provide the average transfer rate of zones while ensuring a continuous display, compared with Min-Z-tfr, which is forced to use the minimum transfer rate of zones. VARB and FIXB increase the throughput of the system, while they also (i) increase startup latency, (ii) waste disk space, and (3) increase the amount of memory required to support more simultaneous displays. A configuration planner is proposed to decrease the drawbacks of VARB and FIXB, in order to meet the performance requirements of applications [4]. As VARB and FIXB [4] take account of a single media type only, RP, MTP, and MVP are proposed in [5] to support multiple media types with different bandwidth requirements. In [4,5], the discussions focus on multimedia data placement across disk drives to support continuous display requirement.

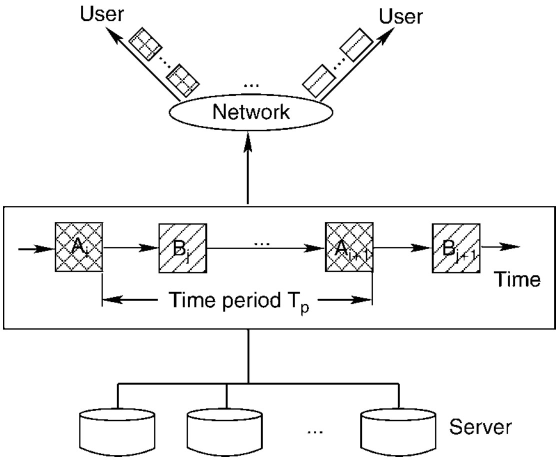
Foundations

Hiccup-Free Display

The size of continuous media, especially videos, can be very large. The transmission of data must be just-in-time. In other words, data must be retrieved from disks and transmitted to the display in a timely manner that prevents hiccups. A cycle-based data retrieval technique [6,12] is designed to provide continuous display for multiple users. As shown in Fig. 1, it is a cycle-based data retrieval technique to support hiccup-free display [5]. Consider a constant-bit-rate (CBR) media. In order to guarantee a continuous display of a continuous media *A*, the system needs to retrieve the block of A_i before its immediate previous block A_{i-1} completes its display. For each block A_i, there are two tasks, namely, block retrieval and display initialization. This process of block retrieval and display initialization repeats in a cyclic manner until all *A* blocks have been displayed. If the time to retrieve a block, termed *block retrieval time*, T_p (as indicated in Fig. 1), is smaller than or equal to the time period to display a block, then the whole display process will be hiccup free [5]. The time interval between the time a request of *A* arrives and the time the display of *A* starts is called *startup latency*.

FIXB and VARB

Modern disk drivers are produced with multiple zones to meet the demands for a higher storage capacity [11]. A zone is a contiguous collection of disk cylinders where the tracks in the cylinders are supposed to have the same storage capacity. The outer zones have a higher transfer rate in comparison with the inner zones. Two approaches, FIXB and VARB, are proposed in [4] to support a continuous display of continuous media using a single disk with multi-zones. Suppose that the disk consists of *m* zones, Z_1, Z_2,...,Z_m, and



Multimedia Data Storage. Figure 1. A hiccup free display (Fig. 3 in [5]).

the transfer rate of zone Z_i is R_i. Assume that each object X is partitioned into f blocks: X_1, X_2,...,X_f.

With FIXB (Fixed Block Size), the blocks of an object X are rendered equi-sized, i.e., $X_i = X_j$, for any i and j. The system assigns the blocks of X to the zones in a round-robin manner. FIXB is designed to support a predetermined number of simultaneous displays (N). The retrieval process of this system is to scan the disk in one direction, for example, starting with the outermost zone moving inward, visiting one zone at a time and multiplexing the bandwidth of that zone among N block reads. A sweep is a scan of the zones. The time to perform one such a sweep is denoted as T_{Scan}. The time of reading N blocks from zone Z_i, denoted $T_{MUX}(Z_i)$, is dependent on the transfer rate of zone Z_i. As the transfer rate of zones varies, the time to read blocks from different zones also varies. To support hiccup-free displays, the system uses buffers to compensate for the low transfer rates of innermost zones.

VARB makes $T_{MUX}(Z_i)$ to be identical for all zones, using variable block sizes. The size of a block, $B(Z_i)$, is a function of the transfer rate of the zone Z_i. This results in an identical transfer time for all the blocks, T_{disk}, i.e., $T_{disk} = \frac{B(Z_i)}{R_i} = \frac{B(Z_j)}{R_j}$, for any i and j. Like FIXB, VARB assigns the blocks of an object to the zones in a round-robin manner. Unlike FIXB, with VARB, the blocks of an object X have different sizes depending on which zones the blocks are assigned to. Also, like FIXB, VARB employs memory to compensate for the low bandwidth of innermost zones.

With FIXB, the blocks of an object is equi-sized, whereas VARB renders the blocks in different sizes, which depends on the transfer rate of its assigned zone. FIXB is easy to be implemented in compared with VARB. But VARB requires a lower amount of memory and incurs a lower latency as compared to FIXB.

RP, MTP, and MVP

Based on zoning, there are different data transfer rates (R_i) to retrieve data from a disk. When a server is required to support multiple media types with different bandwidth requirements, the block reading time varies widely depending on the block size and its assigned zone. Suppose that there are n different media types to be supported. The block size of a media type i object is determined by $B_i = T_p \times D_i$ where D_i is the bandwidth requirement of the media type i, and T_p is a fixed time period which is set to be the same for all the media types. The transfer time (service time) to retrieve a block of a media type i object in zone Z_j is $s_{i,j} = \frac{B_i}{R_j}$. Suppose that there are b blocks, the average service time is computed as

$$\bar{s} = \sum_{i=1}^{b} F_i \sum_{j=1}^{n} P_{i,B_j} \sum_{k=1}^{m} \frac{P_{i,Z_k} B_j}{R_k}$$

where F_i is the access frequency of block i, for $1 \leq i \leq b$, P_{i,B_j} is the probability that the size of block i is B_j, and P_{i,Z_k} is the probability that this block is assigned to zone Z_k. The variance of service time is:

$$\sigma_s^2 = \sum_{i=1}^{b} F_i \sum_{j=1}^{n} \sum_{k=1}^{m} P_{i,B_j} P_{i,Z_k} (s_{j,k} - \bar{s})^2$$

Three approaches are proposed in [5]: RP, MTP, and MVP. RP (Random Placement) assigns blocks to the zones in a random manner. MTP (Maximizing Throughput Placement) sorts blocks based on their size and frequency of access ($F_i \times B_i$). The blocks are assigned to the zones sequentially starting with the fastest zone, i.e., block i with the highest $F_i \times B_i$ value is assigned to the fastest zone. With MVP (Minimizing Variance Placement), a block of size B_i is placed on the zone Z_j (with R_j) which has the closest $\frac{B_i}{R_j}$ value to the average block reading time ($\bar{T}_B$):

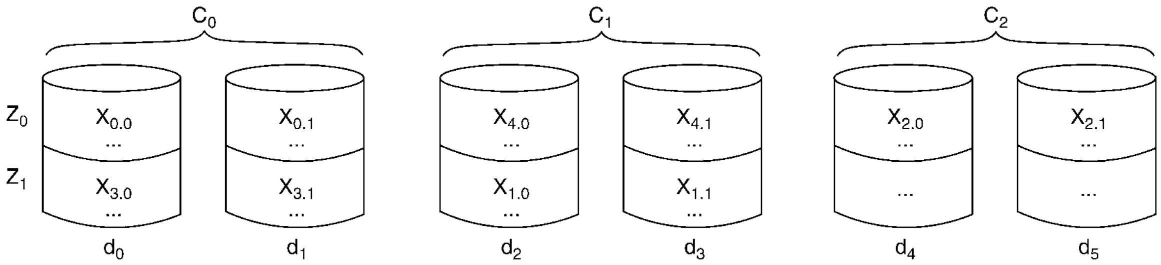
$$\bar{T}_B = \frac{average\ block\ size}{average\ transfer\ rate} = \frac{\frac{1}{n}\sum_{i=1}^{n} B_i}{\frac{1}{m}\sum_{i=1}^{m} R_i}$$

Performance studies in [5] demonstrate that both MTP and MVP are superior to RP. MVP outperforms MTP regarding the average service time and/or variance of service time. One advantage of MVP is that it is not sensitive to the access frequency of objects.

Data Placement across Disk Drivers

The bandwidth of a single disk is insufficient for the multimedia applications that strive to support thousands of simultaneous displays. One approach is to employ a multi-disk architecture. Assuming a system with D homogeneous disks, the data is striped across the disks in order to distribute the load of a display evenly across the disks [2,3,8].

The striping technique is as follows (Fig. 2). First, the disks are partitioned into k disk clusters where each cluster consists of d disks: $k = \lceil \frac{D}{d} \rceil$. An object X is partitioned into f blocks, X_1, X_2,..., X_f, and the blocks



Multimedia Data Storage. Figure 2. Three clusters with two logical zones per cluster (Fig. 12 in [4]).

of X are assigned to the k disk clusters in a round-robin manner, starting with an arbitrarily chosen disk cluster and zone, for example, zone Z_j in disk cluster C_i. In a disk cluster, each block of X, X_i, is declustered [7] into d fragments, $X_{i,j}$, where each fragment is assigned to a different disk in the disk cluster. As shown in Fig. 2, the X_0 block is assigned to the disk cluster C_0, and its two declustered fragments, $X_{0,0}$ and $X_{0,1}$ are assigned to the zone Z_0. Note that the fragments of a block need to be assigned to the same zone on the d disks in the disk cluster where the block is assigned to. In the retrieval of objects, one zone of all disks in a disk cluster is active per time period. To display object X of Fig. 2, it needs to access zone Z_0 in disk cluster C_0, when the disk cluster is idle, followed by accessing zone Z_1 in disk cluster C_1. This process repeats to retrieve/display all blocks of the object X.

Key Applications

Multimedia information systems have emerged as an essential component in many application domains ranging from library information systems to entertainment technology. The data storage management is the basis to support a continuous display of multimedia objects.

Multimodal databases

Definition

Multimedia Databases are databases that contain and allow key data management operations with multimedia data. Traditional databases contained alphanumeric data and managed it for various applications. Increasingly, applications now contain multimedia data that requires defining additional types and requires development of operations for storage, management, access, and presentation of multimedia data. Multimedia databases must increasingly deal with issues related to managing multimedia data as well as the traditional data. Commonly, databases that manage images, audio, and video in addition to metadata related to these and other alphanumeric information are called multimedia databases. When databases contain only one of the images, audio, or video, they are called image databases, audio databases, and video databases, respectively. Considering the current trend, it is likely that most databases will slowly become multimedia databases.

Historical Background

The first in multimedia databases to appear were image databases that started appearing in late 1980s. Researchers in early image databases were more concerned with using databases for maintaining results of image processing operations to analyze and understand image analysis systems. Remote sensing and medical imaging produced images that needed to be saved and analyzed to extract information for various applications. In most of these applications, an environment to save images and processing results of these images were required.

The idea of making images an integral component of databases first started appearing in early 1990s. Relational data model had become the most common data model to deal with structured data and was used to store images as binary large objects (BLOBs) in these databases. To deal with images as first class data objects in images, a multilayered data model was proposed. This model considered image objects, and domain objects and suggested storage of those along with changes in relationships among objects. Some interesting developments in early systems evolved along two independent directions. In one direction [3], a user was considered an integral part of the query environment and feedback from user resulted in continuous refinement of queries leading to finding images that were required. In the other approach, many low level features were computed and used for finding images using query by example approach. These two approaches adopted distinctly different directions, the first used domain knowledge and the second relied only on image features without any use of domain knowledge. The image features used commonly are different types and characteristics of color histograms and texture measures. These approaches are commonly called content-based retrieval, to differentiate them from metadata based retrieval. Commercially image database systems appeared in traditional database systems in mid 1990s. IBM used its QBIC technology in their DB2 database system and Oracle, Sybase, and Illustra used technology developed by a start-up company Virage. All search engines use image retrieval mostly based on the metadata that includes name of the file and text in the context of the image on a webpage.

Content based video retrieval result started in analyzing video into its constituent parts. At the lowest level is a frame, an individual image. Images are grouped into shots, shots into scenes, and scenes into episodes. All this data is extracted from video and stored in the database. Speech recognition techniques are used to prepare the transcript of the video and are also used in the database. Such systems found early use in TV program production and defense applications. Virage technology was used in these applications. Current search engines usually use metadata for searching video. Some specialized video search companies such as Blinkx (http://www.blinkx.com/) use predominantly text obtained using speech recognition or closed captions in television video. News videos have been one of the major application domains due to their applications as well as to good quality of audio available for these.

In audio databases, the signal is analyzed to detect characteristics that could be used in searching musical pieces that are similar to those. Such techniques, sometimes referred to as query by humming, were thought to be useful in finding music of interest.

Some effort has gone into analyzing CAD databases also for retrieving drawing and objects of interest.

Though some research has started in addressing multimedia data, rather than just one of the above multimedia types, most research is in either images, video, or audio. Text or metadata available in context of multimedia data is being considered in multimedia database research increasingly.

Foundations

The most fundamental difference in multimedia databases compared to the traditional databases is in the rich semantics of the data. Multimedia data, in addition to being lot more voluminous, is very rich in semantics. Many queries that users are interested require understanding of the semantics of the data. The problem becomes more complex because the semantics of multimedia is dependent not only on the data, but also on the specific user, the context in which the query is asked, and other sets of data available in the system.

Early approaches to multimedia databases did not consider the nature of multimedia data and just stored multimedia data either as BLOBs or links to files containing the data. These systems could allow only limited operations on multimedia data – usually limited to display or rendering of the data. No other operations or queries could be performed on this data.

With increasing use of multimedia data and applications that require use of multimedia data in many different ways, the nature of multimedia databases started changing. Currently, multimedia databases are still in their early stages. Many different concepts and approaches are being tried. Some of the important emerging ideas that are being tried in multimedia databases are discussed below. This area is currently a very active one and is likely to receive increasing attention both from academic and industrial research community.

A multimedia database system is considered to have the following four clear modules that need to work together to provide the functionality desired from them.

Data Analysis and Feature Extraction

A MMDB contains multimedia data but just storing the data as a BLOB does not allow any queries related to the content of the data. To solve this problem, data is analyzed to extract features from the data. These features can then be used to derive the required semantics. The features extracted depend on the nature of the type of the data and domain of application for the MMDB. These features could range from low-level features that are very general and do not depend on the application domain such as, color histograms and texture features for images to high level features directly tied to application domain such as shape of the tumor.

A significant amount of research related to MMDB is in specific media related research communities such as audio processing or computer vision. There is strong interest in finding efficient and effective features to interpret multimedia data in general as well as in specific applications.

Domain Knowledge and Interpretation

Multimedia data interpretation requires use of domain knowledge. Moreover, the knowledge required for interpretation of this data is not only the traditional domain knowledge represented using ontologies and similar techniques well developed for interpretation of text; but also media dependent models that require sophisticated classification approaches. In audio and video events must be detected in the data and that requires processing time dependent features.

There is a new emerging perspective that multimedia data should be considered evidence for real world events captured using such data. This requires modeling events and representing knowledge about domain events. This knowledge is then used in interpretation of multimedia data not in silos but together. Some progress is being made in representation of events.

Interaction and User Interface

Interaction environments used in traditional databases and search engines are not satisfactory in many applications of MMDB. Using keywords or names of objects, some limited searches can be performed, but many applications require concepts and ideas that require both continuous interactions and successive refinement of queries in what is called emergent semantics environment. Query by example including query using sketches, humming, and some other non-textual approaches are being developed for some applications.

Presentation of results of queries also requires different techniques. Multimedia data is not very suited to list or record based presentations. Also, in many applications different media sources must be combined to create multimedia presentations with which a user can interact to refine and re-articulate their queries in the emergent semantics environment.

Storage, Matching, and Indexing

In most applications, the size of the multimedia data requires special attention. Commonly the video files can not be stored even using BLOBs. It is common to store file names of multimedia data and compute and store features from the data in the database. In most applications, for each file the number of features that should be stored becomes very large from hundreds to hundreds of thousands for each multimedia data item. These features are used in searching for correct results.

Unlike traditional databases, where records are searched based on exact matches, in MMDB search requires similarity matching. It is very rare to find a result using exact matching. Search in MMDB usually becomes finding data that has maximum similarity based on features. The similarity techniques [] requires comparing the features in queried data with all the data in a MMDB for evaluating similarity.

Indexing in MMDB for similarity computation requires representing features in a way that can allow fast computation for potentially similar objects. Many high dimensional techniques have been developed for organizing this data. The dimensionality of data, sometimes called curse of dimensionality, poses interesting challenges in such organization.

Key Applications

Multimedia data is becoming ubiquitous. Ranging from photos to videos, multimedia data is becoming part of all applications. Most emerging applications now have some kind of multimedia data that must be considered integral part of the databases. Moreover, emerging applications in all applications areas, ranging from homeland security to healthcare contain rich multimedia data. Based on current trend, it is safe to assume that in very near future, much of the data managed in databases will be multimedia. Some particular application domains where multimedia is natural and will continue dominating are entertainment, news, healthcare, and homeland security.

Future Directions

From structured data to semi-structured data and then to unstructured data, databases are being challenged to deal with increasingly semantic-rich environment. MMDB offer the biggest challenge to databases in terms of bridging the semantic gap.

Increasingly, applications are talking about situation modeling using real life sensor data. These applications combine live sensory data with other information to project current situation and also predict near future for users to take appropriate actions. These databases will require sophisticated tools to manage streaming multimedia data. Research efforts in these areas have already started and are likely to accelerate significantly in the near future.

Definition

Given a collection of multimedia documents, the goal of multimedia information retrieval (MIR) is to find the documents that are relevant to a user information need. A multimedia document is a complex information object, with components of different kinds, such as text, images, video and sound, all in digital form.

Historical Background

The vast body of knowledge nowadays labeled as MIR, is the product of several streams of research, which have arisen independently of each others and proceeded largely in an autonomous way, until the beginning of 2000, when the difficulty of the problem and the lack of effective results made it evident that success could be achieved only through integration of methods. These streams can be grouped into three main areas:

The first area is that of *information retrieval* (IR) proper. The notion of IR attracted significant scientific interest from the late 1950s in the context of textual document retrieval. Early characterizations of IR simply relied on an "objective" notion of topic-relatedness (of a document to a query). Later, the essentially subjective concept of relevance gained ground, and eventually became the cornerstone of IR. Nowadays, IR is synonymous with "determination of relevance" [9].

Around the beginning of the 1980s, the area of multimedia documents came into existence and demanded an IR functionality that no classical method was able to answer, due to the *medium mismatch problem* (in the image database field, this is often called the *medium clash problem*). This problem refers to the fact that when documents and queries are expressed in different media, matching is difficult, as there is an inherent intermediate mapping process that needs to reformulate the concepts expressed in the medium used for queries (e.g., text) in terms of the other medium (e.g., images). In response to this demand, a wide range of methods for achieving IR on multimedia documents has been produced, mostly based on techniques developed in the areas of *signal processing* and *pattern matching,* initially foreign to the IR field. These methods are nowadays known as *similarity-based* methods, due to the fact that they use as queries an object of the same kind of the sought ones (e.g., a piece of text or an image) [6]. Originally, the term *content-based* was used to denote these methods, where the content in question was not the content of the multimedia object under study (e.g., the image) but that of the file that hosts it.

The last area is that of *semantic information processing* (SIP) which has developed across the information system and the artificial intelligence communities starting in the 1960s. The basic goal of SIP was the definition of artificial languages that could represent relevant aspects of a reality of interest (whence the appellation *semantic*), and of suitable operations on the ensuing representations that could support knowledge-intensive activities. Since the inception of the field, SIP methods are rooted in first-order mathematical logic, which offers the philosophically well-understood and computationally well-studied notions of syntax, semantics and inference as bases on which to build. Nowadays, SIP techniques are mostly employed in the context of Knowledge Organization Systems. In MIR, SIP methods have been used to develop sophisticate representations of the contents (in the sense of "semantics") of multimedia documents, in order to support the retrieval of these documents based on a logical model. According to this model, user's information needs are predicates expressed in the same language as that used for documents representations, and a document is retrieved if its representation logically implies the query. A wide range of logical models for IR have been proposed, corresponding to different ways of capturing the uncertainty inherent in IR, of expressing document contents, of achieving efficiency and effectiveness of retrieval [4].

To a lesser extent, the database area has also contributed to MIR, by providing indexing techniques for fast access to large collections of documents. Initially, typical structures such as inverted files and B-trees were employed. When similarity-based retrieval methods started to appear, novel structures, such as R- or M-trees were developed in order to support efficient processing of range and k nearest neighbors queries [15].

Foundations

MIR is a scientific discipline, endowed with many different approaches, each stemming from a different branch of the MIR history. All these approaches can be understood as addressing the same problem through a different aspect of multimedia documents.

Documents can be broadly divided from a user perspective into two main categories: simple and complex.

A document is *simple* if it cannot be further decomposed into other documents. Images and pieces of text are typically simple documents. A simple document is an arrangement of symbols that carry information via meaning, thus concurring in forming what is called the *content* of the document. In the case of text, the symbols are words (or their semantically significant fractions, such as stems, prefixes or suffixes), whereas for images the symbols are colors and textures. Simple documents can thus be characterized as having two parallel dimensions: that of *form* (or *syntax*, or *symbol*) and that of *content* (or *semantics*, or *meaning*). The form of a simple document is dependent on the medium that carries the document. On the contrary, the meaning of a simple document is the set of states of affairs (or "worlds") in which it is true, and is therefore medium-independent. For instance, the meaning of a piece of text is the set of (spatio-temporally determined) states of affairs in which the assertions made are true, and the meaning of an image is the set of such states of affairs in which the scene portrayed in the image indeed occurs.

Complex documents (or simply documents) are structured sets of simple documents. This leads to the identification of *structure* as the third dimension of documents. Document structure is typically a binary relation, whose graph is a tree rooted at the document and having the component simple documents as leaves. More complex structures may exist, for instance those requiring an ordering between the children of the same parent (such as between the chapters of a book), or those having an arity greater than 2 (such as synchronization amongst different streams of an audio-visual document).

Finally, documents, whether simple or complex, exist as independent entities characterized by (meta-) attributes (often called *metadata* in the digital libraries literature), which describe the relevant properties of such entities. The set of such attributes is usually called the *profile* of a document, and constitutes the fourth and last document dimension.

Corresponding to the four dimensions of documents just introduced, there can be four categories of retrieval, each one being a projection of the general problem of MIR onto a specific dimension. In addition, it is possible, and in some cases desirable, to combine different kinds of retrieval within the same operation.

Retrieval based on document structure does not really lead to a genuine discovery, since the user must have already seen (or be otherwise aware of) the sought document(s) in order to be able to state a predicate on their structure. Retrieval based on document profile, from a purely logical point of view, is not different from content-based retrieval and in fact many metadata schema used for document description (notable, the Dublin Core Metadata Set) include attributes of both kinds.

Form-based Multimedia Information Retrieval

The retrieval of information based on form addresses the syntactic properties of documents. In particular, form-based retrieval methods automatically create the document representations to be used in retrieval by extracting low-level features from documents, such as the number of occurrences of a certain word in a text, or the energy level in a certain region of an image. The resulting representations are abstractions which retain that part of the information originally present in the document that is considered sufficient to characterize the document for retrieval purposes. User queries to form-based retrieval engines may be documents themselves (this is especially true in the non-textual case, as this allows overcoming the medium mismatch problem), from which the system builds abstractions analogous to those of documents. Document and query abstractions are then compared by an appropriate function, aiming at assessing their degree of similarity. A document ranking results from these comparisons, in which the documents with the highest scores occur first.

In the case of text, form-based retrieval includes most of the traditional IR methods, ranging from simple string matching (as used in popular Web search engines) to the classical *tf-idf* term weighting method, to the most sophisticated algorithms for similarity measurement. Some of these methods make use of information structures, such as thesauri, for increasing retrieval effectiveness. However, what makes them form-based retrieval methods is their relying on a form-based document representation. Two categories of queries addressing text can be distinguished:

1. *Full-text* queries, each consisting of a *text pattern*, which denotes, in a deterministic way, a set of texts; when used as a query, the text pattern is supposed to retrieve any text layout belonging to its denotation.
2. *Similarity* queries, each consisting of a text, and aimed at retrieving those text layouts which are similar to the given text.

In a full-text query, the text pattern can be specified in many different ways, e.g., by enumeration, via a regular expression, or via *ad hoc* operators specific to text structure such as proximity, positional and inclusion operators [9].

Queries referring to the form dimension of images are called *visual* queries, and can be partitioned as follows:

1. *Concrete visual queries:* These consist of full-fledged images that are submitted to the system as a way to indicate a request to retrieve "similar" images; the addressed aspect of similarity may concern color [2,7], texture [8,14], appearance [12] or combination thereof [13].
2. *Abstract visual queries:* These are artificially constructed image elements (hence, "abstractions" of image layouts) that address specific aspects of image similarity; they can be further categorized into:
   a. *Color queries:* specifications of color patches, used to indicate a request to retrieve those images in which a similar color patch occurs [6,7].
   b. *Shape queries:* specifications of one or more shapes (closed simple curves in the 2D space), used to indicate a request to retrieve those images in which the specified shapes occur as contours of significant objects [6,11].
   c. Combinations of the above [2].

Visual queries are processed by matching a vector of features extracted from the query image, with each of the homologous vectors extracted from the images candidate for retrieval. For concrete visual queries, the features are computed on the whole image, while for abstract visual queries only the features indicated in the query (such as shape or color) are represented in the vectors involved. For each of the above categories of visual queries, a number of different techniques have been proposed for performing image matching, depending on the features used to capture the aspect addressed by the category, or the method used to compute such features, or the function used to assess similarity.

Semantic Content-based Multimedia Information Retrieval

On the contrary, semantic-based retrieval methods rely on symbolic representations of the meaning of documents, that is descriptions formulated in some suitable knowledge representation language, spelling out the truth conditions of the involved document. Various languages have been employed to this end, ranging from net-based to logical. Description Logics [1], or their Semantic Web syntactic forms such as OWL, are contractions of the Predicate Calculus that are most suitable candidates for this role, thanks to their being focused on the representation of concepts and to their computational amenability. Typically, meaning representations are constructed manually, perhaps with the assistance of some automatic tool; as a consequence, their usage on collections of remarkable size (text collections can reach nowadays up to millions of documents) is not viable. The social networking on which Web 2.0 is based may overcome this problem, as groups of up to thousands of users may get involved in the collaborative indexing process (flicker).

While semantic-based methods explicitly apply when a connection in meaning between documents and queries is sought, the status of form-based methods is, in this sense, ambiguous. On one hand, these methods may be viewed as pattern recognition tools that assist an information seeker by providing associative access to a collection of signals. On the other hand, form-based methods may be viewed as an alternative way to approach the same problem addressed by semantic-based methods, that is deciding relevance, in the sense of connection in meaning, between documents and queries. This latter, much more ambitious view, can be justified only by relying on the assumption that there be a systematic correlation between "sameness" in low-level signal features and "sameness" in meaning. Establishing the systematic correlation between the expressions of a language and their meaning is precisely the goal of a *theory of meaning* (see, e.g., [5]), a subject of the philosophy of language that is still controversial, at least as far as the meaning of natural languages is concerned. So, pushed to its extreme consequences, the ambitious view of form-based retrieval leads to viewing a MIR system *as an algorithmic simulation of a theory of meaning*, in force of the fact that the sameness assumption is relied upon in every circumstance, not just in the few, happy cases in which everybody's intuition would bet on its truth. At present, this assumption seems more warranted in the case of text than in the case of non-textual media, as the representations employed by form-based textual retrieval methods (i.e., vectors of weighted words) come much closer to a semantic representation than the feature vectors employed by similarity-based image retrieval methods. Irrespectively of the tenability of the sameness assumption, the identification of the alleged syntactic-semantic correlation is at the moment a remote possibility, so the weaker view of form-based retrieval seems the only reasonable option.

Mixed Multimedia Information Retrieval

Suppose a user of a digital library is interested in retrieving all documents produced after January 2007, containing a critical review on a successful representation of a Mozart's opera, and with a picture showing Kiri in a blueish dress. This need addresses all dimensions of a document: it addresses structure because it states conditions on several parts of the desired documents; it addresses profile because it places a restriction on the production date; it addresses form- (in particular color-) and semantic-based image retrieval on a specific region of the involved image (the region must be blue and represent the singer Kiri) as well as on the whole image (must be a scene of a Mozart's opera); it addresses from-based text retrieval by requiring that the document contains a piece of text of a certain type and content. This is an example of mixed MIR, allowing the combination of different types of MIR in the context of the same query [10].

Emerging standards in multimedia document representation (notably, the ISO standard MPEG21) address all of the dimensions of a document. Consequently, their query languages support more and more mixed MIR.

Key Applications

Nowadays, MIR finds its natural context in *digital libraries*, a novel generation of information systems [3], born in the middle of the 1990s as a result of the First Digital Library Initiative. Digital Libraries are large collections of multimedia documents which are made on-line available on global infrastructures for discovery and access. MIR is a core service of any DL, addressing the discovery of multimedia documents.

New media metadata; Hypermedia metadata; Meta-knowledge; Mixed-media

Definition

Multimedia is media that utilizes a combination of different content forms. In general, a multimedia asset includes a combination of at least two of the following: text, audio, still images, animation, video, and some sort of interactivity. There are two categories of multimedia content: linear and non-linear. Linear content progresses without any navigation control for the viewer, such as a cinema presentation. Non-linear content offers users interactivity to control progress. Examples are computer games or computer based training applications. Non-linear content is also known as hypermedia content.

Metadata is data about data of any sort in any media, describing an individual datum, content item, or a collection of data including multiple content items. In that way, metadata facilitates the understanding, characteristics, use and management of data.

Multimedia metadata is structured, encoded data that describes content and representation characteristics of information-bearing multimedia entities to facilitate the automatic or semiautomatic identification, discovery, assessment, and management of the described entities, as well as their generation, manipulation, and distribution.

Historical Background

The first appearance of the idea of mixed media was Vannevar Bush's "Memex" system ("memory extender"). In his article "As we may think" [1], published 1945 in the "The Atlantic Monthly," he proposed a device that is electronically linked to a library, able to display books and films from the library and automatically follow cross-references from one work to another. The Memex was the first simple and elegant approach towards multimedia information access. Further important steps toward the use of multimedia in digital systems in the 1960s were the introduction of "hyperlinks and hypermedia" by Ted Nelson [2], which allowed the generation of non-linear presentations, the development of the mouse by Douglas Engelbart [3], which supported the direct manipulation of objects on a computer screen, and the invention of the GUI, developed at Xerox Parc, which introduced media into computing.

In particular, it was the development of the web and digital consumer electronics that allowed computing to leave the realm of research or government organizations and enter society in large. The development of personal computers in the 1980s enabled desktop publishing, which further enhanced in the 1990s into adequate manipulation software for digital media, such as Adobe's Photoshop and Flash, or Appel's Final Cut Express. Yet, only the development of new distribution platforms in the 1990s, such as CD-ROM, DVD, and essentially the World Wide Web (Web) in combination with the rise of media technologies, such as the digital photo and video camera, or midi and MP3 player, stimulated the swift growth of digital media in mixed form. The growing amount of mixed media available to the public, and more recently provided by the public in form of user-generated content, requested for effective access mechanisms, which resulted in a steady development of content description technologies, mainly based on metadata.

Over the years, a number of metadata standards have been developed, which address various aspects of multimedia data, such as

- Low-level features: usually automatically extracted from the content.
- Semantic features: describing high-level concepts in form of key-word, ratings and links.
- Structure and identification: describing the spatial and temporal arrangement of one or more multimedia assets.
- Management: describing the information gathered during the life cycle of the multimedia asset, such as information about reuse, archiving, and rights management.

The major organizations who contributed to the development of standards are: the Dublin Core Metadata Initiative [4], the World Wide Web Consortium (W3C) [5], the Society for Motion Pictures and Television Engineering (SMPTE) [6], the Moving Picture Expert Group (MPEG) [7], the TV-Anytime Consortium [8], and the International Press Telecommunications

Council (IPTC) [9]. The common definition language between all theses languages is in one or the other way the Extensible Markup Language (XML) [10], defined by W3C.

The two major approaches towards open standards for multimedia metadata, with respect to content description and distribution for multimedia assets, were certainly provided by the W3C and MPEG, a working group of ISO/IEC charged with the development of video and audio encoding standards.

The W3C provided, besides the well known markup languages HTML, XHTML, CSS, SVG, in particular the Synchronized Multimedia Integration Language (SMIL). SMIL enables simple authoring of interactive audiovisual presentations, which integrate streaming audio and video with images, text or any other media type. SMIL [11] is an HTML-like language facilitating the authoring of a SMIL application by using a simple text-editor. SMIL 1.0 received recommendation status in 1998, SMIL 2.0 in 2005, and SMIL 3.0 is under development while this article is written.

Work in the Media Annotation Work has started in September 2008. This working group (http://www.w3.org/2008/01/media-annotations-wg.html) is chartered to provide a simple ontology to support cross-community data integration of information related to media objects on the Web, as well as an API to access the information. In addition there is the Media Fragments Working Group (http://www.w3.org/2008/WebVideo/Fragments/), which address temporal and spatial media fragments in the Web using Uniform Resource Identifiers (URI). Both groups should finish their work by June 2010.

MPEG's contribution to multimedia metadata are certainly the three standards MPEG-4 [12], MPEG-7 [13] and MPEG-21 [14].

With MPEG-4 the group entered the realm of media content, arisen due to the growing need for content manipulation and interaction, and expanded MPEG-1 to support video/audio "objects," 3D content, low bitrate encoding and support for Digital Rights Management. With respect to multimedia metadata MPEG4 also provides content authors with a textual syntax for the MPEG-4 Binary Format for Scenes (BIFS) to exchange their content with other authors, tools, or service providers. First, XMT is an XML-based abstraction of the object descriptor framework for BIFS animations. Moreover, it also respects existing practice for authoring content, such as SMIL, HTML, or Extensible 3D (X3D) by allowing the interchange of the format between a SMIL player, a Virtual Reality Modeling Language (VRML) player, and an MPEG player through using the relevant language representations such as XML Schema, MPEG-7 DDL, and VRML grammar. As such, the XMT serves as a unifying framework for representing multimedia content where otherwise fragmented technologies are integrated and the interoperability of the textual format between them is facilitated.

In the mid 1990s, the need for retrieving and manipulating digital media content form exploding digital libraries requested new ways of describing multimedia content on deeper semantic granularity, which resulted in MPEG-7, the multimedia content description standard. MPEG-7 provides a large set of descriptors and description schemata for video (part 3), audio (part 4) and multimedia content, including its presentation (part 5). All schemata are described in the Description Definition Language (DDL), which is modeled on XML-Schema, a schemata language developed by the WC3. Since MPEG-7 tries to establish the richest and most versatile set of audio-visual feature description structures by embracing standards such as SMPTE, or PTC, a 1:1 mapping to the text-oriented XML schema language could not be achieved (see [15] for a detailed description of existing DDL problems). However, the goal to be a highly interoperable standard among well-known industry standards and related standards of other domains – such as the area of digital libraries and ontologies using RDF or Dublin Core, was a useful exercise.

The beginning of the 21st century established an even faster exchange of multimedia data via the web, as higher bandwidth as well as access to high quality data became a commodity. The media businesses, such as the record or film industry, feared, due to peer-to-peer technology, for their markets and requested strict digital rights management enforcement. MPEG reacted with MPEG-21: MPEG describes this standard as a multimedia framework.

Both the W3C as well as MPEG provide open standards, which are able to describe adaptive content, represented in a single file that can be targeted to several platforms, such as mobile, broadband or the web. Both organizations compete with highly successful but rather proprietary industry standards, such as Adobe's Flash standard.

The latest trend on multimedia metadata also reflects the trend towards user-generated content, namely social tagging. A tag is a keyword or term associated with or assigned to a piece of information (a picture, a map, a video clip etc), which enables keyword-based classification and search. The advantage of tagging is its ease of use. This approach, though highly popular (e.g., in YouTube [16] and Flickr [17]), carries serious problems. Typically there is no information about the semantics of a tag, no matter if it is a single tag or a bag of tags. Additionally, different people may use drastically different terms to describe the same concept. This lack of semantic distinction can lead to inappropriate connections.

Foundations

The essential models describing the internal structures of multimedia compositions and the related production processes are: the Dexter Hypertext Reference Model [18], the Amsterdam Hypermedia Model [19], HyTime [20], the reference model for intelligent multimedia presentation systems (IMMPSs) [21], MPEG-4, SMIL, and the model of Canonical processes of media production [22].

The basic five functionalities that every multimedia system needs to address are: media content, layout, timing, linking and adaptivity.

Media Content

Readers who are interested in the fundamentals of the single media elements (i.e., their low-level as well as high-level feature descriptions) are referred to the articles on audio metadata, image metadata and video metadata in this encyclopedia.

Layout

Layout deals with the arrangement and style treatment of media on a screen. This means that layout determines how a particular media item is presented at a point in time and how it is rendered when activated. A multimedia presentation layout describes "the look and feel" of a composite of all of its media components. Thus, layout adds the semantic organization that enables a viewer to quickly and efficiently absorb the multiple content streams in a multimedia presentation.

There are in general three approaches towards multimedia layout, namely

1. *Embedded Layout,* where all layout decisions are resolved at media creation time and then performed by the presentation. Here the control lies ultimately by the designer of the presentation and there is no control, besides the required rendering, at the side of the media player.
2. *Dynamic Layout*, where all layout is dynamically determined by the user's media player, depending on the multimedia document structure or the timeline of the presentation. Here, the actual visual design is mainly in the hand of the media player rather than the presentation's designer.
3. *Compositing Layout*, which decouples media content from media placement. Here, a presentation is understood as a composite of relatively autonomous objects, where each uses embedded or dynamic layout models, which are then positioned into a arrangement by a presentation designer.

The essential classes and their attributes that describe a layout are:

- A root and several region elements, which establish the primary connection between media objects elements and the layout structure.
- Basic layout classes, such as referencing (region name and ID), scaling (z-index fit), positioning (width, height, top, left, bottom, right), background (back ground color, show back ground), and audio (sound level).

Timing

Timing deals with issues on how elements in a multimedia presentation get scheduled. Moreover, once an element is active, it needs to be determined how long it will be scheduled. The aim in a multimedia presentation is to go beyond the timing concepts known from audio and video objects.

Media timing: Media objects in multimedia presentations can either be *discrete* (e.g., text, with no implicit duration) or *continuous* (e.g., a music object, with an explicit duration defined within its encoding).

Presentation timing: A reference list to one or more media objects, describing timing primitives that determine the start and end time relative to one another.

There are basically 4 different ways of defining the active period of an object:

1. *Implicit duration*, as defined when the object was created (e.g., length of a video in sec).
2. *Explicit duration*, which describes the actual duration of the media object in the application (e.g., the actual duration might be shorter or longer than the implicit duration).
3. *Active duration*, which allows repetitions or other temporal manipulations of a media object.

4. *Rendered duration*, which describes the persistence of a media object at the end of its active duration.

There are various ways to describe time in values, such as full clock value (e.g., 7:45:23.76, where the last two items present ms), partial clock values (any sort of short base notation), time count values (numbers with a additional type string, e.g., 10S for "10 s"), and time context values, which are represented in three parts: a date field (YYY:MM:DD), a time field, and a time zone field.

Usually, a type of synchronization is required, as media objects start in relation to the container they belong to. A child element in a parallel container starts relative to the start time of the parent, whereas child elements in a sequential container are started relative to the end of their predecessor.

Linking

Linking defines and activates a non-linear navigation structure within and across documents.

The simplest form of a link is a pointer. The pointer defines an address of a document (e.g., a URI) and, optionally, an offset within the document. The element that identifies that a link exists is called a source anchor. If the anchor points to anything other than the beginning of a document, this anchor is called a destination anchor. The typical elements in HTML for linking are the <a> </a>element, to define the source anchor and link address, and the <area> </area> element, which is roughly the same, but it is applied only to a part of a media object. The basic linking attributes define the uri (href), the source and destination state (e.g., play or pause), the external or target state (e.g., true or false, the display environment) and the impact of link activation on the source and destination presentation (e.g., as non-negative percentage).

Both source and destination anchor need to express temporal moments, as their activation depends on the temporal behavior of the application. The three key temporal moments to be addressable are: the destination is already active, the destination is inactive, and the destination is inactive and the begin time is unresolved.

Finally, the link needs some attribute that describe geometry, as the linking into a region of a media item is possible. The core attributes are shape (values can be rectangle, circle or poly). The size and position of the anchor are defined via the origin of the coordinate space (the 0.0 point) and the resolution of the display device (support of rendering).

Adaptivity

The aim of multimedia presentations is usually to adapt them to the needs of the user, which might address either the runtime environment available to the user, or the personalized presentation wishes by the user.

There are four techniques to customize information in a presentation:

1. *Minimum set:* The multimedia presentation assumes a minimum set of performance, and device and user characteristics and the presentation document is designed based on this lowest denominator set (manageable solution but usually no compelling content)
2. *Multiple presentation set*: Each presentation represents a quality level, which the user selects on runtime (this one-size-fits-all approach is a dead end for the current trend towards portable and quality mix devices).
3. *Over-specified presentation*: All of the potential media items are available and it is the media player at the client side which makes a selection at run time (demands too much during the making phase).
4. *Control presentation*: The presentation contains pointers to all potential alternatives and only those used by the user would be sent from the server to the client (the advantage is that the presentation does not need to send copies of each of the various data streams across the network).

The essential elements a system would need to provide any of the above techniques are:

- Switch: which establishes a collection of alternatives for an interactive multimedia presentation;
- System control attributes, such as sys_language, sys_-captions, sys_bitrate, sys_screensize, syt_cpu, etc.

Key Applications

Multimedia metadata is useful for the creation, manipulation, retrieval and distribution of mixed media sources within domains, such as

- The creative industries (e.g., fine arts, entertainment, commercial art, journalism, games, etc)

- The entertainment industries (e.g., special effects in movies and animations)
- Education (e.g., in computer based training courses and computer simulations, military or industrial training)
- Mathematical and scientific research (e.g., modeling and simulation)
- Medicine (e.g., virtual surgery or simulations of virus spread, etc)

Multimedia presentation databases

Definition

A multimedia presentation consists of a set of media objects (such as images, text objects, video clips, and audio streams) presented in accordance with various temporal constraints specifying when the object should be presented, and spatial constraints specifying where the object should be presented on a screen. Today, multimedia presentations range from the millions of PowerPoint presentations users have created the world over, to more sophisticated presentations authored using tools such as Macromedia Director. Multimedia presentation databases provide the mechanisms needed to store, access, index, and query such collections of multimedia presentations.

Historical Background

Multimedia presentations have been in existence since the 1980s, when PowerPoint emerged as a presentation paradigm and animated computer video games started gaining popularity. Both of these paradigms allowed a multimedia presentation author to specify a set of objects (collections of images, video, audio clips, and text objects) and then specify how these objects should be presented. These objects could be presented in accordance with some temporal constraints that describe when and in conjunction with which other objects a given object should be presented. As an increasing number of authoring frameworks came into being, accompanied by an increasing need to create, collaborate on, and share presentations, the notion of multimedia presentations as a programming paradigm gradually came into existence.

Buchanan and Zellweger [6] were one of the first to recognize the need to treat multimedia presentations in a rigorous framework. They recognized that presentations consisted of a set of media objects, and they proposed presenting these objects in accordance with some very simple precedence constraints.

Later, Candan et al. [8,7] extended the framework of Buchanan and Zellweger by describing a multimedia presentation as a set of media objects together with a very rich, but polynomially computable set of spatial and temporal constraints defining their presentation. They also showed how to help a presentation author identify when their presentation specifications were inconsistent and to minimally modify the presentation constraints so that consistency was restored. Related work by their co-authors showed how to deliver these presentations across a network in the presence of spatial and temporal constraints.

Adali et al. [1] introduced a relational model of data to support interactive multimedia presentations and define a variant of the relational algebra that allows users to dynamically query and create new presentations using parts of existing ones, generalizing select, project, and join operations. Lee et al. [11] present a graph data model for the specification of multimedia presentations, together with two icon-based based graphical query languages for multimedia presentations and the GCalculus (Graph Calculus), a relational calculus-style language that formalizes the use of temporal operators for querying presentation graphs that takes the content of a presentation into account. [5,4] propose methods to present the answer of a query to a multimedia database as a multimedia presentation. [9] focuses on specializations and improvements of the above methods when querying databases consisting solely of PowerPoint information.

[10] treats multimedia presentations like a temporal database, and supports querying and reuse of parts of existing presentations. It considers algebraic operators such as insert, delete, and join, as well as user interface operations such as Fast Forward/Rewind, Skip, and links to other presentation databases, etc. [13] focuses on indexing and retrieving complex Flash movies. A generic framework called FLAME (FLash Access and Management Environment) based on a 3-layer structure is presented to address this problem. This framework mines and understands the contents of the movies to address the representation, indexing and retrieval of the expressive movie elements, including heterogeneous components, dynamic effects, and the way in which the user can interact with the movie.

Foundations

A multimedia presentation consists of a set *O* of media objects and a set of constraints on the presentation of objects in *O*. A media-object *o* is a file such as an image file, a video file, a text file, or an audio file. Each type of file is assumed to have an associated player. For example, a video file may have QuickTime or the Windows Media players as its associated player.

The constraints associated with *o* fall into two categories: temporal and spatial constaints.

On the temporal side, each object *o* in *O* has two associated variables, *st(o)* and *et(o)* denoting, respectively, the start time and end time at which media object *o* is presented using its associated players. The *temporal specification* associated with a presentation is a set of constraints of the form

$$x - y <= c$$

where *x*, *y* are variables of the form $st(o_i)$, $et(o_j)$ and *c* is some constant. For example, if *o* is a video file, and there exists the constraint *et(o') – st(o) = 0*, then this means that the video object *o* should start playing as soon as object *o'* finishes being played out.

Likewise, on the spatial side, each object *o* in *O* has four variables *llx(o), lly(o), urx(y), ury(o)* denoting the *x* coordinate of the lower left corner of object *o*, the *y* coordinate of the lower left corner of object *o*, and likewise for the upper right corner's *x* and *y* coordinates. [8] presents algorithms to check the consistency of spatial and temporal constraints, and to minimally modify the spatial/temporal constraints when they are inconsistent. In addition, each object *o* in *O* has an associated set of properties that can be stored (and queried) using any object oriented database management system.

A *multimedia presentation database* ***M*** consists of a set of multimedia objects (and their associated spatial and temporal constraints). [1] defines methods to query such multimedia presentation databases.

Consider the simplest operation: selection. Suppose the query is "*Select all objects o in* $\boldsymbol{M}$ such that *C[o]* holds and such that $st(o) > 10$." In this case, the goal is to look at each multimedia presentation *m* in $\boldsymbol{M}$, and eliminate all objects *o* from *m* such that $st(o) < 10$. Also, it is necessary to eliminate all remaining objects such that *C[o]* does not hold. The objects that survive this elimination process must be presented in accordance with the original set of temporal and spatial constraints present in *m*. If m^* denotes the modification of *m* in this way, then $\sigma_C(\boldsymbol{M}) = \{m^* \mid m \text{ in } \boldsymbol{M}\}$.

In addition, [1] defines other operations that allow videos to be concatenated together using various chromatic composition operators (such as smoothing, fading, etc.), methods to perform joins across videos, and methods to execute other kinds of relational style operations.

Key Applications

There are numerous possible applications for multimedia presentation databases. A simple application is an engine to query PowerPoint presentations, of which millions exist in the world today. [9] proposes a PowerPoint database query algebra.

Another application is in the area of digital rights management. Suppose a major record company wants to identify all multimedia documents on the web that contain a clip of their copyrighted music. This corresponds to a select query on all multimedia documents on the web. The result would be a set of multimedia documents, some of which might infringe on the copyright holder's rights. The same might apply to online video on sources such as YouTube where it is not uncommon to find copyrighted material. The ability for an entertainment company to find gross violations of their copyright by searching through YouTube archives is critical.

Future Directions

As video games become ever more common, and as virtual worlds such as Second Life become increasingly popular with users, the ability to query games and *avatar* based systems will become increasingly important.

In addition, methods to index multimedia presentation databases are in their very infancy. Taking into account the graph based nature of presentation databases such as those in [1,11,2], it is important to note that methods to index graphs may have a role to play. However, multimedia presentations are more complex than labeled directed graphs because presentation constraints can potentially be satisfied in many different ways.

Multimedia Resource Scheduling

Jeffrey Xu Yu
Chinese University of Hong Kong, Hong Kong, China

Definition

Multimedia information systems are different from the traditional information systems, where continuous media (audio/video) requests special storage and delivery requirements due to (i) the large transfer rate, (ii) the storage space required, and (iii) the real-time and continuous nature. Due to the special characteristic of continuous media, different types of scheduling are proposed, namely, the disk scheduling and stream scheduling. On one hand, the disk scheduling is to tackle both the large storage space and the corresponding large transfer rate requirements. On the other hand, the stream scheduling is to schedule requests from multiple clients, in order to minimize the delay in satisfying the requests. It attempts to support as many requests as possible, and at the same time, keep the real-time and continuous nature.

Historical Background

Continuous media adds additional requirements to the traditional information systems. In order to satisfy these new requirements, new scheduling algorithms are proposed.

Disk scheduling is designed to achieve the low service latency and high disk throughput requirements [14]. Continuous media, such as audio and video, adds additional real-time constraints to the disk scheduling problem. There are two categories of disk scheduling, namely, single disk scheduling and multiple disk scheduling. The disk scheduling algorithms, for continuous media, can possibly adapt one of the conventional disk scheduling strategies, which include round-robin, SCAN [14], and EDF [12]. For single disk scheduling for continuous media, there are SCAN-EDF [13], and sorting-set [8,16] scheduling strategies. For multiple disk scheduling for continuous media, multiple disks can be accessed in parallel. The increased parallelism is mainly used to support more streams. There are two categories of multiple disk scheduling strategies, which are stripe data across the disks and replicate data across the disks. In additional, there are three schema for accessing striped data, which are called, striped retrieval, split-striped retrieval [15], and cyclic retrieval [2,3].

Stream scheduling (or session scheduling) is designed to effectively allocate and share server and network resources. It aims at supporting as many clients as possible simultaneously, within the limited server and network resources, by assigning multiple client requests to a shared data stream. Three policies are proposed to effectively select the multimedia to be shared: FCFS, MQL, and FCFS-n [10]. In [6,7], sharing is studied when a client pauses/resumes while viewing a long video. A two-level hierarchical scheduling policy is proposed to deal with time-varying load, such as the load at peek time and off-peek time, regarding the preservation of resources for the future requests [1]. In the two-level hierarchical scheduling, at the higher level, it focuses on channel allocation with consideration of how many requests will come in near future; at the lower level, it focuses on selecting clients to be served with consideration of the clients waiting time.

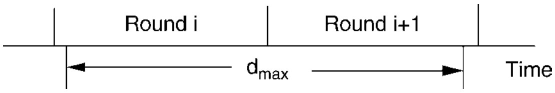
Foundations

There are mainly two types of resource scheduling in a multi-stream environment: (i) disk scheduling, and (ii) stream scheduling.

Disk Scheduling

In a multi-stream environment, multiple users are requesting to retrieve N continuous multimedia data streams in a similar time period. The system will serve each of the N data streams in rounds. In other words, in any i-th round, the system will serve all the requested data streams N by reading enough data for all the requests to be consumed until the next i+1-th round. Because there are differences between the transfer rate and the consumption rate, a scheduling strategy needs to deal with the differences between the transfer rate and the consumption rate.

Let r_c and r_t be the rate of display consumption of a data stream and the rate of data transfer from disk, respectively. And let p_{max} and d_{max} be the maximum time interval in any round and the maximum time interval between two consecutive reads for any data stream, respectively. Figure 1 illustrates the ideas on



Multimedia Resource Scheduling. Figure 1. Round length and delay between reads (Fig. 3 in [9]).

round-length and delay between two consecutive disk reads. In order to have enough data to be consumed by a display, at the consumption rate of r_c, in each round of the time interval at most p_{max} (to prevent starvation until the next round), the amount of data it needs is at least $r_c \cdot p_{max}$. The d_{max} shows the possible delay, called startup delay, to start consuming a data stream, which implies the time interval it needs to wait if it misses in the current round.

Consider the disk scheduling for multiple data streams on a single disk. The round-robin algorithm retrieves data for each data stream in a fixed order in every round. Due to the fixed order, the maximum startup delay (d_{max}) is similar to p_{max}. The SCAN algorithm [13] attempts to read more disk blocks while moving the disk head over the disk, and retrieve the requested blocks when the disk header passes over them [14]. The main advantages of the SCAN algorithm are: (i) it reduces the seek time to move the disk header from one location to another in order to read next disk block, and (ii) it maximizes the throughput of disk accesses. But, because the order of serving each data stream is not fixed, the startup delay for a given data stream can be larger up to $2p_{max}$. The SCAN-EDF algorithm [13] processes the data stream requests with the earliest deadline first, using the idea discussed in EDF [12] (Earliest-Deadline-First), and processes the requests, that be shared, using the SCAN algorithm. Note that the SCAN-EDF algorithm different from the other strategies, is not designed as a round-based algorithm. The sorting-set algorithm [8,16] is designed in a way where round-robin and SCAN are treated as special cases of it. In brief, in the sorting-set algorithm, each round is further divided into several time slots. Each time slot is conceptually considered as a sorting set (or simply set). If a round is divided into m time slots, there are m time slots, and therefore there are m sorting sets, namely, set_1, set_2,..., and set_m. All the sorting sets are served in a fixed order in each run. When there is a request to retrieve a multimedia data stream, the requested data stream is assigned to a sorting set. If the entire round is treated as a single time slot, the sorting-set algorithm behaves like the SCAN algorithm. If the requested data stream is assigned to a unique sorting set, the sorting-set algorithm behaves like the round-robin algorithm.

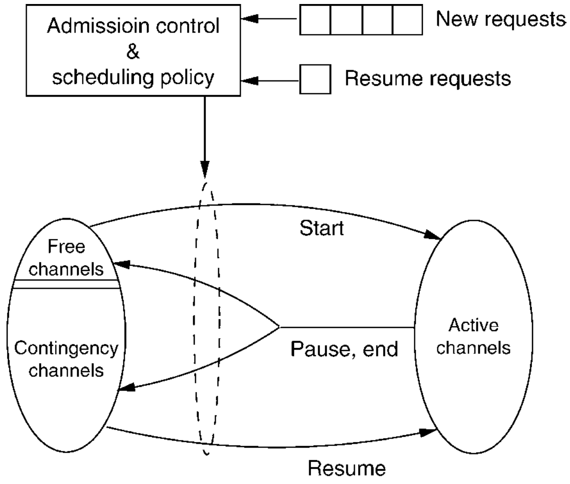
For multiple disks accessing in parallel, there are two main categories of multiple disks scheduling strategies, namely, stripe data across the disks and replicate data across the disks. There are also different schema to retrieve the striped data: striped retrieval, split-striped retrieval, and cyclic retrieval. In the striped retrieval, entire stripes are retrieved in parallel. The split-stripe retrieval [15] retrieves some consecutive units of an entire stripe rather than the entire stripe at one time. The cyclic retrieval [2,3] is designed to retrieve units of stripes for more than one data stream. The main idea behind it is to read a small portion of data for a data stream frequently. As comparison with the other striped approaches, cyclic retrieval does not need a large buffer space. Unlike the stripe based algorithms, data streams can be replicated across disks where each disk is treated individually and independently. If a data stream is requested frequently, it can be replicated in multiple disks.

Stream Scheduling

Continuous data stream retrieval needs to be guaranteed by reserving sufficient resources. The resources are referred to as logical channels (or simply channels). Stream scheduling policies need to increase the server capacity, or in other words, to increase the number of continuous data stream requests to be served with the limited number of channels. The stream scheduling needs to consider several facts regarding the possibility of sharing. There are popular videos which are viewed by many clients most of the time during a certain time period. Several clients may view the same video but start viewing at different times in a short time interval. A client may pause and then resume when viewing a long multimedia (video) at any time. The time interval between such pause and resume is not known, which can be short or long. A client may also change to another video after the pause.

Data stream sharing serves multiple clients by a single I/O stream, which is also referred to as batching of requests [4,6]. A batching factor indicates how many clients can share a single I/O stream. In order to effectively support continuous multimedia requests, some requests need to be delayed, in order to be batched with other requests. There are three batching policies: FCFS, MQL, and FCFS-n [10]. With the FCFS (First Come First Served) policy, it queues all requests into a single queue. When there is a channel available, the FCFS policy selects the video, which is requested by the first client in the queue, to be served, in a first come first served fashion. If there are other requests in the queue that request the same video, they will be served by sharing the I/O stream. The MQL (Maximum Queue Length) policy maintains a queue for a requested video. If there are *n* videos to be requested, there will be *n* queues. The MQL policy chooses the video with the maximum queue length to be served, when a channel becomes available. With the MQL policy, the videos with a small number of requests (short queue) may not be served. Therefore, unlike FCFS which is a fair policy, the MQL policy is seen as unfair to the videos that are not requested by many clients. The FCFS-n policy is similar to the FCFS policy, except that the *n* hottest videos are assigned to dedicated streams. A dedicated stream will be served in a batching window in turn, and the remaining videos, that are not assigned to a dedicated stream, are served following the FCFS policy. With the policies, the batching factor can be increased, but the amount of waiting time for a client to wait may be increased as well.

Sharing a data stream is affected by the fact that a client may pause. A new channel may need to be allocated when the client resumes. Assume that a client may resume shortly after the pause, the system may maintain some channels (contingency channels), which can improve resource utilization. The system needs to guarantee that the delay between the receipt of a resume request from a client and playback is small in order to assure client satisfaction [4,6]. Figure 2 illustrates the scheduling with contingency channels for VCR control operations (pause/resume) [6,7]. The admission control policy determines the acceptance of a new request. The scheduling policy determines which request to be served on the available channel, in order to maximize certain performance objectives [6]. When there is a pause request from a client, the admission control and scheduling policy determines if the client is the only client viewing the multimedia stream. If it is, the channel is freed and returned to either the free channel pool or the contingency pool. A certain number of contingency channels are maintained in the system. When there is a resume request from a client, the scheduling policy checks if there is another request being served within a predetermined time window, in order to maximize the possibility of sharing. If there is another request being served but is beyond the predetermined time window, the scheduling policy tries to use another contingency channel where possible. Otherwise, it will request a free channel with higher priority when such a free channel becomes available.



Multimedia Resource Scheduling. Figure 2. Channel states under contingency policy (Fig. 2 in [5]).

The arrival rate of requests to multimedia system may vary with the time of a day [11], peek time and off-peek time. The scheduling policy also needs to address the issues of time-varying load. Note: the optimal policy at the current may not be the optimal when the load changes shortly. A two-level hierarchical scheduling policy is proposed to deal with such load fluctuations [1]. The high-level scheduler controls channels allocation, whereas the low-level scheduler controls the clients selection to be served. Three high level policies are proposed to control channel allocation rate [1]: on-demand allocation, forced-wait, and pure rate control. The on-demand allocation allocates channels to requests when there are channels available. Under this policy, the waiting time for new requests may be long, which may cause clients to change from one video to another to view at high possibility. The forced-wait policy, as the name implies, forces the first request to a data stream to wait for up to a certain time (minimum wait time). The minimum wait time is a critical parameter, and can be difficult to be selected in a dynamic environment where the load changes dynamically. The pure rate control policy allocates channels uniformly in fixed time intervals (called measurement intervals) during such a time interval only a certain number of channels are used [1].

Key Applications

In a multimedia environment, multimedia objects are retrieved from either a digital library, or a video database, or an audio database, and are delivered to a large number of clients. The applications in such environments range from retrieving small multimedia objects (shopping, medias, education, etc.) to playback of large video objects (movie, entertainment, etc.).

Multimedia Retrieval Evaluation

THIJS WESTERVELD[1,2]
[1]Teezir Search Solutions, Ede, The Netherlands
[2]CWI, Amsterdam, The Netherlands

Definition

Multimedia Retrieval Evaluation is the activity of measuring the effectiveness of one or more multimedia search techniques. A common way of evaluating multimedia retrieval systems is by comparing them to each other in community wide benchmarks. In such benchmarks participants are invited to submit their retrieval results for a given set of topics, the relevance of the submitted items is checked, and effectiveness measures for each of the submissions are reported. Multimedia retrieval evaluation measures the effectiveness of multimedia retrieval systems or techniques by looking at how well the information need as described by a topic is satisfied by the results retrieved by the system or technique. Efficiency of the techniques is typically not taken into account, but may be studied separately.

Historical Background

Until the mid-1990s, no commonly used evaluation methodology existed for multimedia retrieval. An important reason for this is that the field has merely been a showcase for computer vision techniques. Many papers in the field 'proved' the technical merits and usefulness of their approaches to image processing by showing a few well-chosen, and well-performing examples. Since 1996, the problem of systematically evaluating multimedia retrieval techniques has gained more and more interest. In that year, the *Mira* (Multimedia Information Retrieval Applications) working group was formed [2]. The group, consisting of people from the fields of information retrieval, digital libraries, and library science studied user behavior and information needs in multimedia retrieval situations. Based on their findings, they developed performance measures. Around the same time, in the multimedia community, the discussion on proper evaluation started, and Narasimhalu et al. [8] proposed measures for evaluating content-based information retrieval systems. These measures are based on comparing ranked lists of documents returned by a system to the perfect, or ideal, ranking. However, they do not specify how to obtain such a perfect ranking, nor do they propose a common test set. A year later, Smith [10] proposed to evaluate image retrieval using measures from the text retrieval community and in particular from *TREC*, the Text Retrieval Conference [12] for image retrieval evaluation. Again, no dataset was proposed. At the start of the twenty-first century, the evaluation problem gained more attention within the content-based image retrieval community, with the publication of three papers discussing benchmarking in visual retrieval [3,6,7]. These three papers call for a common test collection and evaluation methodology and a broader discussion on the topic. The *Benchathlon* network (http://www.benchathlon.net) was started to discuss the development of a benchmark for image retrieval. Then, in 2001, *TREC* started a video track [9] that evolved into the workshop now known as *TRECVID*.

Today, a variety of initiatives exists for evaluating the retrieval of different types of data in a variety of contexts, a list of these is provided below under data.

Foundations

Information retrieval is interactive. In web search, for example, queries are often changed or refined after an initial set of documents has been retrieved and inspected. In multimedia retrieval, where browsing is common, interactivity is perhaps even more important. Evaluation should take interactivity into account, and measure user satisfaction. The evaluation of a system as a whole in an interactive setting is often called an *operational test*. Such tests measure performance in a realistic situation. Designing such an operational test is difficult and expensive. Many users are needed to free the experiment of individual user effects, the experimental setup should not interfere with the user's natural behavior, and learning effects need to be minimized. Also, because there are many free variables, it is hard to attribute observations to particular causes. In contrast to these tests in fully operational environments, *laboratory tests* are defined as those tests in which possible sources of variability are controlled. Thus, laboratory tests can provide more specific information, even though they are further away from a realistic setting. Also, laboratory tests are cheaper to set up, because the interactive nature is ignored, and the user is removed from the loop. Laboratory tests measure the quality of the document ranking instead of user satisfaction. While some studies exist to evaluate multimedia retrieval systems in an operational setting by investigating user satisfaction, most approaches are studied in laboratory tests.

Current laboratory tests are based on the *Cranfield* paradigm [1]. In this paradigm, a test collection consists of a fixed set of documents, a fixed set of topics, and a fixed set of relevance judgements. Documents are the basic elements to retrieve, topics are descriptions of the information needs, and relevance judgements list the set of relevant documents for each topic.

The focus in laboratory tests is on comparative evaluation. Different approaches are tested, and their relative performance is measured. The process is as follows. Each approach produces a ranked lists of documents for each topic. The quality of the ranked lists is measured based on the positions of the relevant documents in the list. The results are averaged across all topics to obtain an overall quality measure.

For successful evaluation of retrieval techniques, two components are needed in addition to a test collection [4]: a measure that reflects the quality of the search and a statistical methodology for judging whether a measured difference between two techniques can be considered statistically significant. The measures used in multimedia retrieval evaluation are typically based on precision and recall, the fraction of retrieved documents that is relevant and the fraction of relevant documents that is retrieved. To measure recall, the complete set of relevant documents needs to be known. For larger collections this is impractical and a *pooling* method is used instead. With pooling, the assumption is that with a diverse set of techniques contributing runs to the evaluation, the probability that a relevant document is retrieved at a high rank by at least one of the approaches is high. A merged set of top ranked documents is assumed to contain most relevant documents and only this set of documents is manually judged for relevance. Documents that are not judged are assumed not relevant. In reality, some unjudged documents may certainly still be relevant, but it has been shown that this is of no influence to the comparative evaluation of search systems [11,13,14].

A number of aspects influence the reliability of evaluation results. First, a sufficiently large set of topics is needed. ?] suggest a minimum of 75. Second, the measures should be stable. This means it should not be influenced too much by chance effects. Clearly, measures based on few observations are less stable than measures based on many observations. For example, precision at rank 1 (is the first retrieved document relevant) is not a very stable measure. Third, there needs to be a reasonable difference between two approaches before deciding one approach is better than the other. Sparck Jones [5] suggests a 5% difference is noticeable, and a difference greater than 10% is material. Statistical significance tests take all these aspects into account and are useful in deciding whether an observed difference between two approaches is meaningful or simply due to chance.

Key Applications

Multimedia retrieval evaluation helps to better understand what works and what does not in the area of multimedia retrieval. Many practitioners in the field benefit from the area. It gives them the opportunity to test their ideas in a principled manner and allows them to build upon approaches that are known to be successful. More and more, the papers published in renowned journals and conferences demonstrate the usefulness of their techniques by a thorough evaluation on a well-known test collection.

Data Sets

Creating a test collection for multimedia retrieval systems takes a lot of effort. Especially the generation of ground truth data for a sufficient number of topics is something that a small company or research institution cannot manage on its own. Many workshops exist that solve this problem by sharing resources in a collaborative effort to create valuable and re-usable test collections. This approach was first taken in the Text Retrieval Conferences (TREC) [12], but many others followed. Below the main collections and evaluation platforms in multimedia are listed.

The *Corel* document set is a collection of stock photographs, which is divided into subsets each relating to a specific theme (e.g., *tigers*, *sunsets*, or *English pub signs*). The collection is often used in an evaluation setting by using the classification into themes as ground truth. Given a query image, all images from the same theme –and only those– are assumed relevant. Evaluation results based on Corel are highly sensitive to the exact themes used in the evaluation [7]. In addition, Corel has a clear distinction between themes and an unusually high similarity within a theme because the photos in a theme often come from the same photographer or even the same location. This makes the collection more homogeneous than can be expected in a realistic setting.

TRECVID studies video retrieval. The data collections used have been dominated by broadcast news, but other raw and edited professional video footage is studied as well. TRECVID defines a number of tasks and provides test collections for each of them. In 2007, four main tasks existed:

Shot boundary detection: identify shot boundaries in the given video clips with their location and type (hard or soft transition).

High level feature extraction: For each of the predefined high-level features or concepts, detect the shots that contain the feature. Features that have been studied in the past include sky, road, face, vegetation, office and people marching.

Search: Given a textual description of an information need and/or one or more visual examples, find shots that satisfy this need.

Rushes summarization: Given a set of rushes, i.e., raw, unedited footage, provide a visual summary of this data that in a limited number of frames shows the key objects and events that are present in the footage.

As part of the Cross-Language Evaluation Forum (CLEF), *ImageCLEF* studies cross-language image retrieval. ImageCLEF concentrates on two main areas: retrieval of images from photographic collections and retrieval of images from medical collections.

The Initiative for the Evaluation of XML retrieval (INEX) aims to evaluate the effectiveness of XML retrieval systems. Within this initiative, the *INEX multimedia track* evaluates the retrieval of multimedia elements from a structured collection. The data collection used consists of wikipedia documents and the images contained in them. Both the retrieval of multimedia fragments (combinations of text and images) and the retrieval of images in isolation are studied.

ImagEVAL evaluates image processing technology for content-based image retrieval. The assessment focuses on features relating to what collection holders (from defence, industry and cultural sectors) expect in terms of how images may be used. The tasks include recognizing transformed images, combined textual and visual search and object detection. The collections are a heterogeneous mix of professional images including stock photography, museum archives and industrial images.

The Music Information Retrieval Evaluation Exchange (*MIREX*) evaluates subtasks of music information retrieval. The datasets used by MIREX are cd-quality audio originating from (internet) record labels that allow tracks of their artists to be published. The tasks include genre classification, melody extraction, onset detection, tempo extraction and key finding.

Multimodal Interfaces

Monica Sebillo[1], Giuliana Vitiello[1],
Maria De Marsico[2]
[1]University of Salerno, Salerno, Italy
[2]Sapienza University of Rome, Rome, Italy

Definition

Multimodal interfaces are characterized by the (possibly simultaneous) use of multiple human sensory modalities and can support combined input/output modes.

The term *multimodal* recurs across several domains. Since its first use in the field of interface design, its affinity and derivation from the terms "mode" and "modality" were discussed. According to Merriam-Webster, one of the meanings for *mode* is "a possible, customary, or preferred way of doing something," whereas *modality* can be "one of the main avenues of sensation (as vision)." In *multimodal interfaces*, the former influences the way information is conveyed, the latter refers to the exploited communication channel. Both express peculiar aspects of a multimodal system, which is expected to provide users with flexibility and natural interaction.

Early multimodal interfaces simply combined display, keyboard, and mouse with voice (speech recognition/synthesis). Later, pen-based input, hand gestures, eye gaze, haptic input/output, head/body movements have been progressively used. As a result, modern multimodal interfaces aim at emulating the natural multi-sensorial forms of human-human dialogue, relying on the integration of advanced interaction modes. To support the described variety of modes, the system underlying such an interface must include hardware to acquire and render multimodal expressions and must exploit recognition-based technologies to interpret them, with response times compatible with user's interaction pace.

Historical Background

Bolt's "Put That There" demonstration system [2] can be considered as one of the earliest multimodal systems. The underlying technology allowed a joint use of voice and gesture by processing speech in parallel with manual pointing within a virtual graphical space, where users could be made easily aware of the available facility and its usage. Spoken input was semantically processed, while deictic terms in the speech were resolved by processing the spatial coordinates derived from pointing. Since then, different proposals of multimodal interfaces can be found in literature [5,4]. Many of them aim at integrating natural languages and direct manipulation in specific application domains, such as manufacturing environments and interactive maps.

The *CHI'90 Workshop on Multimedia and Multimodal Interface Design* represented a turning point [1]. The growing interest by the international community toward this research area induced the Program Committee to focus on both the integration of scientific knowledge about this discipline and the direction of future developments. Four main topics were identified for discussion, with respect to which interfaces could be designed and examined: structural principles for composition, media appropriateness, enabling technologies, and paradigms/metaphors/models/representations. Important issues emerged, from which some years later the first remarkable set of guidelines for the design of multimodal user interfaces stemmed [9].

Following the scientific attention to the multimodal paradigm, a variety of systems rapidly came out. Both hardware and software were enhanced to integrate parallel input streams, mostly acquired by speech and pen-based gestures. One of the first such prototypes was the QuickSet system developed in 1994 [3]. It was an agent-based, collaborative, multimodal-multimedia map system, allowing the user to issue commands using a combination of speech and pen input. For illustration purposes, in [8] Oviatt provides a comparison among five different speech and gesture systems, which represented the most exemplifying research-level systems developed until the late 1990s. In her evaluation, the author takes into account some characteristics, such as the type of signal fusion and the sizes of gesture and speech vocabularies, on which integration and interpretation functionalities were based.

More recently, new combinations of speech and other modalities, such as lip movements and gaze, have been exploited thanks to advanced input/output technologies, whose effective integration into flexible yet reliable interfaces requires the underlying system robustness and performance stability. As a result, multimodal interfaces have pervaded new application domains, ranging from virtual reality systems, meant to support expert users in decision making and simulation of scenarios, to training systems and to person identification/verification systems for security purposes. Such systems may be further distinguished on the basis of their input modes, which can be either intentionally exploited by users (active input mode) such as speech and gestures, or captured by the system without an explicit request by users (passive input mode), such as facial expressions.

Foundations

In order to clarify the different aspects involved in a multimodal interface, the complexity of multimodal interaction can be described in terms of the well-known *execution-evaluation cycle* defined by Don Norman in 1988 [6].

In the case of multimodal interactive cycles, Norman's model of interaction may be reformulated as follows:

1. Establishing the goal.
2. Forming the intention.
3. Specifying the multimodal action sequence in terms of human output modalities.
4. Executing the multimodal action.
5. Perceiving the system state in terms of human input modalities.
6. Interpreting the system state.
7. Evaluating the system state with respect to the goals and the intentions.

- *Establishing the goal* is, as usual, the stage when the user determines what needs to be done in the given domain, in terms of a suitable task language.
- *Forming the intention*: at this stage the goal is translated into more precise user's intention, which will help the user determining the right sequence of actions that should be performed to achieve the goal
- *Specifying the multimodal action sequence.* The sequence of actions performed to accomplish the required task should be precisely stated at this stage. Here the complexity of multimodal interaction appears for the first time in the cycle. In fact, each multimodal action can be specified in terms of:
  1. Complementary human output sensory modalities (i.e., multiple utterances at once form the action) and/or
  2. Alternative human output sensory modalities (i.e., alternative, redundant utterances for the same action).

Examples of human output modalities include speaking, gesturing, gazing, touching, moving, facial expressions and some unintentional utterances such as blood pressure, temperature, heartbeat, excretion, etc. A user may, for instance, move an object in the interaction scene by speaking and pointing at (gesturing) the new object location (complementary modalities). Then, instead of gesturing (s)he may want to gaze at the new location on the interface where the object should be moved (alternative modality).

- *Executing each multimodal action.* At this stage, each human modality used to specify an action is translated into corresponding interaction modes. Thus, each action is executed through
  1. Complementary modes or
  2. Alternative modes

Text, speech, Braille, mimicking, eye/motion capture, haptics, bio-electrical sensoring are examples of modes used to translate human output modalities into the system input language.

When the execution of the whole sequence of multimodal actions is complete, the system reaches a new state and communicates it to the user again exploiting (possibly multiple) interaction modes, such as speech synthesis, display, haptic/tactile feedback, smell rendering and so on.

- *Perceiving the system state.* At this stage, the evaluation phase of the cycle begins. Depending on the combination of system output modes, the user may perceive the new state through multiple input sensory modalities, such as visual, auditory, tactile, and (in some revolutionary interfaces) even smelling and tasting.
- *Interpreting the system state.* Here the user is supposed to interpret the output of her/his sequence of actions to evaluate what has happened.
- *Evaluating the system state with respect to the goals and the intentions.* At the final stage, the user compares the new system state with her/his expectations, to evaluate if the initial goal has been effectively reached.

Of course a good mapping should be achieved between the execution and the evaluation phases in order to bridge what Norman calls the *gulf of execution* (i.e., the distance between user's specification of the action and the actions allowed by the system) and the *gulf of evaluation* (i.e., the distance between user's perception of the new state and her/his expectation). In multimodal interfaces the effective reduction of both gulfs crucially depends on the underlying interactive technology that must move as close as possible towards human-human forms of interaction and communication. Thus, on the execution side, human output modalities should be supported by suitable computer input devices, e.g., by mapping gaze, speech, touch, gesturing and smelling onto cameras, microphones, keyboard, haptic sensors and the most recent olfactory sensors, respectively. From the evaluation perspective, computer output and its perception by user should be also tightly linked. This requires the adoption of output devices, like display, audio and haptic/olfactory rendering devices, able to quickly and effectively reach the human input sensory system, so that the user sees, hears, touches and, in general, feels the new system state as it is communicated by the multimodal interface.

As an example, the successful execution of direct manipulation tasks within an immersive virtual reality environment may critically depend on the abolition of any latency time between the moment an action is performed, e.g., by means of datagloves, and the moment the user recognizes the touch. In this way the user perceives gesturing as an act that can be directly realized at the interface. If this cannot be achieved, any usability benefits coming from the direct manipulation paradigm would be lost.

The ultimate advantage of multimodal interfaces is increased usability, in terms of both flexibility and robustness of the interaction when either redundant or complementary information is conveyed by modes. Higher flexibility is gained since multimodal interfaces can accommodate a wide range of users, tasks and environments for which each single mode may not be sufficient. Different types of information may be conveyed using the most appropriate or even less error prone modality, while alternation of different channels may prevent from fatigue in computer use intensive tasks. Redundancy of information through different communication channels is especially desirable when supporting accessibility, since users with different impairments may benefit from information and services otherwise difficult to obtain. As for the increased robustness of the interaction, the weaknesses of one modality may be offset by the strengths of another. More semantically rich input streams can support mutual disambiguation for the execution phase. As in human-human communication, the correct decoding of transmitted messages requires interpreting the mix of audio-video signals.

An important research theme in multimodal interface design is how to integrate and synchronize different modes, taking into account that synchrony of different "tracks" of interaction in different modes, does not imply their simultaneity. At present, each unimodal technique is developed separately, with noticeable advances produced by improvements in both software recognition-based techniques and hardware input/output technologies. However, as pointed out in [9], an effective integration of the involved modal technologies requires a deep understanding of the "natural" integration patterns that characterize people's combined use of different communication modes, as widely studied by psychologists and cognitive experts. The issue of integration may become even more complex when a multimodal interface is designed to support collaborative work, namely the work by multiple users who may interact through the interface using several input/output modes, either synchronously or asynchronously, and either locally or remotely.

Key Applications

Recent advances in technology have been urging IT researchers to investigate innovative multimodal interfaces and interaction paradigms, able to exploit the increased technological power. The common key goal is to reproduce in the best possible way the interaction through different channels, typical of a human-human dialogue. As an example, real "physical" manipulation might be simulated even when the latter is not possible due to logistical problems (e.g., remote operation) or to dangerous settings (e.g., radioactive materials and areas), or when it is convenient to just simulate a real operation (e.g., for training purposes). A more natural and familiar way of managing objects and situations is also expected to improve global user performances and increase applications effectiveness.

Among the most recent efforts, research on haptic equipment deserves a mention. Related advances trigger new potentialities and convey novel features towards many domains, especially industrial, medical, and biotechnological. In the industrial world, the goal of improving competitiveness has led to the experimentation of haptic interfaces in fields like automotive and aerospace engineering, and texture manufacturing. In the medical domain, education and research activities are being increasingly improved by the adoption of haptic environments for virtual surgery simulation. Several new challenges are arising in the field of Biology/Biotechnology, where the adoption of visual interfaces connected to haptic devices is recognized as a powerful and straightforward mean to handle nano-objects, such as cells, and the possibility of force feedback offered by certain haptic systems, is envisioned as a considerable improvement of operator's perception. Last but not least, several multimodal interfaces enhanced with haptic feedback have been conceived to address major societal needs, e.g., by visually impaired people or wheelchair users.

In the following, a brief list of some further application domains is presented, where multimodal interfaces are presently investigated.

Interaction in Mobile Environments

The problem that has to be solved in applications designed for mobile environments is that hands, which are the usual interaction mediator for human-computer communication with traditional input devices, must be devoted to different crucial activities, e.g., controlling a steering wheel. In such situation, alternative modes should rather be exploited to interact with software applications such as a map browser. Moreover, user's visual attention must be focused on catching situations such as obstacles approach, so that relevant software events should be communicated for example through auditory signals, so as to relieve the user from continuously inspecting system state.

Geographic Information Systems

Multimodal interfaces are also being employed as a means to support decision makers in accessing and analyzing geospatial information in specific and critical scenarios, such as crisis management procedures and *what if* analyses. Some systems have been recently proposed, which rely on large screen displays and augmented reality tools for enhanced data visualization, as well as on collaborative advanced interfaces supporting speech and gesture recognition.

In these systems, multimodality becomes the way domain expert users can formulate appropriate requests to the underlying geographic information system and receive rapid responses, provided through different perspectives. Rapid feedback is in fact a crucial issue in situations when risk and vulnerability must be predicted as well as during exceptional events when recovery actions must be taken by users with complementary expertises.

Interaction in Adverse Settings

As discussed above, it is often necessary to substitute the human operator in adverse settings in a way that preserves both his/her health and the effectiveness of the interaction with environment objects. A much simpler case is when some communication channel might be hindered by disturbing conditions and the presence of other modes may provide possible missing information.

Multimodal Biometric Databases

Multimodal biometric databases are an example of tight integration of multiple input modes to achieve reliable person identification and verification. Fingerprints are the most well-known biometric method. More biometrics include hand conformation, iris scanning, features from face, ears or voice or handwriting. Despite noticeable progresses in biometrics research, no single bodily or behavioral trait satisfies acceptability, speed and reliability constraints of authentication in real applications. Single biometric systems are vulnerable to possible attacks, and may suffer from acquisition failures, or from the possible non-universality of the biometric feature, as in the case of deaf-mute subjects for voice recognition. The present trend is therefore towards multimodal systems, as flaws of an individual system can be compensated by the availability of a higher number of alternative biometries. Integration of single responses is a crucial point, especially when different reliability degrees can be assigned to them due to input quality or effectiveness of recognition algorithms.

Interaction in Impairment Conditions

Accessibility is a transversal issue relating to different application domains. Physical impairments call for flexible system interfaces allowing universal access to services and information. What should be affected when designing for accessibility is the structure of both input and output for each application function. Functions need parameters including both data and events triggered by user's actions. In both cases, it is necessary to adapt the format manageable by a user possibly bearing a specific disability to the one acceptable by the functions. Such adaptation could be provided by special pieces of software (wrappers). A different wrapper is needed for each different disability situation. They would be connected to suitable interfaces allowing the user to issue commands and data according to his/her ability, and translating them for function call. Information and data returned by the system undergoes a symmetrical translation. In other words, multimodal input/output should be dynamically provided. The contribution of (disabled) accessibility experts to the overall design of wrappers is essential to obtain significant results. They can suggest the best suited interaction mechanisms and the best input/output modes to use.

Future Directions

The future challenge for multimodal interfaces is the ability to better and better mimic human-like sensory perception. Such interfaces will be able to reliably interpret continuous input from more different visual, auditory, and tactile sources, chosen according to the target users' tasks. More advanced recognition of users' natural communication modalities will be supported, and more sophisticated models of multimodal interaction are expected to replace present bimodal systems. One of the problems to solve is to design and implement effective integration schemas among different modalities, based on available literature on human intersensory perception and on natural human-human multimodal interaction patterns. More research is required on human inclination to multimodal communication with applications, depending on different target tasks, and about integration and synchronization characteristics of multimodal input/output in different contexts and situations.

Multi-Pathing

KALADHAR VORUGANTI
Network Appliance, Sunnyvale, CA, USA

Definition

There can be multiple paths between a SCSI initiator and a SCSI target. Multiple paths between a host and a storage device are useful to provide more fault-tolerance as well as to improve system throughput. Multi-pathing software ensures that the same target volume is not seen as two separate LUNs by the host.

Key Points

The multiple paths can be configured in active-active or active-standby modes. In the active-active mode, both paths are actively transferring data. In the active-standby mode, the standby path does not actively transfer data. Some multi-pathing software allows for dynamic load balancing of traffic between the multiple paths. Typically, the storage controller vendor also provides the multi-pathing driver that runs on the host, and this software is usually limited to only operating with the vendor's storage devices. Software vendors are beginning to provide multi-pathing software that can interoperate with storage controllers from multiple storage vendors.

Definition

Geodata management systems (i.e., GIS and DBMS) are said to support *multiple representations* if they have the capability to record and manage multiple representations of the same real-world phenomena. For example, the same building may have two representations, one with administrative data (e.g., owner and address) and a geometry of type point, and the other one with technical information (e.g., material and height) and a geometry of type surface. Multirepresentation is essential to make a data repository suitable for use by various applications that focus on the same real world of interest, while each application has a specific perception matching its goals. Different perceptions translate into different requirements determining what information is kept and how it is structured, characterized, and valued. A typically used case is map agencies that edit a series of national maps at various scales and on various themes.

Factors that concur in generating different representations include the intended use of data and the level of detail matching the applications concerns. The former rules the choice of data structures (which objects, relationships, and attributes are relevant) and of value domains (e.g., whether the temperatures are stored in Celsius or Fahrenheit). The latter rules data resolution from coarse to precise and impacts both the semantic and the spatial representation.

Multiple representation modeling is the activity of designing a data repository that consistently holds multiple representations for various perceptions of a given set of phenomena. It relies on a multirepresentation data model, i.e., a data model with constructs and rules to define and differentiate the various perceptions and for each perception the representations of the phenomena of the real world of interest.

Historical Background

Support for different requirements over the same data set has first been provided by using multiple data files, each one designed for a specific application. Aiming at consistency, databases looked instead for ways to gather data into a single repository, generating the need for multiple representations. First came facilities to define application-specific subschemas, as simple restrictions of the database schema. Later, more flexibility was achieved through the view mechanism. In object-oriented terms, views are virtual representations derived from existing data. They create either an alternative representation for existing objects (object preserving views) or new objects composed from existing objects (object generating views). Each view defines a single new representation. However, views do not provide multiple perceptions, i.e., there is no possibility to identify the collection of views that forms a consistent whole for an application.

Similarly, the concept of is-a link was borrowed from artificial intelligence to provide for various representations of the same object in a classification refinement hierarchy. However, the concept comes with a population inclusion constraint: The subtype population is included in the supertype population. This cannot cope with situations where the populations of two object types only overlap, i.e., the two populations may have specific objects not represented in the other population. Since then, the situation has not changed much. It is only in the last decade that the need for more flexible multirepresentation and explicit support of various perceptions has been stressed by researchers.

Multirepresentation research in spatial databases can be traced back to the 1989 NCGIA program. In the early 1980's, maps began to be stored in geographic databases, and that opened up many new research tracks. The specification and implementation of cartographic generalization was one of them. It relied on the idea that cartographic generalization would allow the automatic derivation of maps at different scales from a single geographic database. Realizing that this full automation was not possible increased the focus on multiple representation databases [7,9,15]. Under the pressure of delivering maps at different scales, the first researches were, in the early 1990's, focusing on multi-scale data structures (i.e., data structures allowing to retrieve geometry of real-world objects for any given scale) and multiscale databases (i.e., databases in which the data for maps at different scales is stored and linked together). Later, the multiscale approach was refined and extended into the multirepresentation approach: scale indeed is not a concept relevant for databases and there is nowadays more to a geographical database than producing maps. The current scope of multirepresentation for GIS database comprises various techniques that can be used, within a single database, to automatically derive a coarser representation from another representation at finer resolution. These techniques aim at computing objects at coarser representations, for multiresolution analyses rather than for display. They include generic cartographic generalization operations (not driven by map display considerations) as well as operations performed on specific object types (e.g., selection of instances based on an ad-hoc predicate, aggregation of instances to create new objects). Some authors use the term model generalization to denote that the use of various techniques leads to the creation of a set of virtual databases for different resolution levels, and the mappings between their schemas (models in GIS terms). The automatic derivation rules (the mappings) allow update propagation from finer to coarser representations.

Currently, only a few simple multi-representation databases exist and are used to their expected potential.

Foundations

Early research on multi-representation in GIS was driven by cartographers' requirements. This explains why the ability to draw maps at different scales has been for long the targeted objective, popularizing the concept of *multi-scale databases*. However, many other spatial applications that need to perform spatial data analysis require storing and managing specific representations where objects may have various geometries (derived one from another or not) and also show varying thematic characteristics (e.g., have different attributes and different relationships). Thus, the research domain evolved from multi-scale databases to *multi-representation databases*. Equally important is the capability to provide each application with a consistent set of data that corresponds to its own perception of the real world of interest, in short its own database. Therefore, support of multirepresentation should be complemented with support of multiperception.

Multiscale Databases

Multiresolution databases are still referred to by the GIS community as multiscale databases, despite the fact that scale does not apply to data storing. Scale is a concept related to the drawing of maps on paper or on screen. It is the ratio between measures on a map and the corresponding measures in the real world. Scale only characterizes an intended use of data. Instead, the level of resolution of a spatial database determines what geometries are stored. It defines a threshold such that only geometries beyond the threshold are captured and stored.

In early work by Timpf, the different map representations of the same real-world entities are interconnected using a directed acyclic graph data structure. The graph allows users to navigate among maps at different scales by zoom-in and zoom-out operations. This work later developed into a more general Map Cube Model [14], supported by a theory on the structure of series of maps of the same region at different scales. Each map is described as a composition of four components: a set of lines representing transportation and hydrology networks, the set of areas, called containers, created by the lines of the trans-hydro network, areas that are a refinement of the container partition, and objects contained in these areas. The elements stored in each of the four components (e.g., streets, land-use areas, buildings) are then organized into aggregation and/or generalization hierarchies. This forms a graph for each component, where each level of the graph corresponds to a given scale.

Stell and Worboys have also proposed a solution to link a series of maps [12]. Their database organization is called a stratified map space. Each map gathers objects of a particular region that share the same semantic and spatial granularity. Maps are grouped by map spaces, i.e., sets of maps at the same granularity, describing various regions. The stratified map space is the set of all maps spaces organized according to a hierarchy based on different granularity levels. Transformation functions allow users to navigate in a stratified map space and propagate updates.

Multi-Representation Databases

Work on spatial multi-representation databases has followed two main tracks: either proposing new (conceptual) data models that include explicit description of multi-representation, or proposing frameworks that organize a set of existing classic (i.e., without multi-representation) databases into a global multirepresentation repository.

Database Models for Multiple Representations Several data models with specific concepts for multiple-representation modeling have been proposed. They range from simple solutions allowing users to associate various geometries to the same objects to more sophisticated solutions. They are discussed here according to the requirements for multiple-representation modeling.

A model for multirepresentation should allow one to characterize the same objects using different sets of attributes, and attributes with different values and different domains. This flexibility is supported by the MADS model [8], where multiple representations of a given phenomenon may be organized according to two strategies. In the first one, the various spatial and semantic descriptions of the same real-world phenomenon are merged into a single database construct. Each element of a description is qualified by a tag (called stamp) whose value identifies the perceptions for which it is relevant. Object and relationship types can thus have various sets of attributes depending on the perception. Attributes may bear various cardinalities or value domains according to the perception stamp; they can also contain a value that is a function of the perception stamp.

The Vuel approach [2] also offers the possibility of associating various semantic and spatial descriptions to the same real-world entities. In addition, various graphical representations, useful for drawing maps at different scales, can be defined. The data model is a snowflake model for spatial data warehousing. The fact table is composed of a specific kind of tuples, called vuels. A vuel fact is a particular representation of a real-world entity. It has three components: a geometry, a graphical description, and a semantic description. The vuel representation may vary according to these three dimensions. Moreover, the semantic dimension is a fact table itself with four dimensions: the class, the attribute, the domain of value, and the value dimensions. This allows the creation of various semantic descriptions by combining the dimensions (different classes, different sets of attributes, attributes with various domains and various values). OMT-G [3], a UML-based model, supports the modeling of multiple representations of data through a specific kind of relationship called conceptual generalization relationship. This relationship allows the definition of various views of the same real-world entities as subclasses of a shared super-class. The superclass describes the thematic attributes that are common to all the representations and it has no spatial representation. Each subclass describes its own view by specifying its own thematic and spatial attributes. The subclasses inherit the common attributes from the superclass. A presentation diagram shows graphical representations that may be associated to a class and the operations to obtain them. MRSL [5], another UML-based model, supports multi-representation through the introduction of two concepts: representation objects (r-objects) and integration objects (i-objects). All r-objects corresponding to the same real-word phenomenon are linked by a monovalued or multivalued link to a single i-object, whose role is to ensure consistency among them. Each r-object specifies a specific set of attributes and values for the same real-world object.

Multiple representation modeling is not limited to associating multiple sets of attributes or values to one object. In particular, when changing the level of detail, objects may disappear, whereas others may be grouped. Thus, in addition, there is the need to put into correspondence one object with several objects or two different sets of objects.

In the second strategy of the MADS approach, the various descriptions of the same phenomena belong to separate object types. They can be linked by inter-representation links that are either traditional associations or multi-associations. Multi-associations are binary relationships that, contrarily to association relationships, do not link two objects but two groups of objects. A multi-association is needed whenever the real-world entities are not represented per se, but through two different decompositions; e.g., a decomposition of a road in segments according to the number of lanes, and one according to crossroads. The other modeling approaches only support correspondence links of kind association, and the supported cardinality of the link varies: in MRSL, a i-object can be linked to r-objects through 1:1 and 1:N links thus providing support for the 1:N and N:M correspondences. In Vuel, corresponding objects can also be linked through 1:1 or 1:N inter-representation links. However, there is no support for N:M inter-representation links. OMT-G does not support inter-representation associations between objects.

Not only do objects need multiple representations, but relationships also do. This is only supported by

MADS. In MADS, all characteristics of a relationship may have various representations: its semantics (e.g., topological, aggregation, or plain), its roles, and its cardinalities. For instance, a relationship type can be a topological adjacency relationship in one description and a near relationship in another one with a more precise resolution.

In the spatial context, as data from one representation may often result from the derivation of the same data represented at another resolution, the representations of the same real-world entity are not independent and one may expect to be able to state constraints between these representations. Consistency constraints in databases are maintained through the definition of integrity constraints. Some constraints, such as cardinalities, are embedded in the concepts of the model – in particular some constraints are inherent to the multiple-representation concepts – while other constraints need to be defined in the application. MRSL is the only model proposing specific multirepresentation constraints: three kinds of rules can be associated to an i-object and its linked r-objects: consistency rules, which can be object or value correspondences, matching rules, and restoration rules. Matching rules specify how to match objects representing the same entity. They can be attribute comparison, spatial match operations, or global identifiers. Restoration rules are used to restore consistency between an i-object and its r-objects when needed.

Finally, considering that a multirepresentation database contains several representations of the same real-world phenomena, it is important to associate metadata to the representations to identify the application(s) they are relevant for, but also in order to know which representations together form a consistent whole for the application. This important requirement is fulfilled by MADS through the concept of perception stamp. In MADS, a perception stamp is a vector of values (e.g., a viewpoint and a resolution) that identifies a particular perception, and all elements of the database (types, properties, instances) are stamped for defining for which perception they are relevant. In Vuel, the designer can define views that are compositions of vuels. Each view defines a particular perception, thus providing a functionality similar to perception stamps.

Architectures for Distributed Representations Instead of proposing new concepts allowing users to integrate multiple representations of the same real-world phenomena into a unique multirepresentation database, other proposals followed a less intrusive approach. Capitalizing on the fact that there already exist many spatial databases, these approaches create a multirepresentation framework out of a set of existing classic (i.e., describing a unique perception and resolution) databases. There are two main kinds of proposals: the first one focuses on the *definition of links between objects* in corresponding databases, the second one aims at building *federated database management systems*.

In the first category, the work of Kilpelainen [6] was one of the first proposals tackling multiple representations from a database point of view. It supports bidirectional links that allow one to propagate updates in both directions and perform reasoning processes in the form of generalization operators.

In federated spatial databases, users access a set of databases through a single integrated schema, which describes virtual multirepresentation objects. During query processing, multirepresentation objects are dynamically constructed by merging all the corresponding monorepresentation objects that exist in the various databases. There have been several proposals for spatial database integration [4]. Particularly interesting are those that build the integrated schema using multirepresentation concepts, e.g., [5], based on MRSL, and [11], based on MADS. Using MRSL, each r-object in the integrated schema holds an UML tag that identifies the corresponding source database. Using MADS, perception stamps can fulfill the same functionality.

Key Applications

Cartography

As they cannot automatically derive maps at different scales from a single detailed database, national map agencies have to create several databases, one per scale. For them, multirepresentation modeling is crucial for two main reasons:

1. To propagate updates [1]: The cost of updating can be lowered by entering updates only once in a database and propagating them, at least semi-automatically, to the other databases.
2. To enforce consistency [10]: Multi-representation databases play an important role in order to

enforce consistency between the same data described at different levels of details. In addition, integrating existing databases to create a multirepresentation database allows one to detect inconsistencies between the databases.

Multi-Scale Analysis

Multirepresentation databases can benefit many applications that need to analyze data at different levels of details or defined for different viewpoints. For example, a fire monitoring application may need very detailed data on current fires (to direct the action of fire brigades as precisely as possible), only need medium-level resolution data for records of past fires, and use low-level resolution data for generic organization of fire management activities.

Other candidate applications are those relying on spatial data warehouses, using spatial OLAP and spatial data cubes to perform multi-dimensional analysis. An example is traffic accident monitoring applications, e.g., for analysis of the number of deadly accidents according to multilevel criteria (by road, region, department, or state). Multirepresentation storage of spatial data is needed in order to drill-up and drill-down the cube [2].

Future Directions

Work in progress explores the use of multirepresentation capabilities in support of modularization of knowledge repositories. In particular, the semantic web community is developing various approaches to turn huge ontologies that are being built in several knowledge domains into smaller sets of more manageable ontological modules. Existing approaches follow both the integrated direction (a single ontology is modularized) and the distributed direction (various existing ontologies are interconnected within a global knowledge sharing system). A forthcoming book on Ontology Modularization [13] is due for publication in 2008.

Synonyms

Multiple query optimization; Global query optimization; Common subexpression elimination; Optimization of DAG-structured query evaluation plans

Definition

Multi-query optimization is the task of generating an optimal combined evaluation plan for a collection of multiple queries. Unlike traditional single-query optimization, multi-query optimization can exploit commonalities between queries, for example by computing common sub-expressions (i.e., subexpressions that are shared by multiple queries) once and reusing them, or by sharing scans of relations from disk.

Historical Background

Early work on multi-query optimization includes work by Sellis [11], Park and Segev [7] and Rosenthal and Chakravarthy [9]. Shim et al. [12] consider heuristics to reduce the cost of multi-query optimization. However, even with heuristics, these approaches are extremely expensive for situations where each query may have a large number of alternative evaluation plans.

Subramanian and Venkataraman [13] consider sharing only among the best plans of the query; this approach can be implemented as an efficient, post-optimization phase in existing systems, but does not guarantee optimality. In fact, Roy et al. [10] show that it can be significantly suboptimal. Rao and Ross [8] address the problem of sharing common computation across multiple invocations of a subquery, which is a special case of multi-query optimization,

Roy et al. [10] address the problem of extending top-down cost-based query optimizers to support multi-query optimization, and present greedy heuristics, as well as implementation optimizations. Their techniques were shown to be practical and to give good results. Dalvi et al. [1] explores the possibility of sharing intermediate results by pipelining, avoiding unnecessary materializations. Diwan et al. [2] consider issues of scheduling and caching in multi-query optimization. Zhou et al. [14] discuss the implementation of multi-query optimization on a commercial query optimizer.

In addition to the motivation of optimizing a collection (batch) of queries, multi-query optimization has also been applied to other settings. For example, Mistry et al. [6] consider the issue of multi-query optimization in the context of view maintenance, while Fan et al. [3] point out the importance of multi-query processing in optimizing XPath queries.

Foundations

Multi-query optimization is more expensive than independent optimization of multiple queries, since a globally optimal plan may involve subplans that are sub-optimal for the individual queries.

Consider a batch consisting of two queries ($A \bowtie B \bowtie C$) and ($B \bowtie C \bowtie D$). A traditional system would evaluate each of these queries independently, using the individual best plans suggested by the query optimizer for each of these queries. Let these best plans be as shown in Fig. 1a. Suppose the base relations A, B, C and D each have a scan cost of 10 units (the actual unit of measure is not relevant to this example). Each of the joins have a cost of 100 units, giving a total evaluation cost of 460 units. On the other hand, in the plan shown in Fig. 1b, the common subexpression ($B \bowtie C$) is first computed and materialized on the disk at a cost of 10. Then, it is scanned twice – the first time to join with A in order to compute ($A \bowtie B \bowtie C$), and the second time to join it with D in order to compute ($B \bowtie C \bowtie D$) – at a cost of 10 per scan. Each of these joins have a cost of 100 units. The total cost of this *consolidated* plan is thus 370 units, which is about 20% less than the cost of the traditional plan of Fig. 1a. Although the benefit here is small, it could be significantly more for batches containing more queries.

The expression ($B \bowtie C$) that is common between the two queries ($A \bowtie B \bowtie C$) and ($B \bowtie C \bowtie D$) in the above example is a *common subexpression* (CSE). A relation used in multiple queries can be thought of as a special case of a common subexpression. Although there is no need to compute and store it, a scan of the relation from disk can be shared by multiple queries.

A plan for a single complex query can have common subexpressions within itself. Traditional optimizers ignore the possibility of exploiting such a common subexpression, but some of the techniques for multi-query optimization, such as [10] can exploit such common subexpressions.

Challenges

The job of a multi-query optimizer can be broken into two parts: (i) recognize possibilities of shared computation by identifying CSEs, and (ii) find a globally optimal evaluation plan exploiting the CSEs identified.

Identifying CSEs Each query can have a large number of alternative evaluation plans. Given a particular evaluation plan for each of a set of queries, it is straightforward to find common subexpressions amongst these plans. However, since the number of possible combinations of such plans is very large, enumerating them is not feasible.

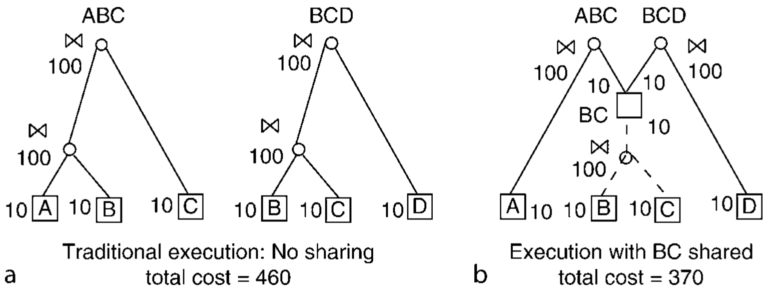
Subexpressions that could be shared between some plans for two or more queries can however be identified without enumerating all possible plan combinations. The number of such potentially common subexpressions is still very large, but smaller than the number of plan combinations.

Finding the Optimal Plan in Presence of CSEs Traditional query optimizers use dynamic programming algorithms to find the best plan for an input query. These dynamic programming algorithms are applicable because, in the absence of sharing of common subexpressions, each subplan of the overall best plan is also the best plan for the subexpression it computes.

In the presence of sharing, such a property does not hold – as shown in the example above, a globally optimal plan can consist of subplans that are not globally optimal – and therefore a straightforward dynamic programming approach does not work. The problem of finding an optimal combined plan in presence of CSEs is therefore a strictly harder problem than traditional query optimization.

Engineering an Efficient Multi-Query Optimizer

As mentioned earlier, a simple minded approach that iterates over all possible plans for each query and analyzes each combination of plans is very expensive, and infeasible for non-trivial queries. And conversely, a heuristic that only considers the individual best plan for each query does not work well, as mentioned earlier.



Traditional execution: No sharing
total cost = 460

Execution with BC shared
total cost = 370

Multi-Query Optimization. Figure 1. Example illustrating benefits of sharing computation.

A more practical approach was presented in [10]. This approach efficiently finds the set of potentially common subexpressions for a set of queries, and then identifies the subset of CSEs to share, and the best resulting consolidated plan, using an iterative greedy heuristic.

Instead of enumerating the search space of possible plan combinations, the idea is to store all the plans across all the queries in a single compact data structure called the Logical Query DAG (LQDAG). The LQDAG is a refinement of the "memo" data structure used in transformational top-down optimizers, such as Volcano [4], to memorize the best plans of the intermediate results. (Such memorization, as done in top-down query optimizers such as Volcano, is equivalent to dynamic programming, as used in System R and other bottom-up query optimizers.)

Figure 2a shows a LQDAG for the query A ⋈ B ⋈ C; this LQDAG represents the three alternative plans for the query: (A ⋈ B) ⋈ C, A ⋈ (B ⋈ C) and B ⋈ (A ⋈ C). Each square node (equivalence node) in the LQDAG represents a distinct intermediate result, and each round node (operation node) below represents a distinct plan to compute the same from the underlying intermediate results. In general, a LQDAG can represent multiple queries in a consolidated manner, with a distinct root node for each distinct query. Figure 2b shows a consolidated LQDAG for the two example queries seen earlier, A ⋈ B ⋈ C, and B ⋈ C ⋈ D.

The CSEs for the given queries correspond to equivalence nodes in the LQDAG that are shared either within the same plan, or between plans for two distinct queries; [10] presents an efficient algorithm that identifies the set of all CSEs in a single bottom-up traversal of the LQDAG.

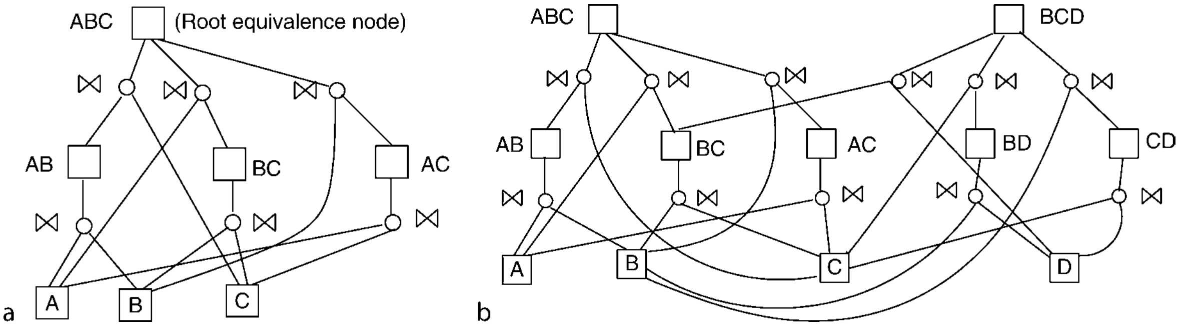
After the CSEs are identified, the next task is to find the best consolidated plan for the queries exploiting these CSEs. When the number of CSEs is large, an exhaustive search is not feasible; a natural approach is then to use a greedy heuristic that iteratively picks the CSE with the greatest benefit (i.e., whose use would result in the greatest decrease in the overall evaluation cost), terminating when no further decrease is possible. This algorithm requires that the benefit of each candidate CSE be recomputed in each iteration – this involves finding the best plan that uses the candidate CSE, in addition to the CSEs selected in earlier iterations.

With multiple such optimization calls in each iteration, a naive implementation of the greedy heuristic would be too expensive to be practical. [10] shows how to make this approach practical by (i) incorporating additional heuristics to significantly reduce the number of benefit computations, and (ii) showing how to efficiently perform a benefit computation by exploiting the LQDAG representation of the plan space. Additional insights on the task of seamlessly incorporating multi-query optimization into the Microsoft SQL-Server query optimizer are presented by Zhou et al. [14].

The above approach assumes that CSEs are materialized and read back from disk when required. Dalvi et al. [1] shows how to schedule queries such that results can be pipelined to multiple uses, even with a limited buffer space, thereby minimizing IO. Diwan et al. [2] addresses the issue of caching results in limited memory, and scheduling queries to minimize cache usage.

Key Applications

The idea of sharing computation among different queries to save on time and resources is ubiquitous.



Multi-Query Optimization. Figure 2. (a) LQDAG for A ⋈ B ⋈ C, and (b) Combined LQDAG for A ⋈ B ⋈ C and B ⋈ C ⋈ D.

As queries become increasingly expensive, the need for multi-query optimization to enable such savings is likely to increase as well. A few representative applications which motivate multi-query optimization are listed below.

- *On-Line Analytic Processing (OLAP) and Reporting*: A typical OLAP and reporting workload consists of queries with a significant amount of overlap. This overlap can occur for several reasons. For instance, queries might overlap in the kind of analysis they perform, or in the subset of data they are interested in; different queries could compute different aggregates over a join of the same set of tables. Alternatively, the queries could be against a virtual view; these queries clearly overlap at least in the computation of the result of the virtual view. Or else, the queries could involve common table expressions (specified using the WITH clause) that could be used in multiple places in the query; parts or whole of such common table expressions could be transiently materialized and reused [14]. Finally, the queries could involve correlated nested subqueries – invariant parts of these nested subqueries could be computed once and shared across invocations of the subquery [8].
- *Materialized View Maintenance*: Materialized views are supported by most major database systems today. Such materialized views must be updated when the underlying relations are updated. The maintenance plans for different views often share common computation. Mistry et al. [6] show how to exploit multi-query optimization to create an optimal view maintenance plan.
- *XML Query Processing*: In systems that store XML data in relational databases, the XPATH queries containing regular path expressions translate into a sequence of queries with significant overlap. Such queries are likely to benefit significantly from multi-query optimization [3].
- *Stream Query Processing*: Monitoring applications such as financial analysis and network intrusion detection often have to process multiple queries over a common stream of data. Such queries are likely to overlap significantly in the expressions they compute, and are likely to gain from multi-query optimization [5].

Level-of-detail (LOD) terrain modeling

Definition

Multi-resolution terrain models provide the capability of using different representations of terrain at different levels of accuracy and complexity, depending on specific application needs. The major motivation behind multi-resolution is improving performance in geometry processing and visualization. Given a terrain database, a multi-resolution model provides the mechanisms to answer queries that combine both spatial and resolution criteria. In the simplest case, one could ask for a representation of terrain on a given area and with a given accuracy in elevation. More sophisticated multi-resolution models support adaptive queries, also known as *selective refinement* queries, where resolution may vary smoothly on the extracted representation, according to some given criterion. For instance, one could ask for an accuracy of at least 10 m on a given range of elevations, and smoothly degrading to say 100 m out of that range; similarly, high resolution could be focused in the proximity of a lineal feature (e.g., a road, a river); in view-dependent visualization, it is useful to have maximal resolution close to the viewpoint, and degrade it smoothly according to distance from it; etc. Multi-resolution engines must be able to answer such queries in real time even on planetary size databases. For instance, in view-dependent visualization it may be necessary to change representation, hence answering a query, at each frame, i.e., 25–30 times per second.

Historical Background

The concept of multi-resolution has been known since the mid 1970s, with seminal work by J. Clark [3]. Since then, many different proposals appeared in the literature, both in the context of terrain modeling and, more generally, in CAD and computer graphics (see [13]).

The design of multi-resolution terrain models is inter-related with *terrain generalization*, i.e., the problem of taking a representation of a terrain and generating another, smaller representation of the same terrain at a lower accuracy. The ideal aim of terrain generalization is to achieve an optimal ratio between accuracy and size of representation. This problem has been shown to be NP-hard by Agarwal and Suri [1]. However, starting with seminal work by Fowler and Little in the late 1970s [8], many algorithms for terrain generalization have been proposed in the literature that achieve good results in practice.

Early multi-resolution models belonged to two general classes: discrete models and tree-like models. In a discrete model, a collection of alternative representations of the same terrain at different resolutions is stored. Tree-like models follow a hierarchical approach: a base model provides a coarse representation of terrain made of a small number of atomic cells; each such cell is refined by decomposition into smaller cells at the next level of resolution; refinement is repeated over several levels and the model in maintained in a tree-like data structure. A notable example is given by *restricted quadtrees*, introduced first by Von Herzen and Barr in 1987 [15] and widely developed later by several authors. This class of models is suited to efficiently manage data with a regular distribution.

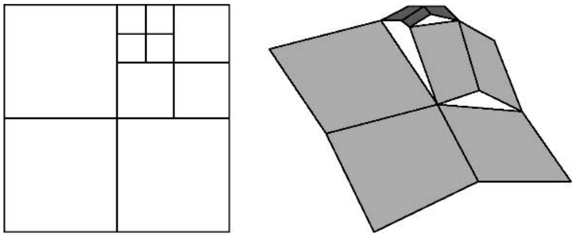
Many models developed (starting in the mid 1990s) are based on Triangulated Irregular Networks (TINs). Such models support also the manipulation of irregularly distributed data and may all be seen as instances of a general framework introduced by Puppo in 1996 [14]. The basic elements of such a framework are local modification operations, which change the resolution of a representation locally, and the hierarchical organization of such modifications on a directed acyclic graph. Such models come in many variants, they all support selective refinement and may achieve the best ratios between level of accuracy and number of triangles used in a representation.

Foundations

The simplest way to perform terrain generalization and implicitly obtain a multi-resolution model from a database of regularly distributed data is based on sub-sampling. Given a grid of elevation data at high resolution, a coarser sub-grid is obtained by regularly sampling data along each axis with a fixed step. In this case, the term *resolution* is referred to the size of cells in the resulting grid, or, in other terms, to the size of the step used to subsample. This method maintains the regular structure of data, but it provides no control on the loss of accuracy and it is not adaptive. Thus, a large number of samples may be used even to represent terrain in flat areas, while vertical error could easily exceed the allowed tolerance on areas that contain sudden variations of altitude.

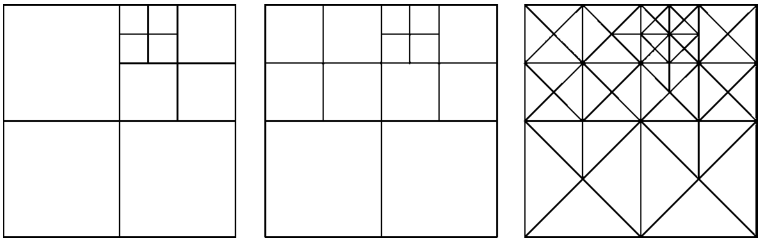
Better results can be obtained by building generalized representations in the form of TINs. Generalization algorithms, run with different thresholds on the same dataset at high resolution, provide a discrete model consisting of a collection of TIN representations at different accuracies. Being adaptive, such representations may contain small triangles in areas where terrain has large variations, and large triangles in relatively flat areas. In this case, the term *resolution* is more related to accuracy than to the size of atomic elements in the representation.

Discrete models support simple queries to extract a representation at fixed resolution. It is sufficient to select the layer corresponding to the desired resolution, and the region of interest within that layer. However, discrete models have several drawbacks: they usually provide only a small number of levels of detail; they cannot relate different representations of the same area at different resolutions; and they cannot combine data at different resolutions within a single representation. The *Delaunay pyramid* proposed by De Floriani in 1989 [5] is a TIN based discrete model in which vertical links between triangles that overlap at successive levels of detail are also maintained. In this sense, it comes midway between discrete and tree-like models. Compact data structures have also been proposed to maintain a Delaunay pyramid with many levels, and some authors have proposed variations of this model that can support selective refinement.

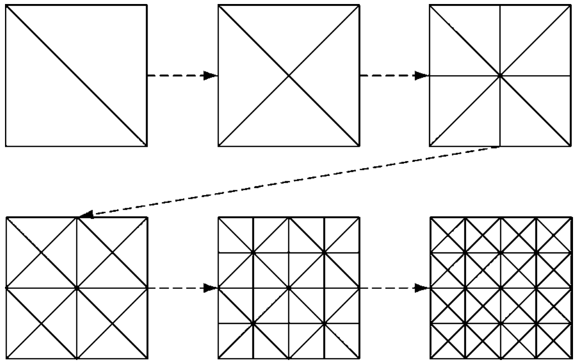


Multi-Resolution Terrain Modeling. Figure 1. A quadtree adaptive subdivision. The corresponding terrain surface has cracks.

In tree-like models, each node represents exactly the same portion of terrain covered by its children. Having a straightforward hierarchical structure, these models can also act as spatial indexes. Most successful models have been developed for regularly distributed data (for instance, the multi-resolution model adopted in *Google Earth* falls in this category). The simplest example consists of a quadtree structure built over a regular grid of data, which directly provides an adaptive version of the discrete model based on subsampling (see Fig. 1). Unfortunately, representations of adjacent portions of terrain from different levels of the quadtree cannot be combined seamlessly, as cracks would appear on the transition between quadrants from different levels (the resulting representation is said to be *non-conforming*). Restricted quadtrees solve this problem by triangulating the quadrants in a quadtree according to some predefined patterns that eliminate cracks, thus obtaining conforming representations (see Fig. 2). In practice, restricted quadtrees may support selective refinement and generate adaptive TINs made of right triangles and having their vertices at a subset of the data in the high resolution grid. Similar results are obtained by a hierarchical decomposition pattern based on triangle bisection (see Fig. 3), proposed in the mid 1990s by Lindstrom et al. [11] and later adopted in many variants by many authors. A square universe S is initially covered by two isosceles right triangles. The bisection rule subdivides a triangle into two similar triangles by splitting it at the midpoint v of its longest edge. A binary tree



Multi-Resolution Terrain Modeling. Figure 2. In a restricted quadtree, cracks can be eliminated by balancing the level of adjacent quadrants and triangulating quadrants with suitable patterns.



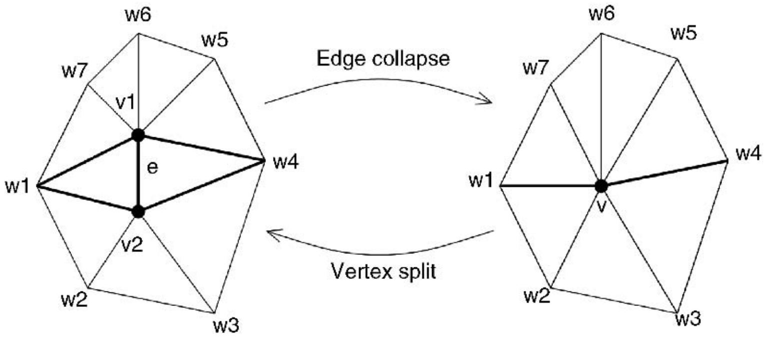
Multi-Resolution Terrain Modeling. Figure 3. Recursive triangle bisection generates a regular hierarchy based on the same triangles that appear in the restricted quadtree, but it exhibits a better flexibility.

of right triangles is thus obtained. In order to extract conforming meshes, such tree must be traversed in a proper way. In practice, adjacent triangles that are split by introducing a given vertex v will have to be split together during selective refinement. This scheme can be easily generalized to a spherical domain starting, e.g., from an octahedron. Efficient algorithms and data structures have been developed for this scheme, which can support selective refinement efficiently even on planetary size databases. A great advantage of restricted quadtrees and triangle bisection schemes comes from the regular distribution of data. Very compact implicit data structures can be designed, which have a small overhead with respect to maintaining just the single resolution data at the highest available detail, and are also suitable for implementation in secondary memory. Most efficient data structures, though, assume that the collection of all data in the database forms a unique regular grid at a given (high) resolution. In most real cases, however, the database is rather a patchwork of partially overlapping grids at different resolutions. In 2003, Gerstner proposed a data structure for the scheme based on triangle bisection, which works also in the latter case [9].

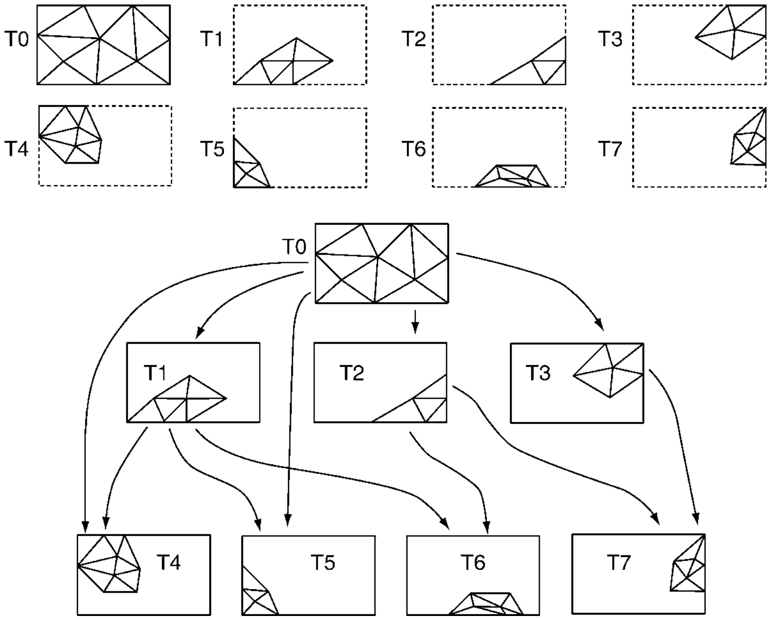
Cignoni et al. in 2003 proposed a model oriented to terrain rendering, the *BDAM*, which combines triangle bisection with adaptive schemes based on TINs [2]. The triangle bisection scheme is used as a spatial index, to obtain a coarse decomposition of the domain. Standard algorithms traverse such an index during selective refinement, and triangular blocks are collected from the proper levels of the tree. A TIN consisting of possibly a large number of triangles is associated to each triangular block in the spatial index. In this way, the representation resulting from selective refinement is in fact given by the collection of TINs corresponding to triangular blocks extracted during traversal of the index. TINs can be maintained on efficient data structures, suitable to be used in combination with Graphics Processing Units (GPUs), which may greatly improve performance. With this mechanism, performances in terrain visualization are excellent even on huge (planetary size) databases.

Other tree-like models have been developed based on TINs, which can work on arbitrary datasets. A triangle in a TIN may be refined by inserting a variable number of points either inside it or on its edges on the basis of an error-driven refinement criterion. Edges that survive across different levels of the hierarchy permit to combine surface patches from different levels of the tree, thus supporting selective refinement. Compared to models for regularly distributed data, these latter models can achieve a better ratio between size and accuracy, because no constraint is imposed on the vertex distribution, but need more complicated and expensive data structures to be stored.

Many other models developed (starting in the mid 1990s) have been oriented to irregularly distributed data and are all based on TINs and local modifications. A *local modification* is an operation that substitutes a small (local) portion of a TIN with another representation, formed by a different number of triangles. Modifications can be described either explicitly, by enumerating triangles that are eliminated and triangles that replace them, or, more often, implicitly through some mesh editing operations. The most famous and widely used editing operation is *edge collapse* (see Fig. 4), which is at the basis of the *Progressive Meshes (PM)* introduced by Hoppe in 1996 [10], and of many other models proposed in the literature. Edge collapse consists of collapsing an edge e of a TIN to a point. As a consequence, the two triangles incident at e will collapse to edges and disappear, thus the number of triangles, edges and vertices in the TIN will decrease by two, three, and one unit, respectively. Iterative edge collapse provides a powerful method for terrain generalization. The resulting sequence of collapses, together with their inverse operations called *vertex splits*, and the base mesh obtained from generalization, constitute a PM. Similar models can be built by using local modifications different from edge collapse, provided that they can be reversed. This simple structure supports the efficient extraction of terrain representations at many different levels of detail, but do not directly support selective refinement. In 1996, Puppo took a more general approach in analyzing models based on local modifications [14]. He proved that the inherent dependency relation between local modifications in a sequence is in fact a partial order, which can be encoded in a directed acyclic graph having such modifications as nodes (see Fig. 5). By traversing such graph in a proper order, selective refinement can be performed efficiently. This general framework consisting of a partial order of local modifications is called a *Multi-Triangulation (MT)*. Among the many schemes that fit in the MT framework, the data structure proposed by El-Sana and Varshney in 1999 is excellent for compactness [7]. Their model is based on edge collapse and just a binary tree of the vertices introduced from collapse operations is maintained, which contains in fact just a subset of the links in the graph of



Multi-Resolution Terrain Modeling. Figure 4. *Edge collapse* is a local modification for iterative terrain generalization: edge *e* together with its endpoints v_1 and v_2 collapse to vertex *v*; triangles adjacent to *e* together with their other edges collapse to edges w_1v and w_4v, respectively. Edge collapse is inverted by a refinement operation called *vertex split.*



Multi-Resolution Terrain Modeling. Figure 5. A sequence of arbitrary local refinement modifications substitute portions of a mesh with other, more refined, groups of triangles. The corresponding Multi-Triangulation is described by a directed acyclic graph: a modification *M* depends on another modification *M′* if and only if *M* eliminates some triangle that was introduced by *M′*.

dependencies of the MT. A clever mechanism based on enumeration of nodes in the tree allows them to retrieve the correct dependencies among nodes and run selective refinement correctly and efficiently.

In the literature, also other kinds of multi-resolution models have been proposed, which follow a functional approach rather than a geometric one (see, e.g., [12]). The basic idea is that a function can be decomposed into a simpler part at low resolution, together with a collection of perturbations called wavelet coefficients which define its details at progressively finer levels of resolution. Wavelets have been widely used for multi-resolution representation and compression of signals and images, while their applications to terrain and surfaces is more recent. The discrete computation of wavelets requires a recursive subdivision of the domain into regular cells like equilateral triangles or squares. Therefore these methods are just suitable for regularly distributed data and resulting hierarchies correspond to either quaternary triangulations or quadtrees.

For a more detailed treatment of multi-resolution terrain modeling see, e.g., [13,4,6] and references therein.

Key Applications

Multi-resolution terrain modeling is essential to manage complexity in those applications that need to either analyze or visualize terrain data at different scales, such as planetary browsers, flight simulators, CAD tools for road design, and all intensive computational tasks related to terrain, such as drainage networks and visibility.

Filter/refinement query processing

Definition

A query on a database reports those objects which fulfill a given query predicate. A query processor has to evaluate the query predicate for each object in the database which is a candidate for the result set. Multi-step query processing (filter/refinement query processing) is a technique to speed up queries specifying query predicates that are complex and costly to evaluate. The idea is to save the costs of the evaluation of the complex query predicate by reducing the candidate set for which the query predicate has to be evaluated applying one or more filter steps. The aim of each filter step is to identify as many true hits (objects that truly fulfill the complex query predicate) and as many true drops (objects that truly do not fulfill the query predicate) as possible by applying a less costly query predicate. The remaining candidates that are not pruned as drops or reported as hits in one of the filter steps need to be tested in a refinement step where the exact (costly) query predicate is evaluated. Obviously, the less costly the filter predicates are and the smaller the number of candidates that need to be refined, the higher the performance gain of a multi-step query processing is over a single-step query processing. In addition, if any of the applied filter steps is able to report true hits, first results can be reported to the user significantly sooner by a multi-step query processor compared to a single-step query processor.

Historical Background

In many database applications the management of complex objects is required. For example, the parts of a geographical map such as streets, lakes, forests – or generally *regions* – are stored as polylines or polygons. Queries on these complex objects usually involve complex query predicates that are costly to evaluate. For example, in order to retrieve all regions of a map that intersect with a given query window it is required to test the intersection of the query window and the database polygons which is computationally rather expensive. In such situations, the evaluation of the query predicate (e.g., "intersects the query window") becomes the bottleneck of query processing. Index structures are designed for shrinking down the search space of tentative hits in order to scale well for very large databases. Principally, the aim of index structures is the same as that of the filter-steps in multi-step query processing. However, index structures are only applicable for the first filter step. The reason is that index structures are designed to organize the entire database and cannot be applied to a reduced set of candidates.

To cope with complex data objects and costly query predicates, the paradigm of multi-step query processing (filter/refinement query processing) has been defined originally for spatial queries such as point queries and region queries on databases of spatial objects [6,2]. This paradigm has been applied to similarity search in databases of complex objects performing general similarity queries such as distance range queries [1,3] and k-nearest neighbor (kNN) queries [4] using costly distance functions. The key idea is to apply one or more filter steps each using cheaper query predicates (e.g., cheaper distance functions), the so-called *filter predicates*, in order to identify as many objects as possible as true hits or true drops. For the remaining candidates, for which the query predicate cannot be decided using any of the filter steps, the exact (more costly) query predicate needs to be evaluated in a refinement step. To ensure correct results, the filter predicates are required to be based on *conservative approximations* of the exact objects. This ensures that if any object does not qualify for a filter predicate, it can also not qualify for the exact query predicate. For example, if the regions of a map are conservatively approximated by minimum bounding rectangles (MBRs) of the corresponding polygons, those regions whose corresponding MBRs do not intersect with the query window cannot intersect with the query window. This conservative property of the filter predicates enables discarding true drops. On the other hand, filter predicates that are based on progressive approximations of the exact objects can be used to identify true hits. For example, if the regions of a map are progressively approximated by an incircle of the corresponding polygons, those regions whose corresponding incircle intersect with the query window do also intersect with the query window.

Foundations

Multi-step query processing is usually used in applications where the objects in the database are complex and the queries launched on objects rely on costly predicates that cannot be evaluated efficiently. In such applications, the evaluation of the query predicate becomes the bottleneck in query execution.

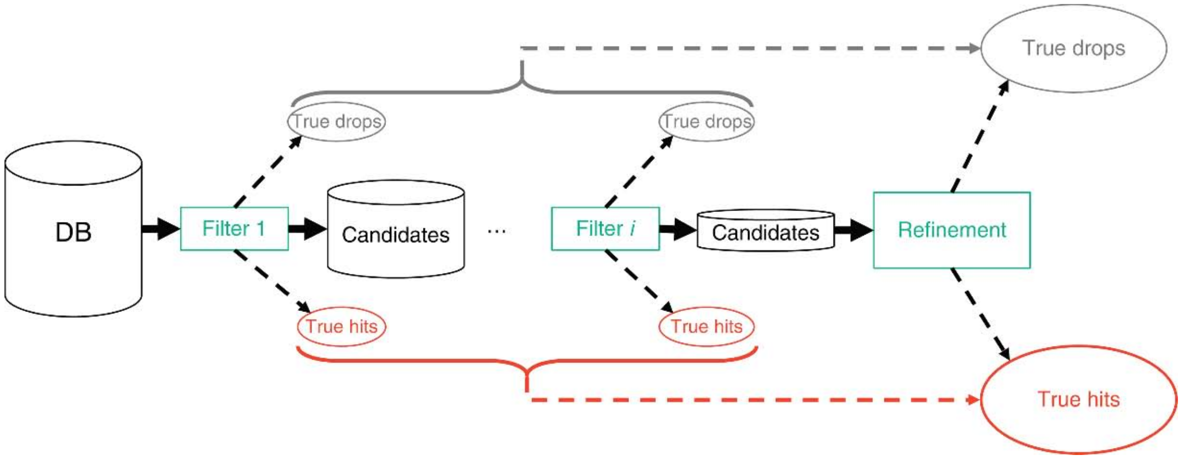
General Schema of Multi-Step Query Processing

Multi-step query processing is based on the following idea: design one or more filter predicates that can be evaluated much faster than the original query predicate and that can be used to shrink down the number of candidates for which it is unknown whether they qualify for the query predicate or not. The query processing starts with all database objects as candidates and applies the designed filters sequentially on the remaining candidates. Each filter ideally identifies true hits that can be added to the result set and true drops that can be pruned. The candidates that cannot be classified as true hits or true drops after all filter steps need to be refined by evaluating the (costly) original query predicate. This general schema is illustrated in Fig. 1. The order in which the single filter steps are applied usually depends on the cost of each filter step and on the *selectivity* of each filter step. The selectivity of a filter step determines the fraction of objects that are identified as true hit or true drop by the corresponding filter and do not need any further processing. In order to produce correct results, obviously, the filter steps must not produce false drops (i.e., drop objects that match the original query predicate according to a filter predicate) and false hits (i.e., report objects that do not match the original query predicate as hits according to a filter predicate).

In order to apply multi-step query processing, it is important to design appropriate filter predicates for the original query predicates of the given application. An appropriate filter predicate can usually be designed by designing a less complex representation that approximates the complex database objects. The evaluation of the query predicate on these less complex object approximations should be less costly than on the original object representation. In the following, special instances of multi-step query processing is discussed in more detail.

Example: Multi-Step Query Processing of Similarity Queries

Usually, similarity between objects is expressed by means of a pair-wise distance function *dist*. A high distance between two objects denotes low similarity of these objects whereas a low distance implies high similarity. For example, if the database objects are points (of any dimensionality), *dist* could be the Euclidean distance, i.e., the vicinity of the corresponding points in the Euclidean space. If the database objects are sequences, *dist* could be the Edit distance. If the database objects are spatial regions (e.g., of a map), *dist* could be the smallest Euclidean distance between the



Multi-Step Query Processing. Figure 1. General schema of multi-step query processing.

corresponding polygons. The two most important and general types of similarity queries are distance range (DR) queries and k-nearest neighbor (kNN) queries.

A distance range query is a general query type in non-standard database systems such as spatial DBS, temporal DBS, and multi-media DBS. Given a query object q, a distance function $dist(.,.)$, and a distance threshold ε, a distance range query returns all database objects o that have a distance less or equal than ε to q, i.e., $dist(q, o) \leq \varepsilon$. They can be efficiently supported using index structures or multi-step query processing.

According to the above definition the query predicate of DR queries is given as follows: all hits o must qualify the predicate $dist(q, o) \leq \varepsilon$, where q is the query object and ε is a distance threshold. The query predicate of kNN queries is quite similar to DR queries: all hits o must qualify the predicate $dist(q, o) \leq d(q, k)$, where q is the query object and $d(q, k)$ is the k-nearest neighbor distance. However, the big difference between DR queries and kNN queries is that the distance threshold ε is given in advance, whereas the value of $d(q, k)$ is usually not known at query time.

A filter predicate for identify true drops (conservative property) can be designed as follows. First, a less complex representations to conservatively approximate the exact objects should to be developed. Usually, this can only be implemented for spatial objects: the conservative approximation must completely contain the exact object, e.g., a minimum bounding box (MBR) is a conservative approximation of a polygon. A second step is essential: A (cheaper) distance function on the approximation must be designed that implements the *lower bounding property.* Let $dist(.,.)$ be the exact distance function on the exact database objects and $LB(.,.)$ the cheaper filter distance. The distance function $LB(.,.)$ lower bounds the exact distance $dist(.,.)$, if the following holds:

$$LB(x, y) \leq dist(x, y)$$

for all database objects x and y. Since the exact predicate of a similarity query usually determines the hits as those objects that have a distance less than a threshold ε to the query object q, all objects o with $\varepsilon < LB(q, o) \leq dist(q, o)$ can be excluded from the result set without further processing. In other words, the filter predicate is similar to the original query predicate, but uses LB instead of $dist$.

For example, if the database contains the regions of a map, and $dist(r_1, r_2)$ is the smallest Euclidean distance between the regions (polygons) r_1 and r_2, an appropriate filter can be designed as follows. The regions are approximated by MBRs and $LB(m_1, m_2)$ is defined as the smallest Euclidean distance between the MBRs m_1 and m_2) of r_1 and r_2, respectively. Obviously, evaluating LB on the MBRs is usually much less complex and costly than evaluating $dist$ on the polygons.

A filter predicate for identifying true hits can be designed analogously. First, a less complex representation to progressively approximate the exact objects should be developed. Again, this can usually be implemented only for spatial objects: the progressive approximation must be completely contained within the exact object, e.g., the maximal circle contained within a polygon (incircle) is a progressive approximation of that polygon. Again, a second step is essential: A (cheaper) distance function on the approximation must be designed that implements the upper bounding property. Again, let $dist(.,.)$ be the exact distance function on the exact database objects and $UB(.,.)$ the cheaper filter distance. The distance function $UB(.,.)$ upper bounds the exact distance $dist(.,.)$, if the following holds:

$$UB(x, y) \geq dist(x, y)$$

for all database objects x and y. All objects o with $\varepsilon > UB(q, o) \geq dist(q, o)$ can be added to the result set without further processing. In other words, the filter predicate is again similar to the original query predicate, but uses UB instead of $dist$.

Sometimes, an approximate representation of the database objects allows the definition of two distance functions, one lower bounding distance and one upper bounding distance. Filter predicates that do not use upper or lower distances cannot be applied to reduce the number of candidates.

Example: Algorithms for Multi-Step Query Processing of Similarity Queries

The algorithm for multi-step distance range queries is rather easy. Since the distance threshold ε is known in advance, in each filter step, true hits and/or true drops are identified as described above, depending on the property of the distance used in the filter predicate.

On the other hand, a multi-step solution for kNN queries is not trivial, because in order to determine the exact value of $d(q, k)$ that can be used to identify objects based on any filter predicates as true hits or true drops, at least k objects need to be refined.

Since the k nearest neighbors are not known in advance, the k objects that need to be refined to determine the exact value of $d(q, k)$ are not known. Obviously, this is a vicious circle.

The multi-step kNN query processing algorithm proposed in [4] tries to approximate $d(q, k)$ by refining any k objects and take the maximum value $d'(q, k)$ of these exact distances. then, a multi-step DR query with query object q and distance threshold $d'(q, k)$ is evaluated. The resulting (refined) objects are ranked in ascending exact distances to q and only the first k objects of this ranking are reported as final result.

In [7], the authors enhance this approach with an algorithm that minimizes the number of refinements. The basic assumption of this algorithm is that only a conservative filter is applied. In the case of only one filter step, the algorithm uses a ranking query in the filter step. Given a query object q and a distance function *dist*(.,.), a ranking query returns a sequence of the database objects in a database D sorted by ascending distances to q. A ranking query is a general query type in non-standard database systems such as spatial DBS, temporal DBS, and multi-media DBS and can be efficiently supported using index structures. In the context of multi-step query processing in the filter step a ranking query returns a ranking of the database objects sorted in ascending filter distances to the query object q. Initially, the first k objects of the ranking are refined and an approximation $d'(q, k)$ of the true value of $d(q, k)$ is determined from these refined distances as above. Then, in each iteration, the next object from the ranking is fetched as long as the filter distance of the next object in the ranking is greater than the current approximation $d'(q, k)$. As long as this is not the case, the currently fetched object is refined and $d'(q, k)$ is updated. This algorithmic schema can easily be extended to applying multiple filter steps. It can be shown that – if only a conservative filter is implemented – this algorithm is optimal with regard to the number of refinements.

Finally, the algorithm in [5] further enhances the preceding algorithms that take only a conservative filter into account, by additionally using a progressive filter. The algorithm is similar to that in [7] but determines $d'(q, k)$ from the progressive filter as long as this is possible rather than from exact distances. As a consequence, the proposed algorithm reduces the number of refinements significantly. It can be shown that – if both a conservative filter and a progressive filter are implemented – this algorithm is optimal with regard to the number of refinements.

Key Applications

More and more applications suffer from the increasing complexity of the objects and of the functions required to evaluate query predicates on such objects, e.g., complex distance functions or spatial intersections. In the meantime, the efficient support of multi-step query processing is essential for many application areas such as molecular biology, medical imaging, CAD systems, and multimedia databases.

In this context, one of the most important application where multi-step query processing is essential for efficient query processing is similarity search in time series databases. Time series may be very large. Typical similarity queries in time series databases are distance range queries and k-nearest neighbor queries. Due to the curse of dimensionality, similarity queries cannot efficiently be supported by indexing the time-series based on the raw data. A common method to overcome this problem is to reduce the dimensionality of the object descriptions and use this lower-dimensional feature space to index the time series. Similarity queries are then performed using the paradigm of multi-step query processing. In the filter step, approximated similarity distances are computed based on the dimensionality reduced representations, while the refinement step applies similarity distance functions based on the raw time series data. Usually, the filter step is conservative, i.e., the filter distances lower bound the exact distances.

Another important application which requires multi-step query processing is the support of proximity queries in spatial networks like road networks where point objects located within the road network that is represented by a graph are queried. Usually, the objects are positions of buildings or individuals like persons or cars that can have a static location or may move within the network. Example queries could be "retrieve all cars within the road network having a smaller distance to the fast-food restaurant Pinky than 5.0 km" or "give me the three filling stations having the smallest distance to my actual position." Since the motion of the objects is restricted by the network, i.e., objects can only move along a path in the network graph, the distance between two objects is not measured using the Euclidean distance. Rather, the length of the shortest path between two objects is used as distance measure. For each distance computation it is necessary to apply the Dijkstra algorithm which is too expensive to answer such proximity queries on large databases in real time. Therefore, distance approximations are needed, which can be computed more efficiently and can be used in the filter step of a multi-step query processing algorithm. The simplest road-network distance approximation that fulfills the lower bound criterion is the Euclidean distance. Another method to achieve suitable distance approximations is the pre-computation of distances based on certain landmarks (reference nodes). The distance approximation based on landmarks has the advantage that, in addition to the lower bounding distance approximation, it is possible to compute a distance approximation which fulfills the upper bounding property.

A further important application of multi-step query processing is the support of spatial queries in spatial databases, i.e., databases containing objects having a spatial extension. One of the most important query types in such databases is the point-in-polygon test. Given a database with two-dimensional polygon objects and a certain query point, retrieve all polygons that include the query point. Several filter steps can be applied for this problem to avoid unnecessary point-in-polygon-tests. For example, the polygons can be conservatively approximated by minimum bounding rectangles (MBRs). Obviously, MBRs that do not contain the query point can be discarded as true drops. On the other hand, progressive approximations of the polygons can be used to identify true hits.

Multi-Tier Architecture

HEIKO SCHULDT
University of Basel, Basel, Switzerland

Synonyms

n-tier architecture; Multi-layered architecture

Definition

A *Multi-tier Architecture* is a software architecture in which different software components, organized in tiers (layers), provide dedicated functionality. The most common occurrence of a multi-tier architecture is a three-tier system consisting of a data management tier (mostly encompassing one or several database servers), an application tier (business logic) and a client tier (interface functionality). Novel deployments come with additional tiers. Web information systems, for instance, encompass a dedicated tier (web tier) between client and application layer.

Conceptually, a multi-tier architecture results from a repeated application of the client/server paradigm. A component in one of the middle tiers is client to the next lower tier and at the same time acts as server to the next higher tier.

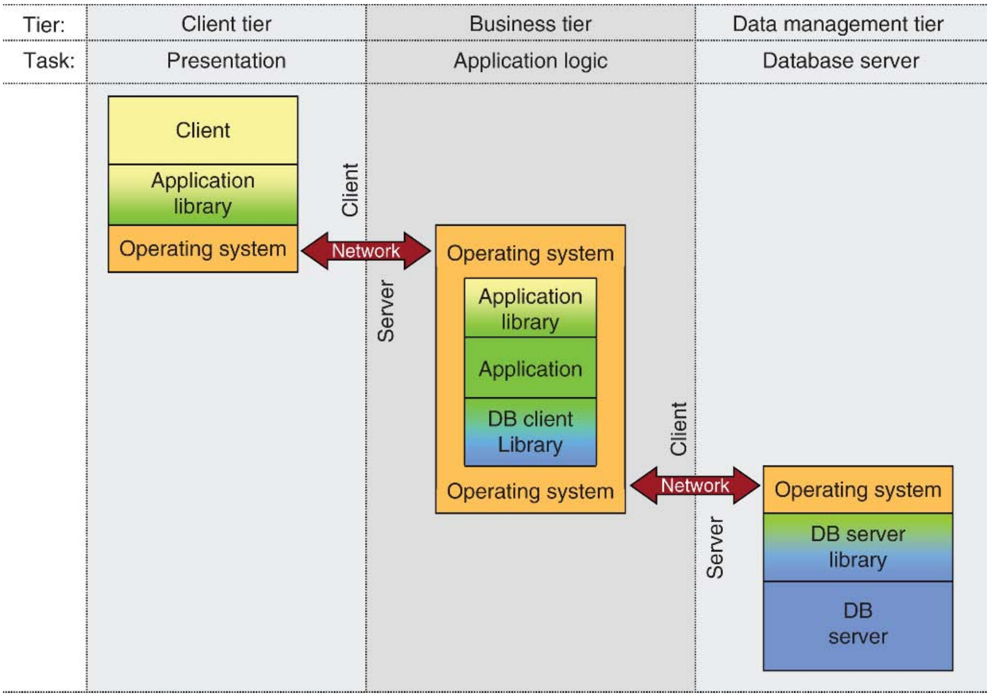
Historical Background

Early generation software systems have been built in a monolithic way. This means that all the different tasks for implementing a particular application and presenting the results to a user are provided by a single dedicated software component. With the advent of client/server architectures in the 1980s, different tasks could be separated and possibly even be distributed across network boundaries. In a client/server architecture (two tier architecture), the client is responsible for presenting the application to the user while the server is in charge of data management. For the provision of business logic, two alternatives have emerged. First, in so-called fat client/thin server architectures, the client also provides business logic, in addition to presentation and user interfaces. This can be realized by using SQL against the underlying database server in the application program run by the client, either by embedding SQL into a higher programming language or by using the database server's call level interface (e.g., JDBC, ODBC). Second, in thin client/fat server architectures, the database server also provides business logic while the client solely focuses on presentation issues. Fat servers can be realized by using persistent stored modules or stored procedures inside the database server. In the case of evolving business logic, fat client architectures, although being the most common variant of client/server systems, impose quite some challenges when new client releases need to be distributed in large deployments. In addition, a fat client architecture usually comes along with a high network load since data is completely processed at the client side. Fat servers, in contrast, impose a single point of failure and a potential performance bottleneck.

Three-tier architectures thus are the next step in the evolution of client/server architectures where both client and database server are freed from providing business logic. This task is taken over by an application layer (business tier) between client and database server. In multi-tier architectures, additional tiers are introduced, such as for instance a web tier between client and application layer.

Foundations

Multi-tier systems follow an architectural paradigm that is based on separation of concerns. The architecture considers a vertical decomposition of functionality into a stack of dedicated software layers. Between each pair of consecutive layers, a client/server style of interaction is applied, i.e., the lower layer acts as server for the next higher layer (see Fig. 1). Typical tiers in a three-tier architecture are *data management*, *business* and *client* tier. Multi-tier architectures consider additional layers, such as a web tier which hosts servlet containers and a web server and which is located between client tier and application tier.



Multi-Tier Architecture. Figure 1. Structure of a three tier architecture.

In addition to vertical decomposition and distribution across tiers, in many cases multi-tier architectures also leverage horizontal distribution within tiers. For the data management tier, this means that several distributed database servers can be used. Most commonly, horizontal distribution is applied at the business tier, i.e., providing several application server instances [7].

The main benefit of multi-tier applications is that each tier can be deployed on different heterogeneous and distributed platforms. Load balancing within tiers, especially for the application tier, is supported by distributing requests across the different application server instances. This can be implemented by a dispatcher which accepts calls from the next higher layer and distributes them accordingly (this is done, for instance, in TP Monitors which allow to distribute requests among application processes at the middle tier in a three-tier architecture).

When multi-tier architectures are used in a business context, they have to support transactional interactions. Due to the inherent distribution of software components across layers and potentially even within layers, distributed transactions are needed. This is usually implemented by a two-phase commit protocol (2PC) [5] (depending on the application server and the middleware used, this can be done, for instance, via CORBA OTS, the Java Transaction Service JTS, etc.). While 2PC provides support for atomicity in distributed transactions, it does not take into account the layered architecture where transactions at one layer are implemented by using services and operations of the next lower layer. Multi-level transactions [11] take this structure into account. SAP ERP [4], for instance, applies multi-level transactions by jointly considering the application server and data management tier. Asynchronous interactions between components in a multi-tier architecture require a message-oriented middleware (MOM). In this case, transactional semantics can be supported by persistent queues and queued transactions [1].

In order to increase the performance of multi-tier systems and to improve response times, caching is used at the application tier. For this, different database technologies such as replication, materialized views, etc. can be applied outside the DBMS [6].

Key Applications

Due to the proliferation of both commercial and open source application servers, multi-tier architectures can be found in a very large variety of different domains. Applications include, but are not limited to, distributed information systems, Web information systems, e-Commerce, etc.

Experimental Results

The Transaction Processing Performance Council (TPC) has defined a benchmark, *TPC-App*, for evaluating the business tier and in particular the performance of application servers in a three- or multi-tier architecture [10]. It includes Web Service interactions, distributed transactions, and asynchronous interactions via message-oriented middleware (reliable messaging and persistent queues).

Multivalued Dependency

Solmaz Kolahi
University of British Columbia, Vancouver,
BC, Canada

Synonyms

MVD

Definition

A *multivalued dependency (MVD)* over a relation schema $R[U]$, is an expression of the form $X \twoheadrightarrow Y$, where X, $Y \subseteq U$. An instance I of $R[U]$ satisfies $X \twoheadrightarrow Y$, denoted by $I \models X \twoheadrightarrow Y$, if for every two tuples t_1,t_2 in I such that $t_1[X] = t_2[X]$, there is another tuple t_3 in I such that $t_3[X] = t_1[X] = t_2[X]$, $t_3[Y] = t_1[Y]$, and $t_3[Z] = t_2[Z]$, where $Z = U - XY$ (XY represents $X \cup Y$). In other words, for every value of X, the value of attributes in Y is independent of the value of attributes in Z. A multivalued dependency $X \twoheadrightarrow Y$ is a special case of a *join dependency* expressed as $\bowtie[XY, X(U - XY)]$, which specifies that the decomposition of any instance I satisfying $\bowtie [XY, X(U - XY)]$ into $\pi_{XY}(I)$ and $\pi_{X(U-XY)}(I)$ is lossless, i.e., $I = \pi_{XY}(I) \bowtie \pi_{X(U-XY)}(I)$.

Movies			
Title	Director	Actor	Year
Pulp Fiction	Quentin Tarantino	John Travolta	1994
Pulp Fiction	Quentin Tarantino	Samuel L. Jackson	1994
The Matrix	Andy Wachowski	Keanu Reeves	1999
The Matrix	Andy Wachowski	Laurence Fishburne	1999
The Matrix	Larry Wachowski	Keanu Reeves	1999
The Matrix	Larry Wachowski	Laurence Fishburne	1999

Key Points

Multivalued dependencies, like functional dependencies, can cause redundancy in relational databases. For instance, in the following table, each director of the movie *The Matrix* is recorded once per actor of the movie, and this is because the instance satisfies the MVD *title* $\twoheadrightarrow$ *director.*

Multivalued dependencies have been considered in the normalization techniques that try to improve the schema of a database by disallowing redundancies. The most common normal form that takes MVDs into account is the Fourth Normal Form (4NF). The implication problem for MVDs can be solved in polynomial time. That is, given a set Σ of MVDs, it is possible to check whether an MVD $X \twoheadrightarrow Y$ is logically implied by Σ, denoted by $\Sigma \models X \twoheadrightarrow Y$, in the time that is polynomial in the size of Σ and $X \twoheadrightarrow Y$. Multivalued dependencies are usually considered together with functional dependencies (FDs) in the normalization of relational data. There is a sound and complete set of rules (axioms) that can be used to infer new dependencies from a set of MVDs and FDs defined over a relation $R[U]$:

MVD0 (complementation): If $X \twoheadrightarrow Y$, then $X \twoheadrightarrow (U - X)$.
MVD1 (reflexivity): If $Y \subseteq X$, then $X \twoheadrightarrow Y$.
MVD2 (augmentation): If $X \twoheadrightarrow Y$, then $XZ \twoheadrightarrow YZ$.
MVD3 (transitivity): If $X \twoheadrightarrow Y$ and $Y \twoheadrightarrow Z$, then $X \twoheadrightarrow (Z - Y)$.
FMVD1 (conversion): If $X \rightarrow Y$, then $X \twoheadrightarrow Y$.
FMVD2 (interaction): If $X \twoheadrightarrow Y$ and $XY \rightarrow Z$, then $X \rightarrow (Z - Y)$.

It is also known that the set {MVD0,...,MVD3} is an axiomatization for MVDs considered alone.

Graphical displays of many variables

Definition

Multivariate datasets contain much information. One- and two-dimensional displays can reveal some of this, but complex pieces of information need more sophisticated displays that visualize several dimensions of the data simultaneously. Usually several displays are needed.

Historical Background

Graphical displays have been used for presenting and analysing data for many years. Playfair [10] produced some fine work over 200 years ago. Minard prepared what Tufte has called "the finest graphic ever drawn" in the middle of the nineteenth century, showing Napoleon's advance on and retreat from Moscow, including information on the size of the army and the temperature at the time. Neugebaur introduced many innovative ideas in the 1920s and 1930s. Most of these graphics are primarily one- or two-dimensional. Techniques for displaying higher dimensional data have mainly been suggested more recently.

Foundations

There are two quite different aims of data display: analysis and presentation. Graphics aid analysts in understanding data and in determining structure. Graphics are good for identifying outliers, for picking out local patterns, and for recognizing global features. Graphics are also valuable for conveying that information to others. Wilkinson's book [13] defines a formal structure. Unwin et al. [12] discuss graphics for large datasets. Theus et al. [11] present interactive graphics for exploring data. The Handbook of Data Visualization [2] provides an overview of the current state of play.

For displaying multivariate data, indeed for displaying data in general, it is important to distinguish between different data types. Variables may be categorical, ordinal, continuous, temporal, spatial or logical (and other specialist types could be added as well). In data analysis the most common types are continuous and categorical. Ordinal may sometimes be treated as categorical (when there are only a few distinct values) and sometimes as continuous (when there are many).

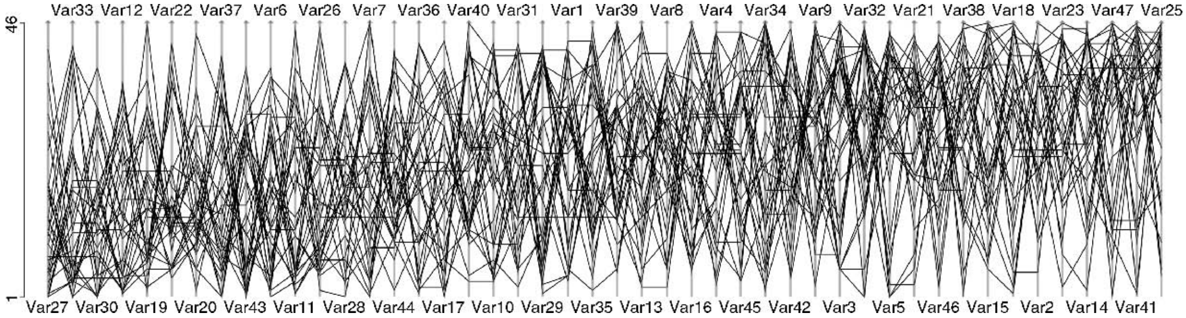
No printed graphic can display more than two dimensions fully at once. Multivariate graphics use projections, conditioning, and linking to capture higher dimensional information. Some displays can deal with very large numbers of cases (area displays such as mosaic plots), and some can potentially handle very many variables (parallel coordinate plots). Most displays are limited in both dimensions. One strategy is to use small multiples, multiple versions of the same graphic restricted to subsets of the data. Trellis plots [1] are the most important example of this approach. Whether many small displays are used or a range of large displays (which might be referred to as large multiples), more than one display will always be necessary to reveal the information in the data.

It is essential to bear in mind that to have enough evidence to confirm complex relationships lots of data are needed. Think of determining the effects of all the influences on car insurance premiums or of estimating the effects of factors in health studies (for instance breast cancer risk). Graphical methods must be able to deal with large datasets to be fully useful [12].

Multivariate Continuous Data

For multivariate continuous data the most popular graphic solution is parallel coordinate plots [8]. Further approaches include scatterplot matrices (sploms), showing all scatterplots of two variables at a time, and trellis plots, which display the data in subsets defined by conditioning variables. Glyphs, individual images for each case whose form depends on the separate variable values, can be an interesting possibility for smaller datasets (at most a few hundred cases). Matrix visualizations [2] are also interesting for smaller datasets and display each value by a color coding, with cases in the rows and variables in the columns. Including options for ordering both rows and columns is essential. Microarray data are often displayed in this way.

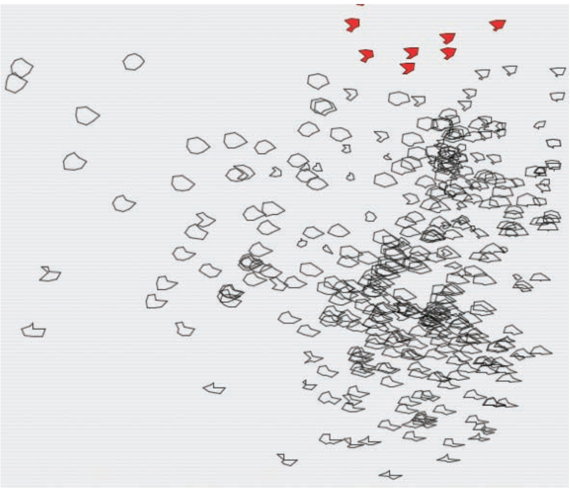
Other alternatives, known under the common heading of dimension reduction plots, display two-dimensional approximations of multivariate data, e.g., multi-dimensional scaling (MDS) and biplots. Dynamic methods include the grand tour and projection



Multivariate Visualization Methods. Figure 1. A parallel coordinate plot of the ratings of 46 wines by 32 judges. The axes are common scaled and have been ordered by mean values.

pursuit [3], both of which work by moving smoothly through two dimensional projections of the data.

Figure 1 shows a parallel coordinate plot of 32 judges' rankings of 46 American and French Cabernet wines from a 1999 tasting. The axes (one for each wine) have been given a common scale and sorted by their mean ratings from left to right, so that the highest ranked wine is on the far left and the lowest on the far right. What is striking is the lack of agreement amongst the judges. While there is a discernible trend, it is obscured by the high variability of the ratings. Most wines were ranked best by at least one judge and worst by at least one other. So the main message of this plot is that while the league table of results and statistical tests (whether the ordering was significantly non-random) imply a consensus ranking of the wines, the data convey otherwise. Parallel coordinate plots, like all high-dimensional plots, require fine-tuning to reveal information. In this case, common scaling and sorting were important tools. As parallel coordinate plots are covered in another entry, they are not discussed in detail here. One interesting new variant is represented by textile plots [9] in which the axes are rescaled to make the individual lines linking cases as horizontal as possible.



Multivariate Visualization Methods. Figure 2. An MDS display based on five variables for cars sold in Germany. Each car is represented by a circular-based glyph.

In MDS [4] the attempt is made to find a low-dimensional (almost always two dimensional) approximation to high dimensional data by positioning points so that the distances between them in the low dimensional display are close to the distances between them in the original dimension. For a high number of dimensions this is unlikely to be effective, but it often produces interesting views. The MDS display depends on the criterion used to match the distances (e.g., emphasising the absolute differences or the relative differences). Since all possible pairs must be considered, it is not efficient for large datasets. MDS displays are not unique for two reasons: an optimal solution in terms of the criterion will not necessarily be found; any solution is rotation invariant. Figure 2 shows an MDS plot of five-dimensional data on 381 cars sold in Germany. Each case is represented by a circular-based glyph using these five dimensions and two additional ones. The selected group at the top of the display seem relatively well separated in this view. They are all midsize luxury cars.

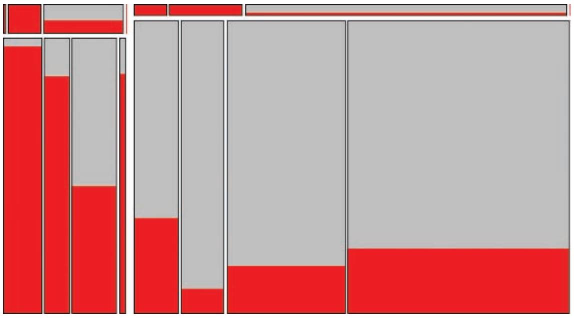
Biplots were developed by Gabriel [5]. He pointed out that both cases and variables could be plotted on the same approximating low dimensional plot. The two axes are usually chosen to be the first two principal components. Lines representing variables which are well approximated appear longer than those which represent variables badly approximated and the angles between the lines reflect the correlations between the variables in the low dimensional hyperplane. More complex biplots are also possible [6]. Like MDS displays, biplots will not work well in general, neither for many cases nor many variables, but often the two-dimensional projections produced can offer insightful views of the data.

Multivariate Categorical Data

Continuous data can always be sensibly binned and compressed, while retaining the option of zooming in to reveal the full level of detail. This does not hold for categorical data, where it may not be possible to combine any of the individual categories with others. While displays of single categorical variables are simple, the number of combinations rises exponentially with the number of variables. One binary variable can be displayed in a barchart of two columns. Twenty binary variables would give rise to 2^{20} combinations, a little over a million, many of which are likely to be empty, even for extremely large datasets.

Classic mosaicplots were suggested by Hartigan [7] for displaying a small number of categorical variables in a multivariate way. Other variations (multiple barcharts, fluctuation diagrams, equal binsize plots, doubledecker plots) [12] are often more useful. All depend very much on a careful choice of the ordering of variables and on an informative choice of size and aspect ratio. The ordering of variables determines which comparisons can be made, while the aspect ratio influences how well the comparison can be made.

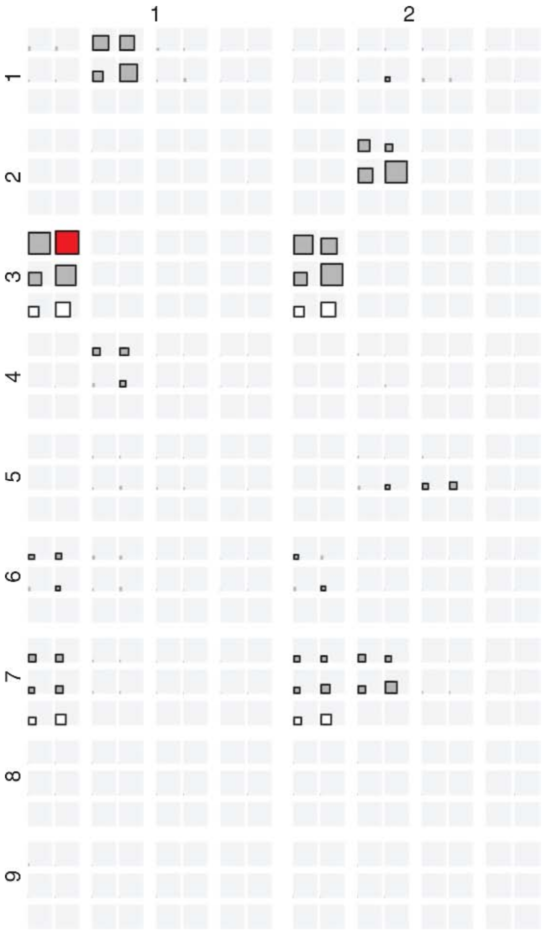
Figure 3 shows a mosaic plot of the Titanic data with the order of variables, gender, age, class. The block of four equally tall columns at the left of the display shows the numbers of adult women in each of the three passenger classes and the crew, with the proportion who survived highlighted. It is obvious that survival rates for adult women declined across the three passenger classes (the number of women in the crew was too small for any conclusion to be drawn). The next block of four columns relates to adult males and shows that the second class adult males had the lowest survival rate, a rather surprising result. The smaller bars at the top of the display refer to the children on board. The survival rates for males and females within classes can be compared approximately in this display, but clearly another display would be better for that, one using the variable ordering class, age, gender. Even in this dataset with only four variables, one plot is not enough.



Multivariate Visualization Methods. Figure 3. A mosaicplot of the numbers who sailed on the Titanic with the survivors selected. Women are to the left and men to the right, adults are below and children above. Within these groups the classes are ordered first, second, third, crew.

The main idea underlying all mosaicplots is that each combination of variable values is displayed by a rectangle whose area is proportional to the number of cases with that combination. The layout of the combinations is key in determining the interpretation, which can be difficult at the best of times, and is eased by providing interactive tools to query and adjust the graphic. Multiple barcharts are for comparing distributions of subsets (and are therefore related to trellis plots). Fluctuation diagrams are best for larger numbers of combinations to identify which are most common. Equal binsize plots and doubledecker plots are for comparing highlighted proportions.

Figure 4 shows a fluctuation diagram of a dataset from the Pakistan Labour Force Survey. Five variables are considered (the numbers of categories, including missings, are in brackets): gender [2], relation to head of household [9], marital status [4], literacy [3], and urban/rural [2], making 432 possible combinations in all. Although there are just under 140,000 cases, many of the combinations are empty or rare (e.g., few women and few single men are heads of households). The biggest single combination (male, son in household, never married, literate, living in a rural area) is highlighted and includes 9,678 cases or 7% of the dataset. Using interactive querying and animating the construction of the plot, one variable at a time, aids interpretation considerably. No display of several categorical variables



Multivariate Visualization Methods. Figure 4. A fluctuation diagram of five variables from the Pakistani Labour Force Survey: gender, relation to head of household, marital status, literacy, urban/rural. The biggest single combination is highlighted.

at once can either be easy to grasp immediately or convey all the potentially available information.

Interactive Graphics and Multivariate Graphics

Although both parallel coordinate plots and mosaicplots can be used for static plots, they are much more effective when used interactively. Their necessarily complex nature (after all, they have to display multivariate structure) demands careful scrutiny to grasp the information in them to the full, and the gain of understanding can be considerably enhanced when these graphics are empowered with interactive tools.

Interactive graphics may also be used to gain insight into multivariate datasets using one- or two-dimensional displays. Multiple linked simple displays of the same dataset can be easier to interpret than complex multivariate plots.

Key Applications

Descriptive statistics and Exploratory Data Analysis.

Future Directions

Many other more or less esoteric multivariate visualizations have been proposed. None should be dismissed out of hand, every visualization is probably ideal for some particular dataset. Nevertheless any succesful graphic should satisfy a number of criteria: it should be based on a readily recognizable and interpretable concept; it should be flexible and capable of being made interactive; it should be able to handle more than just three or four dimensions.

Displaying and interpreting even four-dimensional data is tricky. Dominating features can usually be seen, more subtle effects cannot. In higher dimensions the difficulties become much greater. At the moment it is impossible to visualize large numbers of categorical variables and although several hundred continuous variables can readily be displayed in parallel coordinate plots, the chances of identifying important features are slim. Nevertheless, graphics displays are useful for checking results found analytically and this can be very valuable. Visualizing multivariate data is new and progress is to be expected.

Visualization is currently mainly used for presentation of data, rather than for exploration of data. A single graphic can only display a limited number of aspects of a multivariate dataset and many are needed to convey all information available. The development of multivariate graphics should consider the design of sets of graphics rather than more elaborate versions of single ones. More interactive tools will have be developed. Sorting, rescaling, and querying are just some of the basics required.

Visualization is an important component of data analysis. It provides a complementary approach to analytic modeling and is much more suited to carrying out exploratory data analysis. Results found by models should be checked with graphics and ideas generated with graphics should be investigated analytically. The tighter integration of analytic and graphical methods would be of great advantage.

Multi-version databases; Multi-version concurrency control; Multi-version concurrency control algorithms

Definition

Given a multi-version database, where each data item is a sequence of its versions. The number of versions of a data item may be limited or not. If it is unlimited, then each update of a data item over the limit gives rise to its next version. If it is limited, than each update of a data item replaces its oldest version. In case of limited number of versions, a database is called a K-version database. In multi-version databases any read operation of a data item, subsequent to a write operation of this data item, may access any of its currently existing versions. Thus, a multi-version schedule of a transaction set differs form the ordinary, mono-version schedule by a mapping of the data item read operations into the data item version read operations. Multi-version serializability plays the same role for the multi-version databases, as serializability for the ordinary, mono-version ones. Multi-version serializability is used to prove correctness of a concurrent execution of a set of transactions, whose read and write operations interleave, and moreover, read operations may access one of many available versions of a data item.

Historical Background

Multi-version serializability problem was a hot research topic in mid eighties. First works were published by P.A. Bernstein and N. Goodman [2,3] in 1983. Research was continued by G. Lausen [7], next by S. Muro, T. Kameda, and T. Minoura [8]. The next group of researchers involved was composed of C.H. Papadimitriou, P.C. Kanellakis, and T. Hadzilacos [6,9]. There is a lot of work devoted to different variants of multi-version concurrency control algorithms. A comprehensive background may be found in [5].

Foundations

Definition of a multiversion schedule. A *multiversion schedule mvs* of a set of transactions τ is a triple $mvs(\tau) = (T(\tau), h, <_{mvs})$, where (i) $T(\tau)$ is a the set of all database operations involved in the transactions of the set τ extended by the database operations of two hypothetical initial and final transactions and which respectively write the initial state of the database and read the final state of the database; (ii) h is a function which maps each read operation $r_{ij}(x) \in T(\tau)$ into a write operation $w_{kl}(x) \in T(\tau)$; and (iii) $<_{mvs} = \cup_i <_{T_i}$ is a partial order relation over $T(\tau)$ such that: if $T_{ij} <_{T_i} T_{ik}$ then $T_{ij} <_{mvs} T_{ik}$, and if $h(r_{ij}(x)) = w_{kl}(x)$ then $w_{kl}(x) <_{mvs} r_{ij}(x)$. Function h defined above maps a read operation of a data item into the write operation of a version of this data item – more precisely – into the write operation which creates the version of the data item read. Relation $<_{mvs}$ is defined by two conditions. The first one states that $<_{mvs}$ honors all orderings stipulated by transactions of the set τ. The second one states that a transaction cannot read a version of a data item until it has been created. A multi-version schedule is *serial* if no two transactions are executed concurrently, otherwise, it is *concurrent.*

Multiversion schedule equivalence. Two multiversion schedules are equivalent if they are *view* and *state equivalent.* Two multiversion schedules $mvs(\tau) = (T(\tau), h, <_{mvs})$ and $mvs'(\tau) = (T(\tau), h', <_{mvs'})$ of the set τ are *view equivalent* if and only if $h = h'$. If the transactions of two multi-version schedules $mvs(\tau)$ and $mvs'(\tau)$ receive an identical view of the database, i.e., if both multiversion schedules are view equivalent, then all the write operations issued by transactions in both schedules are the same. Two multiversion schedules $mvs(\tau) = (T(\tau), h, <_{mvs})$ and $mvs'(\tau) = (T(\tau), h', <_{mvs'})$ of the set of transactions τ are *final-state equivalent* if and only if for every initial state of the database and any computations performed by the transactions contained in τ the final states of the database reached as the result of schedules $mvs(\tau)$ and $mvs'(\tau)$ are identical.

Standard serial multiversion schedule. A serial multiversion schedule $mvs(\tau) = (T(\tau), h, <_{mvs})$ is *standard* if each read operation $r_{ij}(x) \in T(\tau)$ accesses the version of a data item x created by the last write operation w_{kl} (x) $\in$ $T(\tau)$ preceding r_{ij} (x). Since in a serial schedule, for every two transactions T_i and T_k, either all database operations of T_i precede all database operations of T_k or vice versa, the last write operation preceding a read operation is well defined. Note that a standard serial multi-version schedule in multi-version databases corresponds to a serial mono-version schedule in mono-version databases. From the consistency property of each transaction, i.e., from the assumption that each transaction separately preserves database consistency, it follows that a standard serial multi-version schedule must also preserve database consistency. On the basis of the above observation it is possible to define the multi-version serializability criterion [3].

Multi-version serializability criterion. A multi-version schedule $mvs(\tau)$ is *correct* if it is equivalent to any standard serial multi-version schedule of the set τ. Intuitively, the above criterion can be interpreted as follows. A concurrent schedule of a set of transactions in a multi-version database is correct if it is equivalent to a serial schedule of the transactions in which data replication over versions is transparent.

Key Applications

Multi-version serializability is used to prove correctness of concurrency control algorithms devoted to multiversion databases. As an example, consider a multi-version two-phase locking algorithm, called *WAB* [3,1,4], devoted to K-version databases. The concept of multi-version two-phase locking is broader than the concept of mono-version two-phase locking (cf. section on two-phase locking). An algorithm is a *multi-version two-phase locking algorithm* if it satisfies the following conditions:

1. There are two phases of transaction execution: the *locking phase* and the *unlocking phase.* During the locking phase a transaction must obtain all locks it requests. The moment when all locks are granted, which is equivalent to the end of the locking phase and the beginning of the unlocking phase, is called the *commit point* of a transaction. New versions of the data items prepared in the transaction's private workspace are written to the database during the unlocking phase.
2. The execution order of a set of transactions τ is determined by the order of transaction commit points.
3. The execution of any transaction $T \in (\tau)$ does not require locking data items that T does not access.

The concepts of locking and unlocking phases do not have exactly the same meaning as the similar notions used in the mono-version two-phase locking algorithm. In the *WAB* algorithm, the process of setting the so called "certify lock" is two-phase, but not as in the two-phase locking algorithm, the process of accessing data. In the *WAB* algorithm, each transaction initiated in the database and each version of a data item is *certified* or *uncertified*. When a transaction begins, it is uncertified. Similarly, each new version of a data item prepared in the transaction's workspace is uncertified. A *certify operation* is introduced, denoted by $c(w_{ij}(x))$, where $w_{ij}\ (x)$ is a T_i's write operation, and a new lock mode – the *certify lock* denoted by $CL(x)$. Certify locks are mutually incompatible. The algorithm requires that all certify and read operations of a data item x be $<_{mvs}$ related. Similarly, all certify operations must be $<_{mvs}$ related. The execution order of the certify operations determines a precedence relation $\ll_w$ defined on the set τ. The precedence relation $\ll_w$ specifies the order of transaction executions as follows: $T_i \ll_w T_k$ if and only if there exist such certify operations $c(w_{ij}(x))$ and $c(w_{kl}(x))$ that $c(w_{ij}(x)) \ll_{mvs} c(w_{kl}(x))$.

According to the *WAB* algorithm, any read operation $T_{ij}\ (x)$ concerns the last certified version of a data item x or any uncertified version of this data item. The version selected depends on a particular implementation of the *WAB* algorithm. Any write operation $w_{ij}\ (x)$ prepares a new version of a data item x in the workspace of transaction T_i (the version prepared is uncertified). At the end of transaction execution, the transaction and the new versions of the data items it prepared are being certified. The T_i's certification is a two-phase locking procedure. It consists of certify-locking all data items that the transaction T_i accessed to write. The T_i's certification is completed, when all certify locks are set and the following conditions are satisfied:

1. at the moment of T_i's certification, the versions of all data items read by T_i are certified;
2. for each data item x that T_i wrote, all transactions that read certified versions of x are certified.

To satisfy condition (ii), a *certify token* is allocated to each data item x to forbid reading certified versions of x other than the last one. On the other hand, all uncertified versions of x are allowed to be read. When the transaction T_i's certification is completed (the commit point), the procedure for certifying the versions of data items prepared by T_i is initiated. It was proved in [3] that the *WAB* algorithm is correct in the sense that any schedule produced by it is multi-version serializable. The main drawback of this algorithm is a possibility of a deadlock.

Future Directions

In database systems, multiple versions of data items are necessary to ensure transaction atomicity and to recover form crashes. The original idea of multiversion concurrency control based on multiversion serializability was to use those versions also to increase the degree of transaction concurrency, and as a result to improve database performance. However, such double use of versions decreases database reliability, because of the complexity of multiversion concurrency control. For practice, reliability of databases is of ultimate importance. This is why the concept of multiversion concurrency control was not well accepted in practice, except some implementations of two-version concurrency control concerning two values of each data item: before and after write operations. The concept of multiversion concurrency control may find attention in database systems applied in areas where ACID properties may be relaxed.

Relations with marked nulls; Extended relations

Definition

The simplest way to incorporate unknown values into the relational model, is to allow *variables*, in addition to *constants*, as entries in the columns of relations. Such constructs are called *tables*, instead of *relations*. A table is an incomplete database, and *represents a set of complete databases*, each obtained by substituting all variables with constants. Different occurrences of the same variable (marked null) are substituted with the same constant. The substitution is thus a function from the variables and constants, to the constants, such that the function is identity on the constants. A table T then represents the set of relations, denoted $rep(T)$, defined as $\{v(T) : v$ is a valuation$\}$. Then the *certain answer* to a query q on a table T, denoted $sure(q, T)$ is the set of tuples that occur in every answer obtained by applying the query to every database in $rep(T)$. In other words, the certain answer to q on T is $sure(q, T) = \cap q(rep(T))$.

Key Points

To illustrate the above concepts, let tables T_1 and T_2 be as below, and let q be the relational expression $\sigma_{A=a \vee A=c}(\pi_{AC}(R_1 \bowtie R_2))$. (The schema of T_i is that of R_i, $i = 1,2$). Then applying q to T_1,T_2, which is denoted $\sigma_{A=a \vee A=c}(\pi_{AC}(T_1 \bowtie T_2))$, yields table $q(T_1, T_2)$ below.

T_1

A	B
a	*X*
Y	*b*
c	*b*

T_2

B	C
X	*d*
b	*Z*

$q(T_1, T_2)$

A	C
a	*d*
c	*Z*

The variables/null-values are written in uppercase, to clearly distinguish them from the (lowercase) constants. Note, however, that $q(T_1, T_2)$ is not (necessarily) yet the certain answer. How was $q(T_1, T_2)$ derived from q and T_1, T_2, and how is the certain answer $sure(q,(T_1, T_2))$ obtained from $q(T_1, T_2)$? The answer to the second question is very simple: just drop all tuples containing variables from $q(T_1, T_2)$. The remaining tuples form the certain answer. In the example, the certain answer consists of tuple (a, c) only. The answer to the first question is not much more complicated: evaluate q on the tables, treating variables as "constants," pairwise distinct, and distinct from all "real" constants. This is also known as the Naive evaluation of q on T [2,3]. In the example above, tuple (a, X) is joined with tuple (X, c) since they have the same value, represented by X, in the join column. This is done even though the "actual" value of X is not known, since in any valuation v the two occurrences of X are mapped to the same value. On the other hand, when performing the selection $\sigma_{A=a \vee A=c}$ the tuple (Y, Z) is not picked, since there is at least one valuation v, for which both $v(Y) \neq a$ and $v(Y) \neq c$. A characterization of the correctness of the Naive evaluation is given below.

Before going to the characterization, note that it is not always ideal to only return the certain answer. Namely, if the answer to q is to be materialized as a view for further querying, essential information is lost if the tuples with variables are dropped. For a simple example, a evaluating π_A on $sure(q, (T_1, T_2))$ gives tuple (a) as a sure answer, whereas evaluating $\pi_A(q(T_1, T_2))$, puts tuples (a) and (c) in the sure answer. As a consequence, query evaluation would not be compositional, unless $q(T_1, T_2)$ is stored as an "intermediate" answer. This "intermediate" answer is called the *exact answer* in [1], where the theory of query rewriting in information integration systems is extended to use the exact answer, instead of the certain one.

The correctness and completeness criteria for tables and query-evaluation is formalized using the notion of the representation system [2]. Here an alternative, equivalent formulation given in [3] is used: Consider a class of tables T, and a query language $\mathcal{Q}$. A triple (T, *rep*, $\mathcal{Q}$) is said to be a *representation system* if for every table $T \in$ T, and for every applicable $q \in \mathcal{Q}$, there exists a function (here also named) q, such that

$$\cap\, rep(q(T)) = \cap q(rep(T)), \text{ and} \tag{1}$$

$$q' \circ q(T) = q'(q(T)), \tag{2}$$

for all applicable $q' \in \mathcal{Q}$.

Condition (1) says that the system can correctly compute the certain answer, and condition (2) states that the computation has to be uniformly recursive, following the structure of q. The important result is that, the class of Naive tables, and the class of all negation-free relational algebra expressions, together with Naive evaluation, form such a representation system. And this result comes without any computational penalty.

Narrowed Extended XPath I

Andrew Trotman

NEXI

Definition

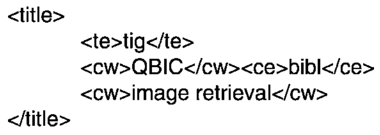
NEXI is an information retrieval (IR) query language for searching structured and semi-structured document collections. The language was first introduced for searching XML documents at the annual INEX [3] evaluation forum in 2004, and it has been used ever since.

Designed as the simplest query language that could possibly work, the language is a tiny subset of XPath [1] with an added *about*() function for identifying elements about some given topic. The language has extensions for question answering, multimedia searching, and searching heterogeneous document collections. NEXI is a language with a strict syntax defined in YACC but it has no semantics; the interpretation of the query is the task of the search engine.

Historical Background

A common information retrieval query language for searching XML documents was needed for specifying information retrieval queries at the first INEX in 2002. There, XML markup was chosen as the method of identifying keywords and the elements in which they should appear. It was also chosen as the method of identifying the preferred XML element to return to the user (the target element). The INEX 2002 query from topic 05 is given in Fig. 1. In this example, QBIC should be in a bibl element, image retrieval may appear anywhere in the document, and the user is interested in a list of tig elements as the result of the query.

Two problems with this format were identified: first it allowed the specification of queries that could be resolved by a simple mechanical process; second the



```
<title>
        <te>tig</te>
        <cw>QBIC</cw><ce>bibl</ce>
        <cw>image retrieval</cw>
</title>
```

Narrowed Extended XPath I. Figure 1. INEX topic 05 in the 2002 XML format.

language was not sufficiently expressive for information retrieval queries.

A modified XPath [1] was used at INEX 2003. In this variant the *contains*() function that required an element to contain the given content was replaced by an *about*() function that required an element to be about the content. Changing XPath in this way allowed fuzzy IR queries to be specified using a highly expressive language. However, an analysis of the XPath queries showed high syntactic and semantic error rates [6].

O'Keefe and Trotman [6] proposed using the simplest query language that could possibly work and a novel syntax. The INEX Queries Working Group [7] rejected the syntax but embraced the philosophy. It identified the minimum requirements of an IR query language for information retrieval queries containing structural constraints. This language, although at the time without syntax or semantics, was to be used at INEX for evaluation purposes.

Trotman and Sigurbjörnsson [9] proposed the Narrowed Extended XPath I (NEXI) language based on the working group report. It was narrowed in so far as only the descendant axis was supported, and extended in so far as the *about*() function was added, all other functions and axis were dropped. A formal grammar and parser were published, and an online syntax checker was hosted by the authors.

The decision to reduce XPath resulted in fewer errors because it reduced the chance of making mistakes. NEXI has a precise mathematical formulation which matches intuitive user profiles [4]. For both naïve users with knowledge of just the tag names, and for more advanced users with additional knowledge of the inter-relationships of those tags, the language is safe and complete. That is, the user cannot make semantic mistakes, and can express every information need they have.

Foundations

Web queries typically contain between 2 and 3 terms per query [8]. Formal query languages for semi-structured data tend to be comprehensive. This mismatch became apparent at INEX 2003 where XPath was chosen as the preferred language for information retrieval experts to specify relatively simple queries, but where they were unable to write syntactically and semantically correct queries. Just as SQL is not an end-user query language, neither, it turned out, was XPath.

Requirements

After two years of experimentation with XML query languages at INEX, the needs of such a language became apparent. The INEX, Queries Working Group [7] specified that the language should:

- Be compatible with existing syntax for specifying content only (keyword) queries.
- Be based on XPath as that language was already well understood, but:
- Remove all unnecessary XPath axis used for describing paths. Limit to just the descendant axis was suggested. The child operator was considered particularly problematic as it was open to misinterpretation.
- Drop exact match of strings, and inequality of numbers. XPath path filtering remained, however all strings were expressed as aboutness.
- Support multiple data types including numeric and string.
- Be open for extensions for new data types (including names, locations, dates, etc.).
- Not include tag instancing (for example author[1], the first author).
- Have vague semantics open to interpretation by the search engine.
- Loosen the meaning of the Boolean operators AND and OR.
- Disallow the multiple target elements. Although not explicit in the requirement, the implication is that the target element must be about the final clause in the query. It is a simple mechanical process to add non-target elements that are not about the query to the result – such as the author, title, source details to sections about something.
- Allow queries in which the target element was not specified and in which the search engine identified the ideal element.

Content Only (CO) Queries

NEXI addresses two kinds of queries on semi-structured and structured data: Content Only (CO) and Content And Structure (CAS) queries.

Content Only (CO) queries are the traditional IR query containing only keywords and phrases. No XML restrictions are seen and no mention is given of a preferred result (target) element. For these the NEXI syntax is derived from popular search engines: search terms can be keywords, numbers, or phrases (delineated with quotes). Term restrictions can be specified using plus and minus.

Information Retrieval queries are by their very nature fuzzy. A user has an information need and from that need they express a query. There are many different queries they might specify from the same need, some of which might be more precise than the others. If a document in the document collection satisfies the user's information need, that document is relevant regardless of the query. That is, no query term might appear in a relevant document, or all the query terms might appear, either way the document is relevant. When specifying an IR query language it is important to avoid specifying semantics that violate this principle of relevance. The semantics of the terms with and without restriction in NEXI is, for example, specified this way:

- *"The '+' signifies the user expects the word will appear in a relevant element. The user will be surprised if a '-' word is found, but this will not prevent the document from being relevant. Words without a sign are specified because the user anticipates such terms will help the search engine to find relevant elements. As restrictions are only hints, it is entirely possible for the most relevant element to contain none of the query terms, or for that matter only the '-' terms."*

Or, in other words, it is the task of the search engine to identify relevant documents even if this involves ignoring the query.

In INEX topic 210 the author states:

- *"I'm developing a new lecture for the Master course 'Content Design' and want to discuss the topic "Multimedia document models and authoring". Therefore I want to do a quick background search to collect relevant articles in a reader. I expect to find information in abstracts or sections of articles. Multimedia content is an essential component of my lecture, thus for fragments to be relevant they should address document models of content authoring approaches for multimedia content. I'm not interested in single media approaches or issues that discuss storing multimedia objects."*

The query they give is

- +multimedia "document models" "content authoring"

in which "`document models`" is a phrase and `+multimedia` is a term-restricted search term (is positively selected for by the user).

Content and Structure (CAS) Queries

The second kind of query addressed by NEXI is the Content and Structure (CAS) query. These queries contain not only keywords but also structural constraints know as *structural hints*. Just as the keywords are hints passed to the search engine in an effort to help with the identification of relevant documents, so too are structural hints. CAS queries contain two kinds of structural hints, where to look (support elements), and what to return to the user (target elements).

Formally, queries many take one of the forms in Table 1:

A and C are paths and B and D are filters. Other forms could easily be added, but since NEXI was originally designed to address the INEX query problem, they are not formally included.

Paths (A and C in Table 1) are specified as a list of descendants separated by the descendant axis //. Formally, a path is an ordered sequence of nodes $//E_1...//E_n$ starting with E_1 and finishing at E_n, and for all e∈n, E_e is a ancestor of E_{e+1}. An attribute node is indicated by the prefix @. Alternative paths are specified $(E_{na}|E_{nb})$. The wildcard * is used as a place holder.

For example, the path:

```
//article//*//(sec|section)//@author
```

describes an `author` attribute beneath either a `sec` or `section` element beneath something beneath an `article` element. The interpretation by the search engine is, of course, loose.

Filters (B and D in Table 1) can be either arithmetic or string. Arithmetic filters are specified as arithmetic comparisons (>, <, =, >=, <=) of numbers to relative-paths, for example:`.//year >= 2000`. String filters take the form `about(relative-path,`

Narrowed Extended XPath I. Table 1. Valid forms of NEXI CAS queries

Form	Target Element	Meaning
`//A[B]`	`A`	Return A tags about B
`//A[B]//C`	`A//C`	Return C descendants of A where A is about B
`//A[B]//C[D]`	`A//C`	Return C descendants of A where A is about B and a C descendant of A are about D

`COquery`). Filters can be combined using the Boolean operators and, and or. Paths and filters are all considered hints and there is no requirement for the search engine to distinguish between the Boolean operators.

The target elements for the forms given in Table 1 are specified in column 2. Target elements, like support elements, are also hints. If, for example, the user specified paragraphs a subsection element might fulfill the user's information need.

An example of a valid NEXI CAS query (again from INEX topic 230) is:

```
//article[about(.//bdy, “artificial intelligence”) and.//yr < = 2000]//bdy[about(., chess) and about(., algorithm)]
```

in which the target element is `//article//bdy`. The user has specified an arithmetic filter.`//yr <= 2000`. Several string filters are used including `about(.//bdy, ‘‘artificial intelligence”)`. A Boolean operator is also used to separate two filters `about(., chess) and about(., algorithm)`.

The NEXI CAS query from INEX topic 210 is an alternative expression of the information need given in the previous section. That query is:

```
//article//(abs|sec)[about(.,+multimedia ‘‘document models’’ ‘‘content authoring’’)]
```

in which the target element is either `//article//abs` or `//article//sec`. The same documents and elements are relevant to both queries, as relevance is with respect to the information need and not the specific query.

Key Applications

Information retrieval from structured and semi-structured document collections.

Future Directions

Although proposed as an XML query language for use in an evaluation forum, there is evidence it may also be an effective end-user language. Van Zwol et al. [13] compared NEXI to a graphical query language called Bricks. They found that a graphical query language reduced the time needed to find information, but that users were more satisfied with NEXI. Inherent in text query languages is the problem that users are required to know the structure (the DTD) of the documents. In a heterogeneous environment this may not be possible, especially if new and different forms of data are constantly being added. Graphical query languages that translate into an intermediary text-based query language are one solution. This solution is seen with graphical user interfaces to relational databases.

Woodley et al. [12] further the model of NEXI as an intermediate language and compare NLPX (a natural language to NEXI translator) to that of Bricks (a graphic to NEXI translator). They show that users prefer a natural language interface, and that the performance of the two is comparable.

Ogilvie [10] examined the use of NEXI for question answering and proposed extensions to the language for this purpose. Dignum and van Zwol [2] proposed extensions for heterogeneous searching. Trotman and Sigurbjörnsson [10] unified these proposals and formally extended the language to include both – however, these extensions are not considered core to the language (language extensions philosophically deviate from the principle of simplest that could possibly work). Multimedia extensions to the language have also been used at INEX [11], again the extensions are not considered core to the language.

Experimental Results

The analysis of XPath queries used at INEX 2003 showed 63% of queries containing either syntactic or semantic errors [3]. An analysis of the errors in NEXI queries used at INEX 2004 showed that only 12% contained errors [12]. NEXI has been in use at INEX ever since.

Data Sets

NEXI queries from INEX 2004 onwards can be downloaded from the INEX web site: http://inex.is.informatik.uni-duisburg.de/

INEX queries for 2003 and 2002 were translated into NEXI (where possible) and can be downloaded from the NEXI web page hosted by the University of Otago: http://metis.otago.ac.nz/abin/nexi.cgi

URL to Code

An online syntax checker, lex and yacc scripts, and a command line syntax checker can be downloaded from the NEXI web page hosted by the University of Otago: http://metis.otago.ac.nz/abin/nexi.cgi

Natural human-computer interaction; NHCI

Definition

The aim of Natural Human-Computer Interaction (NHCI) research is to create new interactive frameworks that integrate human language and behaviour into tech applications, focusing on the way people live, work, play and interact with each other. Such frameworks have to be easy to use, intuitive, entertaining and non-intrusive.

The design of *natural interaction* systems is focused on recognizing innate and instinctive *human expressions* in relation to some object, and return to the user a corresponding feedback that has the characteristics of being both *expected* and *inspiring*. All of the technology and the intelligence is built inside the digital artifacts and the user is not asked to use external devices, wear anything, or learn any commands or procedures. An interesting challenge for NHCI is therefore to make systems self-explanatory by working on their “affordance” [11] and introducing simple and intuitive interaction languages.

The human expressions that can be utilized are those considered innate, meaning that they don’t have to be learned. This includes vocal expressions and all the gestures used by humans to explore the nearby space or the immediate surroundings with their bodies, like: touching, pointing, stepping into zones, grabbing and manipulating objects (see Fig. 1). These direct actions express a clear sign of interest and necessitate a sudden reaction from the system.

The application fields range from browsing multimedia contents to exploration of knowledge structures; the scenarios involved can be either task-specific (in office or research contexts) or experiences created for casual interaction between the visitors and the media contents (like in museum exhibits and creative installations).

Natural interaction interfaces are very interesting to access, and explore large data sets like the ones contained in multimedia or geo-referenced databases. Data mining applications, which usually ask the user to enter complex search criteria and tweak the parameters to obtain the wanted data, can be designed with a visual analytic interface following these design guidelines. Queries are expressed visually, selecting interactive objects that embody selection criteria, creating clusters of them. Result sets provided by the database back-end can be iteratively shaped by directly manipulating the visual elements mapping the data, including other sets or reducing them.

Historical Background

At the beginning of the nineties, Human-Computer Interaction [17] was completely integrated into the Computer Science field, its quick growth led to the development of technologies able to go over the standard limiting user-computer communication paradigm, approaching a kind of natural interaction.

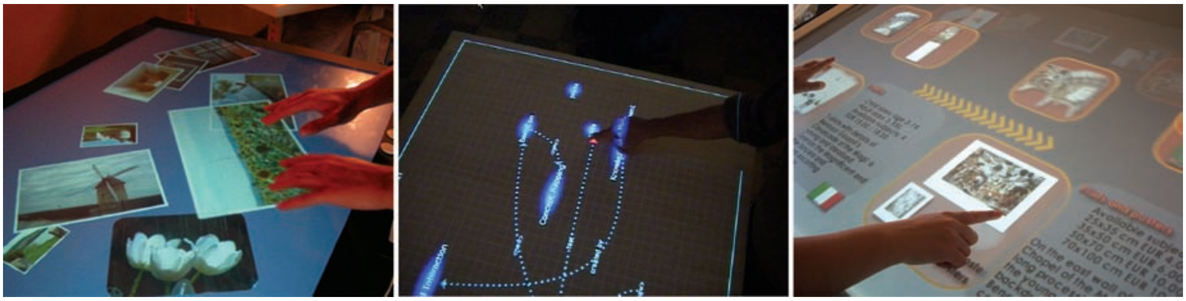
Alex Pentland in his “The Dance of Bits and Atoms” (1996, [13]) said that “There is a deep divide between the world of bits, and the world of atoms. Current machines are blind and deaf; they are unaware of us or our desires unless we explicitly instruct them. Consequently, only experts use most machines, and even they must spend most of their time battling arcane languages and strange, clunky interface devices.”

The key point is that technologies must be designed and developed adapting them to the users, not the contrary: this is the foundation of the “human centered design” [11,12].

The goal, finally, becomes a technology at one user’s service, suitable to the task requested and characterized by the complexity naturally embedded in the task itself [11,12].

Foundations

Interactive artifacts, augmented spaces, ambient technology and ubiquitous computing are all fields of study in HCI, which concentrate on both the technological aspects and the modalities in which users can perform activities. The techniques proposed are often referred to as *multi-modal interaction*, focusing on how machines can understand commands coming from different channels of human communication [10]. Among those: speech recognition, natural language understanding and gesture recognition, have been applied in different mixtures with roles ranging from active (the system observes the user and is pro-active in interacting with him) to passive (the system expects some kind of command, often through a device that is worn by the user). In the last years, studies have been following the concept of natural interaction as a conjunction of



Natural Interaction. Figure 1. Examples of natural interfaces for accessing digital contents and structures.

different technologies and design principles, with a more radical view about the user freedom in using interactive artifacts.

Natural interaction systems can be modelled as the sum of different modules: the *sensing* subsystem, which gathers sensor data about user expressions and behaviour, and the *presentation* module, which realizes the dialogue with the user orchestrating the output of different kind of actuators (graphics display, audio, haptics).

Sensing

The initial expression of interest towards the digital artefact is distracted from its main role: transferring information and stimuli. For this reason, the artefact should hide all the needs for an external controlling device, and be able to *sense* what the user is trying to do.

From a technological point of view, sensing involves the use of different sensors that provide data about some physical dimension in the surroundings of the artefact. There are a great number of electronic sensors that have been used in many industrial fields for robotics, automation and automatic inspection. Ranging from video cameras and image processing algorithms, to capacitive sensors for touch and pressure sensing or accelerometers for gesture recognition and body articulation.

Every sensor can have very different ways of providing this kind of data in terms of resolution, range, tolerances and errors. Some of them are able to provide discrete data with a high certainty, while others (like video cameras) just provide a great amount of data that has to be processed and interpreted by algorithms in order to extract useful information.

Considering the sensing architecture as a whole, a processing logic must be applied on top of it to abstract all the singularities of the sensors and create a homogeneous model of events for the later stages of interaction. Discrete events arriving from the sensors can be considered as belonging to three different categories of data:

- *Presence*: this data usually comes with a high signal-to-noise ratio, meaning that it cannot be directly interpreted as a human expression. Nonetheless, it reports a general activity in a spatial area.
- *Behaviour*: as the certainty level of some event increases (thanks to the combination of different sensors data), data can be studied for a certain period of time and provide information about the behaviour of single users or groups.
- *Activity*: this kind of data are considered "certain" and interpreted as a clear user intention to be used for a direct control of the interface. Instead of providing just the bi-dimensional screen coordinates as, it happens with traditional touch-screens, advanced sensing can interpret speed or pressure as well as distance of the hands as they approach a surface.

Sensors can be displaced in the environment, embedded in the artefact and also worn by the user but for natural interaction systems the last option is not suggested. For indoor use, the most meaningful displacement of sensors is inside the artefact itself. In this way, space can remain flexible and structures can be moved around. Such a thing could not be done if the whole environment was disseminated with.

Intelligence and Presentation

The intelligence substratum is what orchestrates the signals coming from sensors and generates output for presentation.

The devices embedded in the artefacts that manage the output phase are called *actuators* and can range from visual displays, to audio systems, surfaces with tactile feedback, holograms and many others. In scenarios like museums or art installations, even simple forms of stimuli can be used and mixed to convey a sensation or to catch the attention of the user. In an information space like an office or a data-intensive environment, the main channel of parallel communication remains the visual one, and the actuator is the graphical display.

On traditional GUIs (Graphical User Interfaces), what happens "inside the screen" can be subject to inference and prediction. Modern interfaces gather data about their use and are predictive in searching and suggesting data to the user in a light and "polite" way. Natural interfaces can extend this reasoning to a lot more data coming from the sensors, because the interactive artefact itself tries to *sense* beyond the screen. Also, unlike traditional interfaces whose informational layout is totally independent from the physical place in which the device is installed and used, digital artefacts can consider their position in the environment and what is happening around them.

In natural graphical interfaces, the basic assumption is that digital elements are not just a representation of data, but a part of the environment, and they need to follow aesthetics rules too. As a first principle: digital elements should behave like objects in physical systems. Following this *analogy* the graphical display becomes a real *space*, and therefore has to provide the same affordance of a normal surface. If something changes on the visual interface it should happen in a smooth way, without sudden jumps, similar to what happens with hyperlinks on web pages. The models of movement and forces used in transitions have to mimic those of one real world, like: gravity, accelerating forces, momentum and friction. The user has the chance to understand what is going on without feeling disoriented, and thanks to these visual cues he can also expect what is going to happen.

The anticipation is more important because in shared natural interfaces the model of control of traditional interfaces, modelled around a question to confirm every action, cannot be used. A popup message box would block the interface occupying space and this is not feasible in a shared user environment. Instead, every action is directly executed and, in the time in which this happens, the visual features of objects influenced by the action gradually change. Another guideline for the visual interface design is *lightness*. On every graphical display, there is a conflict between the level of contents belonging to the domain of the application (diversified media), and the level of widget elements (labels, buttons, etc) that explain the interface to the user and give hints about the options. In natural interfaces this is even truer. Basically, the space is for contents, so any other element is stealing some attention from the user. For this reason, the widget level is kept to a minimal amount of symbols and there is little or no use of "global" interface elements.

Handling Complexity with TUIs

A challenge in natural interaction systems is tackling the complexity with simplicity. While the category of exploring applications can be realized using only innate gestures, in the case of complex applications (featuring multiple options and actions) simple and spontaneous hand gestures turn out to be not enough, and methods like speech understanding do not adapt well to noisy environments or to scenarios in which multiple people are interacting simultaneously.

The solutions could be:

1. Enriching the interaction language by adding new complex gestures that map to actions. This could distort the naturalness of interaction forcing users to learn unnatural gestures.
2. Introducing an intermediate visual level using interface elements (such as menus, icons etc.). This would reduce the interaction directness causing a conflict between digital contents and interface elements, both sharing the same visualization area.

The result is that such solutions could increase the user cognitive load. Tangible user interfaces (TUIs [8]) can be an alternative solution to those mentioned. They introduce physical, tangible objects that the system interprets as embodiment [6] of the elements of the interaction language. Users, manipulating those objects, inspired by their physical affordance, can have a more direct access to functions mapped to different objects [2].

There is a broad literature about TUIs which dates back to the first experiments of Hiroshi et al at the MIT, where a set of normal objects where "sensed" by a system who could recognize and track some of their features, like the position in space. Many other systems have been developed using this paradigm, and today there is a growing familiarity with taxonomies that try to define the different styles and scenarios in which it can be used [7]. Table 1 illustrates the main different branches.

The physical objects, called *tangibles*, could address some of the issues related to complexity. They can become the *embodiment* of some aspects of the interaction between the user and the domain of multi-media contents handled by the application. In particular three possible roles can be distinguished.

- *The tangible as a simulacrum*. The physical object can be used as a representative of a single digital object or a collection. This means either a uniquely identified static element

Natural Interaction. Table 1. Tangible interaction themes

Theme	Features
Tangible manipulation	Physical manipulation of tactile qualities
Spatial interaction	Movement in space
Embodied facilitation	Configuration of objects affecting group behavior
Expressive representation	Focus on digital and physical expressiveness

with a one-to-one mapping between the physical and the digital world, or a re-assignable element that can be associated with different data (like a container).

- *The tangible as a manipulator.* In this case the tangible represents a *function* that can be applied to a digital object. The closest metaphor is that of a tool in order to change one of its aspects, reveal other connected contents etc. This modality can be also extended to global functions whose target is the entire viewport or collection of digital objects.
- *The tangible as an avatar of the user.* In this case, every user would have a personal object that represents himself, to move across the contexts. An avatar object can be used in conjunction with the others when the application needs an authentication or when the activity proposed requires the user to express a preference.

While the manipulator role is specific to the nature and local interaction with the artefact (e.g., a digital tabletop), the simulacrum and avatar roles exactly provide the abstraction that is needed in order to expand the affordance of the environment, providing a natural way to transport the productions across the artifacts. In this fashion, activities can be initiated on an artefact and continued somewhere else, like in a laboratory, different places provide different contexts and options for the same data.

Key Applications

Multimedia Browsing

Usually they are easy-to use systems where people can interact simultaneously with multimedia contents through their own bare-hand gesture.

This kind of application offers an intuitive approach to various multimedia objects, they don't require any kind of training or instructions.

Knowledge Exploration and Building

Interactive workspace featuring vision-based gesture recognition that allows multiple users to collaborate [3] in order to realize face-to-face contexts, designing a common workspace where users can build knowledge (activities like brainstorming or problem solving sessions), exploiting the useful scenario-specific characteristics.

Interactive Museum and Cultural Exhibits

Museums and exhibitions are often just a collection of objects, standing deaf in front of visitors. In many cases, objects are accompanied by textual descriptions, usually too short or long to be useful for the visitor. In the last decade, progress in multimedia has allowed for new, experimental forms of communication (using computer technologies) in public spaces [1].

Interactive Music Systems

Usually built over a tabletop tangible user interface, Interactive Music Systems allow several simultaneous performers to share complete control over the instrument by moving physical artefacts on the table surface while constructing different audio topologies in a kind of tangible modular synthesizer. The reacTable [9], a clear example, is a novel multi-user electro-acoustic musical instrument with a tabletop tangible user interface.

Nearest Neighbor Classification

Thomas Seidl
RWTH Aachen University, Aachen, Germany

Synonyms

NN classification; *k*-nearest neighbor classification; k-NN classification

Definition

Nearest neighbor classification is a machine learning method that aims at labeling previously unseen query objects while distinguishing two or more destination classes. As any classifier, in general, it requires some training data with given labels and, thus, is an instance of supervised learning. In the simplest variant, the query object inherits the label from the closest sample object in the training set. Common variants extend the decision set from the single nearest neighbor within the training data to the set of k nearest neighbors for any $k > 1$. The decision rule combines the labels from these k decision objects, either by simple majority voting or by any distance-based or frequency-based weighting scheme, to decide the predicted label for the query object. Mean-based nearest neighbor classifiers group the training data and work on the means of classes rather than on the individual training objects. As nearest neighbor classifiers only require distance computation of objects as a basic operation, their applicability exceeds the domain of vector spaces and attribute-based tuple data, and includes metric data spaces even if there are no attributes or dimensions available. Nearest neighbor classification counts for being highly accurate but inefficient; the latter assessment is to be invalidated by using appropriate indexing structures that support fast k-nearest neighbor retrieval. The abbreviation "NN classification" tends to cause confusion with the totally different concept of neural network classification.

Historical Background

Nearest neighbor classification is one of the earliest classification schemata. Nevertheless, it is one of the most highly accurate ones, whilst obeying a very broad range of applicability. The following aspects distinguish it from other classification methods.

Multiple class labels. Nearest neighbor classification is not restricted to two-class problems where classification decisions have to distinguish two classes only. Moreover, a high number of different classes does not deteriorate the efficiency in contrast to many other classifiers which create individual models for all the classes in the training set.

Applicability to general metric data spaces. Nearest neighbor classification is applicable to data without any structured attribute representation, i.e., to non-vectorial data. As distance computations are the only required basic operation, the applicability includes complex multimedia data, time series and measurement series data, sequences and structural data to name just a few supported domains. Among the competing approaches in the field, only support vector machines equipped with respective kernel functions share this advantage. Other classifiers including decision trees, neural networks and Bayes density models rely on the attribute structure of the data.

Instance-based learning. Nearest neighbor classification derives decisions close to the individual training instances as any other method. No model is created for the training data and, thus, it is called lazy evaluation. Most of the competing classification approaches follow the eager evaluation paradigm which spends significant training effort in the determination of models for the training data. They produce decision tree structures, synaptic weights in neural networks, support vector weights, or density probability functions, respectively. The lazy model of nearest neighbor classification nevertheless allows for fast class decisions when spending (training) effort in the creation of an index on the training data.

Training data that changes dynamically. If the classifier has to follow training data that changes over time, without or even with respect to its statistical characteristics, a nearest neighbor classifier is superior to almost all of the competing classifiers. No model parameters such as decision tree structures or density weights have to be recomputed where the training data has changed. The lazy evaluation strategy ensures that the results always rely on the current training data status. The efficiency depends on how the underlying index structure supports the dynamic data changes.

Intuitive explanation component. Nearest neighbor classifiers provide illustrative explanations of their decisions by revealing the closest neighbors of the query object from the training data. Moreover, the corresponding similarity scores, i.e., the distances of the training items to the query object, provide some insight into the decision process, and the users may derive their confidence in the final decision result. In comparison, support vector machines analogously give illustrative weights to individual training objects, Bayes classifiers have a similar explanation power by providing probability values for each target class, and decision trees are slightly more intuitive by presenting the rules that produced the decision result. On the other hand, neural network classifiers lack illustrative explanations of their decisions.

Foundations

Classification Model

Nearest neighbor classifiers are a common classification model for which several variants exist. Along with the simple nearest neighbor model, *k*-nearest neighbor classification uses a set of k neighbors and the mean-based nearest neighbor model where individual training objects are generalized uses group representatives.

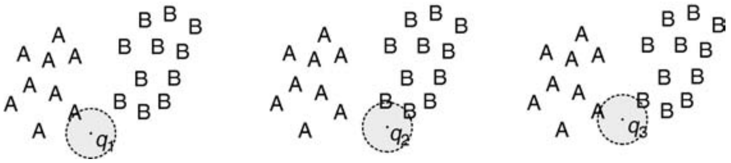
Simple nearest neighbor classification. The simplest variant of nearest neighbor classification may be formalized as follows: For any metric object space O, let $TS \subseteq O$ denote the set of labeled training data and $d : O \times O \rightarrow \Re_0^+$ is the chosen and thus distance function that reflects the dissimilarity of any two objects from O. Then, for any query object $q \in O$, the classifier evaluates the function $C_{\text{preliminary}}(q) = \{label(o)|\ o \in TS, \forall p \in TS - \{o\}: d(o,q) < d(p,q)\}$.

Unfortunately, this formalization is not valid for cases where several objects $o \in TS$ share the same minimal distance $d(o,q)$ to the query object, i.e., when the query hits perpendicular bisectors of these objects. Though in practice, these ties occur very rarely, a formalization that is equivalent to the previous one in other respects but in which ambiguities may be broken simply in a nondeterministic way is preferred (Fig. 1):

$$C_{nn}(q) = \{label(o)|\ o \in TS, \forall p \in TS : d(o,q) \leq d(p,q)\} \quad (1)$$

The decision model of nearest neighbor classification allows for a particularly broad range of applications. Its applicability covers vector data which are characterized by numerical attributes and includes general relational data where the tuples are represented by both numerical and categorical data as long as some metrics are defined on the categories. Moreover, if training and test data are neither taken from a vector space nor carry any categorical attributes but are only compared in terms of a distance function that reflects the dissimilarity of objects, nearest neighbor classifiers are still applicable. Examples of such applications include sequence data or structural data which may be compared by the edit distance, time series and measurement series compared by dynamic time warping, text and document data compared by the cosine distance, or multimedia data compared by complex similarity models.

Mean-based nearest neighbor classification. Nearest neighbor classifiers yield high quality decisions in



Nearest Neighbor Classification. Figure 1. Ambiguity of nearest neighbors for a sample training data set with two classes, A and B. Query object q_1 has a unique nearest neighbor and will be assigned to class A. For query object q_2, two neighbors share the smallest distance but there is no ambiguity with respect to the class decision since both neighbors are in class B. Query q_3 yields a conflict as it has two nearest neighbors from different classes, namely A and B, respectively. In practice, these ties occur very rarely at least for numerical reasons but may be solved nondeterministically.

terms of classification accuracy, and they are quite robust even for small training sets. Nevertheless, they tend to suffer from overfitting since the decisions are made closer at the training data than it is the case for any other method. As a consequence, erroneous training data, noise and outliers may badly affect the decisions. In order to increase the generalization power and to approach the overfitting problem, mean-based nearest neighbor classifiers and *k*-nearest neighbor classifiers have been developed as common variants of the simple model.

For mean-based nearest neighbor classification, the objects in the training data set are grouped into one or more clusters per class. These clusters are represented by their means, and nearest neighbors are then selected among the means rather than among the original individual training objects. The means inherit the class label of their cluster members, and the decision rule (1) from simple nearest neighbor classification is easily adopted to the mean model just by replacing the training data set by the set of means:

$$C_{m-nn}(q) = \{label(m)|\ m \in means(TS), \forall n \in means(TS) : d(m,q) \leq d(n,q)\} \tag{2}$$

Note that the computation of mean values requires the object space O to be a vector space, since the objects of a cluster need to be summed up followed by a scalar multiplication by the reciprocal value of the group's cardinality. Thus, the mean-based model does not apply to non-vectorial metric spaces which, in contrast, are supported by *k*-nearest neighbor classifiers.

k-nearest neighbor classification. Beside mean-based nearest neighbor classifiers, *k*-nearest neighbor classification is another quite common approach to increase the generalization power and to decrease overfitting effects. Instead of looking at a single object to the query among the training data, a set of *k* nearest neighbors, $k > 1$, is taken into account when making the decision. One starts by defining the decision set to be a subset of the training data TS that contains the *k* objects closest to the query object *q*. Again, ties may be broken by a nondeterministic choice among equidistant neighbors:

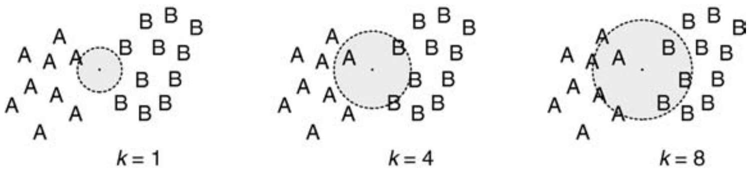
$$NN(q,k) = \{o|\ o \in TS, \forall p \in TS - NN(q,k) : d(o,q) \leq d(p,q)\},\ \ |NN(q,\ k)| = k \tag{3}$$

The decision rule based on majority vote now looks as follows (Fig. 2):

$$C_{majority}(q) = \arg\max_{l \in label(NN(q,\,k))} \{card\{o \in NN(q,k)|\ label(o) = l\}\}. \tag{4}$$

Weighted k-nearest neighbor classification. For *k*-nearest neighbor classifiers, different weighting schemata have been developed which introduce distances or frequencies into the decision rule. Conceptually, majority voting represents a weighting schema with unit weights. A quite common variant is to use the squared distances of the decision objects to the query object as reciprocal weights. This way, the desired effect is obtained that the closer an object is to the query, the higher is its influence to the classification decision. The corresponding decision rule is as follows:

$$C_{dist}(q) = \text{argmax}_{l \in label(NN(q,k))} \left\{ \sum_{\substack{o \in NN(q,k) \\ label(o)=l}} \frac{1}{d(o,q)^2} \right\}. \tag{5}$$



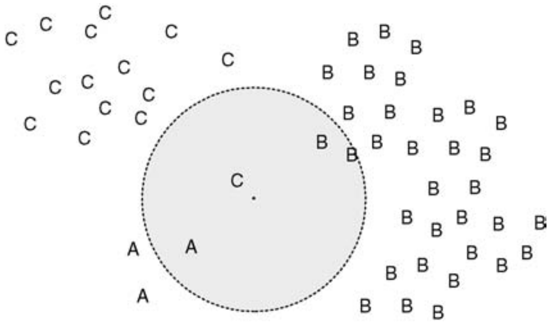
Nearest Neighbor Classification. Figure 2. Dependency of the classification decision on the number of nearest neighbors. In the examples from left to right, the same query object is considered. A choice of k = 1 yields the class label A. For k = 4, class B holds the majority in the nearest neighbor set, and for k = 8, again label A is assigned to the query object.

An alternative weighting schema takes the relative frequency of the classes into account. Naturally, rare classes are represented only by a small number of instances in the training data. If at decision time, a nearest neighbor set contains a few of these rare instances, this occurrence is honored by the frequency weighting schema. This way, rare classes may outvote highly frequent classes even if these dominate the decision set by their number. Formally speaking, decisions are based on the fraction of training instances a class contributes to the decision set rather than on the absolute number of instances among the nearest neighbors (Fig. 3).

$$C_{freq}(q) = \operatorname{argmax}_{l \in label(NN(q,k))} \left\{ \frac{card\{o|\ o \in NN(q,k), label(o) = l\}}{card\{o|\ o \in TD, label(o) = l\}} \right\}. \qquad (6)$$

Lazy Evaluation Model

Nearest neighbor classification follows the model of lazy evaluation. This means that there is no computation or estimation of model parameters at training time, but all calculations to make decisions are deferred to query time. Lazy evaluation is in contrast to the eager evaluation paradigm which requires some effort at training time to build an appropriate model. Examples of eager classifiers include decision trees, Bayes classifiers, neural networks, or support vector machines for which attribute-oriented decision flow diagrams, probability (mixture) density models, synaptic weights, or support vector weights are computed at training time, respectively. Lazy evaluation does not build models for the training data but derives its decisions directly from the training objects and, therefore, is called instance-based learning. Nearest neighbor classification is a prominent example of lazy evaluation, and the simple 1-nn and extended *k*-nn variants purely reflect the instance-based paradigm. The mean-based variant, however, deviates a little from this idea since means of classes are computed at training time, and decisions are based on the means rather than on the individual instances. For lazy evaluation in general, questions about decision efficiency, dynamic changes of training data, and explanations of decisions arise; these issues are discussed in the following subsections. Note that mean-based nearest neighbor classification is not a pure lazy variant since means of classes are computed at training time.



Nearest Neighbor Classification. Figure 3. Dependency of class decision on the weighting schema. In the example, a 4-nearest neighbor set is selected for the query object. Pure majority voting decides for class B as the decision set includes two instances of class B. Distance weighting decides for class C as the close neighbor from class C dominates the farer neighbor from class A and even the two neighbors from class B. Frequency-based weighting yields class A since A contributes the highest fraction of its overall occurrences in the training data to the nearest neighbor set.

Decision efficiency. By following the lazy evaluation model, nearest neighbor classifiers defer all data analysis to query time. So query processing tends to be computationally more expensive than with eager classifiers. Obviously, the most complex task is to determine the decision set, that is the set of (k) nearest neighbors for a query object; the subsequent weighting and voting is negligibly done in $O(k)$. Retrieving the k nearest neighbors in a set of n training objects depends on the data organization. Whereas a sequential scan requires $O(n)$ operations, the use of multidimensional or metric indexing structures may significantly speed-up the retrieval of the decision set depending on the dimensionality and on the statistical characteristics of the data. For high-dimensional data, techniques for reduction of dimensionality and multi-step query processing help to keep k-nearest neighbor retrieval efficient. As strict lazy evaluation does not waste any training time to create a model, it is nevertheless highly recommended to spend some effort for the creation of an appropriate index on the training data. In short, to train an efficient nearest neighbor classifier means to instantiate model creation by index creation.

Dynamically changing training data. As for lazy evaluation, no model is created at training time, a lazy classifier in general allows for dynamic changes of training data particularly well. For a nearest neighbor classifier, efficiency depends on how the underlying index structure maintains the dynamic data set. This represents a common requirement for indexing and is supported well by almost all multidimensional or metric access methods. As training data changes, new examples are inserted into the index and outdated training instances are removed. This way, incremental training for low change rates and also online training with potentially high rates of incoming training data are enabled. Nearest neighbor classification, thus, always produces a result that relies on the current training data status.

Decision explanation. Lazy classifiers do not create models for the training data and, as an inherent limitation, no explicit knowledge is extracted which reflects the structure of the data. Though nearest neighbor classifiers do not provide intuitive models of the data characteristics, they nevertheless explain their individual decisions illustratively by revealing the closest neighbors of the query object within the labeled training data to the user. Additional information is provided by the similarity scores, i.e., the distances of the training items to the query object, thus yielding some insight into the decision process from which the users may derive their confidence in the final decision result.

Key Applications

Key applications of nearest neighbor classification include all areas where classification problems occur. Particularly well suited are nearest neighbor classifiers in the following cases:

1. Many classes need to be distinguished
2. Objects are represented by general metric data without an attribute structure
3. Classifier has to follow training data that change dynamically
4. Users require intuitive explanations of the system's decisions

Real applications are found in all areas of multimedia data exploration and cognitive systems including computer vision, speech recognition, medical imaging, robot motion planning, or sensor-based object recognition in general to name just a few.

Nearest Neighbor Query

Dimitris Papadias
Hong Kong University of Science and Technology,
Hong Kong, China

Synonyms

NN query; *k*NN query

Definition

Given a dataset *P* and a query point *q*, a *k nearest neighbor* (*k*NN) query returns the *k* closest data points $p_1,p_2,...,p_k$ to *q*. For any point $p \in P-\{p_1,p_2,...,p_k\}$: $dist(p_i, q) \leq dist(p, q)\ \forall\ 1 \leq i \leq k$, where *dist* depends on the underlying distance metric. The usual metric is the L_x norm, or formally, given two points *q*, *p* whose coordinates on the *i*-th dimension ($1 \leq i \leq m$) are q_i and p_i respectively, their L_x distance is:

$$L_x(p,\ q) = (\Sigma_{i=1\sim m}|p_i - q_i|^x)^{1/x},\ \text{for}\ x \neq \infty,$$

$$L_x(p,\ q) = \max\ _{i=1\sim m}(|p_i - q_i|),\ \text{for}\ x = \infty.$$

Most work on spatial and spatio-temporal databases focuses on Euclidean distance (i.e., L_2), but alternative definitions have been used in various domains (e.g., road networks, time series).

Key Points

Nearest neighbor search constitutes an important component for several tasks such as clustering, outlier detection, time series analysis, and image and document retrieval. For instance, finding the most similar series, image, or document to a given input is a NN query in a corresponding data space defined by the features of interest. Unlike spatial and spatio-temporal databases that usually involve 2–3 dimensions, these applications may lead to high-dimensional spaces. In order to avoid the high cost of distance computations in such cases, several methods follow a multi-step framework for processing NN queries [3]: (i) a dimensionality reduction technique is used to decrease the number of dimensions, (ii) the low dimensional data are indexed, (iii) the index is used to efficiently retrieve a candidate NN (in low dimensional space), (iv) the actual distance of the candidate (in the original space) is computed, and (v) steps (iii) and (iv) are repeated until no other candidate can lead to a better solution than the one already discovered.

In addition to conventional NN search, several alternative types of nearest neighbor queries have been proposed in the database literature. Given a multi-dimensional dataset *P* and a point *q*, a *reverse nearest neighbor* query retrieves all the points $p \in P$ that have *q* as their NN (The nearest neighbor relationship is not symmetric; i.e., the fact that *q* is the NN of *p* does not necessarily imply that *p* is the NN of *q*.) [1]. Given a set *P* of data points and a set *Q* of query points, an *aggregate nearest neighbor* query returns the data point *p* with the minimum *aggregate distance* [2]. The *aggregate distance* between a data point *p* and $Q = \{q_1,...,q_n\}$ is defined as $f(dist(p,q_1),...,dist(p, q_n))$. If, for instance, $f = sum$, the corresponding query reports the data point that minimizes the total distance from all query points.

Nearest Neighbor Query in Spatio-temporal Databases

Dimitris Papadias

Synonyms

NN query; NN search

Definition

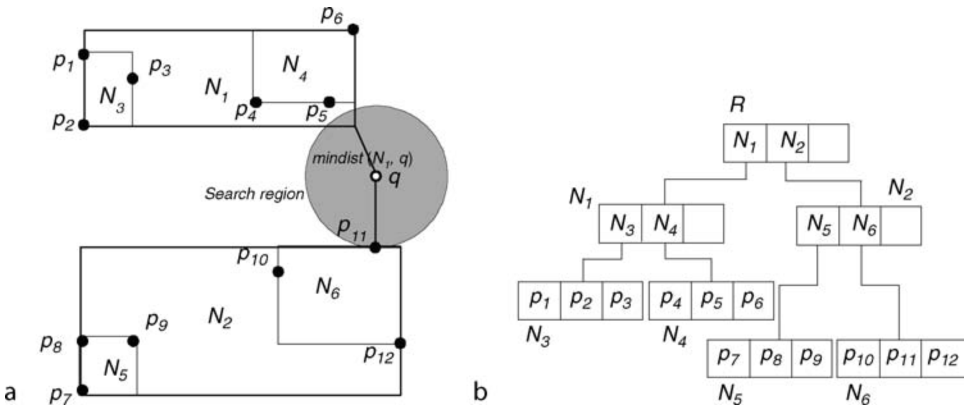
Given a set of points P in a multi-dimensional space, the nearest neighbor (NN) of a query point q is the point in P that is closest to q. Similarly, the k nearest neighbor (kNN) set of q consists of the k points in P with the smallest distances from q. In spatial and spatio-temporal databases, the distance is usually defined according to the Euclidean metric, and the dataset P is disk-resident. Query algorithms aim at minimizing the processing cost. Other optimization criteria in the case of moving objects (or queries) include the network latency, or the number of queries required for keeping the results up-to-date.

Historical Background

Nearest neighbor (NN) search is one of the oldest problems in computer science. Several algorithms and theoretical performance bounds have been devised for exact and approximate processing in main memory [1]. In spatial databases, existing algorithms assume that P is indexed by a spatial access method (usually an *R-tree* [2]) and utilize some pruning bounds to restrict the search space. Figure 1 shows an *R-tree* for point set $P = \{p_1,p_2,\dots,p_{12}\}$ with a capacity of three entries per node (typically, the capacity is in the order of hundreds). Points that are close in space (e.g., p_1, p_2, p_3) are clustered in the same leaf node (N_3). Nodes are then recursively grouped together with the same principle until the top level, which consists of a single root. Given a node N and a query point q, the *mindist* (N,q) corresponds to the closest possible distance between q and any point in the subtree of node N.

The first NN algorithm for *R-trees* [8] searches the tree in a *depth-first* (DF) manner, recursively visiting the node with the minimum *mindist* from q, e.g., in Fig. 1, DF accesses the root, followed by N_1 and N_4, where the first potential nearest neighbor is found (p_5). Note that p_5 is not the actual NN (it is p_{11}), and the search continues. During backtracking to the upper level (node N_1), the algorithm prunes entries whose *mindist* is equal to or larger than the distance (*best_dist*) of the nearest neighbor already retrieved. In the example of Fig. 1, after discovering p_5, (i) *best_dist* is set to $dist(p_5,q)$, (ii) DF backtracks to the root level (without visiting N_3), and (iii) it follows the path N_2, N_6 where the actual NN p_{11} is found. DF can be easily extended for the retrieval of $k > 1$ nearest neighbors: the k points discovered so far with the minimum overall distances are maintained in an ordered list of k pairs $<p, dist(p,q)>$ (sorted on ascending $dist(p,q)$ order) and *best_dist* equals the distance of the k-th NN. Whenever a better neighbor is found, it is inserted in the list, the last element is removed, and the value of *best_dist* is updated.

The DF algorithm is sub-optimal, i.e., it accesses more nodes than necessary. Specifically, an optimal algorithm should visit only nodes intersecting the

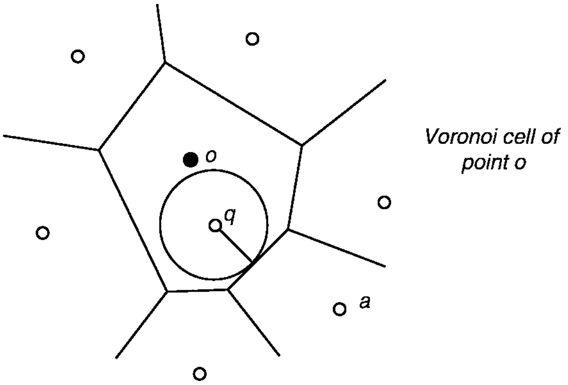


Nearest Neighbor Query in Spatio-temporal Databases. Figure 1. Example of an R-tree and a point NN query.

search region, i.e., a circle centered at the query point q with radius equal to the distance between q and its nearest neighbor [4]. In Fig. 1, for instance, an optimal algorithm should visit only the root, N_1, N_2, and N_6, whereas DF also visits N_4. The *best-first* (BF) algorithm of [5] achieves the optimal I/O performance by maintaining a heap H with the entries visited so far, sorted by their *mindist*. As with DF, BF starts from the root, and inserts all the entries into H (together with their *mindist*), e.g., in Fig. 1, $H = \{<N_1, mindist(N_1,q)>, <N_2, mindist(N_2,q)>\}$. Then, at each step, BF visits the node in H with the smallest *mindist*. Continuing the example, the algorithm retrieves the content of N_1 and inserts all its entries in H, after which $H = \{<N_2, mindist(N_2,q)>, <N_4, mindist(N_4,q)>, <N_3, mindist(N_3,q)>\}$. The next two nodes accessed are N_2 and N_6 (inserted in H after visiting N_2), in which p_{11} is discovered as the current NN. At this time, the algorithm terminates (with p_{11} as the final result) since the next entry (N_4) in H is farther (from q) than p_{11}. Similarly to DF, BF can be easily extended to *k*NN queries ($k > 1$). In addition, BF is *incremental*, i.e., it can output the nearest neighbors in ascending order of their distance to the query without a pre-defined termination condition.

Foundations

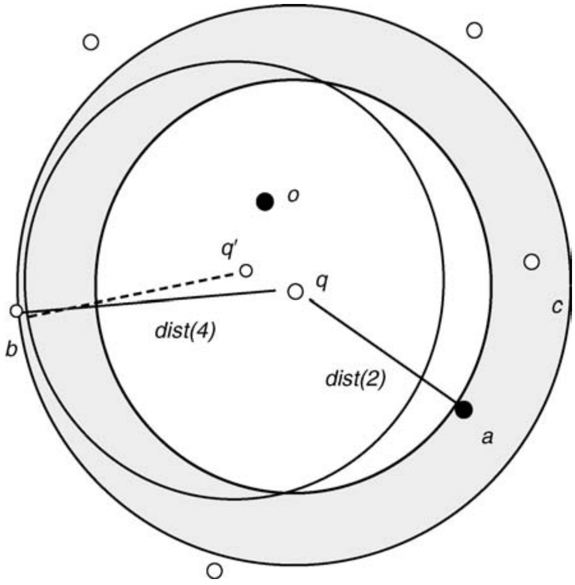
In dynamic environments, the result of a conventional NN query may be immediately invalidated due to the query or data movement. Several techniques augment the result with some additional information regarding its validity. For instance, Zheng and Lee [14] assume an architecture where moving clients (e.g., mobile devices) send their queries to a server. The server precomputes and stores in an *R-tree* the *Voronoi diagram* of the (static) dataset. When a NN query q arrives at the server, the *Voronoi diagram* is used to efficiently compute its nearest neighbor; i.e., the point (o in Fig. 2), whose Voronoi cell covers q. In addition to the result, the server sends back to the client its *validity time T*, which is a conservative approximation assuming that the query speed is below a maximum value. In particular, T is the time that q will cross the closest boundary of the Voronoi cell of object o (in which case point a will become the nearest neighbor). Zhang et al. [13] propose the concept of *location-based* queries that return the *validity region* around the query point, where the result remains the same. For instance, in Fig. 2, a location-based query q will return object o and its Voronoi cell, which is computed on-the-fly using an *R-tree* on the data points.



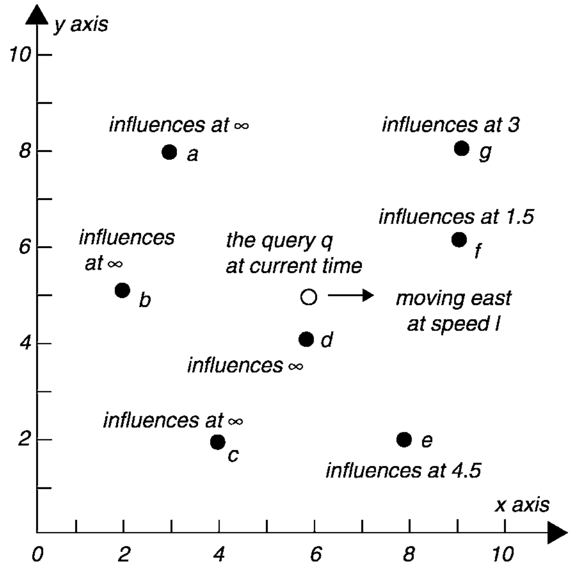
Nearest Neighbor Query in Spatio-temporal Databases. Figure 2. Example of [6].

For the same settings (moving query - static data objects), Song and Roussopoulos [10] reduce the number of queries required to keep the result up-to-date by introducing redundancy. In particular, when a *k*NN query arrives, the server returns to the client a number $m > k$ of neighbors. Let *dist*(k) and *dist*(m) be the distances of the kth and mth nearest neighbor from the query point q. If the client re-issues the query at a new location q', it can be proven that the new k nearest neighbors will be among the m objects of the first query, provided that $2{\cdot}dist(q',q) \leq dist(m)\text{-}dist(k)$. Figure 3 shows an example for a 2NN query at location q, where the server returns four results o, a, b and c (the two nearest neighbors are o and a). When the client moves to a nearby location q', the 2 NN are o and b. If $2{\cdot}dist(q,q') \leq dist(4)\text{-}dist(2)$, the client can determine this by computing the new distances (with respect to q') of the four objects, without having to issue a new query to the server.

Tao and Papadias [11] propose *time-parameterized* (TP) queries, assuming that the clients move with linear and known velocities. In addition to the current result R, the output of a TP query contains its *validity period T* and the *next change C* of the result (that will occur at the end of the validity period). Given the additional information (C and T), the client only needs to issue another TP query after the expiry of the current result. Figure 4 shows a TP NN, where the query point q is moving east with speed 1. Point d is the current nearest neighbor of q. The *influence time* $T_{INF}(p, q)$ of an object p is the time that p starts to get closer to q than the current nearest neighbor. For



Nearest Neighbor Query in Spatio-temporal Databases. Figure 3. Example of [8].



Nearest Neighbor Query in Spatio-temporal Databases. Figure 4. Example of TP NN query.

example, $T_{INF}(g,q) = 3$, because at this time g will come closer to q than d. The expiry time of the current result is the minimum $T_{INF}(o,q)$ of all objects, i.e., in Fig. 4, $T = 1.5$, at which point f will replace d as the NN of q. Based on the above observations, a TP NN query is processed in two steps: (i) a conventional algorithm (e.g., [5,8]) retrieves the NN at the current time, and (ii) a second pass computes the time-parameterized component (i.e., C and T) by applying again NN search and treating $T_{INF}(o,q)$ as the distance metric: the goal is to find the objects (C) with the minimum T_{INF}.

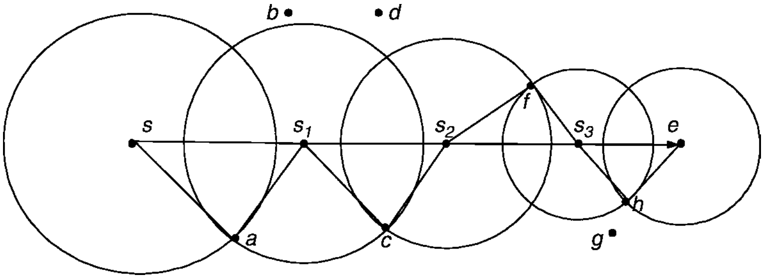
A *continuous* nearest neighbor (CNN) query [3,11] retrieves the nearest neighbor (NN) of every point in a line segment $q = [s, e]$. In particular, the result contains a set of $<R,T>$ tuples, where R (for result) is a point of P, and T is the interval during which R is the NN of q. As an example consider Fig. 5, where $P = \{a,b,c,d,f,g,h\}$. The output of the query is $\{<a, [s,s_1]>, <c, [s_1,s_2]>, <f, [s_2,s_3]>, <h, [s_3,e]>\}$, meaning that point a is the NN for interval $[s,s_1]$; then at s_1, point c becomes the NN etc. The points of the query segment (i.e., s_1, s_2, s_3) where there is a change of neighborhood are called *split points*. CNN algorithms use DF or BF traversal on *R-trees* to visit nodes and data points according to their proximity to the query segment. Visited data points introduce new split points, which are used to prune the search space. For instance, in Fig. 5, if a, c, f and h have already been discovered, every node and data point (b, d, g) outside a circle defined by a split point (center) and its NN (radius) can be eliminated since they cannot affect the result.

A *predictive* NN query retrieves the expected nearest neighbor of a (static or moving) query point (e.g., 30 seconds from now) based on the current motion patterns. Assuming that data points move linearly, they can be indexed by a TPR-tree [9]. The TPR-tree is similar to the *R-tree*, but takes into account both location and velocity in order to group data objects into nodes. Furthermore, each node is assigned a velocity vector so that its extent continuously encloses all the objects inside (i.e., a moving node that may grow with time). A predictive query is answered in the same way as in the *R-tree* (e.g., by adaptations of [5,8]), except that the node extends at the (future) query time are dynamically computed (using the current location and velocity vector of the node). The concepts of TP and continuous queries also apply in this case. Tao et al. [12] propose an architecture and index for processing queries on objects moving with arbitrary motion patterns, unknown in advance.

Key Applications

Geographic Information Systems

Nearest neighbor search is one of the most common query types. Efficient algorithms are important for



Nearest Neighbor Query in Spatio-temporal Databases. Figure 5. Example CNN query.

dealing with the large and ever increasing amount of spatial data in several GIS applications.

Location-based Services

Advanced NN algorithms will provide the means for enhanced location-based services based on the proximity of mobile clients to potential facilities of interest.

Multi-criteria Decision Making

A number of decision support tasks can be modeled as nearest neighbor search. For instance, news WWW-sites usually recommend to users the articles that are most similar to their previous choices. Nearest neighbor algorithms have also been used to process skyline queries.

Future Directions

All the above techniques take as input a single query, and report its nearest neighbor set at the current time, possibly with some validity information (e.g., expiration time, Voronoi cell), or generate future results based on predictive features (e.g., velocity vectors of queries or data objects). On the other hand, *continuous monitoring of spatial queries* [6] (i) involves multiple, long-running, queries (from geographically distributed clients), (ii) is concerned with both computing *and* keeping the results up to date, (iii) usually assumes main-memory processing to provide fast answers in an on-line fashion, and (iv) attempts to minimize factors such as the CPU or communication cost (as opposed to I/O overhead).

Another interesting problem concerns NN search in non-Euclidean spaces. For instance, in road networks the distance between two points can be defined as the length of the shortest path connecting them, or by the minimum time it takes to travel between them. In either case, the problem requires different algorithmic solutions [7].

Experimental Results

In general, for every presented method, there is an accompanying experimental evaluation in the corresponding reference. [5] compares BF and DF traversal for conventional NN search. [9] proposes cost models for TP NN and CNN queries and evaluates their accuracy, as well as the relative performance of the two query types for static (indexed by *R-trees*) and dynamic (indexed by *TPR-trees*) objects.

Data Sets

A large collection of real datasets, commonly used for experiments, can be found at:

Nested Loop Join

Jingren Zhou
Microsoft Research, Redmond, WA, USA

Synonyms

Nested loop join; Loop join

Definition

The nested loop join is a common join algorithm in database systems using two nested loops. The algorithm starts with reading the *outer* relation *R*, and for each tuple $\mathcal{R} \in R$, the *inner* relation *S* is checked and matching tuples are added to the result.

```
Algorithm 1: Nested Loop Join: $R \bowtie_{pred(r,\ s)} S$
  foreach R ∈ R do
      foreach S ∈ S do
          if pred (R.r, S.s) then
              add {R, S} to result
          end
      end
  end
```

Key Points

One advantage of the nested loop join is that it can handle any kind of join predicates, unlike the sort-merge join and the hash join which mainly deal with an equality join predicate. An improvement over the simple nested loop join is the block nested loop join which effectively utilizes buffer pages and reduces disk I/Os.

Block Nested Loop Join

Suppose that the memory can hold *B* buffer pages. If there is enough memory to hold the smaller relation, say *R*, with at least two extra buffer pages left, the optimal approach is to read in the smaller relation *R* and to use one extra page as an input buffer to read in the larger relation *S* and the other extra buffer page as an output buffer.

If there is not enough memory to hold the smaller relation, the best approach is to break the outer relation *R* into *blocks* of $B - 2$ pages each and scan the whole inner relation *S* for each block of *R*. As described before, one extra page is used as an input buffer and the other as an output buffer. In this case, the outer relation *R* is scanned only once while the inner relation *S* is scanned multiple times.

Nested Transaction Models

George Karabatis
University of Maryland, Baltimore Country (UMBC),
Baltimore, MD, USA

Definition

A *nested transaction model* as proposed by Moss is a generalization of the flat transaction model that allows nesting. A nested transaction forms a tree of transactions with the root being called a *top-level transaction* and all other nodes called *nested transactions (subtransactions).* Transactions having no subtransactions are called *leaf* transactions. Transactions with subtransactions are called *parents (ancestors)* and their subtransactions are called *children (descendants).*

A subtransaction can commit or rollback by itself. However, the effects of the commit cannot take place unless the parent transaction also commits. Therefore, in order for any subtransaction to commit, the top-level transaction must commit. If a subtransaction aborts, all its children subtransactions (forming a subtree) are forced to abort even if they committed locally.

Historical Background

Nested transactions were introduced by Moss in 1981 [8] to overcome some of the limitations of the flat transaction model, as they allow a finer level of control in a transaction. For example, a failed operation in a flat transaction causes the entire transaction to be rolled back. On the contrary, a failed operation in a part of a nested transaction may be acceptable and the entire transaction may be allowed to commit, even if some of its operations failed. As an example, a trip consisting of a flight reservation, hotel accommodation and car rental can be implemented as a nested transaction with three subtransactions. If some of its subtransactions commit (e.g., flight and hotel), and some fail (e.g., car rental) the outcome may still be acceptable and allow the nested transaction to commit with partial results.

Nested transactions are based on the underlying concept of *spheres of control* developed by Bjork and Davies in 1973 [1,3]. Davies describes the spheres of control in more detail in [2]; however, he portrays overall semantics of the spheres which convey a more abstract concept than nested transactions. Moss provides implementation details of nested transactions for a distributed environment. Prior to that, Reed in his dissertation [9] also describes an implementation of nested transactions in a distributed environment and one can see similarities and differences between the two approaches. For example, Moss uses locking whereas Reed uses timestamps. For a detailed comparison of the two approaches see [8].

Foundations

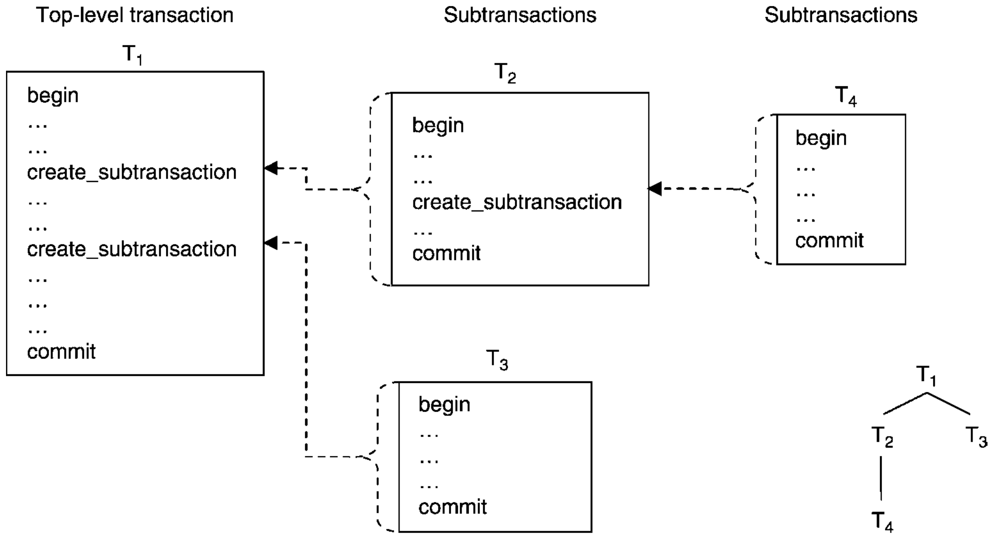
Structure of a Nested Transaction

The structure of a nested transaction is depicted by a transaction tree: its root represents the *top-level* transaction and its children represent *subtransactions* each one corresponding to a transactional unit. A subtransaction may be either a simple (*leaf)* transaction or a nested transaction, recursively expanding the structure to a hierarchy with multiple levels of transactions.

Leaf transactions are very similar to traditional ACID transactions, but they do not preserve the durability property of ACID transactions as will be explained in the Commit/Abort rules. Leaf transactions are the ones that actually manipulate the data in the database and perform the work. Intermediate level subtransactions and the top-level transaction operate on a higher level of abstraction: their purpose is to control when to create a new subtransaction. This hierarchy corresponds to the notion of nested spheres of control [3]. Figure 1 illustrates an example of a nested transaction and its corresponding transaction tree. It consists of a top-level transaction T_1 with two subtransactions T_2 and T_3; subtransaction T_2 is itself a nested transaction invoking subtransaction $T_{4.}$ In this example, subtransactions T_3 and T_4 are leaf transactions performing the actual work. When multiple such nested transactions coexist their trees form a forest.

Synchronization of Nested Transactions

Subtransactions of nested transactions can execute concurrently and for proper synchronization Moss devised the following locking protocol: A subtransaction can either *hold* a lock or *retain* a lock. When a lock is held the transaction has exclusive rights to the object. After a subtransaction commits, its held or retained locks are *inherited* by the parent subtransaction. These inherited locks are not available to other subtransactions outside the subtree (sphere of control) of the holder; however, subtransactions within the subtree (descendants) can acquire a retained lock.



Nested Transaction Models. Figure 1. Structure of an example nested transaction; to the lower right is a depiction of the corresponding nested transaction tree.

The Locking Rules of nested transactions slightly paraphrased from Moss [8] are the following:

1. A transaction may hold a lock in write mode if no other transaction holds the lock (in any mode) and all retainers of the lock are ancestors of the requester.
2. A transaction may hold a lock in read mode if no other transaction holds the lock in write mode and all retainers of write locks are ancestors of the requester.
3. When a transaction commits, its parent inherits all locks the descendants held or retained in the same mode as the child held or retained them.
4. When a transaction aborts, all locks it holds or retains are released. Ancestors of the aborted transaction who were retaining the lock they continue to do so in the same mode as before the abort.

Commit/Abort of Nested Transactions

Moss describes a set of rules (state restoration algorithm in [8]) that dictate the behavior of nested transactions at commit/abort time. A subtransaction can unilaterally commit or abort independently of the others preserving atomicity, consistency and isolation from the ACID properties. The rules reworded from [8] are:

1. All children of a subtransaction must be resolved (committed or aborted) before it commits itself.
2. A subtransaction that unilaterally commits, first reaches its local commit point. However, it cannot finally commit until its parent transaction commits. Consequently, a subtransaction will commit only if it commits locally and all its ancestors commit including the top-level transaction.
3. If one of the ancestors of a subtransaction aborts, then the subtransaction itself will have to abort. In other words, the abort of a subtransaction causes the abort of all its children. Even if the subtransaction commits, its actions must be undone due to the abort of an ancestor. This is the reason that nested subtransactions violate the durability of ACID properties.

A nested transaction at the top level (i.e., the entire nested transaction as a whole) does observe durability. Therefore, nested transactions as a whole obey the ACID properties, despite the fact that individual nested subtransactions may violate the durability property.

Advantages of Nested Transactions

1. Nested transactions allow for a simple composition of subtransactions improving modularity of the overall structure.
2. The concurrent execution of subtransactions that follow the prescribed rules allows for enhanced concurrency while preserving consistency. This enhanced concurrency occurs because transactions can create subtransactions which execute concurrently.
3. The success or failure of a subtransaction is independent of the success of its siblings. When a subtransaction fails, its parent may try to execute it again, or ignore the failure, depending on the

situation. Therefore, failures that are contained within the scope of a subtransaction may be tolerated and do not necessarily cause the failure of the entire nested transaction.

Gray and Reuter present a mechanism to emulate nested transactions using database savepoints [6]. This approach emulates recovery as accurately as prescribed in the nested transaction model; however, it emulates locking not as flexibly as described in nested transactions.

Key Applications

Several systems were influenced by the nested transactions model, and as such they either incorporated or adapted its concept. The implementation of nested transactions by Moss, and especially the locking mechanism was used in the Argus system in which Moss worked with Liskov [7]. Camelot is another system that used nested transactions. It is a transaction processing system developed at Carnegie Mellon University using the Avalon programming language [5]. Camelot was a precursor to the Encina distributed transaction processing monitor which uses the Transactional-C language. Encina was commercialized under the name Transarc Corporation, which was acquired by IBM in 1994.

Nested transactions have also been implemented in Berkeley DB – a database library with bindings for several programming languages, which originated at the University of California – Berkeley, distributed by Sleepycat Software, which was acquired by Oracle Corporation in 2006.

Several researchers have also proposed systems with transaction processing components that are designed for application domains such as manufacturing, CSCW, software engineering, etc. where the ACID properties may be considered too strict; therefore, relaxed or advanced transaction models have been proposed to address the specific requirements that exist in these domains. Several of these transaction models appear in a book by Elmagarmid [4].

A notable example of an extension to the concept of nested transactions is the *multi-level transaction model* and its closely related *open nested transaction model* by Weikum and Schek [10,12]. The multi-level transaction model is represented by a transaction tree like in nested transactions; however, unlike nested transactions the transaction tree is balanced. Multi-level concurrency control takes advantage of the semantics of conflicting operations in the same level of the tree, such as commutativity, in order to enhance concurrency. In open nested transactions, the subtransactions are not restricted to have the same depth and are allowed to commit their results without waiting for their ancestors to commit [11].

.NET Remoting

Aniruddha Gokhale
Vanderbilt University, Nashville, TN, USA

Synonyms

Subsumed by windows communication framework

Definition

.NET Remoting [1,2] is a Microsoft technology comprising a set of application programming interfaces (APIs) for interprocess communication available within the .NET Framework. .NET Remoting serves as the distribution middleware layer, which enables communication between distributed applications that can choose their own transport protocol, serialization format, an application model and different schemes to manage object lifetimes.

Key Points

Central to the .NET Remoting architecture is the notion of a *remotable object* and a brokering capability that enables communication between *application domains*. An application domain in the .NET framework provides a type-safe and secure unit of execution and isolation. .NET Remoting makes it feasible for multiple application domains to communicate with each other without concern for whether they are hosted within the same operating system process, or across multiple different processes within the same node or across a network.

A remotable object is an object which is declared to be serializable remotable objects can cross application domain boundaries. Remotable Objects are published via an *Activation URL*. Client applications invoking services of a remotable object do so via proxies.

An important feature of .NET Remoting is its ability to allow applications to define their own serialization format, the choice of transport protocol used, and application model used by the communicating entities. By virtue of using the Common Language Runtime (CLR), .NET Remoting can provide interoperability across multiple managed languages. But its portability is restricted to Microsoft platforms only.

NASD; Object-based Storage Device; OSD

Definition

A Network Attached Secure Device (often abbreviated to NASD) is a networked storage device which offers object-level storage accesses. NASD was first explored in a research project of the same name, which started at Carnegie Mellon University in 1995. NASD is now more often called Object based Storage Device (shortened to OSD).

Key Points

NASD is an approach of decoupling only low-level functions of file systems from NAS devices. A NASD manages only stored objects, each of which is identified with a unique file descriptor, and their additional information such as metadata and attributes, whereas a central policy server manages higher-level information which is used for name space management and authorization. A bunch of NASDs, with the assistance of the central policy server, can together work as a file store. This may look similar to NAS at a glance, but the difference is that most commands and data are directly transferred between clients and NASDs. Conventional storage subsystems have a number of storage devices under a storage controller, which is thus likely to become a performance bottleneck. NASD has benefits of scaling aggregate bandwidth by spreading partial functions over a number of disk processors.

Object-level storage abstraction, introduced by NASD, is recognized to be the third alternative in addition to block-level storage abstraction typically seen in SAN storage environments and file-level storage abstraction in NAS storage environments. Content-Addressable Storage is another example which offers object-level storage accesses and is now widely deployed in enterprise systems.

The idea of NASD has been standardized as ANSI T10 SCSI OSD, which specifies an extension of the SCSI protocol for clients and devices to exchange objects and their related information. Thus, OSD is sometimes seen as a promising infrastructure of intelligent storage devices in which more intelligence will be incorporated.

Network Attached Storage

Kazuo Goda
The University of Tokyo, Tokyo, Japan

Synonyms

NAS

Definition

Network attached storage is a storage device which is connected to a network and provides file access services. Network attached storage is often abbreviated to NAS. Although the term NAS refers originally to such a storage device, when the term is used in the context of explaining and comparing storage network architectures it sometimes refers to a storage network architecture in which NAS devices are mainly implemented.

Key Points

A NAS device is basically comprised of disk drives which store files and controllers which export access services to the files. A file sever which runs network file system (NFS) and/or common internet file system (CIFS) to export file sharing services is a type of NAS implementation, but recent NAS products are sometimes implemented using dedicated hardware and software to increase reliability and performance. A diskless NAS device which contains only controllers is sometimes referred to as a NAS gateway or a NAS head. A NAS gateway/head has two types of network ports: one is connected to disk storage devices over a SAN and the other is to NAS clients over IP networks. The clients are thus provided with access services towards files stored in the storage devices. That is, a NAS gateway/head can be seen as a service bridge between SAN and NAS systems.

CODASYL data model; DBTG data model

Definition

A database management system complies with the *network data model* when the data it manages are organized as data records connected through binary relationships. Data processing is based on navigational primitives according to which records are accessed and updated one at a time, as opposed to the set orientation of the relational query languages. Its most popular variant is the CODASYL DBTG data model that was first defined in the 1971 report from the CODASYL group, and that has been implemented into several major DBMSs. They were widely used in the seventies and eighties, but most of them are still active at the present time.

Historical Background

In 1962, C. Bachman of General Electric, New-York, started the development of a data management system according to which data records were interconnected via a network of relationships that could be navigated through [2]. Called Integrated Data Store (IDS), this disk-based system quickly became popular to support the storage, the management and the exploitation of corporate data.

IDS was the main basis of the work of the CODASYL Data Base Task Group (DBTG) that published its first major report in 1971 [3,6], followed by a revision in 1973 [3,9]. This report described a general architecture for DBMSs, where the respective roles of the operating system, the DBMS and application programs were clearly identified. It also provided a precise specification of languages for data structure definition (Data Description Language or Schema DDL), for data extraction and update (Data Manipulation Language or DML) and for defining interfaces for application programs through language-dependent views of data (Sub-schema DDL).

The 1978 report [7,9] clarified the model. In particular physical specifications such as indexing structures and storage were removed from the DDL and collected into the Data Storage Description Language (DSDL), devoted to the physical schema description. In 1985, the X3H2 ANSI Database Standard committee issued standards for network database management systems, called NDL and based on the 1978 CODASYL report. However, due to the increasing dominance of the relational model these proposals have never been implemented nor updated afterwards.

Some of the most important implementations were Bull IDS/II (an upgrade of IDS), NCR DBS, Siemens UDS-1 and UDS-2, Digital DBMS-11, DBMS-10 and DBMS-20 (now distributed by Oracle Corp.), Data General DG/DBMS, Philips Phollas, Prime DBMS, Univac DMS 90 and DMS 1100 and Cullinane IDMS, a machine-independent rewriting of IDS (now distributed by Computer Associates). Other DBMSs have been developed, that follow more or less strictly the CODADYL specifications. Examples include Norsk-Data SYBAS, Burroughs DMS-2, CDC IMF, NCR IDM-9000, Cincom TOTAL and its clone HP IMAGE (which were said to define the *shallow* data model), and MDBS and Raima DbVista that both first appeared on MS-DOS PCs.

In the seventies, IBM IMS was the main competitor of CODASYL systems [11]. From the early eighties, they both had to face the increasing influence of relational DBMSs such as Oracle (from 1979) and IBM SQL/DS (from 1982 [8]). Nowadays, most CODASYL DBMSs provide an SQL interface, sometimes through an ODBC API. Though the use of CODASYL DBMSs is slowly decreasing, many large corporate databases are still managed by network DBMSs. This state of affairs will most probably last for the next decade. Network databases, as well as hierarchical databases, are most often qualified *legacy*, inasmuch as they are often expected to be replaced, sooner or later, by modern database engines.

Foundations

The presentation of the network model is based on the specifications published in the 1971 and 1973 reports, with which most CODASYL DBMSs comply.

The Languages

The data structures and the contents of a database can be created, updated and processed by means of four languages, namely the *Schema DDL* and *Sub-schema DDL*, through which the global schema and the subschemas of the database are declared, the *Data Storage Description Language* or *DSDL* (often named *DMCL*) that allows physical structures to be defined and tuned, and the *DML* through which application programs access and update the contents of the database.

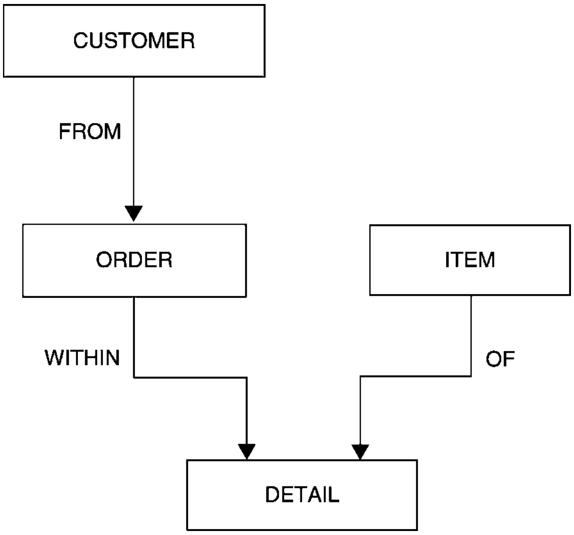
Gross Architecture of a CODASYL DBMS

The CODASYL reports define the interactions between client application programs and the database. The resulting architecture actually laid down the principles of modern DBMSs. The DBMS includes (at least) three components, namely the DDL compiler, the DML compiler and the database control system (DBCS, or simply system). The DDL compiler translates the data description code into internal tables that are stored in the database, so that they can be exploited by the DML compiler at program compile time and by the DBCS at program run time. Either the DML compiler is integrated into the host language compiler (typically COBOL) or it acts as a precompiler. It parses applications programs and replaces DML statements with calls to DBMS procedures. The DBCS receives orders from the application programs and executes them. Each program includes a *user working area* (UWA) in which data to and from the database are stored. The UWA also comprises registers that inform the program on the status of the last operations, and in particular references to the last records accessed/updated in each record type, each area, each set type and globally for the current process. These references, called *currency indicators*, represent static predefined cursors that form the basis for the navigational facilities across the data.

The Data Structures

The pictorial representation of a schema, or *Data Structure Diagram* [1], looks like a graph, where the nodes are the database *record types* and the edges are *set types*, that is, binary 1:N relationship types between record types, conventionally directed from the *one* side to the *many* side. Both record types and set types are named (Fig. 1). In this popular representation, record fields as well as various characteristics of the data structures are ignored.

Records and Record Types A *record* is the data unit exchanged between the database and the application program. A program reads one record at a time from the database and stores one record at a time in the database. Records are classified into *record types* that define their common structure and default behavior. The intended goal of a record type is to represent a real world entity type. A database key, which is a database-wide system-controlled identifier, is associated with each record, acting as an object-id.



Network Data Model. Figure 1. Diagram representation of the schema of a sample database.

Each database includes the SYSTEM record type, with one occurrence only, that can be used to define access paths across user record types through SYSTEM-owned singular set types.

The schema specifies, via the record type *location mode*, how a record is stored and how it is retrieved when storing a dependent record. This feature is both very powerful and, when used at its full power, fairly complex. Two main variants are proposed:

- location mode *calc using field-list*: the record is stored according to a hashing technique (or later through B-tree techniques) applied to the record key, composed of one or several fields of the record type (*field-list*); at run time, the default way to access a record will be through this record key;
- location mode *via set type S*: the record is physically stored as close as possible to the current record of set type *S*; later on, the default way to access a record will be through an occurrence of S identified by its *set selection* mode.

Record Fields A record type is composed of *fields*, the occurrences of which are *values*. Not surprisingly (CODASYL was also responsible for the COBOL specifications), their structure closely follow the record declaration of COBOL. The DDL offers the following field structures:

- *data item*: elementary piece of data of a certain type (arithmetic, string, implementor defined);
- *vector*: array of values of the same type; its size can be fixed or variable;
- *repeating group*: a somewhat misleading name for a possibly repeating aggregate of fields of any kind.

The fields of a record type can be atomic or compound, single-valued or multi-valued, mandatory or optional (through the null value); these three dimensions allow complex, multi-level field structures to be defined.

Sets and Set Types Basically, a CODASYL *set* is a list of records made up of a head record (the *owner* of the set) followed by zero or more other records (the *members* of the set). A *set type* S is a schema construct defined by its name and comprising one owner record type and one or more member record type(s). Considering set type S with owner type A and member type B, any A record is the owner of one and only one occurrence of S and no B record can be a member of more than one occurrence of S. In other words, a set type materializes a 1:N relationship type. The owner and the members of a set type are distinct. This limitation has been dropped in the 1978 specifications, but has been kept in most implementations (exceptions: SYBAS and MDBS). Cyclic structures are allowed provided they include at least two record types. It must be noted that a set type can include more than one member record type.

The member records of S can be ordered (first, last, sorted, application-defined). This characteristic is static and cannot be changed at run-time as in SQL. The insertion of a member record in an occurrence of S can be performed at creation time (automatic insertion mode) or later by the application program (manual insertion mode). Once a record is a member of an occurrence of S, its status is governed by the retention mode; it can be removed at will (optional), it cannot be changed (fixed) or it can be moved from an occurrence to another but cannot be removed (mandatory).

The *set [occurrence] selection* of S defines the default way an occurrence of S is determined in certain DML operations such as storing records with automatic insertion mode.

Areas An area is a named logical repository of records of one or several types. The records of a definite type can be distributed in more than one area. The intended goal is to offer a way to partition the set of the database records according to real world dimensions, such as geographic, organizational or temporal. However, since areas are mapped to physical devices, they are sometimes used to partition the data physically, e.g., across disk drives.

Schema and Sub-schemas The data structures of each database are described by a schema expressed in the DDL. Though DDL is host language independent, its syntax is reminiscent of COBOL. Views are defined by sub-schemas. Basically, a subschema is a host language dependent description of a subset of the data structures of a schema. Some slight variations are allowed, but they are less powerful than relational database capabilities. Figure 2 shows a fragment of the schema declaring the data structures of Fig. 1.

Data Manipulation

The DML allows application programs to ask the DBCS data retrieval and update services. The program accesses the data through a sub-schema that identifies the schema objects the instances of which can be retrieved and updated as well as their properties, such as the data type of each field. Exchange between the host language and the DBCS is performed via the UWA, a

```
schema name is ORDER-MANAGEMENT.

area name is DOMESTIC.
area name is FOREIGN.

record name is CUSTOMER within DOMESTIC, FOREIGN;
location mode is calc using CUST-NO duplicates not allowed.
2 CUST-NO type is character 10.
2 CUST-NAME type is character 45.
2 CUST-ADDRESS.
  4 STREET character 32.
  4 CITY character 20.
  4 PHONE type is character 15 occurs 3 times.

record name is ORDER within DOMESTIC;
location mode is via FROM set;
duplicates not allowed for ORD-NO.
  2 ORD-NO type is decimal 12.
  2 ORD-DATE type is date.

set name is FROM;
owner is CUSTOMER;
order is sorted duplicates not allowed;
member is ORDER mandatory automatic key is ascending ORD-NO;
set selection is through current of FROM.
```

Network Data Model. Figure 2. Fragment of the DDL code defining the schema of Fig. 1.

shared set of variables included in each running program. This set includes the currency indicators, the process status (e.g., the error indicators) and record variables in which the data to and from the database are temporarily stored. Many DML statements use the currency indicators as implicit arguments. Such is the case for set traversal and for record storing. Based on the currency indicators, on the *location mode* of record types and on the *set selection* option of set types, sophisticated positioning policies can be defined, leading to tight application code.

Data Retrieval The primary aim of the *find* statement is to retrieve a definite record on the basis of its position in a specified collection and to make it the current of all the *communities* which it belongs to, that is, its database, its area, its record type and each of its set types. For instance, if an *ORDER* record is successfully retrieved, it becomes the current of the database for the running program (the *current of run unit*), the current of the *DOMESTIC* area, the current of the *ORDER* record type and the current of the *FROM* and *WITHIN* set types. The variants of the *find* statement allow the program to scan the records of an area, of a record type and of the members and the owner of a set. They also provide selective access among the members of a set.

The *get* statement transfers field values from a current record in the UWA, from which they can then be processed by the program.

Data Update

A record *r* is inserted in the database as follows: first, field values of *r* are stored in the UWA, then the current of each set in which *r* will be inserted is retrieved and finally a *store* instruction is issued. The *delete* instruction applies to the current record. For this operation, the DBCS enforces a *cascade* policy: if the record to be deleted is the owner of sets whose members have a mandatory or fixed retention mode, those members are deleted as well. The *modify* statement transfers in the current of a record type the new values that have been stored in the UWA. Insertion and removal of the current of a record type is performed by *insert* and *remove* instructions. Transferring a mandatory member from a set to another cannot be carried out by merely removing then inserting the record. A special case of the *modify* statement makes such a transfer possible. Later specifications as well as some implementations propose a specific statement for this operation.

Figure 3 shows, in an arbitrary procedural pseudocode, a fragment that processes the orders of customer *C400* and another fragment that creates an *ORDER* record for the same customer.

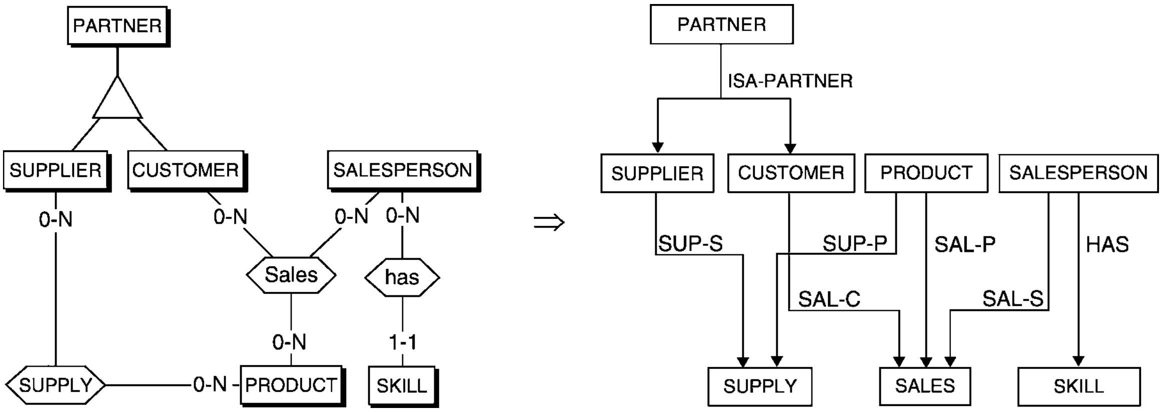
Entity-relationship to Network Mapping

Among the many DBMS data models that have been proposed since the late sixties, the network model is probably the closest to the Entity-Relationship model [5]. As a consequence, network database schemas tend to be more readable than those expressed in any other DBMS data model, at least for simple schemas. Each entity type is represented by a record type, each attribute by a field and each simple relationship type by a set type. Considering modern conceptual formalisms, the network model suffers from several deficiencies,

```
CUSTOMER.CUST-NO := "C400"                      /* store search key value in the UWA
find CUSTOMER record                            /* find CUSTOMER record "C400"
find first ORDER record of FROM set             /* find first ORDER record owned by this CUSTOMER record
while ERROR-COUNT = 0
    get ORDER                                   /* get item values of current ORDER record
    <process item values of current ORDER>
    find next ORDER record of FROM set          /* find first ORDER record
end-while

CUSTOMER.CUST-NO := "C400"
find CUSTOMER record                            /* make CUSTOMER record "C400" the current of FROM
if ERROR-COUNT = 0 then
    ORDER.ORD-NO := 30183                       /* store value of ORD-NO in the UWA
    ORDER.CUST-DATE := "2008/08/19"             /* store value of ORD-DATE in the UWA
    store ORDER                                 /* store ORDER record and insert it in the current FROM set
end-if
```

Network Data Model. Figure 3. Two examples of data manipulation code.



Network Data Model. Figure 4. Partial translation of a representative Entity-relationship schema (left) into a network schema (right).

notably the lack of generalization-specialization (is-a) hierarchies and the fact that relationship types are limited to the 1:N category. Translating an Entity-relationship schema into the network model requires the transformation of these missing constructs into standard structures.

Is-a hierarchies. Three popular transformations can be applied to express this construct in standard data management systems, namely one record type per entity type, one record type per supertype and one record type per subtype. Representing each entity type by a distinct record type and forming a set type *S* with each super-type (as owner of *S*) and all its direct subtypes (as members of *S*) is an appropriate implementation of the first variant.

1:1 relationship type. This category is a special case of 1:N and can be expressed by a mere set type, together with dynamic restriction on the number of members in each set. However, merging both record types when one of them depends on the other one (e.g., as an automatic, mandatory member) is also a common option.

Complex relationship type. In most implementations, n-ary and N:N relationship types as well as those with attributes must be reduced to constructs based on 1:N relationship types only through standard transformations. A complex relationship type *R* is represented by a relationship record type *RT* and by as many set types as *R* has roles. The attributes of *R* are translated into fields of *RT*. Cyclic relationship types, if necessary, will be translated in the same way.

Figure 4 illustrates some of these principles.

Discussion

The network model offers a simple view of data that is close to semantic networks, a quality that accounts for much if its past success. The specifications published in the 1971 and 1973 reports exhibited a confusion between abstraction levels that it shared with most proposals of the seventies and that was clarified in later recommendations, notably the 1978 report and X3H2 NDL. In particular, the DDL includes aspects that pertain to logical, physical and procedural layers.

Though they were not implemented in most commercial DBMSs, the CODASYL recommendations included advanced features that are now usual in database technologies such as database procedures, derived fields, check and some kind of triggers.

Key Applications

CODASYL DBMSs have been widely used to manage large corporate databases submitted to both batch and OLTP (On-line Transaction Processing) applications. Compared with hierarchical and relational DBMS, their simple and intuitive though powerful model and languages made them very popular for the development of large and complex applications. However, their intrinsic lack of flexibility in rapidly evolving contexts and the absence of user-oriented interface made them less attractive for decisional applications, such as data warehouses.

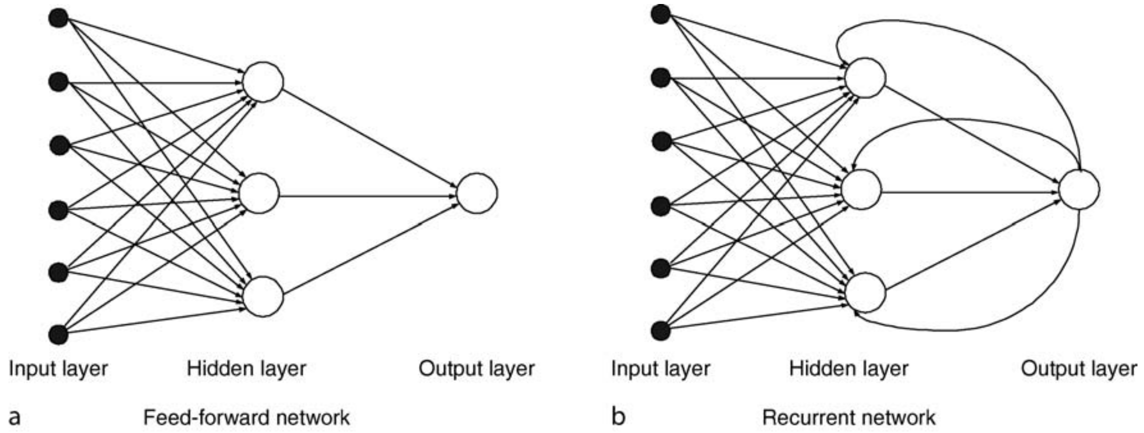
Definition

An artificial neural network (ANN) is an abstract computational model designed to solve a variety of supervised and unsupervised learning tasks. While the discussion in this chapter focuses only on supervised classification, readers who are interested in unsupervised learning using ANN may refer to the literature on vector quantization [6] and self organizing maps [11]. An ANN consists of an assembly of simple processing units called neurons connected by a set of weighted edges (or synapses), as shown in Fig. 1. The neurons are often configured into a feed-forward multi-layered topology, with outputs from one layer being fed into the next layer. The first layer, which is known as the input layer, encodes the attributes of the input data, while the last layer, known as the output layer, encodes the neural network's output. Hidden layers are the intermediary layers of neurons between the input and output layers. A feed-forward ANN without any hidden layer is called a perceptron [16]. Another common ANN architecture is the recurrent network, which allows a neuron to feed its output back into the inputs of other preceding neurons in the network. Such a network topology is useful for modeling temporal and sequential relationships in dynamical systems.

Historical Background

The design of an ANN was inspired by the desire to emulate how a human brain works. Interest in this field began to emerge following the seminal work of McCulloch and Pitts [13], who attempted to understand how complex patterns can be modeled in the brain using a large number of inter-connected neurons. They presented a simplified model of a neuron and showed how a collection of these neurons could be used to represent logical propositions. Nevertheless, they did not provide an algorithm to estimate the weights of the network.

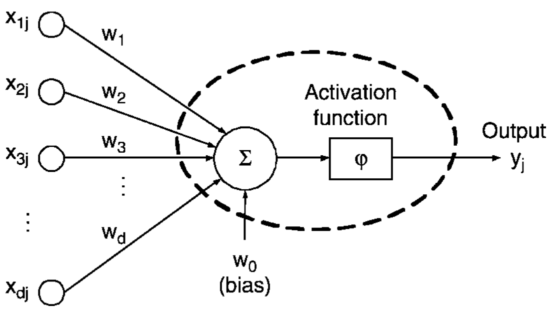
A major step forward in the study of ANN occurred when Hebb [7] formulated a postulate relating the cerebral activities of the brain to the synaptic connections between neurons. Hebb theorized that the process of learning takes place when a pair of neurons is activated repeatedly, thus making their synaptic connection stronger. By strengthening the connection, this enables the network to recognize the appropriate response when the same stimulus is re-applied. This idea forms the basis for what is now known as Hebbian learning.



Neural Networks. Figure 1. Architecture of artificial neural network.

The invention of the perceptron by Rosenblatt [16] marked another major development of the field. Rosenblatt demonstrated that a simple perceptron can be trained to recognize visual patterns by modifying its weights using an iterative error correcting algorithm. A theorem was subsequently proposed to show the guaranteed convergence of the perceptron training rule in finite time – a result that subsequently triggered a wave of interest in the field. During this period, new perceptron training algorithms began to emerge, such as the Widrow-Hoff [18] and stochastic gradient descent [2] algorithms. Such interest, however, began to wane as Minsky and Papert [14] showed the practical limitations of perceptrons, particularly in terms of solving nonlinearly separable problems such as the exclusive-or (XOR) function. Though multi-layer neural networks may overcome these limitations, there has yet to be any feasible learning algorithms that can automatically adjust the weights of the neurons in the hidden layer.

Interest in ANN was finally rekindled in the 1980s, fueled by the successful development of the Boltzmann machine [1] and the re-discovery of the backpropagation algorithm [17], both of which demonstrated the feasibility of training multi-layer neural networks. Furthermore, as computers become cheaper, this permits more researchers to participate in the field and experiment with the capabilities of neural networks, unlike the situation in the 1960s. Research in ANN continued to flourish with the development of more complex networks such as radial basis function networks [15], Hopfield networks [8], Jordan networks [10], and Elman networks [4].



Neural Networks. Figure 2. Structure of an artificial neuron.

Foundations

Neurons are the elementary processing units of an ANN. The structure of a neuron is shown in Fig. 2. Each neuron consists of a set of weighted edges $\{w_1,w_2,,w_d\}$, a threshold w_0 (known as the bias), an adder Σ that computes the weighted sum of its input, and an activation function φ that transforms the weighted sum into its output value. The computation performed by a neuron can be expressed in the following form:

$$y_j = \varphi\left(\sum_{i=1}^{d} w_i x_{ij} + w_0\right) \equiv \varphi(z_j) \qquad (1)$$

The output of a neuron can be discrete or continuous, depending on the choice of activation function. For example, the Heaviside function can be used to produce a binary-valued output:

$$\varphi(z) = \begin{cases} 1, z \geq 0 \\ 0, \text{otherwise} \end{cases}$$

while the linear function $\varphi(z) = z$ and sigmoid function

$$\varphi(z) = \frac{1}{1 + \exp\left(-z\right)}$$

produce a continuous-valued output.

An ANN must be trained to determine the appropriate set of weights for a given classification task. Training is accomplished by processing the training examples one at a time and comparing the predicted class of a training example to its actual class. The error in prediction is then used to modify the weights of the network. This process is repeated until a stopping criterion is satisfied.

Table 1 shows the activation functions and weight update formula employed by several perceptron learning algorithms. Notice that the amount of weight adjustment is proportional to the difference between the true output y_j and the predicted output $\varphi(z_j)$ of a neuron. Computing the error term $[y_j - \varphi(z_j)]$ in the weight update formula is straightforward for perceptrons, but is more challenging for multi-layer networks because the true output of each hidden neuron is unknown. Furthermore, it is unclear the extent to which each of the neuron's weight contributes to the overall network error, an issue that is known as the credit assignment problem. The backpropagation algorithm attempts to overcome this problem by employing a differentiable activation function (such as the sigmoid function) so that a gradient descent strategy can be used to derive the weight update formula. In the backpropagation algorithm, the weight update step is decomposed into two phases. During the forward phase, the outputs of the neurons are computed one layer at a time, starting from neurons in the first hidden layer, followed by those in the next layer until the neurons in the output layer are computed. Next, during the backward phase, the errors are propagated in the reverse direction, starting from neurons in the output layer, followed by those in the preceding layer until the errors of neurons in the first hidden layer are computed.

Neural Networks. Table 1. Perceptron training rules

Perceptron training rule	Activation function	Weight update formula
Rosenblatt's perceptron	Heaviside function	$w_i \leftarrow w_i + \eta[y_j - \varphi(z_j)]x_{ij}$
Widrow-Hoff	Linear function	$w_i \leftarrow w_i + \eta \sum_j [y_j - \varphi(z_j)]x_{ij}$
Stochastic gradient descent	Linear function	$w_i \leftarrow w_i + \eta[y_j - \varphi(z_j)]x_{ij}$

There are several issues that must be considered when building an ANN model. First, the structure of the network must be appropriately chosen to avoid model overfitting. To determine the structure with the right model complexity, model selection approaches such as cross-validation may be used. Regularization methods are also applicable to penalize network structures that are overly complex. Another possibility is to apply the Bayesian approach, which provides a principled framework for handling the model complexity problem. A review of the Bayesian approach for neural networks can be found in [16]. The cascade correlation algorithm [17] is another useful approach to grow the network dynamically from a structure with no hidden layers. Hidden nodes are then added one at a time until the residual error of the network falls within some acceptable level.

Since the error function of a multi-layer neural network is not convex, convergence of the backpropagation algorithm to a local minimum is another potential issue to consider. One way to mitigate the problem is by adding a momentum term to the weight update formula to escape from the local minimum. Alternative strategies include repeating the network simulation with different initial weights and applying a stochastic gradient descent method to estimate the network weights.

Instead of learning a discriminant function to distinguish instances from different classes, an ANN can also be trained to produce posterior probabilities of their class memberships. This is desirable because a probabilistic framework provides a natural way to compensate for imbalanced class distributions, to incorporate the cost of misclassification into decision making, and to fuse the outputs from multiple networks. An ANN can be designed to generate probabilistic outputs by training its weights to minimize the cross-entropy error function [12] instead of the sum-of-square error function.

As ANN encodes a sophisticated mathematical function, the ability to explain how it makes its prediction is crucial for a number of applications, particularly in the medical and legal domains. Algorithms have been developed to extract symbolic representations or rules from a trained network [18]. Such algorithms generally fall into two categories. The first category generates rules based on features constructed from the weights of the network connections. The second category uses the trained network to label a data set and then applies rule extraction algorithms on the labeled data set.

In general, multi-layer neural networks are universal approximators, allowing them to fit any type of function. Furthermore, since it is an abstract computational model, it is also applicable to a variety of supervised, unsupervised, and semi-supervised learning tasks.

Key Applications

ANN has been successfully applied to various applications including pattern recognition (face, handwriting, and speech recognition), finance (bankruptcy prediction, bond rating, and economic forecasting), manufacturing (process control, tool condition monitoring, and robot scheduling), and computer aided diagnosis (arrhythmia identification and tumor detection in biological tissues).

Future Directions

As ANN is an abstract computational model that is applicable to a wide spectrum of learning tasks, much of the future advances in this field are tied to progress in the areas of supervised, unsupervised, and semi-supervised learning.

Experimental Results

The experimental evaluation often depends on the learning tasks. For supervised classification, some of the typical evaluation criteria include model accuracy, specificity, sensitivity, F-measure, and run-time for model building.

Data Sets

A large collection of data sets are available at the UCI data mining and machine learning repository. For a more comprehensive list of data sets and other information about neural networks, go to http://www.neural-forecasting.com/.

Url to Code

A comprehensive set of functions for implementing feed-forward and recurrent neural networks is available in MATLAB toolbox.

N-Gram Models

Djoerd Hiemstra
University of Twente, AE Enschede, The Netherlands

Definition

In language modeling, *n*-gram models are probabilistic models of text that use some limited amount of history, or word dependencies, where *n* refers to the number of words that participate in the dependence relation.

Key Points

In automatic speech recognition, *n*-grams are important to model some of the structural usage of natural language, i.e., the model uses word dependencies to assign a higher probability to "how are you today" than to "are how today you," although both phrases contain the exact same words. If used in information retrieval, simple unigram language models (*n*-gram models with $n = 1$), i.e., models that do not use term dependencies, result in good quality retrieval in many studies. The use of bigram models (*n*-gram models with $n = 2$) would allow the system to model direct term dependencies, and treat the occurrence of "New York" differently from separate occurrences of "New" and "York," possibly improving retrieval performance. The use of trigram models would allow the system to find direct occurrences of "New York metro," etc. The following equations contain respectively (1) a unigram model, (2) a bigram model, and (3) a trigram model:

$$P(T_1, T_2, \cdots T_n|D) = P(T_1|D)P(T_2|D) \cdots P(T_n|D) \tag{1}$$

$$\begin{aligned} &P(T_1, T_2, \cdots T_n|D) \\ &\quad = P(T_1|D)P(T_2|T_1, D) \cdots P(T_n|T_{n-1}, D) \end{aligned} \tag{2}$$

$$\begin{aligned} &P(T_1, T_2, \cdots T_n|D) \\ &\quad = P(T_1|D)P(T_2|T_1, D)P(T_3|T_1, T_2, D) \\ &\quad \cdots P(T_n|T_{n-2}, T_{n-1}, D) \end{aligned} \tag{3}$$

The use of *n*-gram models increases the number of parameters to be estimated exponentially with *n*, so special care has to be taken to smooth the bigram or trigram probabilities. Several studies have shown small but significant improvements of using bigrams if smoothing parameters are properly tuned [2,3]. Improvements of the use of *n*-grams and other term dependencies seem to be bigger on large data sets [1].

Noise Addition

Josep Domingo-Ferrer
Universitat Rouira i Virgili, Tarragona, Catalonia

Synonyms

Additive noise

Definition

Noise addition is a masking method for statistical disclosure control of numerical microdata that consists of adding random noise to original microdata.

Key Points

The noise addition algorithms in the literature are:

1. *Masking by uncorrelated noise addition.* The vector of observations x_j for the jth attribute of the original dataset X_j is replaced by a vector

$$z_j = x_j + \epsilon_j$$

where ϵ_j is a vector of normally distributed errors drawn from a random variable $\varepsilon_j \sim N(0, \sigma^2_{\varepsilon_j})$, such that $Cov(\varepsilon_t, \varepsilon_l) = 0$ for all $t \neq l$. This does not preserve variances nor correlations.
2. *Masking by correlated noise addition.* Correlated noise addition also preserves means and additionally allows preservation of correlation coefficients. The difference with the previous method is that the covariance matrix of the errors is now proportional to the covariance matrix of the original data, i.e., $\varepsilon \sim N(0, \Sigma_\varepsilon)$, where $\Sigma_\varepsilon = \alpha\Sigma$.
3. *Masking by noise addition and linear transformation.* In Kim [1], a method is proposed that ensures by additional transformations that the sample covariance matrix of the masked attributes is an unbiased estimator for the covariance matrix of the original attributes.
4. *Masking by noise addition and nonlinear transformation.* An algorithm combining simple additive noise and nonlinear transformation is proposed in Sullivan [2]. The advantages of this proposal are that it can be applied to discrete attributes and that univariate distributions are preserved. Unfortunately, the application of this method is very time-consuming and requires expert knowledge on the data set and the algorithm.

See Brand [3] for more details on specific algorithms.

Nonparametric Data Reduction Techniques

Rui Zhang
University of Melbourne, VIC, Australia

Definition

A nonparametric data reduction technique is a data reduction technique that does not assume any model for the data.

Key Points

Nonparametric data reduction (NDR) techniques is opposite to parametric data reduction (PDR) techniques. A PDR technique must assume a certain model for the data. Parameters of the model are determined before the data reduction is performed. A NDR technique does not assume any model and is applied to the data directly. The data reduction effectiveness of a PDR technique heavily depends on whether the model suits the data well. If well-suited, good accuracy as well as substantial data reduction can be achieved; otherwise, both cannot be achieved at the same time. A NDR technique yields more uniform effectiveness irrespective of the data, but it may not achieve as high data reduction as a well-suited PDR technique.

Popular NDR techniques include histograms, clustering and indexes. Histograms are used to approximate data distributions. An equidepth histogram can adjust itself to the data distribution and always gives good approximation of the data, no matter how the data are distributed. Clustering techniques also find the cluster centers automatically, irrespective of the data distribution. Although parameters are used in some clustering algorithms, such as the value of k in a k-means algorithm, k is a given parameter instead of a parameter determined by the actual data. Conceptually, indexes are similar to clustering and they also adjust themselves to the data distribution. No parameter needs to be determined from the data for indexes. A summary of data reduction techniques including NDR techniques can be found in [1].

Non-Perturbative Masking

► Non-Perturbative Masking Methods

Non-Perturbative Masking Methods

Josep Domingo-Ferrer
The Public University of Tarragona, Tarragona, Spain

Synonyms

Non-perturbative masking

Definition

Non-perturbative masking methods are SDC methods for microdata protection which do not alter data; rather, they produce partial suppressions or reductions of detail in the original dataset. Sampling, global recoding, top and bottom coding and local suppression are examples of non-perturbative masking methods.

Key Points

1. Sampling is a non-perturbative masking method for statistical disclosure control of microdata. Instead of publishing the original microdata file, what is published is a sample S of the original set of records. Sampling methods are suitable for categorical microdata, but for continuous microdata they should probably be combined with other masking methods. The reason is that sampling alone leaves a continuous attribute V_i unperturbed for all records in S. Thus, if attribute V_i is present in an external administrative public file, unique matches with the published sample are very likely: indeed, given a continuous attribute V_i and two respondents o_1 and o_2, it is

highly unlikely that V_i will take the same value for both o_1 and o_2 unless $o_1 = o_2$ (this is true even if V_i has been truncated to represent it digitally).

2. Global recoding or generalization is a masking method for statistical disclosure control of microdata. For a categorical attribute V_i, several categories are combined to form new (less specific) categories, thus resulting in a new V'_i with $|D(V'_i)| < |D(V_i)|$ where $|\cdot|$ is the cardinality operator. For a numerical attribute, global recoding means replacing V_i by another attribute V'_i which is a discretized version of V_i. In other words, a potentially infinite range $D(V_i)$ is mapped onto a finite range $D(V'_i)$. This technique is more appropriate for categorical microdata, where it helps disguise records with strange combinations of categorical attributes. Global recoding is used heavily by statistical offices. Global recoding is implemented in the μ-Argus package. In combination with local suppression, it can be used to achieve *k*-anonymity.
3. Top coding and bottom coding are special cases of the global recoding masking method for statistical disclosure control of microdata. Their operating principle is that top values (those above a certain threshold), respectively bottom values (those below a certain threshold), are lumped together to form a new category. Top and bottom coding can be used on attributes that can be ranked, that is, numerical or categorical ordinal.
4. Local suppression or blanking is a masking method for statistical disclosure control of microdata. Certain values of individual attributes are suppressed with the aim of increasing the set of records agreeing on a combination of key values. Local suppression is implemented in the μ-Argus package. Ways to combine local suppression and global recoding are discussed in DeWaal and Willenborg (1995). In fact, the combination of both methods can be used to attain *k-anonymity.* If a numerical attribute V_i is part of a set of key attributes, then each combination of key values is probably unique. Since it does not make sense to systematically suppress the values of V_i, it can be asserted that local suppression is rather oriented to categorical attributes.

Nontemporal semantics

Definition

Nonsequenced semantics guarantees that query language statements can reference and manipulate the timestamps that capture the valid and transaction time of data in temporal databases as regular attribute values, with no built-in temporal semantics being enforced by the query language.

Key Points

A temporal database generalizes a non-temporal database and associates one or more timestamps with database entities. Different authors have suggested temporal query languages that provide advanced support for formulating temporal statements. Results of these efforts include a variety of temporal extensions of SQL, temporal algebras, and temporal logics that simplify the management of temporal data.

Languages with built-in temporal support are attractive because they offer convenient support for formulating a wide range of common temporal statements. The classical example of advanced built-in temporal support is *sequenced semantics*, which makes it possible to conveniently interpret a temporal database as a sequence of non-temporal databases. To achieve built-in temporal support, the timestamps are viewed as implicit attributes that are given special semantics.

Built-in temporal support, however, may also limit the expressiveness of the language when compared to the original non-temporal language where timestamps are explicit attributes. Nonsequenced semantics guarantees that statements can manipulate timestamps as regular attribute values with no built-in temporal semantics being enforced. This ensures that the expressiveness of the original language is preserved.

The availability of legacy statements with the standard non-temporal semantics is also important in the context of migration where users can be expected to be well-acquainted with the semantics of their non-temporal language. Nonsequenced semantics ensures that users are able to keep using the paradigm they are familiar with and to incrementally adopt the new features. Moreover, from a theoretical perspective, any variant of temporal logic, a well-understood language that only provides built-in temporal semantics, is strictly less expressive than a first order logic language with explicit references to time [1,4].

Each statement of the original language has the potential to either be evaluated with temporal or non-temporal semantics. For example, a count query can count the tuples at each time instant (this would be temporal, i.e., sequenced, semantics) or count the tuples actually stored in a relation instance (this would be non-temporal, i.e., nonsequenced, semantics).

To distinguish the two semantics, different approaches have been suggested. For instance, TempSQL distinguishes between so-called current and classical users. ATSQL and SQL/Temporal offer so-called statement modifiers that enable the users to choose between the two semantics at the granularity of statements. Below, statement modifiers are used for illustration. Specifically the ATSQL modifier `NSEQ VT` signals standard SQL semantics with full control over the timestamp attributes of a valid-time database.

The illustrations assume a database instance with three relations:

Employee

ID	Name	VTIME
1	Bob	5–8
3	Pam	4–12
4	Sarah	1–5

Salary

ID	Amt	VTIME
1	20	4–10
3	20	6–9
4	20	6–9

Bonus

ID	Amt	VTIME
1	20	1–6
1	20	7–12
3	20	1–12

and the following queries

```
NSEQ VT
   SELECT COUNT(*) FROM Bonus;

NSEQ VT
   SELECT E.ID
   FROM Employee AS E, Salary AS S
   WHERE VTIME(E) PRECEDES VTIME(S) AND
   E.ID = S.ID;
```

Both queries are nonsequenced, i.e., the valid time is treated as a regular attribute without any special processing going on. The first query determines the number of bonuses that have been paid. It returns the number of tuples in the `Bonus` relation, which is equal to three. Note that if the sequenced modifier was used (cf. *sequenced semantics*) then the time-varying count had been computed. With the given example, the count at each point in time would be two. The second query joins `Employee` and `Salary`. The join is not performed at each snapshot (cf. *sequenced semantics*). Instead it requires that the valid time of `Employee` precedes the valid time of `Salary`. The result is a non-temporal table.

Nonsequenced statements offer no built-in temporal support, but instead offer complete control. This is akin to programming in assembly language, where one can do everything, but everything is hard to do. The query language must provide a set of functions and predicates for expressing temporal relationships (e.g., `PRECEDES` [2]) and performing manipulations and computations on timestamps (e.g., `VTIME`). The resulting new query-language constructs are relatively easy to implement because they only require changes at the level of built-in predicates and functions. Instead of using functions and predicates on timestamps, the use of temporal logic with temporal connectives has also been suggested.

NF-SS; Normalizing ORA-SS diagrams

Definition

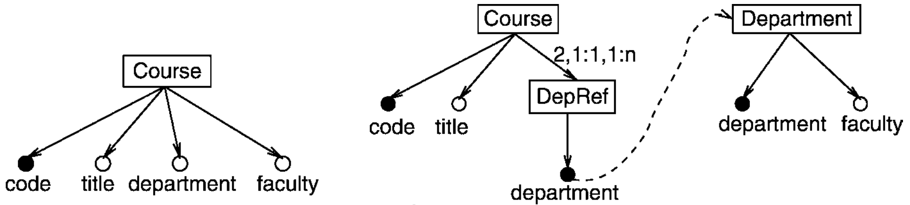
Normal forms have been defined for data models, such as the relational data model, the nested relational data model, the object-oriented data model and more recently, the semi-structured data model, to recognize (and remove) certain kinds of redundant data. A normal form that has been defined for semi-structured data, based on the ORA-SS data model, is described.

Key Points

The definition of a normal form for ORA-SS (Object-Relationship-Attribute data model for Semi-structured data) diagrams is based on the definition of a normal form for the nested relational data model as described by Ling and Yan [1], recognizing the similarity between the nesting relationship in the nested relational data model and hierarchies in the semi-structured data model.

The definition for NF ORA-SS (normal form for the ORA-SS data model) can be broken into three main parts. The first part ensures that every object class is normalized. The second part ensures that every relationship type is normalized. The third part ensures that there is no data that can be derived from other data in the diagram. Examples of ORA-SS schemas that are not in NF ORA-SS are shown below, along with schemas that are in NF ORA-SS that capture the same information.

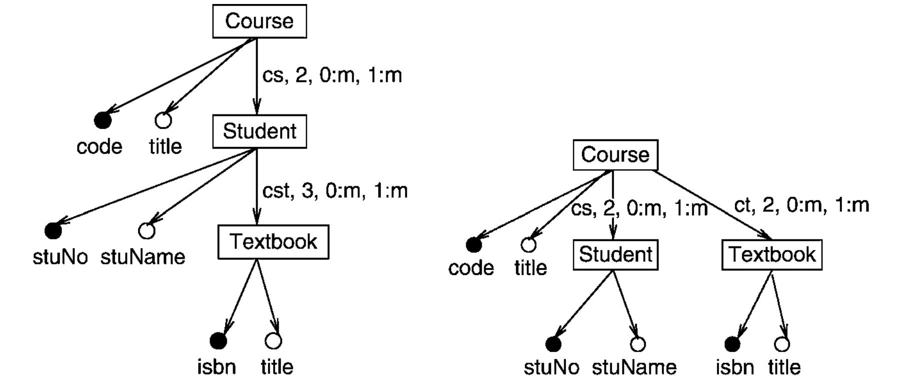
Figure 1a represents an object class *Course*. The attributes of course are *code*, *title*, *department* and *faculty*. This object class is not normalized since *code* determines *title* and *department*, but *department* determines *faculty*. What this means is that a department belongs to only one faculty, and this information needs to be stored once rather than once for every course. Figure 1b has object classes *Course*, *DepRef* and *Department*. Object class *DepRef* has a reference to object class *Department*, so the information about the faculty a department belongs to is stored only once. The object classes in Fig. 1b are normalized.



a Object class *course* is not normalized

b Object classes *course* and *department* are normalized

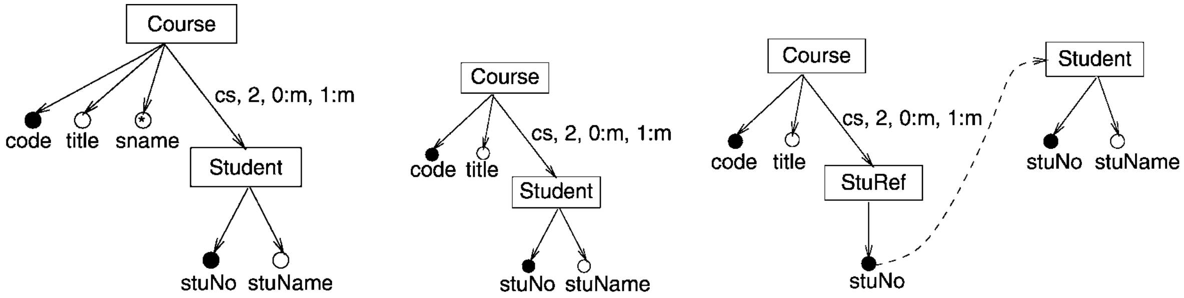
Normal Form ORA-SS Schema Diagrams. Figure 1. Example of object class normal form.



a Relationship type *cst* is not normalized

b Relationship types *ct* and *cs* are normalized

Normal Form ORA-SS Schema Diagrams. Figure 2. Example of relationship type normal form.



a ORA-SS schema where student name is duplicated

b ORA-SS schema where student is duplicated

c An ORA-SS schema in NF ORA-SS

Normal Form ORA-SS Schema Diagrams. Figure 3. Example of ORA-SS normal form (NF ORA-SS).

Figure 2a shows a relationship type *cst*, which is a ternary relationship type among the object classes *Course*, *Student*, and *Textbook*. Intuitively it makes sense because courses have students and textbooks. However, students and textbooks are independent of each other. A course has a certain set of students, irrespective of the textbooks for the course, and a course has a certain set of textbooks irrespective of the students taking the course. In the schema in Fig. 2a, the textbooks for a given course are repeated for each student taking the course. Figure 2b has two relationship types *cs* and *ct*, between *Course* and *Student*, and *Course* and *Textbook*, respectively. Both of these relationship types are normalized. However, the object classes *Student* and *Textbook* in Fig. 2b are still not normalized.

Figure 3a shows two object classes *Course* and *Student*. Object class *Course* has attributes *code*, *title* and *sname*. Attribute *sname* is a multivalued attribute and has the names of the students taking the course. This information is repeated in the attribute *stuName* that belongs to object class *Student*, so the ORA-SS schema in Fig. 3a is not in NF ORA-SS. If the student names are stored only in the attribute *stuName* of object class *Student*, as shown in Fig. 3b that redundancy is removed. Of course the many-to-many relationship type leads to the students name being repeated in every course the student takes. Using a reference to represent this relationship removes this redundancy and the resulting ORA-SS diagram in Fig. 3c is in NF ORA-SS.

Normal Forms and Normalization

Marcelo Arenas
Pontifical Catholic University of Chile, Santiago, Chile

Definition

A normal form defines a condition over a set of data dependencies, or semantic constraints, that has been specified as part of a database schema. This condition is used to check whether the design of the database has some desirable properties (for example, the database does not store redundant information), and if this is not the case, then it can also be used to convert the poorly designed database into an equivalent well-designed one.

Historical Background

Information is one of the most – if not the most – valuable assets of a company. Therefore, organizations need tools to allow them to structure, query and analyze their data, and, in particular, they need tools providing simple and fast access to their information.

During the last 30 years, relational databases have become the most popular computer application for storing and analyzing information. The simplicity and elegance of the relational model, where information is stored just as tables, has largely contributed to this success.

To use a relational database, a company first has to think of its data as organized in tables. How easy it is for a user to understand this organization and use the database depends on the design of these relations. If tables are not carefully selected, users can spend too much time executing simple operations, or may not be able to extract the desired information.

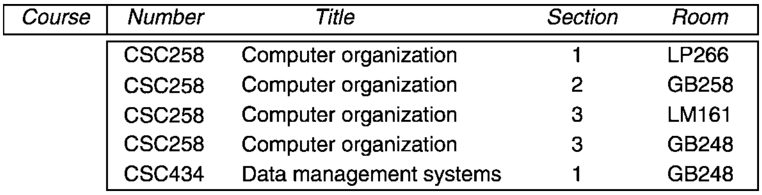
Since the beginnings of the relational model, it was clear for the research community that the process of designing a database is a nontrivial and time-consuming task. Even for simple application domains, there are many possible ways of storing the data of interest. Soon the difficulties in designing a database became clear for practitioners, and the design problem was recognized as one of the fundamental problems for the relational technology.

During the 70s and 80s, a lot of effort was put into developing methodologies to aid in the process of deciding how to store data in a relational database. The most prominent approaches developed at that time – which today are a standard part of the relational technology – were the entity-relationship and the normalization approaches. In the former approach, a diagram is used to specify the objects of an application domain and the relationships between them. The *schema* of the relational database, i.e., the set of tables and column names, is then automatically generated from the diagram. In the normalization approach, an already designed relational database is given as input, together with some semantic information provided by a user in the form of relationships between different parts of the database, called *data dependencies*. This semantic information is then used to check whether the design has some desirable properties, and if this is not the case, it can also be used to convert the poor design into an equivalent well-designed database.

Foundations

In the relational model, a database is viewed as a collection of relations or tables. For instance, a relational database storing information about courses in a university is shown in Fig. 1. This relation consists of a time-varying part, the data about courses, and a part considered to be time independent, the *schema* of the relation, which is given by the name of the relation (*Course*) and the names of the attributes of this relation.

Usually, the information contained in a database satisfies some *semantic* restrictions. For example, in the



Course	Number	Title	Section	Room

Normal Forms and Normalization. Figure. 2. Example of a normalized relational database.

relation *Course* shown in Fig. 1, it is expected that only one title is associated with each course number. These restrictions are called *data dependencies*, and they are expressed by using suitable languages. For example, the previous constraint corresponds to a functional dependency, which is an expression of the form $X \rightarrow Y$, where X and Y are sets of attributes. A relation satisfies $X \rightarrow Y$ if for every pair of tuples t_1,t_2 in it, if t_1 and t_2 have the same values on X, then they have the same values on Y. Thus, for example, the relation shown in Fig. 1 satisfies functional dependency *Number* → *Title* since each course has only one title.

In [2], Codd showed that a database containing functional dependencies may exhibit some anomalies when the information is updated. For example, consider again the relational database shown in Fig. 1, which includes functional dependency *Number* → *Title*. This database is prone to three different types of anomalies. First, if the name of the course with number CSC258 is changed to Computer Organization I, then four distinct cells need to be updated. If any of them is not updated, then the information in the database becomes inconsistent. This anomaly was called an *update anomaly* by Codd [2], and it arises because the instance is storing redundant information. Second, if the information is updated because a new semester is starting, and the course with number CSC434 is not given in that semester, then the last tuple of the instance is deleted and no information about CSC434 appears in the updated instance. This has the additional effect of deleting the title of the course, which will be the same the next time that CSC434 is offered. This anomaly was called a *deletion anomaly* by Codd [2], and it arises because the relation is storing information that is not directly related; the sections of a course vary from one term to another while its title is likely not to be changed from one semester to the next one. This can also lead to *insertion anomalies* [2]; if a new course (CSC336, Numerical Methods) is created, then it cannot be added to the database until at least one section and one room is assigned to the course.

To avoid updates anomalies, Codd introduced three increasingly restrictive *normal forms* [2,3], which specify some syntactic properties that the set of functional dependencies in a database must satisfy. The most restrictive among them is known today as Boyce-Codd Normal Form (BCNF). Informally, a database schema S including a set Σ of functional dependencies is in BCNF, if there is no set of attributes $X \cup \{A\} \cup \{B\}$ such that $A, B \notin X$, $X \rightarrow A$ holds in S but $X \rightarrow B$ does not hold in S, that is, if there are no attributes in S with different levels of association between them according to Σ (If $X \rightarrow A$ holds in S but $X \rightarrow B$ does not hold in S, then for every value of X, there exists only one value of A in the database but possibly many values of B.). For example, the database shown in Fig. 1 is not in BCNF since *Number* → *Title* holds in this database, while *Number* → *Section* does not hold.

In [2], Codd also introduced the first *normalization algorithm*, that is, a procedure that takes as input a relational schema that includes some data dependencies and does not satisfy some particular normal form, and produces a new schema that conforms to this normal form. For example, if S is the relational schema *Course* (*Number*, *Title*, *Section*, *Room*) and Σ is the set of functional dependencies $\{Number \rightarrow Title\}$, then the standard normalization algorithm for BCNF [1] produces a new schema where *Course* is split into two tables: *CourseInfo*(*Number*, *Title*) and *CourseTerm*(*Number*, *Section*, *Room*). In Fig. 2, it is shown how the information in the initial database in Fig. 1 is stored under the new schema. It should be noticed that the new schema is not prone to any of the anomalies mentioned at the beginning of this section:

- If the name of the course with number CSC258 is changed to Computer Organization I, then only one cell needs to be updated.
- If the information is updated because a new semester is starting, and the course with number CSC434 is not given in that semester, then the last tuple of relation *CourseTerm* is deleted. This does not have the additional effect of deleting the title of the course (this information is kept in the relation *CourseInfo*).
- If a new course (CSC336, Numerical Methods) is created, then it can be added to the database even if no section has been created for this course (tuple (CSC336, Numerical Methods) is included only in the relation *CourseInfo*).

A normalization algorithm takes as input a relational schema and generates a database schema in some particular normal form. It is desirable that these two are as similar as possible, that is, they should contain the same data and the same semantic information. These properties have been called *information losslessness* and *dependency preservation* in the literature, respectively.

Let S_1,S_2 be two database schemas. Intuitively, two instances I_1 of S_1 and I_2 of S_2 contain the same information if it is possible to retrieve the same information from them, that is, for every query Q_1 over I_1 there exists a query Q_2 over I_2 such that $Q_1(I_1) = Q_2(I_2)$, and vice versa. To formalize this notion, a query language has to be chosen. If this query language is relational algebra, then this notion is captured by the notion of calculously dominance introduced by Hull [7]. Schema S_2 *dominates* S_1 *calculously* if there exist relational algebra expressions Q over S_1 and Q' over S_2 satisfying the following property: For every instance I of S_1, there exists an instance I' of S_2 such that $Q(I) = I'$ and $Q'(I') = I$. Thus, every query Q_1 over I can be transformed into an equivalent query $Q_2 = Q_1 \circ Q'$ over I', since $Q_2(I') = Q_1(Q'(I')) = Q_1(I)$, and, analogously, every query Q_2 over I' can be transformed into an equivalent query $Q_1 = Q_2 \circ Q$ over I, since $Q_1(I) = Q_2(Q(I)) = Q_2(I')$.

Normalization algorithms try to achieve the goal of information losslessness; if any of them transforms a database schema S into a database schema S', then S' should dominate S calculously. The standard normalization algorithm for BCNF uses only the projection operator to transform a schema [1] and, thus, calculously dominance is defined in terms of this operator and its inverse, the join operator. More precisely, the normalization algorithm mentioned in this section takes as input a relation R and a set of functional dependencies Σ, and uses the projection operator to transform it into a database schema in BCNF that is composed by some relations $R_1,\ldots,R_n$. Then $R_1,\ldots,R_n$ is a *lossless decomposition* of R if for every instance I of R there is an instance I' of $R_1,\ldots,R_n$ such that:

- For every $i \in \{1,\ldots,n\}$, it holds that $I'_i = \pi_{U_i}(I)$, where I'_i is the R_i-relation of I' and U_i is the set of attribute of R_i, and
- $I = I'_1 \bowtie I'_2 \bowtie \ldots \bowtie I'_n$, where each I'_i is the R_i-relation of I'.

That is, every instance I of S can be transformed into an instance I' of S' by using the projection operator, and I can be reconstructed from I' by using the join operator. For example, the relation *CourseInfo* in Fig. 2 can be obtained by projecting the relation *Course* in Fig. 1 over the set of attributes $\{Number, Title\}$, while the relation *CourseTerm* in Fig. 2 can be obtained by projecting the relation *Course* in Fig. 1 over the set of attributes $\{Number, Section, Room\}$. Moreover, the relation *Course* in Fig. 1 can be obtained by joining relations *CourseInfo* and *CourseTerm* in Fig. 2. Given that this holds for every instance I of the initial schema *Course* (*Number*,*Title*,*Section*,*Room*), the new schema *CourseInfo* (*Number*,*Title*), *CourseTerm* (*Number*, *Section*, *Room*) is said to be a lossless decomposition of the initial one.

Normalization algorithms also try to achieve the goal of dependency preservation; if any of them transforms a database schema S including a set Σ of data dependencies, into a database schema S' including a set Σ' of data dependencies, then Σ should be equivalent to Σ' (no semantic information is lost). In the running example, the standard normalization algorithm for BCNF produces a new schema *CourseInfo*(*Number*, *Title*) and *CourseTerm*(*Number*, *Section*, *Room*), and also includes dependency *Number* → *Title* in the relation *CourseInfo*. Thus, the new schema is a dependency preserving decomposition of the initial one.

The normalization approach was proposed in the early 70s by Codd [2]. Since then, many researchers have studied the normalization problem for relational databases and other data models, and today it is possible to find normal forms for many different types of data dependencies: 3NF [2] and BCNF [3] for functional dependencies, 4NF [4] for multivalued dependencies, PJ/NF [5] and 5NFR [8] for join dependencies, and DK/NF [6] for general constraints. These normal forms, together with normalization algorithms for converting a poorly designed database into a well-designed database, can be found today in every database textbook.

Key Applications

Normal forms and normalization algorithms are essential to schema design, redundancy elimination, update anomaly prevention and efficient storage.

Current time; Current date; Current timestamp; Until changed

Definition

The word *now* is a noun in the English language that means "at the present time." This notion appears in databases in three guises. The first use of *now* is as a function within queries, views, assertions, etc. For instance, in SQL, `CURRENT_DATE` within queries, etc., returns the current date as an SQL `DATE` value; `CURRENT_TIME` and `CURRENT_TIMESTAMP` are also available. These constructs are nullary functions.

In the context of a transaction that contains more than one occurrence of these functions, the issue of which time value(s) to return when these functions are invoked becomes important. When having these functions return the same (or consistent) value, it becomes a challenge to select this time and to synchronize it with the serialization time of the transaction containing the query.

The second use is as a database variable used extensively in temporal data model proposals, primarily as timestamp values associated with tuples or attribute values in temporal database instances. As an example, within transaction-time databases, the stop time of data that has not been logically deleted and thus is current is termed "until changed." A challenging aspect of supporting this notion of *now* has been to contend with instances that contain this variable when defining the semantics of queries and modification and when supporting queries and updates efficiently, e.g., with the aid of indices.

The third use of *now* is as a database variable with a specified offset (a "now-relative value") that can be stored within an implicit timestamp or as the value of an explicit attribute. Challenges include the specification of precise semantics for database instances that contain these variables and the indexing of such instances.

Historical Background

Time variables such as *now* are of interest and indeed are quite useful in databases, including databases managed by a conventional DBMS, that record time-varying information, the validity of which often depends on the current-time value. Such databases may be found in many application areas, such as banking, inventory management, and medical and personnel records.

The SQL nullary functions CURRENT_DATE, CURRENT_TIME, and CURRENT_TIMESTAMP have been present since SQL's precursor, SEQUEL 2 [1]. The transaction stop time of *until changed* has been present since the initial definition of transaction-time databases (e.g., in the early work of Ben-Zvi [2]).

The notion of *now* and the surprisingly subtle concerns with this ostensibly simple concept permeate the literature, and yield quite interesting solutions.

Foundations

The three notions of "now" in temporal databases are explored in more detail below.

SQL Nullary Functions

The following example illustrates the uses and limitations of *now*, specifically the SQL CURRENT_DATE, CURRENT_TIME, and CURRENT_TIMESTAMP, in conventional databases. Banking applications record when account balances for customers are valid. Examine the relation AccountBalance with attributes AccountNumber, Balance, FromDate, and ToDate. To determine the balance of account 12345 on January 1, 2007, one could use a simple SQL query.

```
SELECT Balance
FROM AccountBalance
WHERE Account = 12345
  AND FromDate <= DATE '2007-01-01'
  AND DATE '2007-01-01' < ToDate
```

To determine the balance of that account *today*, the nullary function CURRENT_DATE is available.

```
SELECT Balance
FROM AccountBalance
WHERE Account = 12345
  AND FromDate <= CURRENT_DATE
  AND CURRENT_DATE < ToDate
```

Interestingly, in the SQL standard, the semantics of the function are implementation-dependent, which opens it to various interpretations: "If an SQL-statement generally contains more than one reference to one or more <datetime value functions>s then all such references are effectively evaluated simultaneously. The time of evaluation of the <datetime value function > during the execution of the SQL-statement is implementation-dependent." (This is from the SQL:1999 standard.) So an implementation is afforded considerable freedom in choosing a definition of "current," including perhaps when the statement was presented to the system, or perhaps when the database was first defined.

Transactions take time to complete. If a transaction needs to insert or modify many tuples, it may take minutes. However, from the point of view of the user, the transaction is atomic (all or nothing) and serializable (placed in a total ordering). Ideally "current" should mean "when the transaction executed," that is, the instantaneous time the transaction logically executed, consistent with the serialization order.

Say a customer opens an account and deposits $200. This transaction results in a tuple being inserted into the AccountBalance table. The transaction started on January 14 at 11:49 P.M. and committed at 12:07 A.M. (that is, starting before midnight and completing afterwards). The tuple was inserted on 11:52 P.M. Another user also created a second account with an initial balance of $500 in a transaction that started on January 14 at 11:51 P.M. and committed on 11:59 P.M., inserting a tuple into the AccountBalance relation at 11:52 P.M. If the system uses the transaction start time, the following two tuples will be in the relation.

According to these two tuples, the sum of balances on January 14 is $700. But note that though both transactions began on January 14, only the second transaction committed by midnight (also note that the second transaction is earlier in the serialization order since it commits first). Hence, the actual aggregate balance on January 14 was never $700: the balance started at $0 (assuming there were initially no other tuples), then changed to $500. Only on January 15 did it increase to $700.

Suppose that instead of using the time at which the entire transaction began, the time of the actual insert statement (e.g., for the first transaction, January 14, 11:52 P.M.) is used; then the same problem occurs.

What is desired is for a time returned by CURRENT_DATE to be consistent with the serialization order and with the commit time, which unfortunately is not known when CURRENT_DATE is executed. Lomet et al. [3] showed how to utilize the lock manager to assign a commit time in such a way that it is consistent with the serialization order as well as with dates assigned as values to prior CURRENT_DATE invocations. Specifically, each use of CURRENT_DATE, etc. defines or narrows a *possible period* during which the commit time of the transaction must reside. For CURRENT_DATE this period is the particular 24 hours of the day returned by this function. Read-write conflicts with other transactions further narrow the possible period. For example, if a particular transaction reads values written by another transaction, the transaction time of the reader must be later than that of the writer. At commit time, it is attractive to assign the earliest instant in the possible period to the transaction. Alternatively, if the possible period ever becomes empty, the transaction must be aborted. Lomet et al. outline important optimizations to render such calculations efficient.

Now in End or Stop Columns

The above discussion concerned how to determine what to store in the begin time of a tuple (e.g., in the FromDate column for the two example tuples in the table displayed above) and how to make this time consistent with that returned by CURRENT_DATE. We now consider what to store in the end time of a tuple (e.g., in the ToDate column). The validity of a tuple then starts when a deposit is made and extends until the current time, assuming no update transactions are committed. Thus, on January 16, the balance is valid from January 14 until January 16; on January 17, the balance is valid from January 14 until January 17; etc.

It is impractical to update the database each day (or millisecond) to correctly reflect the valid time of the balance. A more promising approach is to store a variable, such as *now*, in the ToDate field of a tuple, to indicate that the time when a balance is valid depends on the current time. In the example, it would be recorded on January 14 that the customer's balance of $200 is valid from January 14 through *now*. The CURRENT_DATE construct used in the above query cannot be stored in a column of an SQL table. All major commercial DBMSs have similar constructs, and impose this same restriction. The user is forced instead to store a specific time, which is cumbersome and inaccurate (Clifford et al. explain these difficulties in great detail [4]).

The solution is to allow one or more free, current-time variables to be stored in the database. Chief among these current-time variables is "*now*" (e.g., [5]), but a variety of other symbols have been used, including "–" [2], "∞" [6], "@" [7], and "*until-changed*" [8]. Such stored variables have advantages at both the semantic and implementation levels. They are expressive and space efficient and avoid the need for updates at every moment in time.

As an example, consider a variable database with the tuple ⟨*Jane*, *Assistant*, [*June 1*, *now*]⟩, with *now* being a variable. The query "List the faculty on June 15," evaluated on June 27, results in {⟨*Jane*, *Assistant*⟩}.

Now-Relative Values

A now-relative instant generalizes and adds flexibility to the variable *now* by allowing an offset from this variable to be specified. Now-relative instants can be used to more accurately record the knowledge of Jane's employment. For example, it may be that hiring changes are recorded in the database only 3 days after they take effect. Assuming that Jane was hired on June 1, the definite knowledge of her employment is accurately captured in the tuple ⟨*Jane*, *Assistant*, [*June 1*, *now* − 3 *days*]⟩ . This tuple states that Jane was an Assistant Professor from June 1 and until three days ago, but it contains no information about her employment as of, e.g., yesterday.

A now-relative instant thus includes a displacement, which is a signed duration, also termed a span, from *now*. In the example given above, the displacement is minus 3 days. Now-relative variables can be extended to be indeterminate [4], as can regular instants and the variable *now*.

AccountNumber	Balance	FromDate	ToDate
121345	200	2007-01-14	...
543121	500	2007-01-14	...

The semantics of now variables has been formalized with an *extensionalization* that maps from a *variable database level* containing variables as values to an *extensional database level*. The extensional database exhibits three key differences when compared to the variable database level. First, no variables are allowed – the extensional level is fully ground. Second, timestamps are instants rather than intervals. Third, an extensional tuple has one additional temporal attribute, called a *reference time attribute*, which may be thought of as representing the time at which a meaning was given to the temporal variables in the original tuple. Whereas the variable-database level offers a convenient representation that end-users can understand and that is amenable to implementation, the mathematical simplicity of the extensional level supports a rigorous treatment of temporal databases in terms of first order logic.

When a variable database is queried, an additional problem surfaces: what to do when a variable is encountered during query evaluation. In the course of evaluating a user-level query, e.g., written in some dialect of SQL, it is common to transform it into an internal algebraic form that is suitable for subsequent rule or cost-based query optimization. As the query processor and optimizer are among the most complex components of a database management system, it is attractive if the added functionality of current-time-related timestamps necessitates only minimal changes to these components.

Perhaps the simplest approach to supporting querying is that, when a timestamp that contains a variable is used during query processing (e.g., in a test for overlap with another timestamp), a ground version of that timestamp is created and used instead. With this approach, only a new component that substitutes variable timestamps with ground timestamps has to be added, while existing components remain unchanged.

Put differently, a *bind* operator can be added to the set of operators already present. This operator is then utilized when user-level queries are mapped to the internal representation. The operator accepts any tuple with variables. It substitutes a ground value for each variable and thus returns a ground (but still variable-level) tuple. Intuitively, the *bind* operator sets the perspective of the observer, i.e., it sets the reference time. Existing query languages generally assume that the temporal perspective of an observer querying a database is the time when the observer initiates the query.

Torp et al. has shown how to implement such variables within a database system [9].

With *now* as a database variable, the temporal extent of a tuple becomes a non-constant function of time. As most indices assume that the extents being indexed are constant in-between updates, the indexing of the temporal extents of now-relative data poses new challenges.

For now-relative transaction-time data, one may index all data that is not now-relative (i.e., has a fixed end time) in one index, e.g., an R-tree, and all data that is now-relative (i.e., the end time is *now*) in another index where only the start time is indexed.

For bitemporal data, this approach can be generalized to one where tuples are distributed among four R-trees. The idea is again to overcome the inabilities of indices to cope with continuously evolving regions, by applying transformations to the growing bitemporal extents that render them stationary and thus amenable to indexing. Growing regions come in three shapes, each with its own transformation. These transformations are accompanied by matching query transformations [10].

In another approach, the R-tree is extended to store *now* for both valid and transaction time in the index. The resulting index, termed the GR-tree, thus accommodates bitemporal regions and uses minimum bounding regions that can be either static or growing and either rectangles or stair shapes. This approach has been extended to accommodate bitemporal data that also have spatial extents [11].

Key Applications

The notion of *now* as a nullary function representing the current time is common in database applications. For relational database management, SQL offers `CURRENT_DATE`, `CURRENT_TIME`, and `CURRENT_TIMESTAMP` functions that return an appropriate SQL time value. In other kinds of database management systems, such as native XML database management systems, similar constructs can be found. For example, XQuery has a `fn:current-time()` function that returns a value of XML Schema's `xs:time` type. XQuery also has a `fn:current-date()` function.

Less common in existing database applications are the other notions of now: as a variable stored in a database to represent the ever-changing current time or as a time related to, but displaced from, the current time.

Future Directions

The convenience of using now variables poses challenges to the designers of database query languages.

The user-defined time types available in SQL-92 can be extended to store now-relative variables as values in columns. The TSQL2, language [12] does so, and also supports those variables for valid and transaction time. In TSQL2, the "bind" operation is implicit; NOBIND is provided to store variables in the database. However, such variables have yet to be supported by commercial DBMSs. It may also be expected that at least one of the three uses of *now* will re-emerge as part of a temporal extension of XQuery or a language associated with the Semantic Web.

The impact of stored variables on database storage structures and access methods is a relatively unexplored area. Such stored variables may present optimization opportunities. For example, if the optimizer knows (through attribute statistics) that a large proportion of tuples has a "to" time of *now*, it may then decide that a sort-merge temporal join will be less effective. Finally, new kinds of variables, such as *here* for spatial and spatio-temporal databases, might offer an interesting extension of the framework discussed here.

Null Values

Leopoldo Bertossi
Carleton University, Ottawa, ON, Canada

Definition

Null values are used to represent *uncertain data values* in a database instance.

Key Points

Since the beginning of the relational data model, *null values* have been investigated, with the intention of capturing and representing data values that are uncertain. Depending on the intuitions and cases of uncertainty, different kinds of null values have been proposed, e.g., they may represent information that is withheld, inapplicable, missing, unknown, etc. Thus, in principle, it could be possible to find in a hypothetical database diverse classes of null values, and also several null values of the same class. However, in commercial relational DBMSs and in the SQL Standard, only a single constant, `NULL`, is used to represent the missing values.

Many semantic problems appear when null values are integrated with the rest of the relational data model, which essentially follows the semantics of predicate logic. Among them, (i) the interpretation of nulls values (for a particular intuition); (ii) the meaning of relational operations when applied to both null values and certain data values; and (iii) the characterization of consistency of databases containing null values.

Different formal semantics for null values have been proposed. A common and well-studied semantic for *incomplete databases* uses null values to represent unknown or missing values. Each null value in the database represents a whole set of possible values from the underlying data domain. The combination of concrete values that null values might take generates a class of alternative instances containing certain values. This *possible worlds semantics* makes true whatever is true in every alternative instance. However, the usage of null values in the SQL Standard and commercial DBMS still lacks a clear and complete formal semantic.

OASIS

Serguei Mankovskii
CA Labs, CA Inc, Thornhill, ON, Canada

Synonyms

Organization for the advancement of structured information standards

Definition

OASIS is a non-for-profit consortium aiming at collaborative development and approval of open international, mainly XML-based, standards.

Key Points

OASIS was founded in 1993 under the name "SGML Open." The initial goal of the organization was to develop guidelines for interoperability among products using Standard Generalized Markup Language (SGML). In 1998 it changed name to OASIS to reflect on changing scope of its technical work.

OASIS consists of an open group of member organizations whose representatives work in committees developing standards, promoting standards adoption, product interoperability and standards conformance. In 2007 OASIS had 5,000 participants representing 600 organizations and individual members in 100 countries. OASIS is governed by a member-elected Board in an annual election process. The board membership is based on the personal merits of Board nominees.

OASIS process allows participants to influence standards that affect their business, contribute to standards advancement and start new standards. The process is designed to promote industry consensus. OASIS strategy values creativity and consensus over conformity and control. It relies on the market to determine the particular approach taken in the development of sometimes overlapping standards.

OASIS maintains collaborative relationships with the International Electrotechnical Commission (IEC), International Organization for Standardization (ISO), International Telecommunication Union (ITU) and United Nations Electronic Commission for Europe (UN/ECE), and National Institute of Standards and Technology (NIST).

Among major accomplishments of the OASIS are such influential of standards as a group of ebXML standards, SAML, XACML, WSRP, WSDM, BPEL, OpenDocument, DITA, DocBook, LegalXML and others.

Object Constraint Language

Martin Gogolla
University of Bremen, Bremen, Germany

Synonyms

OCL

Definition

The Unified Modeling Language (UML) includes a textual language called Object Constraint Language

(OCL). OCL allows users to navigate class diagrams, to formulate queries, and to restrict class diagrams with integrity constraints. From a practical perspective, the OCL may be viewed as an object-oriented version of the Structured Query Language (SQL) originally developed for the relational data model. From a theoretical perspective, OCL may be viewed as a variant of first-order predicate logic with quantifiers on finite domains only. OCL has a well-defined syntax [1,3] and semantics [2].

Key Points

The central language features in OCL are: navigation, logical connectives, collections and collection operations.

Navigation: The navigation features in OCL allow users to determine connected objects in the class diagram by using the dot operator ".". Starting with an expression `expr` of start class `C`, one can apply a property `propC` of class `C` returning, for example, a collection of objects of class `D` by using the dot operator: `expr.propC`. The expression `expr` could be a variable or a single object, for example. The navigation process can be repeated by writing `expr.propC.propD`, if `propD` is a property of class `D`.

Logical Connectives: OCL offers the usual logical connectives for conjunction (`and`), disjunction (`or`), and negation (`not`) as well as the implication (`implies`) and a binary exclusive (`xor`). An equality check (=) and a conditional (`if then else endif`) is provided on all types.

Collections: In OCL there are three kinds of collections: sets, bags, and sequences. A possible collection element can appear at most once in a set, and the insertion order in the set does not matter. An element can appear multiple times in a bag, and the order in the bag collection does not matter. An element can appear multiple times in a sequence in which the order is significant. Bags and sequences can be converted to sets with `->asSet()`, sets and sequences to bags with `->asBag()`, and sets and bags to sequences with `->asSequence()`. The conversion to sequences assumes an order on the elements. The arrow notation is explained in more detail below.

Collection Operations: There is a large number of operations on collections in OCL. A lot of convenience and expressibility is based upon them. The most important operations on all collection types are the following: `forAll` realizes universal quantification, `exists` is existential quantification, `select` filters elements with a predicate, `collect` applies a term to each collection element, `size` determines the number of collection elements, `isEmpty` tests for emptiness, `includes` checks whether a possible element is included in the collection, and `including` builds a new collection `including` a new element.

In addition to the central language features, OCL also has special operations available only on particular collection, e.g., the operation `at` on sequences for retrieving an element by its position. All collection operations are applied with the arrow notation mentioned above. Roughly speaking, the dot notation is used when a property follows, i.e., an attribute or a role follows, and the arrow notation is employed when a collection operation follows.

Variables in collection operations: Most collection operations allow variables to be declared (possibly including a type specification), but the variable may be dropped if it is not needed.

Retrieving all Current Instances of a Class: Another important possibility is a feature to retrieve the finite set of all current instances of a class by appending `.allInstances` to the class name. In order to guarantee finite results `.allInstances` cannot be applied to data types like `String` or `Integer`.

Return types in collection operations: If the collection operations are applied to an argument of type `Set/Bag/Sequence(T)`, they behave as follows: `forAll` and exists returns a `Boolean`, `select` yields `Set/Bag/Sequence(T)`, `collect` returns `Bag/Bag/Sequence(T')`, size gives back `Integer`, `isEmpty` yields `Boolean`, `includes` returns `Boolean`, and `including` gives back `Set/Bag/Sequence(T)`.

Most notably, the operation `collect(...)` changes the type of a `Set(T)` collection to a `Bag(T')` collection. The reason for this is that term inside the `collect` may evaluate to the same result for two different collection elements. In order to reflect that the result is captured for each collection element, the result appears as often as a respective collection element exists. This convention in OCL resembles the same approach in SQL: SQL queries with the additional keyword `distinct` return a set; plain SQL queries without `distinct` return a bag. In OCL, the convention is similar: OCL expressions using the additional conversion `asSet()` as in `collect(...)->asSet()` return a set; plain `collect(...)` expressions without `asSet()` return a bag.

Synonyms

ODB (object database); OODB (object-oriented database); ORDB (object-relational database)

Definition

An object data model provides support for objects as the basis for modeling in a database application. An object is an instance of a class, which is a complex type specification that defines both the state of its instance fields and the behavior provided by its methods. Object features also include a unique object identifier that can be used to refer to the object, as well as the organization of data into class hierarchies that support inheritance of state and behavior. The term object data model encompasses the data model for both object-oriented databases (OODBs) and object-relational databases (ORDBs). OODBs use an object-oriented programming language as the database language and provide inherent support for the persistence of objects with typical database functionality. ORDBs extend relational databases by providing additional support for objects.

Historical Background

The relational data model was developed in the 1970's, providing a way to organize data into tables with rows and columns [4]. Relationships between tables were defined by the concept of foreign keys, where a column (or multiple columns) in one table contained a reference to a primary key value (unique identifier) in another table. The simplicity of the relational data model was complemented by its formal foundation on set theory, thus providing powerful algebraic and calculus-based techniques for querying relational data.

Initially, relational data modeling concepts were used in business-oriented applications, where tables provided a natural structure for the organization of data. Users eventually began to experiment with the use of relational database concepts in new application domains, such as engineering design and geographic information systems. These new application areas required the use of complex data types that were not supported by the relational model. Furthermore, database designers were discovering that the process of normalizing data into table form was affecting performance for the retrieval of large, complex, and hierarchically structured data, requiring numerous join conditions to retrieve data from multiple tables. Around the same time, object-oriented programming languages (OOPLs) were also beginning to develop, defining the concept of user-defined classes, with instance fields, methods, and encapsulation for information hiding [14].

The OOPL approach of defining object structure together with object behavior eventually provided the basis for the development of Object-Oriented Database Systems (OODBs) in the mid-1980's. The *Object-Oriented Database System Manifesto*, written by leading researchers in the database field, was the first document to fully outline the characteristics of OODB technology [1]. OODBs provided a revolutionary concept for data modeling, with data objects organized as instances of user-defined classes. Classes were organized into class hierarchies, supporting inheritance of attributes and behavior. OODBs differed from relational technology through the use of internal object identifiers, rather than foreign keys, as a means for defining relationships between classes. OODBs also provided a more seamless integration of database and programming language technology, resolving the impedance mismatch problem that existed for relational database systems. The impedance mismatch problem refers to the disparity that exists between set-oriented relational database access and iterative one-record-at-a-time host language access. In the OODB paradigm, the OOPL provides a uniform, object-oriented view of data, with a single language for accessing the database and implementing the database application.

The relational database research community responded to the development of OODBs with the *Third Generation Database System Manifesto*, defining the manner in which relational technology can be extended to support object-oriented capabilities [13]. Rowe and Stonebraker developed Postgres as the first object-relational database system (ORDB), illustrating an evolutionary approach to integrating object-oriented and relational concepts [10]. ORDB concepts parallel those found in OODBs, with the notions of user-defined data types, object tables formed from user-defined types, hierarchies of user-defined types and object tables, rows of object tables with internal object identifiers, and relationships between object tables that use object identifiers as references.

Today, several OODB products exist in the market, and most relational database products provide some form of ORDB support. The following section elaborates on the common features of object data models and then differentiates between OODB and ORDB modeling concepts.

Foundations

Characteristics of Object Data Models

An object is one of the most fundamental concepts of the object data model, where an object represents an entity of interest in a specific application. An object has state, describing the specific structural properties of the object. An object also has behavior, defining the methods that are used to manipulate the object. Each method has a signature that includes the method name as well as the method parameters and types. The state and behavior of an object is expressed through an object type definition, which provides an interface for the object. Objects of the same interface are collected into a class, where each object is viewed as an instance of the class. A class definition supports the concept of encapsulation, separating the specification of a class from the implementation of its methods. The implementation of a method can therefore change without affecting the class interface and the way in which the interface is used in application code.

When an object of a class is instantiated, the object is assigned a unique, internal object identifier, or oid [6]. An oid is immutable, meaning that the value of the identifier cannot be changed. The state of an object, on the other hand, is mutable, meaning that the values of object properties can change. In an object data model, object identity is used as the basis for defining relationships between classes, instead of using object state, as in the relational model. As a result, the values of object properties can freely change without affecting the relationships that exist between objects. Object-based relationships between classes are referred to as object references.
