Table

Hans Hinterberger
ETH Zurich, Zurich, Switzerland

Synonyms

Table; List; Matrix

Definition

A data structure to organize the tuples of a relation: {<$value_{ix}$, $value_{iy}$,...>, <$value_{jx}$, $value_{jy}$,...>, ...} in a structured way.

An arrangement of numbers, words, symbols or items of any kind, in columns and rows.

One-way table. The values of one or more variables (sets of data) are displayed either horizontally or vertically as a list. Each row or each column represents one data item.

Two-way table. Also known as a contingency table or cross tabulation (cross tab). The rows are labeled with values of one of two variables and the columns with values of the other. The cell at each row and column intersection displays the value of a characteristic of the data that is shared by the two variables when they have the value displayed in the row and column headings.

Multi-way table. The general idea of cross tabulation extended to more than two variables. The rows or columns or both are grouped by values of additional variables.

Key Points

In database terminology a (one-way) table is the data structure used to represent data that are organized with the relational model.

Two-way and multi-way tables are widely used tools to explore data by examining frequencies of observations that belong to specific categories on more than one variable.

In the context of data visualization, tables are an effective way to show exact numerical values and are usually better suited than graphical methods to represent small data sets. They assist users in making comparisons and provide them with a convenient way of storing data for rapid reference. Tables can be formatted in many different ways to suit the type of data, the purpose of the table and its intended use.

Ehrenberg [3] discusses tables in the context of readability, Bertin [1] considers tables as part of an information processing system, Card et al. [2] use them as a step in the process of mapping data to visual form while Harris [4] lists terms and key elements used in the design of tables.

The terminology for tables has also been influenced by the widespread use of table-based spreadsheet programs. One example is the notion of a *pivot table*, a practical feature to reorganize lists as user specified tables, particularly useful for cross tabulations.

Table

Definition

From microdata, *tabular data* can be generated by crossing one or more categorical attributes. Formally, a table is a function

$$T : D(V_{i1}) \times D(V_{i2}) \times \cdots \times D(V_{il}) \rightarrow \mathbb{R} \text{ or } \mathbb{N}$$

where $l \leq t$ is the number of crossed categorical attributes V_{ij} and D(V_{ij}) is the domain of attribute V_{ij}.

Key Points

There are two kinds of tables: *frequency tables* that display the count of respondents at the crossing of the categorical attributes (in $\mathbb{N}$) and *magnitude tables* that display information on a numerical attribute at the crossing of the categorical attributes (in $\mathbb{R}$). For example, given some census microdata containing attributes "Job" and "Town," one can generate a *frequency table* displaying the count of respondents doing each job type in each town. If the census microdata also contain the "Salary," attribute, one can generate a magnitude table displaying the average salary for each job type in each town. The number n of cells in a table is normally much less than the number r of respondent records in a microdata file. However, tables must satisfy several linear constraints: marginal row and column totals. Additionally, a set of tables is called *linked* if they share some of the crossed categorical attributes: for example "Job" × "Town" is linked to "Job" × "Gender."

Taxonomy: Biomedical Health Informatics

Vipul Kashyap
Partners Healthcare System, Wellesley, MA, USA

Synonyms

Health informatics; Healthcare informatics; Biomedical informatics

Definition

Health informatics or medical informatics is the intersection of information science, computer science, and health care [2]. It deals with the resources, devices, and methods required to optimize the acquisition, storage, retrieval, and use of information in health and biomedicine. Health informatics tools include not only computers but also clinical guidelines, formal medical terminologies, and information and communication systems. Subdomains of (bio) medical or health care informatics include: clinical informatics, nursing informatics, imaging informatics, consumer health informatics, public health informatics, dental informatics, clinical research informatics, bioinformatics, veterinary informatics, pharmacy informatics, and healthcare management informatics. An alternative characterization refers to this field as biomedical informatics [1] takes a broader perspective including the application of computer and information science, informatics, cognitive science and human computer interaction in the practice of biological research, biomedical science, medicine and healthcare [3].

Foundations

This field is now characterized by means of a taxonomy comprising of the various subdomains identified above. The key sub domains are:

1. *Clinical Informatics* focuses on computer applications that address medical data (collection, analysis, representation), and is a combination of information science, computer science, and clinical science designed to assist in the management and processing of data, information and knowledge to support the practice and delivery of clinical care. Key activities covered by this area include Electronic Medical Records (EMRs), Decision Support Systems, Medical Data Mining, Hospital Information Systems and Laboratory Information Systems.
2. *Nursing Informatics* is the multidisciplinary scientific endeavor of analyzing, formalizing, and modeling how nurses collect and manage data, process data into information and knowledge, make knowledge-based decisions and inferences for patient care, and use this empirical and experiential knowledge in order to broaden the scope and enhance the quality of their professional practice. The scientific methods central to nursing informatics are focused on: (i) Using a discourse about motives for computerized systems, (ii) Analyzing, formalizing and modeling nursing information processing and nursing knowledge for all components of nursing practice: clinical practice, management, education and research, (iii) Investigating determinants, conditions, elements, models and processes in order to design, and implement as well as test the effectiveness and efficiency of computerized information, (tele)communication and network systems for nursing practice, and (iv) Studying the effects of these systems on nursing practice.
3. *Imaging Informatics* combines knowledge and capabilities from the fields of medicine, medical imaging (also known as diagnostic radiology), biomedical informatics and Information Technology. Imaging informatics includes the mining of information or knowledge from medical image databases, the use of technology to enhance the medical image interpretation process, and the utility of computer software to digitize medical imaging. The more commonly recognized areas of Imaging Informatics include Picture Archiving and Communications Systems (PACS), Radiology Information Systems (RIS), and Computer-Aided Detection and Diagnosis (CAD).
4. *Consumer Health Informatics* has been defined as a branch of medical informatics that analyses consumers' needs for information; studies and implements methods of making information accessible to consumers; and models and integrates consumers' preferences into medical information systems.
5. *Public Health Informatics* has been defined as the systematic application of information and computer science and technology to public health practice, research, and learning. It is distinguished from healthcare informatics by emphasizing data about populations rather than that of individuals. The activities of public health informatics can be broadly divided into the collection, storage, and analysis of data related to public health.
6. *Dental Informatics* is the understanding, skills and tools that enable the sharing and use of information to promote oral health and improve dental practice, research, education, and management. It encompasses electronic health records, CAD/CAM technology, diagnostic digital imaging and administrative information for all dentistry disciplines.
7. *Clinical Research Informatics* is concerned with the application of informatics theory and methods to design, conduct and improve clinical research and disseminate the knowledge gained. It overlaps considerably with the related rapidly developing domain of Translational Research Informatics. Clinical research is defined by the National Institutes of Health (NIH) as being comprised of studies and trials in human subjects that fall into the three sub-categories: (i) Patient-oriented research conducted with human subjects (or on material of human origin such as tissues, specimens and cognitive phenomena) for which an investigator (or

colleague) directly interacts with human subjects. It includes research on mechanisms of human disease, therapeutic interventions, clinical trials, or development of new technologies; (ii) Epidemiologic and behavioral studies; and (iii) Outcomes research and health services research.

8. *Translational Research Informatics* as defined by the NIH includes two areas of translation. One is the process of applying discoveries generated during research in the laboratory, and in preclinical studies, to the development of trials and studies in humans. The second area of translation concerns research aimed at enhancing the adoption of best practices in the community. Cost-effectiveness of prevention and treatment strategies is also an important part of translational science.
9. *Bioinformatics and Computational Biology* involves the use of techniques including applied mathematics, informatics, statistics, computer science, artificial intelligence, chemistry, and biochemistry to solve biological problems usually on the molecular level. The core principle of these techniques is the use of computing resources in order to solve problems on scales of magnitude far too great for human discernment. Research in computational biology often overlaps with systems biology. Major research efforts in the field include sequence alignment, gene finding, genome assembly, protein structure alignment, protein structure prediction, prediction of gene expression and protein-protein interactions, and the modeling of evolution.
10. *Pharmacy Informatics* is the application of computers to the storage, retrieval and analysis of drug and prescription information. Pharmacy informaticists work with pharmacy information management systems that help the pharmacist make excellent decisions about patient drug therapies with respect to medical insurance records, drug interactions, as well as prescription and patient information. Pharmacy informatics is the study of interactions between people, their work processes and engineered systems within health care with a focus on pharmaceutical care and improved patient safety.

Key Applications

This field is characterized by the key aspects and applications, some of which are discussed in more detail through cross-referenced encyclopedia entries:

- Systems and architectures for electronic medical records.
- Health information systems used for billing, scheduling and other financial operations.
- Information systems used for biomedical and clinical research.
- Decision support systems in healthcare, including clinical decision support systems.
- Standards (e.g., DICOM, HL7) and integration profiles (e.g., Integrating the Healthcare Enterprise) to facilitate the exchange of information between healthcare information systems.
- Information Models such as the HL7/RIM and the openEHR for storage and representation of clinical data in a standardized manner.
- Controlled medical vocabularies (CMVs) such as the Systematized Nomenclature of Medicine, Clinical Terms (SNOMED CT), Logical Observation Identifiers Names and Codes (LOINC), OpenGALEN Common Reference Model or the highly complex UMLS used to allow a standardized way of characterizing medication, laboratory results, and clinical findings.
- Use of hand-held or portable devices to assist providers with data entry/retrieval or medical decision-making, sometimes called mHealth.

Point-versus period-based semantics

Definition

In the context of temporal databases, telic (atelic) data are used to store telic (atelic) facts, and the distinction between telic and atelic data are drawn using the properties of downward and upward inheritance.

- *Downward inheritance*. The *downward inheritance* property implies that one can infer from temporal data d that holds at valid time t (where t is a time period) that d holds in any sub-period (and sub-point) of t.
- *Upward inheritance*. The *upward inheritance* property implies that one can infer from temporal data d that holds at two consecutive or overlapping time periods t_1 and t_2 that d holds in the union time period $t_1 \cup t_2$.

In temporal databases, the semantics of atelic data implies that both downward and upward inheritance holds; on the other hand, neither downward nor upward inheritance holds for telic data.

Historical Background

The distinction between telic and atelic facts dates back to Aristotle's categories [2] and has had a deep influence in the Western philosophical and linguistic tradition. In particular, the distinction between different classes of sentences (called aktionsart classes) according to their linguistic behavior and temporal properties is at the core of the modern linguistic tradition (consider, e.g., the milestone categorization by Vendler [11]). For instance, the upward and downward inheritance properties were used (without adopting terminology, which is imported from Shoham [7] and, more generally, from the artificial intelligence tradition) by Dowty [4] in order to distinguish between Vendler's accomplishments (telic facts) and states along with processes (atelic facts). Starting from the pioneering work by Bennet and Partee [3], several linguistic approaches have pointed out that the traditional point-based semantics, in which facts can be evaluated at each time point, properly applies only to atelic facts, while a period-based semantics is needed in order to properly cope with telic facts. Starting from Allen's milestone approach [1], the telic/atelic dichotomy has also played a major role in the area of artificial intelligence. In the field of temporal databases, the point-based vs. period-based dichotomy was initially related to representation and query evaluation issues (rather than to data semantics); later the connection was made between Aristotle's categories and the telic/atelic data semantics [9,10]. It is the emphasis on data semantics that renders "telic" and "atelic" the preferred term.

Foundations

The distinction between telic and atelic data regards the time when facts hold or occur, i.e., their valid time. The following discussion focuses on the temporal *semantics* of data and queries, independent of the *representation* that is used for time. Moreover, while in several database approaches the semantics of data is not distinguished from the semantics of the query, this presentation follows the logical tradition, stating that data has its own semantics independently of any query language and operators just in the same way in which a knowledge base of logical formulæ have their own semantics – usually expressed in model-theoretic terms.

Data Semantics

In the linguistic literature, most approaches classify facts (or sentences describing facts) according to their temporal properties. In particular, most approaches distinguish between telic and atelic facts, and prior research (see, e.g., [3]) points out that, while the point-based semantics is useful to cope with atelic facts, it is not suitable for telic ones, for which a period-based semantics is needed.

Point-based semantics of data: The data in a temporal relation is interpreted as a sequence of states (with each state a conventional relation, i.e., a set of tuples) indexed by points in time. Each state is independent of every other state.

Such temporal relations can be encoded in many different ways (data language). For example the following are three different encodings of the same information, within a point-based semantics, of John being married to Mary in the states indexed by the times 1, 2, 7, 8, and 9:

$$\text{(i)} < \text{John, Mary}||\{1,2,7,8,9\} >\in \text{R}$$

$$\text{(ii)} < \text{John, Mary}||\{[1-2],[7-9]\} >\in \text{R}$$

$$\text{(iii)} < \text{John, Mary}||[1-2] >\in \text{R and}$$
$$< \text{John, Mary}||[7-9] >\in \text{R}$$

Independently of the representation, the point-based semantics implies that the fact denoted by

<John, Mary> includes 5 individual states as follows:

$$\begin{aligned} 1 &\rightarrow \{< \text{John, Mary} >\}\\ 2 &\rightarrow \{< \text{John, Mary} >\}\\ 7 &\rightarrow \{< \text{John, Mary} >\}\\ 8 &\rightarrow \{< \text{John, Mary} >\}\\ 9 &\rightarrow \{< \text{John, Mary} >\} \end{aligned}$$

Notice that the point-based semantics naturally applies to atelic facts, since both downward and upward inheritance are naturally supported.

Period-based semantics of data: Each tuple in a temporal relation is associated with a multiset of time periods, which are the temporal extents in which the fact described by the tuple occur. In this case, time periods are atomic primitive entities in the sense that they cannot be decomposed. Note, however, that time periods can overlap, unlike time points.

For example, let <John || {[10–20]}> represent the fact that John started to build a house at time 10 and finished at time 20. If a period-based semantics is adopted, the period [10–20] is interpreted as an atomic (indivisible) one.

$$[10, 20] \rightarrow \{< \text{John} >\}$$

Note that a period-based semantics does not imply that John built the house in [12–15], or at the time point 12, or at any other time period other than [10–20]. As a consequence, the period-based semantics is naturally suited to cope with telic facts, for which (by definition) neither downward nor upward inheritance hold.

Although several query and data representation languages include time periods, most temporal database approaches adopt, explicitly or implicitly, the point-based semantics, interpreting a temporal database as a set of conventional databases, each one holding at a specific snapshot of time. This is the approach followed, e.g., by the Bitemporal Conceptual Data Model (BCDM) [5], a model that has been proven to capture the semantic core of many prior approaches in the temporal database literature, including the TSQL2 "consensus" approach [8]. While point-based semantics works perfectly when coping with atelic data, the problem with using it to cope with telic fact is illustrated by the following example.

Example

Phone calls are durative telic facts. For instance, if John made a call to Mary from time 10 to time 12, he didn't make it from 10 to 11. Similarly, two consecutive calls, one from 10 to 12 (inclusive) and the other from 13 to 15 (inclusive), are clearly different from a single call from 10 to 15. However, such a distinction cannot be captured at the semantic level, if the point-based semantics is used. In fact, the point-based semantics for the two phone calls of John is as follows:

$$\begin{aligned} 10 &\rightarrow \{< \text{John, Mary} >\}\\ 11 &\rightarrow \{< \text{John, Mary} >\}\\ 12 &\rightarrow \{< \text{John, Mary} >\}\\ \\ 13 &\rightarrow \{< \text{John, Mary} >\}\\ 14 &\rightarrow \{< \text{John, Mary} >\}\\ 15 &\rightarrow \{< \text{John, Mary} >\} \end{aligned}$$

Based on point-semantics, there is no way of grasping that two different calls were made. In other words, there is a loss of information. Note that such a loss of information is completely independent of the representation language used to model data. For instance, the above example could be represented as

$$\text{(i)} < \text{John, Mary}||\{10, 11, 12, 13, 14, 15\} > \in \text{R}$$

$$\text{(ii)} < \text{John, Mary}||\{[10-12], [13-15]\}\} > \in \text{R}$$

$$\text{(iii)} < \text{John, Mary}||[10-12] > \in \text{R and} \\ < \text{John, Mary}||[13-15] > \in \text{R}$$

But, as long as the point-based semantics is used, the data semantics is the one elicited above.

On the other hand, independently of the representation formalism being chosen, the semantics of telic facts such as phone calls is properly coped with if the period-based semantics is used. For instance, in the phone example, the semantics

$$[10-12] \rightarrow \{< \text{John, Mary} >\} \\ [13-15] \rightarrow \{< \text{John, Mary} >\}$$

correctly expresses the distinction between the two consecutive phone calls.

In an analogous way, period-based semantics is not suitable to model atelic facts. In short, both upward and downward inheritance holds for them, and the period-based semantics does not support such properties.

Terenziani and Snodgrass have proposed a two-sorted data model, in which telic data can be stored in telic relations (i.e., relations to be interpreted using a period-based semantics) and atelic data in atelic relations (i.e., relations to be interpreted using a point-based semantics) [9].

Query Semantics

It is interesting that the loss of information due to the treatment of telic data in a point-based (atelic) framework is even more evident when queries are considered. Results of queries should depend only on the data semantics, not on the data representation. For instance, considering the phone example above (and independently of the chosen representation), queries about the number or duration of phone calls would not provide the desired answers. For instance, the number of calls from John to Mary would be one, and a call from John to Mary would (incorrectly) be provided to a query asking for calls lasting for at least five consecutive units.

In order to cope with a data model supporting both telic and atelic relations, temporal query languages must be extended. Specifically, queries must cope with atelic relations, telic relations, or a combination of both.

Furthermore, linguistic research suggests a further requirement for telic/atelic query languages: *flexibility*. It is widely accepted within the linguistic community that while basic facts can be classified as telic or atelic, natural languages provides several ways to switch between the two classes. For instance, given a telic fact (such as "John built a house"), the progressive form (e.g., "John *was* build*ing* a house") coerces it into an atelic one, stripping away the culmination (and, in fact, "John was building a house" does not imply that "John built a house," i.e., that he finished it) [6]. For the sake of expressiveness, it is desirable that a database query language provides the same flexibility.

Queries About Atelic Data

As already mentioned above, most database approaches are interpreted (implicitly or explicitly) on the basis of the point-based semantics. Therefore, the corresponding algebraic operators already cope with atelic data. As an example, in BCDM, the union of two relations is simply obtained by taking the tuples of both relations, and "merging" the valid time of value equivalent tuples performing the union of the time points in their valid time. This definition is perfectly consistent with the "snapshot-by-snapshot" view enforced by the underlying point-based (atelic) semantics.

However, the algebrae in the literature also contain operators which contrast with such a "snapshot-by-snapshot" underlying semantics. Typical examples are temporal selection operators. For instance, whenever a duration is asked for (e.g., "retrieve all persons married for at least n consecutive time units"), the query implicitly relies on a telic view of data, in which snapshots are not taken into account independently of each others.

Queries About Telic Data

Algebraic operators on telic data can be easily defined by paralleling the atelic definitions, and considering that, in the telic case, the basic temporal primitives are not time points, but time periods [9]. For instance, telic union is similar to atelic one, except that the merging of valid times of value-equivalent tuples is performed by making the union of multisets of time periods, considered as primitive entities, e.g.,

$$\{[10-12],[13-15]\} \cup \{[10-14],[13-18]\}$$
$$=\{[10-12],[13-15],[10-14],[13-18]\}$$

Note that temporal selection operators perfectly fit with the telic environment. On the other hand, algebraic operators that intuitively involve a snapshot-by-snapshot view of data (e.g., Cartesian product, involving a snapshot-by-snapshot intersection between valid times) have an awkward interpretation in the telic context; for this reason, difference and "standard" Cartesian product have not been defined in the telic algebra in [9].

Queries Combining Telic and Atelic Data

In general, if a two-sorted data model is used, queries combining relations of both kinds are needed. In general, such queries involve the (explicit or implicit) coercion of some of the relations, to make the sort of the relations consistent with the types of the operators being used. For instance, the following query utilizes the example atelic relation modeling marriages and the telic one considering phone calls: Who was being married when John was calling Mary?

In such a case, the English clause "when" demands for an atelic interpretation: the result can be obtained by first coercing the relation about phone calls into an atelic relation, and then by getting the temporal intersection through the application of the atelic Cartesian product.

On the other hand, the query "list the marriage ceremonies that had a duration of more than 3 hours" requires a coercion of marriages into a telic relation, so that the whole valid time is considered as (a set of) time periods (instead as a set of independent points, as in the atelic interpretation), and the telic temporal selection operator can be applied.

In general, two coercion operators need to be provided [9]. Coercion from telic to atelic is easy: each time period constituting the (semantics of the) valid time is converted into the set of time points it contains, e.g., *to-atelic*({[10–12],[13–15]}) = {10,11,12,13,14,15}. Of course, since multisets of time periods are more expressive than sets of time points, such a conversion causes a loss of information. On the other hand, coercion from atelic to telic demands the formation of time periods out of sets of points: the output is the set of maximal convex time periods exactly covering the input set of time points, e.g., to-telic({10,11,12,13,14, 15}) = {[10–15]}.

Key Applications

Most applications involve differentiating between telic and atelic data.

Telos

Manolis Koubarakis
University of Athens, Athens, Greece

Definition

Telos (From the Greek word τέλοςτΘ which means *end*; the object aimed at in an effort; purpose.) is a knowledge representation language designed especially to support the development of information systems. Telos is based on the premise that information system development is knowledge-intensive and that the main design goal of any language intended for the task should be to formally represent the relevant knowledge. Telos is founded on core concepts from data modeling and knowledge representation, and shares ideas with semantic networks and frame systems, semantic and object-oriented data models, logic programming and deductive databases. The main features of Telos include: a structurally object-oriented framework which supports aggregation, generalization and classification; a novel treatment of attributes as first class citizens in the language; a powerful way of defining meta-classes; an explicit representation of time; and facilities for specifying integrity constraints and deductive rules.

Historical Background

The research on Telos follows the paradigm of a number of software engineering projects initiated around the 1990s with the premise that software development is *knowledge-intensive* and that the primary responsibility of any language intended to support this task is to be able to *formally represent the relevant knowledge*. Thus, Telos was designed as a knowledge representation language that is intended to support software engineers in the development of information systems throughout the software lifecycle.

Telos has evolved from RML (a requirements modeling language developed in Sol Greenspan's Ph.D. thesis), and later CML (presented in the Master thesis of Martin Stanley at the University of Toronto). The main difference between RML and CML is that CML adopts a more sophisticated model for representing knowledge, and supports the representation of temporal knowledge and the definition of meta-classes. Telos is essentially a "cleaned-up" and improved version of CML which was originally defined and implemented in the Master thesis of Manolis Koubarakis at the University of Toronto. The original paper on Telos is [7]. Ontological and semantical issues for Telos are discussed in [10]. The history of knowledge representation languages for information systems development related to Telos is surveyed in [3]. An important dialect of Telos is O-Telos defined in the Ph.D. thesis of Manfred Jeusfeld at the University of Passau, and implemented in the ConceptBase system [4]. Since ConceptBase is the most mature implementation of Telos available today, this entry uses the ConceptBase syntax for Telos.

Foundations

The main (and essentially the only) concept of Telos is the *proposition*. Propositions are used to model any aspect of the application domain. Propositions have unique identities and are distinguished into *individuals* and *attributes*. Individuals are intended to represent entities in the application domain (concrete ones such as John Doe, or abstract ones such as the class of all persons). Attributes represent binary relationships between entities (concrete or abstract). Two special kinds of attribute propositions exist: instantiation propositions and specialization propositions. The proposition abstraction gives great flexibility to Telos users. Everything in the application domain that is represented by a proposition (e.g., an entity or a relationship) immediately becomes a first-class citizen of the knowledge base.

Propositions

Every proposition `p` consists of an *identifier*, a *source*, a *label* and a *destination*, denoted by the functions `id(p)`, `from(p)`, `label(p)` and `to(p)`. For example, the following are propositions:

```
P1: [..., Martin, ...]
P2: [..., "21 Elm Avenue," ...]
P3: [Martin, homeAddress, "21 Elm
    Avenue"]
P4: [..., Person, ...]
P5: [..., GeographicLocation, ...]
P6: [Person, address,
    GeographicLocation]
```

Propositions in Telos are what *objects* are in object-oriented formalisms but also what *statements* are in logic-based formalisms. Thus, an application can use the above propositions to represent the following pieces of knowledge:

- `P1`: There is somebody called Martin.
- `P2`: There is something called "21 Elm Avenue."
- `P3`: Martin lives in 21, Elm Avenue.
- `P4`: There is an abstract concept, the class of all persons.
- `P5`: There is an abstract concept, the class of all geographic locations.
- `P6`: Persons have addresses that are geographic locations.

`P1`, `P2`, `P4` and `P5` are individual propositions while `P3` and `P6` are attribute propositions. The source and destination components of an individual proposition are not important, thus they are shown as "...". Notice that while P1 and P2 represent concrete individuals, P4 represents an abstract one, the class of all persons. Similarly, P3 represents a concrete relationship (relating Martin with his address) while P6 represents an abstract one (relating the class of all persons with the class of all geographic locations).

Following are some examples of special propositions:

```
P7: [P1, *instanceOf, P4]
P8: [P3, *instanceOf, P6]
P9: [..., Employee, ...]
P10:[P9, *isA, P4]
```

P7 and P8 are *instantiation propositions*. P7 represents the fact that Martin is a member of the class of all persons. P8 represents the fact that the concrete relationship relating Martin with his address is an instance of the abstract relationship relating the class of all persons with the class of all geographic locations. Finally, P10 is a *specialization proposition* asserting that every employee is a person.

A graphical view of some of the above propositions is given in Fig. 1.

Organizing Propositions

Propositions (individual or attribute ones) can be organized along three dimensions: *decomposition/aggregation*, *instantiation/classification* and *specialization/generalization*.

The aggregation dimension enables one to see an entity of the application domain as a collection of propositions with a common proposition as source. For example, individual Martin can be seen to be the following aggregation:

```
{Martin,
 [Martin, age, 35],
 [Martin, homeAddress, "21 Elm
 Avenue"],
 [Martin, workAddress, "10 King's
 College Road"] }
```

The classification dimension calls for each proposition to be an instance of one or more generic propositions or classes. Classes are themselves propositions, and therefore instances of other, more abstract classes. For example, Person is a class and Martin is an instance of this class. Similarly,

```
[Person, address, GeographicLocation]
```

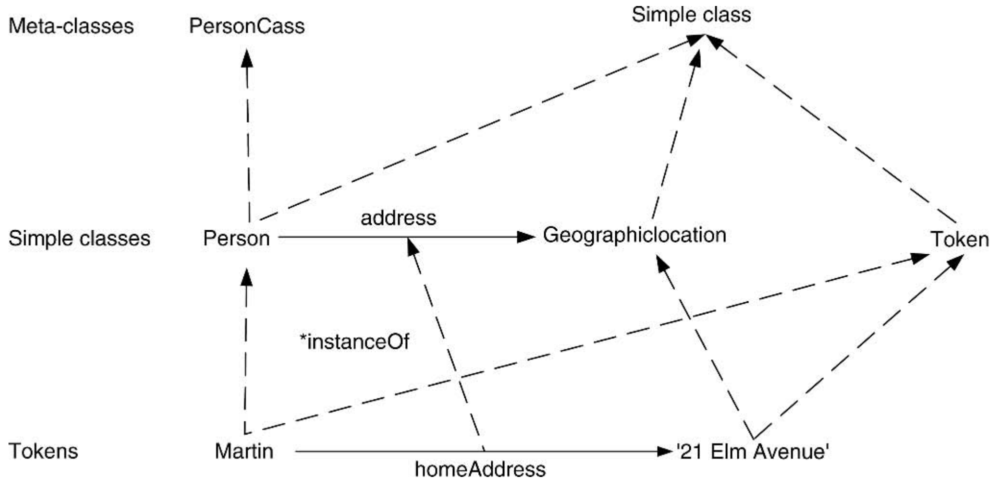
is a class and

```
[Martin, homeAddress, "21 Elm Avenue"]
```

is an instance of this class.

With respect to the classification dimension, propositions can be distinguished into:

- *Tokens:* propositions having no instances and intended to represent concrete entities in the application domain.
- *Simple classes:* propositions having only tokens as instances.



Telos. Figure 1. A graphical view of a set of Telos propositions.

- *Meta-classes:* propositions having only simple classes as instances.
- *Meta-meta-classes:* propositions having only meta-classes as instances.
- ...

Thus, classification in Telos defines an *unbounded* linear order of planes of ever more abstract propositions. Implementations restrict this unbounded hierarchy (e.g., ConceptBase restricts it to four levels: tokens to meta-meta-classes). There are also *ω-classes* with instances along more than one plane:

- `Proposition`. Contains all propositions as instances.
- `Class`. Contains all classes as instances.
- `Token`. Contains those individuals that may never have instances themselves.
- `SimpleClass`. Contains individuals that may have instances which are tokens.
- `MetaClass`. Contains individuals that may have simple classes as instances.
- `MetametaClass`. Contains individuals that may have meta-classes as instances.
- ...

Classification in Telos is a form of *weak typing*: the classes of which a structured object is an instance determine the kinds of attributes it can have optionally, and the properties it must satisfy. For example, by virtue of being an instance of `Person`, `Martin` can have attributes that are instances of the attribute class

```
[Person,address,GeographicLocation].
```

These *zero or more* attributes can have arbitrary labels, e.g., `homeAddress` and `workAddress`, but their values must be instances of `GeographicLocation`.

Finally, classes in Telos can be specialized along generalization or ISA hierarchies. For example, `Person` may have subclasses such as `Professor`, `Student`, and `TeachingAssistant`. Classes may form a partial order, rather than a tree (i.e., multiple inheritance is supported). Non-token attributes of a class are inherited by more specialized ones and can be refined. Inheritance in Telos is strict rather than default.

Interacting with Telos Knowledge Bases

A few examples of Telos are now given. The example application considered is the development of an information system to support organizing international scientific conferences. The knowledge to be represented in this case is about entities such as papers, authors, conferences etc.

The original definition of Telos in [7] defines the operations `TELL`, `UNTELL`, `RETELL` and `ASK` for interacting with a Telos knowledge base. These operations can be used to add new knowledge, discard existing knowledge, update existing knowledge and query a knowledge base, respectively. Implementations such as ConceptBase have followed the original definition and offer these (and other) operations. The above operations have Telos statements such as the following as their means of interaction with a knowledge base:

```
Individual p133 in Token, Paper with
      author
         firstAuthor: Stanley;
         secondAuthor: LaSalle;
         thirdAuthor: Wong
    title
         called: "The language Telos"
end
```

The above statement introduces an individual with name `p133`. The `in` clause specifies the classes of which `p133` is an instance (in this case, the predefined class `Token` and the application class `Paper`). The `with` clause introduces `p133`'s attributes. The first attribute of `p133` has label `firstAuthor` and is an instance of an attribute class which has source `Paper` and label `author` (the latter is denoted by the *attribute category* `author`). Before introducing individual paper `p133`, one might have defined the class of all papers using the following statement:

```
Individual Paper in SimpleClass with
      attribute
         author: Person;
         referee: Person;
         title: String;
         pages: Integer
end
```

A class definition prescribes the attributes that can be associated with its instances: `p133` can have `author`, `referee`, `title` and `page` attributes as seen previously, because it is an instance of class `Paper` that has these *attribute classes*. Moreover,

```
      [p133,firstAuthor,Stanley]
```

is an instance of attribute class

```
      [Paper,author,Person]
```

in exactly the same sense that p133 is an instance of Paper.

Once Paper has been defined, one can introduce specializations such as InvitedPaper using the isA clause of class definitions:

```
Individual AcceptedPaper in
SimpleClass isA Paper with
    attribute
      session: ConfProgrammeSession
end
```

AcceptedPaper inherits all attributes from Paper and adds a session attribute, to indicate the programme session during which the accepted paper will be presented.

Metaclasses

Metaclasses are a very powerful concept for modeling power and extensibility in Telos. It is the metaclass mechanism combined with its other features that makes Telos a powerful modeling language (one might wonder about this, since Telos offers only very simple primitives). From a modeling point of view, one can use Telos metaclasses in the following situations:

- To define concrete attributes of classes e.g., cardinality of a class. This is exactly the same to what a simple class does for its instances (tokens).
- To group together semantically similar classes of a domain in a generic way. For example, in the conference organization example, the classes Paper, Announcement, Letter, Memo could be grouped under the metaclass DocumentClass.
- To define concepts that are built-in in other frameworks e.g., necessary attributes, single-valued attributes etc.
- To do other forms of meta-level logical reasoning (again, for language expressibility).

The conference organization example is now revisited and defined:

```
DocumentClass in MetaClass with
    attribute
        source: AgentClass;
        content: SimpleClass;
        destination: AgentClass;
        cardinality: Integer
end
```

The class Paper can now be defined as follows:

```
Paper in DocumentClass with
      source
            author: Person;
      content
            title: String;
            abstract: String
      cardinality
            how_many: 120
end
```

Note that attribute categories such as source introduced in metaclass DocumentClass are then used to define attributes for the instance class Paper (this mechanism is the same along the instantiation hierarchy).

Integrity Constraints and Deductive Rules

Telos borrows the notions of integrity constraints and deductive rules from logic-based formalisms such as deductive databases. *Integrity constraints* are formulas that express conditions that knowledge bases should satisfy. They are used to express rich language or application semantics that cannot possibly be expressed only by the structural framework of Telos. *Deductive rules* are formulas that can be used to derive new knowledge. Integrity constraints and deductive rules in Telos are expressed in appropriately defined assertional languages that are subsets of first-order logic [4,7].

Integrity constraints and rules are defined as attributes of Telos classes that are instances of the built-in object Class. For example, the following Telos statement defines well-understood constraints and rules regarding employees, their managers and their respective salaries.

```
Class Employee with
  rule
    BossRule: $ forall e/Employee
    m/Manager (exists d/Department
    (e dept d) and (d head m))
    ==> (e boss m) $
  constraint
    SalaryBound: $ forall e/Employee
    b/Manager x,y/Integer (e boss b)
```

```
      and (e salary x) and (b salary y)
      ==> x <= y $
  end
```

Language Extensibility Through Metaclasses and Integrity Constraints

In Telos, one can use integrity constraints together with the metaclass mechanism to define concepts that are built-in in other representational frameworks. For example, in many object-oriented models one can constrain an attribute to be single-valued using some built-in construct of the model. In Telos, one can do this by using only the primitive mechanisms of the language as follows. First, one defines the class `Single`: (The syntax of this statement is from the original paper of Telos [7] (O-Telos allows one to specify the same thing in a slightly more complex way).)

```
  Class Single
    components [Class, single, Class]
    in AttributeClass, MetaClass with
    integrityConstraint
      : $ forall u/Single
           p,q/Proposition(p in u) and
           (q in u) and from(p)=from(q)
           ==> p=q $
  end
```

Then, one uses attribute class `Single` in the definition of class `Paper`:

```
  Individual Paper in SimpleClass with
      attribute
        author: Person;
        referee: Person
    single
        title: String;
        pages: Integer
  end
```

Now in every instance of `Paper`, a `title` attribute is constrained to be single-valued due to the integrity constrain and the instantiation relationships introduced by the above Telos statements.

Query Languages for Telos

The papers [4,7,11] give various query languages for Telos knowledge bases ranging from ones based purely on first-order logic [7] to ones exploiting the structurally object-oriented features of the language as well [4,11].

The paper [8] presents work on a knowledge base management system based on Telos.

Temporal Knowledge in Telos

The original paper of Telos [7] presents a powerful framework for representing and reasoning about temporal knowledge. In Telos, the history of an application domain is modeled by augmenting propositions with a *history time* i.e., an interval representing the time during which these facts are true in the application domain. Historical knowledge in Telos is allowed to be incomplete and a modification of Allen's interval algebra [1] is used to capture the relevant knowledge.

A knowledge base records essentially the *beliefs* of the system, which may be distinct from the actual state of the world at that time. So, for example, the title of a paper might have been changed in March, but the knowledge base is only told of it in May. Or one may make a correction to some previously told fact. Just like it represents the full history of an application domain, Telos also records the full history of its beliefs. For this reason, Telos represents *belief times*; these are intervals associated with every proposition in the knowledge base, which commence at the time when the operation responsible for the creation of the corresponding proposition was committed.

For efficiency reasons, implementations of Telos such as ConceptBase [4] have restricted the kinds of temporal knowledge that can be represented.

Telos and RDF

Telos is probably the pre-Web knowledge representation language most closely related to the Resource Description Framework (RDF) and the RDF Vocabulary Description Language or RDF Schema proposed by the W3C for representing knowledge about Web resources (see e.g., http://www.w3.org/TR/rdf-primer/). This relationship has been exploited by the prominent RDF query language RQL defined by ICS-FORTH [6] but also in the O-Telos-RDF proposal [9].

Key Applications

Telos was designed as a knowledge representation language that is intended to support software engineers in the development of information systems throughout the software lifecycle [7]. The strengths of the language made it the choice of many prominent research projects in Europe and North America including DAIDA [5], ITHACA [2] and others.

URL to Code

The most mature implementation of Telos is the ConceptBase system available at http://conceptbase.cc/.

Synonyms

Time-based access control

Definition

Temporal access control refers to access control service that restricts granting of authorization based on time. The authorization may be given to a subject for a particular interval or duration of time or based on the temporal characteristics of the objects being accessed. Such a need arises from the fact that a subject's need to access a resource and the sensitivity (and hence the protection requirement) of the objects being accessed may change with time.

Historical Background

Work related to temporal access control has only a brief history and goes back to early 1990s. In many real-world situations, access to information and resources may have to be restricted based on time as the subject and object characteristics may change and so can the need for the subject to access the object. For example, in a hospital, the head of the hospital may need to grant the permissions related to a part-time doctor only during certain time intervals. Similarly, an external auditor may need to be given access to sensitive company data for a specific duration only.

Bertino et al.'s *Temporal Authorization Model* (TAM) is the first known access control model to support the time-based access control requirements in a discretionary access control (DAC) model [2]. TAM associates a periodicity constraint with each authorization indicating the valid time instants of the authorization. TAM also defines three derivation rules that allow an authorization to be derived based on another authorization. The TAM model, however, is limited to specifying the temporal interval for an entire authorization and does not consider the temporal characteristics of data/objects [1]. For example, there may be a need for be an authorization such as "a subject *s* is allowed to read object *o* one month after it has been created/written." Furthermore, the states of an object can change with time and access to such different object-states may need to be carefully specified. Atluri et al. propose a Temporal and Derived Data Authorization Model (TDAM) for a Web information portal [1]. An information portal mainly aims to provide access to data from different sources and hence the temporal characteristics of such data need to be properly captured in an access control policy [1]. TDAM uses a logic formula to capture time-related conditions to specify authorization rules and address the consistency issues.

Another significant work related to temporal access control can be seen within the context of the Role Based Access Control (RBAC) model. Bertino et al. proposed the Temporal Role Based Access Control Model (TRBAC) model by extending the existing RBAC model [3]. The TRBAC model supports the periodicity/interval constraints on the role enabling/disabling and uses triggers to define dependencies that may exist among basic role related events such as "*enable role*" and "*disable role*."

One limitation of the TRBAC model is that it only supports specification of a set of temporal intervals on the role enabling/disabling events. For example, the user-role and the role-permission assignments are not time-constrained in TRBAC, neither are the role activations. Joshi et al. proposed a General Temporal RBAC (GTRBAC) model to allow specification of more fine-grained temporal access control policies [5]. The GTRBAC model allows the interval and duration constraints on user-role assignment, role-permission assignment, and role enabling events. It also defines the duration and cardinality constraints on role activation. GTRBAC uses constraint enabling events to trigger the duration constraints and uses run-time requests to allow dynamic changes in the authorization states by administrators and users. GTRBAC uses triggers, first introduced in the TRBAC model, to support the dependencies among events. The other features of the GTRBAC include the temporal hybrid hierarchy and Separation of Duty (SoD) constraints.

More recently, work on access control approaches based on the location context and the integration of temporal and location based access control has emerged. Such work includes the GEO-RBAC model, the spatial-temporal access control model [4], the spatial-temporal RBAC model [7], the LRBAC model [6], and the location and time-based RBAC (LoT-RBAC) model.

Foundations

In this section, the existing time-based access control models mentioned above are reviewed in more detail, namely TAM, TDAM, the TRBAC model, and the GTRBAC model. The major features of each model are discussed below.

TAM: Temporal Authorization Model

TAM models the temporal context as a periodicity constraint. A periodicity constraint is of the form <[*begin*, *end*], *P*>; here, *P* represents a recurring set of intervals and the entire expression indicates every time instant in *P* between "begin" and "end." For example, "[1/1/1994, ∞], *Monday*" indicates every *Monday* starting 1/1/1994. The model uses the symbol ∞ in place of *P* to indicate all time instants. The temporal authorization in TAM associates such a periodicity constraint with a normal discretionary authorization. The authorization is valid at any time instant specified in the periodicity constraint. At any given time instant, if there are two authorization rules that try to grant and deny an operation on the same object, a conflict is said to occur. In such a case, the model uses the "*denials-take-precedence*" principle to favor negative authorizations.

It is possible that several authorizations have temporal dependencies among them. For example, suppose user u_1 grants a permission p to u_2 (authorization A_1), and u_2 further grants p to u_3 (authorization A_2). It is easy to see that A_2 can only be valid after A_1 becomes valid. Therefore, a requirement such as "u_2 is allowed to grant p to u_3 whenever he/she acquires p from u_1," can be specified as a derivation rule "A_2 WHENEVER A_1." TAM uses three such derivation rules to capture various relationships among different authorizations.

The derivation rules are of the form "[*begin*, *end*], *P*, *A* <*op*>, **A**", where, *A* is an authorization, **A** is a boolean expression on authorizations, and <*op*> is one of the following: WHENEVER, ASLONGAS, UPON. **A** is true at time instant *t*, if **A** evaluates to *true* by substituting each authorization in it by *true* if it is valid at *t*, and by *false* if not valid. For example, $\mathbf{A} = \neg\,(A_1 \text{ and } A_2)$ is *true* at time *t* if either or both of A_1 and A_2 is *false* at time *t*. ([*begin, end*], *P*, *A* WHENEVER **A**) specifies that one can derive *A* for each instant in $\Pi(P) \cap \{[t_b, t_e]\}$ (here, $\Pi(P)$ is the set of all time instants in *P*) for which **A** is valid. ([*begin*, *end*], *P*, *A* ASLONGAS **A**) specifies that one can derive *A* for each instant in $\Pi(P) \cap \{[t_b, t_e]\}$ such that **A** is valid for each time instant in $\Pi(P)$ that is greater than or equal to t_b and lesser than or equal to t_e. ([*begin*, *end*], *P*, *A* UPON **A**) specifies that *A* holds *true* for each instants in $\Pi(P) \cap \{[t_b, t_e]\}$ if there exists an instant $t' \varepsilon \Pi(P)$ that is greater than or equal to t_b and lesser than or equal to t_e such that **A** is valid at time t' in. The difference between WHENEVER and ASLONGAS is that the former only evaluates the authorization state for a time instant while the latter evaluates the history of the authorization states in a given time interval. The difference between ASLONGAS and UPON is that the former evaluates the authorization state for the entire time interval in the history while the latter only evaluates the authorization states at a time instant in the history.

Given a set of initial authorizations and rules, the derived authorizations may depend on the order in which the rules are evaluated. This is due to the existence of both positive and negative authorizations and the *denials-take-precedence* rule. To analyze this problem, the authors define the unique set of valid authorizations using the notion of critical set and propose a Critical Set Detection (CSD) algorithm to verify that a given set is critical [2].

TDAM: Temporal and Derived data Authorization Model

The TDAM model, as mentioned earlier, focuses on the temporal characteristics of data/objects. This is achieved by associating a formula τ instead of a simple temporal interval to each authorization. At any time instant, if τ is evaluated to be *true*, then the corresponding authorization is valid. By carefully designing the formula τ, the model can support specification of a fine-grained temporal access control policy. It is possible to use the temporal context of a single data item by making it a variable in τ. For example, assume a company maintains a database including the current and future predicted price for some goods; now, let each price of a data item d be associated with a time interval $[t_b, t_e]$ to indicate the temporal interval the specified price is predicted for. It is also possible to restrict a subject to read the current price only by specifying τ as "$t_b \leq t \leq t_e$" where t is the current time.

Similarly, the temporal dependency can also be indicated by τ. For example, consider the policy "a subject s is allowed to read object o one month after it has been created/written." Such a requirement can be specified by including τ as "$t \geq t_w + 1$ month" where t_w indicates the time when the object o is created/written and t is the current time.

TRBAC: Temporal Role Based Access Control Model

The TRBAC model allows the specification of temporal constraints to specify when a role can be enabled or disabled, and triggers to capture possible temporal dependencies among role events. The TRBAC model also uses periodic time expression instead of simple time interval to represent the periodicity constraint. In RBAC, the users can acquire the permissions only by activating enabled roles within a session; the model associates the periodic time expressions with role enabling/disabling events to define periodicity constraints.

Triggers constitute an important part of the TRBAC model, and they are used to capture temporal dependencies among RBAC authorization states. A trigger simply specifies that if some events occur and/or some role status predicates are evaluated to true then another event can occur, with a possible time delay. For example, assume that a hospital requires that when a part-time doctor is on duty a part-time nurse can also be allowed to log on to help the part-time doctor. Here, the trigger "enable *part-time doctor* → enable *part-time nurse*" can be used to capture such a requirement.

Bertino et al. introduces a soft notion of *safety* to formally characterize the efficiency and practicality of the model. In essence, because of triggers and other periodicity constraints, ambiguous semantics can be generated. They propose an efficient graph based analysis technique to identify such ambiguous policies so that a unique execution model can be guaranteed by eliminating any ambiguous specification. When such a unique execution model is ensured the policy base is said to be *safe.* Conflicts could also occur because of the opposing *enable* and *disable* role events. The TRBAC model uses *denial-takes-precedence* in conjunction with *priority* to resolve such conflicts.

GTRBAC: Generalized Temporal Role Based Access Control Model

Joshi et al. have proposed the GTRBAC model by extending the TRBAC model to incorporate more comprehensive set of periodicity and duration constraints and time-based activation constraints. The GTRBAC model introduces the separate notion of *role enabling* and *role activation*, and introduces role states. An *enabled* role indicates that a valid user can activate it, whereas a *disabled* role indicates that the role is not available for use. A role in *active* state indicates that at least one user has activated it. Such a distinction makes the semantics and implementation of any RBAC compatible system much clearer. Besides events related to user-role assignment, permission-role assignment and role enabling, the GTRBAC model also includes role activation/deactivation events. The model associates the temporal constraints with every possible event in the system. In particular, it uses the periodicity constraint to constrain the validity of role enabling events, user-role assignment events as well as the permission-role assignment events. As the role activation events are initiated by the users at their discretion, GTRBAC does not associate temporal constraints with activation events. Besides the periodic temporal constraints, GTRBAC also supports duration constraints. A duration constraint specifies how long should an event be valid for once it occurs. For example, one duration constraint could specify that once a role *r* has been enabled it should be in the enabled state for 2 hours. Note that the duration constraint has a non-deterministic start time and requires some other actions to initiate the start of the duration. For example, consider a duration constraint (2 hours, enable *r*). Here, when the "enable *r*" event occurs because of a trigger, the event becomes valid for 2 hours because of this constraint. At times, one may need to also enable duration or activation constraints – GTRBAC uses constraint enabling events to facilitate that.

The GTRBAC model also supports the temporal and cardinality constraints on role activation. Cardinality constraints have often been mentioned in the literature but have not been addressed much in the existing models. A cardinality constraint simply limits the number of activations (applies for assignments as well) within a given period of time. For example, GTRBAC supports limiting the total number of activations of a role or the maximum concurrent number of activations of a role in a given interval or duration. Furthermore, GTRBAC allows the activation constraint to be applied to all the activations of a role (per-role constraint) or applied to each activation of a role by a particular user (per-user constraint). The model uses the trigger framework introduced in the TRBAC model. In addition to these, the GTRBAC model also extends work on role hierarchy and constraints, and introduces hybrid hierarchy and time-based SoD constraints.

The GTRBAC model uses three conflict types (Type-1, Type-2, and Type-3) to categorize the different types of conflicting situations that may arise and provides a resolution technique using a combination of the following approaches: (i) *priority-based*, (ii) *denial-takes precedence*, and (iii) *more specific constraint takes precedence.*

Suroop et al. have recently proposed the LoTRBAC model by extending the GTRBAC model to address both time and location for security of mobile applications.

Key Applications

Temporal access control models are suitable for the applications where temporal constraints and temporal dependencies among authorizations are important protection requirements. One example is workflow systems that often have timing constraints on tasks and their dependencies. In particular, TAM is suitable for the system implementing the discretionary access control policies. TDAM is suitable for access control for data dissemination systems such as a web information portal where data have different states at different times. TRBAC and GTRBAC are suitable for large scale systems that have very fine-grained time-based access requirements.

Future Directions

With the development of networking and mobile technologies, context based access control is becoming very crucial. Time is very crucial context information, as is location. Hence, the work on temporal access control have provided a basis for looking at the intricacies of the context parameters that need to be used to restrict authorization decisions. In addition to context-based access, content-based access control is also becoming significant issues because of the growing need to dynamically identify content and make authorization decisions based on its semantics. Again, the work on temporal access control has provided a basis for capture the dynamic feature of the object content. Authorization models that capture context and content parameters using temporal access control are being pursued to develop more fine-grained access control models.

Definition

In database management, aggregation denotes the process of consolidating or summarizing a database instance; this is typically done by creating so-called aggregation groups of elements in the argument database instance and then applying an aggregate function to each group, thus obtaining an aggregate value for each group that is then associated with each element in the group. In a relational database context, the instances are relations and the elements are tuples. Aggregation groups are then typically formed by partitioning the tuples based on the values of one or more attributes so that tuples with identical values for these attributes are assigned to the same group. An aggregate function, e.g., *sum*, *avg*, or *min*, is then applied to another attribute to obtain a single value for each group that is assigned to each tuple in the group as a value of a new attribute. Relational projection is used for eliminating detail from aggregation results.

In temporal relational aggregation, the arguments are temporal relations, and the tuples can also be grouped according to their timestamp values. In temporal grouping, groups of values from the time domain are formed. Then an argument tuple is assigned to each group that overlaps with the tuple's timestamp, this way obtaining groups of tuples. When aggregate functions are applied to the groups of tuples, a temporal relation results. Different kinds of temporal groupings are possible: instantaneous temporal aggregation where the time line is partitioned into time instants/points; moving-window (or cumulative) temporal aggregation where additionally a time period is placed around a time instant to determine the aggregation groups; and span aggregation where the time line is partitioned into user-defined time periods.

Historical Background

Aggregate functions assist with the summarization of large volumes of data, and they were introduced in early relational database management systems such as System R and INGRES. During the intensive research activities in temporal databases in the 1980s, aggregates were incorporated in temporal query languages, e.g., the Time Relational model [1], TSQL [8], TQuel [9], and a proposal by Tansel [10]. The earliest proposal aimed at the efficient processing of (instantaneous) temporal aggregates is due to Tuma [12]. Following Tuma's pioneering work, research concentrated on the development of efficient main-memory algorithms for the evaluation of instantaneous temporal aggregates as the most important form of temporal aggregation [6,7].

With the diffusion of data warehouses and OLAP, disk-based index structures for the incremental computation and maintenance of temporal aggregates were investigated by Yang and Widom [14] and extended by Zhang et al. [15] to include non-temporal range predicates. The high memory requirements of the latter approach were addressed by Tao et al. [11], and approximate solutions for temporal aggregation were proposed. More recently, Vega Lopez et al. [13] formalized temporal aggregation in a uniform framework that enables the analysis and comparison of the different forms of temporal aggregation based on various mechanisms for defining aggregation groups. In a similar vein, Böhlen et al. [3] develop a new framework that generalizes existing forms of temporal aggregation by decoupling the partitioning of the time line from the specification of the aggregation groups.

It has been observed that expressing queries on temporal databases is often difficult with SQL, in particular for aggregation. As a result, temporal query languages often include support for temporal aggregation. A recent paper [2] studies the support for temporal aggregation in different types of temporal extensions to SQL. A subset of the temporal aggregates considered in the entry are also found in non-relational query languages, e.g., τXQuery [5].

Foundations

A discrete time domain consisting of a totally ordered set of time instants/points is assumed together with an interval-based, valid-time data model, i.e., an interval timestamp is assigned to each tuple that captures the time when the corresponding fact is true in the modeled reality. As a running example, the temporal relation *CheckOut* in Fig. 1 is used, which records rentals of video tapes, e.g., customer C101 rents tape T1234 from time 1 to 3 at cost 4.

Defining Temporal Aggregation

Various forms of temporal aggregation that differ in how the temporal grouping is accomplished have been studied. In *instantaneous temporal aggregation (ITA)* the time line is partitioned into time instants and an aggregation group is associated with each time instant *t* that contains all tuples with a timestamp that intersects with *t*. Then the aggregate functions are evaluated on each group, producing a single aggregate value at each time *t*. Finally, identical aggregate results for consecutive time instants are coalesced into so-called constant intervals that are maximal intervals over which all result values remain constant. In some approaches, the aggregate results in the same constant interval must also have the same lineage, meaning that they are produced from the same set of argument tuples. The following query, Q_1, and its result in Fig. 2a illustrate ITA: *What is the number of tapes that have been checked out?* Without the lineage requirement, the result tuples (1,[17,18]) and (1,[19,20]) would have been coalesced into (1,[17,20]). While, conceptually, the time line is partitioned into time instants, which yields the most detailed result, the result tuples are consolidated so that only one tuple is reported for each constant interval. A main drawback is that the result relation is typically larger than the argument relation and can be up to twice the size of the argument relation.

With *moving-window temporal aggregation (MWTA)* (first introduced in TSQL [8] and later also termed *cumulative temporal aggregation* [9,14]), a time window is used to determine the aggregation groups. For each time instant *t*, an aggregation group is defined as the set of argument tuples that hold in the interval $[t-w,\ t]$, where $w \geq 0$ is called a window offset. In some work [13], a pair of offsets w and w' is used, yielding a window $[t-w,\ t+w']$ for determining the aggregation groups. After computing the aggregate functions for each aggregation group, coalescing is applied similarly to how it is done for ITA to obtain result tuples over maximal time intervals. The following query, Q_2, and its result in Fig. 2b illustrate MWTA: *What is the number of tapes that have been checked out in the last three days?* To answer this query, a window is moved along the time line, computing at each time point an aggregate value over the set of tuples that are valid at some point during the last three days. While both ITA and MWTA partition the time line into time instants, the important difference is in how the aggregation groups for each time instant are defined.

Next, for *span temporal aggregation (STA)*, the time line is first partitioned into predefined intervals that are defined independently of the argument relation. For each such interval, an aggregation group is then given as the set of all argument tuples that overlap the interval. A result tuple is produced for each interval by evaluating an aggregate function over the corresponding aggregation group. The following query, Q_3, and its result in Fig. 2c illustrate STA: *What is the weekly number of tapes that have been checked out?* The time span is here defined as a period of seven days. Unlike in ITA and MWTA, in STA the timestamps of the result tuples are specified by the application and are independent of the argument data. Most approaches consider only regular time spans expressed in terms of granularities, e.g., years, months, and days.

The *multi-dimensional temporal aggregation (MDTA)* [3] extends existing approaches to temporal aggregation, by decoupling the definition of result groups and aggregation groups. A result group specifies the part of a result tuple that is independent of the actual aggregation (corresponds to the group by

attributes in SQL). Each result group has an associated aggregation group, namely the set of tuples from which the aggregated value is computed. In general, the grouping attributes of the tuples in an aggregation group might differ from the grouping attributes of the result group. For the specification of the result groups, two different semantics are supported: constant-interval semantics that covers ITA and MWTA and fixed-interval semantics that covers STA. The fixed-interval semantics supports the partitioning of the time line into arbitrary, possibly overlapping time intervals. The following query, Q_4, and its result in Fig. 2d illustrate some of the new features of MDTA: *For each week, list the number of expensive and the number of cheap checkouts during the preceding week?* (expensive being defined as a cost equal or greater than 4 and cheap as a cost equal or smaller than 2). The result groups are composed of a single temporal attribute that partitions the time line, the tuples in the associated aggregation groups do not have to overlap the timestamp of the result group, and two aggregates over different aggregation groups are computed for each result group.

Temporal Aggregation Processing Techniques

The efficient computation of temporal aggregation poses new challenges, most importantly the computation of the time intervals of the result tuples that depend on the argument tuples and thus are not known in advance.

Two Scans The earliest proposal for computing ITA was presented by Tuma [12] and requires two scans of the argument relation – one for computing the constant intervals and one for computing the aggregate values over these intervals. The algorithm has a worst case running time of $O(mn)$ for m result tuples and n argument tuples.

Following Tuma's pioneering work, research concentrated on algorithms that construct main-memory data structures that allow to perform both steps at once, thus requiring only one scan of the argument relation.

Aggregation Tree The *aggregation tree* algorithm for ITA by Kline and Snodgrass [6] incrementally constructs a tree structure in main memory while scanning the argument relation. The tree stores a hierarchy of intervals and partial aggregation results. The intervals at the leaf nodes encode the constant intervals. Accumulating the partial results in a depth-first traversal of the tree yields the result tuples in chronological order. Figure 3a shows the tree for Query Q_1 after scanning the first two argument tuples. The path from the root to the leaf with time interval [3,3] yields the result tuple (2,[3,3]). The algorithm is constrained by the size of the available main memory, and it has a worst case time complexity of $O(n^2)$ for n argument tuples since the tree is not balanced.

An improvement, although with the same worst case complexity, is the *k*-ordered aggregation tree [6], which requires the argument tuples to be chronologically ordered to some degree. This allows to reduce the memory requirements by garbage collecting old nodes that will not be affected by any future tuples. Gao et al. [4] describe a number of parallel temporal aggregation algorithms that are all based on the aggregation tree.

Balanced Tree Moon et al. [7] propose the *balanced tree* algorithm for the main memory evaluation of ITA queries involving *sum*, *count*, and *avg*. As the argument tuples are scanned, their start and end times are stored in a balanced tree together with two values for each aggregate function being computed, namely the partial

d End-point tree

Temporal Aggregation. Figure 3. Different forms of tree structures for temporal aggregation.

aggregate result over all tuples that start and end here, respectively. An in-order traversal of the tree combines these values to compute the result relation. Whenever a node, *v*, is visited, a result tuple is produced over the interval that is formed by the time point of the previously visited node and the time point immediately preceding *v*. Figure 3b shows the balanced tree for Query Q_1. The aggregate value of the result tuple (2,[3,3]) is determined as $1 + (1 - 0) = 2$. Although the balanced tree requires less memory than the aggregation tree, it is constrained by the amount of available memory. For the *min* and *max* functions a merge-sort like algorithm is proposed. Both algorithms have $O(n \log n)$ time complexity for *n* argument tuples. To overcome the memory limitation, a bucket algorithm is proposed, which partitiones the argument relation along the time line and keeps long-lived tuples in a meta-array. Aggregation is then performed on each bucket in isolation.

SB-Tree Yang and Widom [14] propose a disk-based index structure, the *SB-tree*, together with algorithms for the incremental computation and maintenance of ITA and MWTA queries. It combines features from the segment tree and the B-tree and stores a hierarchy of time intervals associated with partially computed aggregates. To find the value of an aggregate at a time instant *t*, the tree is traversed from the root to the leaf that contains *t* and the partial aggregate values associated with the time intervals that contain *t* are combined. Figure 3c shows the SB-tree for Query Q_1. The value at time 8 results from adding 0 and 1 (associated with [10,11] and [7,11], respectively). The time complexity of answering an ITA query at a single time point is $O(h)$, where *h* is the height of the tree, and $O(h + r)$ for retrieving the result over a time interval, where *r* is the number of leaves that intersect with the given time interval. The same paper extends the basic SB-tree to compute MWTA. For a fixed window offset *w*, the timestamps of the argument tuples are extended by *w* to account for the tuples' contributions to the results at later time points. For arbitrary window offsets, a pair of SB-trees is required.

MVSB-Tree With the SB-tree, aggregate queries are always applied to an entire argument relation. The *multi-version SB-tree* (MVSB-tree) by Zhang et al. [15] tackles this problem and supports temporal aggregation coupled with non-temporal range predicates that select the tuples over which an aggregate is computed. The MVSB-tree is logically a sequence of SB-trees, one for each timestamp. The main drawbacks of this approach are: the tree might be larger than the argument relation, the range restriction is limited to a single non-timestamp attribute, and the temporal evolution of the aggregate values cannot be computed. Tao et al. [11] present two approximate solutions that address the high memory requirements of the MVSB-tree. They use an MVB-tree and a combination of B- and R-trees, respectively. These achieve linear space complexity in the size of the argument relation and logarithmic query time complexity.

MDTA Böhlen et al. [3] provide two memory-based algorithms for the evaluation of MDTA queries. The algorithm for fixed-interval semantics keeps in a *group table* the result groups that are extended with an additional column for each aggregate being computed. As the argument relation is scanned, all aggregate values to which a tuple contributes are updated. The group table contains then the result relation. The memory requirements only depend on the size of the result relation. With an index on the group table, the average runtime is *n* log *m* for *n* argument tuples and *m* result groups, the worst case being $O(nm)$ when each argument tuple contributes to each result tuple.

The algorithm for constant-interval semantics processes the argument tuples in chronological order and computes the result tuples as time proceeds. An *endpoint tree* maintains partial aggregate results that are computed over all argument tuples that are currently valid, and they are indexed by the tuples' end points. Figure 3d shows the endpoint tree for Query Q_1 after processing the first two argument tuples. When the third argument tuple is read, the result tuples (2,[3,3]) and (1,[4,5]) are generated by accumulating all partial aggregate values; the nodes are then removed from the tree. The size of the tree is determined by the maximal number of overlapping tuples, n_o. The average time complexity of the algorithm is nn_o. The worst-case complexity is $O(n^2)$, when the start and end points of all argument tuples are different and all tuples overlap.

Key Applications

Temporal aggregation is used widely in different data-intensive applications, which become more and more important with the increasing availability of huge volumes of data in many application domains, e.g., medical, environmental, scientific, or financial applications. Prominent examples of specific applications include data warehousing and stream processing. Time variance is one of four salient characteristics of a data warehouse, and there is general consensus that a data warehouse is likely to contain several years of time-referenced data. Temporal aggregation is a key operation for the analysis of such data repositories. Similarly, data streams are inherently temporal, and the computation of aggregation functions is by far the most important operation on such data. Many of the ideas, methods, and technologies from temporal aggregation have been and will be adopted for stream processing.

Future Directions

Future research work is possible in various directions. First, it may be of interest to study new forms of temporal aggregation. For example, a temporal aggregation operator that combines the best features of ITA and STA may be attractive. This operator should follow a data-driven approach that approximates the precision of ITA while allowing to limit the size of the result. Second, it is relevant to study efficient evaluation algorithms for more complex aggregate functions beyond the five standard functions for which most research has been done so far. Third, the results obtained so far can be adapted for and applied in related fields, including spatio-temporal databases where uncertainty is inherent as well as data streaming applications.

Temporal Algebras

Abdullah Uz Tansel
Baruch College – CUNY New York, NY, USA

Synonyms

Historical algebras; Valid-time algebras; Transaction-Time algebras; Bitemporal algebras

Definition

Temporal algebra is a generic term for an algebra defined for a data model that organizes temporal data. A temporal data model may support Valid-time (the time over which a data value is valid), Transaction-time (time when a data value is recorded in the database), or both (Bitemporal). So an algebra can be defined for each case, a Valid-time relational algebra, a Transaction-time relational algebra, or a Bitemporal relational algebra, respectively. Temporal algebras include the temporal versions of relational algebra operations in addition to new operations for manipulating temporal data like Time-slice, Rollback, Temporal Coalesce, temporal restructuring operations, and others. For a Temporal algebra, it is desirable to be closed (common algebras are closed), a consistent extension of the relational algebra and to reduce to relational algebra when only current data are considered.

Historical Background

Temporal algebraic languages first appeared as extensions to the relational algebra in early 1980s, mostly Valid–time or Transaction-time algebras, followed by Bitemporal algebras. These extensions differed according to their operations and how temporal data are represented. McKenzie and Snodgrass surveyed temporal algebras and identified desirable criteria that are needed in a temporal algebra [10]. However, some of these criteria are conflicting.

Foundations

Temporal Algebra Basics

Let *T* represent the time domain which has a linear order under "≤". A time point (instant) is any element of *T*. A period is a consecutive sequence of time points. A temporal element is a set of disjoint maximal periods [6], and a temporal set is any set of time points. Any of these time constructs can be used to timestamp data values. A Bitemporal atom, <*Valid-Time*, *Transaction-time*, *Data*> asserts that *data* are valid during *Valid-time* and is recorded during *Transaction-time*. Either Valid-time or Transaction-time may be omitted and the result is a Valid-time Atom, or a Transaction-time atom, respectively.

A temporal relational algebra is closely related to how the temporal data (temporal atoms) are represented, i.e., the type of timestamps used, where they are attached (relations, tuples, or attribute values), and whether temporal atoms are kept atomic or broken into their components. In other words, time specification may be explicit or implicit. This in turn determines possible evaluation (semantics) of temporal algebra expressions. There are two commonly adopted approaches: (i) Snapshot (Point or Sequenced [1]) evaluation that manipulates the snapshot relation at each time point, like Temporal Logic [6,11,17]; (ii) Traditional (Nonsequenced [1]) evaluation that manipulates the entire temporal relation much like the traditional relational algebra. It is also possible to mix these approaches.The syntax and the operations of a temporal algebra are designed to accommodate a desired type of evaluation. Moreover, specifying temporal algebra operations at an attribute level, instead of tuples keeps the tuple structure intact after the operation is executed, so preserving the rest of a temporal relation that is beyond the scope of operation applied.

Let Q(A, B, C), R(A, D) and S(A, D) be temporal relations in attribute timestamping, whose attribute values are sets of temporal atoms except attribute A which has constant values. It is possibly a temporal grouping identifier [4] (or a temporal key). For the sake of simplicity, attributes B, C, and D are assumed to have one temporal atom in each tuple, i.e., they are already flattened. Q_t stands for the snapshot of temporal relation Q at time t. Temporal Algebras generally include temporal equivalents of traditional relational algebra operations. The five basic Temporal Algebra operations, $\cup^t$, $-^t$, π^t, σ^t, and $\times^t$ in snapshot evaluation are [2,4,5]:

- $R \cup^t S_t$ is $R_t \cup S_t$ for all t in T
- $R -^t S_t$ is $R_t - S_t$ for all t in T
- $\pi^t_{A1,A2,\ldots,An}$ (R) is $\pi_{A1,A2,\ldots,An}$ (R_t) for all t in T
- σ^t_F (R) is $\sigma_F(R_t)$ for all t in T; Formula F includes traditional predicates and temporal predicates like *Before*, *After*, *Overlaps*, etc
- $R \times^t Q$ is $R_t \times Q_t$ for all t in T

An important issue in Snapshot Evaluation is the homogeneity of the temporal relations. A temporal relation is homogenous if each tuple is defined on the same time, i.e., in a tuple, all the attributes have the same time reference [6]. If attributes in a tuple have different time references then a snapshot may have null values leading to complications. Thus, a Temporal Algebra may be homogenous, depending on the relations scheme on which it is defined.

In Temporal Algebras that use traditional evaluation, $\cup^t$, $-^t$, π^t, σ^t, and $\times^t$ may be defined exactly the same as the relational algebra operations or they have temporal semantics incorporated in their definitions. The temporal set operations may specially be defined by considering the overlapping timestamps in tuples. Two temporal tuples are value equivalent if their value components are the same, but their timestamps may be different. Let {(a1,<[2/07,11/07), d1>)} and {(a1, <[6/07,8/07), d1>)} be tuples in R and S, respectively. These two tuples are value equivalent. In case of $R \, U^t \, S$, value equivalent tuples are combined into one if their timestamps overlap. Considering the former tuples the result is {(a1,<[2/07,11/07), d1>)}. In case of $R -^t S$, the common portion of the timestamps for the value equivalent tuples is removed from the tuples of R. For the above tuples the result is {a1, <[2/07,6/07), d1>), (a1, <[8/07,11/07), d1>)}. Existence of value equivalent tuples makes query specification more complex but, query evaluation is less costly. On the other hand, eliminating them is also more costly. Temporal Coalescing operation combines value equivalent tuples into one tuple [2]. Temporal algebras may include aggregates.

The definition of Temporal Projection (π^t) is straightforward. However, it may generate value equivalent tuples much like the traditional projection operation creates duplicate tuples. Moreover, the projection operation may also be used to discard the time of a relation if it is explicitly specified. In the case of implicit time specification, it needs to be converted to an explicit specification before applying the projection operation. The formula F in the Selection operation ($\sigma^t_F(Q)$) may include time points, the end points of periods, and periods in temporal elements, or temporal predicates like *Before*, *After*, *Overlaps*, etc. It is possible to simulate the temporal predicates by conditions referring to time points or end points of periods.

Other temporal algebra operations such as Temporal Set Intersection or Temporal Join are similarly defined. There are different versions of Temporal Join. Intersection join is computed over the common time of operand relations (see the entry on temporal joins). For instance, if {(a1, <[1/07, 5/07), b1>, <[1/07, 4/07), c1>)} is a tuple in Q, the natural join ($Q \bowtie R$) contains the tuple {(a1, <[1/07, 5/07), b1>, <[1/07, 4/07), c1>, <[2/07,11/07), d1>)}. If this were an intersection natural join, times of the attributes in this tuple would be restricted to their common time period [2/07, 4/07). It is also possible to define temporal outer joins [11].

Temporal algebra operations are defined independent of time granularities. However, if operand relations are defined on different time granularities, a granularity conversion is required as part of processing the operation.

Algebras for Tuple Timestamping

In tuple timestamping relations are augmented with one column to represent time points, periods or temporal elements, or two columns to represent periods. Relation Q is represented as Q1(A, B, From, To) and Q2(A, C, From, To) where From and To are the end points of periods. Similarly, R(A, D, From, To) and S(A, D, From, To) correspond to the relations R and S, respectively. The tuple of Q given above is represented as the following tuples: (a1, b1, 1/07, 5/07) in Q1 and (a1, c1, 1/07, 4/07) in Q2. For accessing time points within a period snapshot evaluation may be used [6,17] or in case of Traditional Evaluation, attributes representing the end points of periods may be specified in operations. Another path followed is to define temporal expansion and contraction operations [9]. A period is expanded to all the time points included in it by temporal expansion and temporal contraction does the opposite, converts a sequence of time points to a period. Relation instances indexed by time points are used to define a temporal algebra by Clifford, Croker, and Tuzhilin [17].

Algebras for Attribute Timestamping

Timestamps are attached to attributes and N1NF relations are used and the entire history of an object is represented as a set of temporal atoms in one tuple. These temporal relations are called temporally grouped in contrast to temporally ungrouped relations that are based on tuple timestamping [17]. Naturally, temporally grouped algebras are more expressive than temporally ungrouped algebras and the former is more complex than the latter [17]. A temporal algebra that is based on snapshot evaluation and allows set theoretic operations on temporal elements is given in [6]. For the algebra expression e, the construct [[e]] returns the time over which e's result is defined [6] and it can further be used in algebraic expressions. An algebra, based on time points and lifespans, that uses snapshot evaluation is proposed in [3,5]. The nest and unnest operations for the transformations between 1NF and N1NF relations and operations which form and break temporal atoms are included in a temporal algebra [5,12,13]. N1NF Temporal relations and their algebras may or may not be homogonous [6,12,13].

Valid-time and Transaction-time Algebras

Most of the algebras mentioned above are Valid-time Relational Algebras. A Valid-time Relational Algebra includes additionally a Slice operation ($\varsigma\tau\Theta$) that is a redundant, but very useful operation. Let R be a Valid-time Relation and t be a time point (period, temporal element, or temporal set). Then, $\varsigma\tau\Theta_t$ (R) cuts a slice from R, the values that are valid over time t and returns them as a relation [1,5,12,13]. Common usage of the Slice operation is to express the "when" predicate in natural languages. Slice may also be incorporated into the selection operation or the specification of a relation to restrict the time of a temporal relation by a temporal element, i.e., R[t] [6]. Slice may be applied at an attribute level to synchronize time of one attribute by another attribute [5,12,13]. For instance, $\varsigma\tau\Theta_{B,C}$ (Q) restricts the time of attribute B by the time of attribute C. Applying the Slice operation on all the attributes by the same time specification returns a snapshot at the specified time.

A Transaction-time relational algebra includes a Rollback operation (τ), another form of Slice for rolling back to the values recorded at a designated time. Let R be a Transaction-time relation and t be a time point (period, temporal element, or temporal set). Then, τ_t (R) cuts a slice from R, the values that were recorded over time t and returns them as a relation [1,5,8]. Note the duality between the Valid-time relational algebra and the Transaction-time relational algebra; each has the same set of operations and an appropriate version of the slice operation.

Bitemporal Relational Algebras

Bitemporal algebra operations are more complicated than temporal algebras that support one time dimension only [1,8,15]. A Bitemporal algebra includes both forms of the Slice operation in addition to other algebraic operations. A Bitemporal query has a context that may or may not imply a Rollback operation [15]. However, once a Rollback operation is applied on a Bitemporal relation, Valid-time algebra operations can be applied on the result. It is also possible to apply Bitemporal Algebra operations on a bitemporal relation before applying a Rollback operation. In this case, the entire temporal relation is the context of the algebraic operations. In coalescing Bitemporal tuples, starting with Valid-time or Transaction-time may result in different coalesced tuples [8]. For the data maintenance queries, Valid-time needs to be coalesced within the Transaction-time.

Key Applications

Use of temporal algebra includes query language design [14], temporal relational completeness [16,17], and query optimization [14]. Some Relational algebra identities directly apply to temporal relational algebra whereas other identities do not hold due to the composite representation or semantics of temporal data [10]. Naturally, identities for the new temporal algebra operations and their interaction with the operations borrowed from the relational algebra need to be explored as well [5,7].

Temporal Coalescing

Definition

Temporal coalescing is a unary operator applicable to temporal databases that is similar to duplicate elimination in conventional databases. Temporal coalescing merges value-equivalent tuples, i.e., tuples with overlapping or adjacent timestamps and matching explicit attribute values. Tuples in a temporal relation that agree on the explicit attribute values and that have adjacent or overlapping timestamps are candidates for temporal coalescing. The result of operators may change if a relation is coalesced before applying the operator. For instance, an operator that counts the number of tuples in a relation or an operator that selects all tuples with a timestamp spanning at least 3 months are sensitive to temporal coalescing.

Historical Background

Early temporal relational models implicitly assumed that the relations were coalesced. Ben Zvi's Time Relational Model [13, Chap. 8], Clifford and Croker's Historical

Relational Data Model (HRDM) [13, Chap. 1], Navathe's Temporal Relational Model (TRM) [13, Chap. 4], and the data models defined by Gadia [13, pp. 28–66], Sadeghi [9] and Tansel [13, Chap. 7] all have this property. The term *coalesced* was coined by Snodgrass in his description of the data model underlying TQuel, which also requires temporal coalescing [10]. Later data models, such as those associated with HSQL [13, Chap. 5] and TSQL2 [11], explicitly required coalesced relations. The query languages associated with these data models generally did not include explicit constructs for temporal coalescing. HSQL is the exception; it includes a `COALESCE ON` clause within the select statement, and a `COALESCED` optional modifier immediately following `SELECT` [13, Chap. 5]. Some query languages that do not require coalesced relations provide constructs to explicitly specify temporal coalescing; VT-SQL [8] and ATSQL [2] are examples.

Navathe and Ahmed defined the first temporal coalescing algebraic operator; they called this COMPRESS [13, Chap. 4]. Sarda defined an operator called COALESCE [13, Chap. 5], Lorentzos' FOLD operator includes temporal coalescing [13, Chap. 3], Leung's second variant of a temporal select join operator TSJ_2 [13, Chap. 14] can be used to effect temporal coalescing, and TSQL2's representational algebra also included a coalesce operator [11].

In terms of performance and expressiveness Leung and Pirahesh provided a mapping of the coalesce operation into *recursive* SQL [6, p. 329]. Lorentzos and Johnson provided a translation of his FOLD operator into Quel [7, p. 295]. Böhlen et al. [3] show how to express temporal coalescing in terms of standard SQL and compare different implementations. SQL-based solutions to coalescing have also been proposed by Snodgrass [12] and Zhou et al. [14].

Foundations

Temporal databases support the recording and retrieval of time-varying information [13] and associate with each tuple in a temporal relation one or more timestamps that denote some *time periods*. The discussion assumes that each tuple is associated with a *valid time* attribute VT. This attribute is called the timestamp of the tuple. The timestamps are half open time periods: the start point is included but the end point is not. The non-timestamp attributes are referred to as the explicit attributes.

In a temporal database, tuples are uncoalesced when they have identical attribute values and their timestamps are either adjacent in time ("meet" in Allen's taxonomy [1]) or have some time in common. Consider the relations in Fig. 1. The relation records bonus payments that have been given to employees. Ron received two 2K bonuses: one for his performance from January 1981 to April 1981 and another one for his performance from May 1981 to September 1981. Pam received a 3K bonus for her performance from April 1981 to May 1981. Bonus1 is uncoalesced since the tuples for Ron have adjacent timestamps and can be coalesced. Bonus2 is coalesced. Coalescing Bonus1 yields Bonus2.

As with duplicate elimination in nontemporal databases, the result of some operators in temporal databases changes if the argument relation is coalesced before applying the operator [11]. For instance an operator that counts the number of tuples in a relation or an operator that selects all tuples with a timestamp spanning at least 3 months are sensitive to temporal coalescing.

In general, two tuples in a *valid time* relation are candidates for temporal coalescing if they have identical explicit attribute values (see *value equivalence* [10]) and have adjacent or overlapping timestamps. Such tuples can arise in many ways. For example, a projection of a coalesced temporal relation may produce an uncoalesced result, much as duplicate tuples may be produced by a duplicate preserving projection on a duplicate-free nontemporal relation. In addition, update and insertion operations may not enforce temporal coalescing, possibly due to efficiency concerns.

Bonus1

Name	Amount	VT
Ron	2K	[1981/01–1981/06)
Ron	2K	[1981/01–1981/05)
Pam	3K	[1981/05–1981/10)

Bonus2

Ron	2K	[1981/01–1981/10)
Pam	3K	[1981/04–1981/06)

Temporal Coalescing. Figure 1. Uncoalesced (Bonus1) and coalesced (Bonus2) valid time relations.

Thus, whether a relation is coalesced or not makes a semantic difference. In general, it is not possible to switch between a coalesced and an uncoalesced representation without changing the semantics of programs. Moreover, as frequently used database operations (projection, union, insertion, and update) may lead to potentially uncoalesced relations and because many (but not all) real world queries require coalesced relations, a fast implementation is imperative.

Temporal coalescing is potentially more expensive than duplicate elimination, which relies on an equality predicate over the attributes. Temporal coalescing also requires detecting if the timestamps of tuples overlap, which is an inequality predicate over the timestamp attribute. Most conventional DBMSs handle inequality predicates poorly; the typical strategy is to resort to exhaustive comparison when confronted with such predicates [5], yielding quadratic complexity (or worse) for this operation.

Implementing Temporal Coalescing

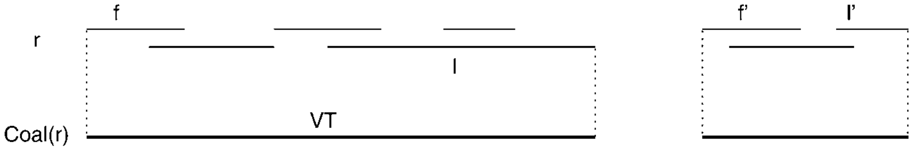
Temporal coalescing does not add expressive power to SQL. Assuming that time is linear, i.e., totally ordered, it is possible to compute a coalesced relation instance with a single SQL statement (see also [4, p. 291]). The basic idea is to use a join to determine the first (f) and last (l) time period of a sequence of *value equivalent* tuples with adjacent or overlapping timestamps as illustrated in Fig. 2.

The SQL code assumes that the *time period* is represented by start (*S*) and end (*E*) point, respectively. Besides start and end point there is an explicit attribute *c*. This yields a relation with schema *R*(*S*, *E*, *c*). Two subqueries are used to ensure that there are no temporal gaps (for example between l and f' is a temporal gap) and that the sequence is maximal (there is no tuple with a time period that starts before the start point of f and that temporally overlaps with f; there is no tuple with a time period that ends after the end point of l and that temporally overlaps with l), respectively.

```
SELECT DISTINCT f.S, l.E, f.c
FROM r AS f, r AS l
WHERE f.S < l.E
AND f.c = l.c
AND NOT EXISTS (SELECT *
                FROM r AS m
                WHERE m.c = f.c
                AND f.S < m.S AND
                m.S < l.E
AND NOT EXISTS  (SELECT *
                FROM r AS a1
                WHERE a1.c = f.c
                AND a1.S < m.S AND m.S
                <= a1.E))
AND NOT EXISTS (SELECT *
                FROM r AS a2
                WHERE a2.c = f.c
                AND (a2.S < f.S AND f.S
                <= a2.E OR
                   a2.S <= l.E AND l.E
                   < a2.E))
```

The above SQL statement effectively coalesces a relation. However, current database systems cannot evaluate this statement efficiently. It is possible to exploit the fact that only the maximal time periods are relevant. Rather than inserting a new tuple (and retaining the old ones) it is possible to update one of the tuples that was used to derive the new one. This approach can be implemented by iterating an update statement. The statement is repeated until the relation does not change anymore, i.e., until the fixpoint with respect to temporal coalescing is reached.

```
repeat
   UPDATE r l
   SET (l.E) =
     (SELECT MAX(h.E)
      FROM r h
      WHERE l.c = h.c
      AND l.S < h.S AND l.E >= h.S AND l.
      E < h.E)
```



Temporal Coalescing. Figure 2. Illustration of temporal coalescing.

```
    WHERE EXISTS (
      SELECT *
      FROM r h
      WHERE l.c = h.c
      AND l.S < h.S AND l.E >= h.S AND
      l.E < h.E)
  until fixpoint(r)
```

One means to further improve the performance is to use the DBMS as an enhanced storage manager and to develop main memory algorithms on top of it. Essentially, this means to load the relation into main memory, coalesce it manually, and then store it back in the database. If tuples are fetched ordered primarily by explicit attribute values and secondarily by start points it is possible to coalesce a relation with just a single tuple in main memory. The core of the C code of the temporal coalescing algorithm is displayed below. It uses ODBC to access the database.

```
SQLAllocEnv(&henv);
SQLAllocConnect(henv, &hdbc);
SQLConnect(hdbc,"Ora10g",
SQL_NTS,"scott",SQL_NTS,"tiger",
SQL_NTS;
SQLAllocHandle(SQL_HANDLE_STMT,
hdbc, &hstmt1)
SQLAllocHandle(SQL_HANDLE_STMT,
hdbc, &hstmt2)

/* initialize buffer curr_tpl (a one
tuple buffer) */
SQLExecDirect(hstmt1, "SELECT S, E, c
FROM r ORDER BY c, S", SQL_NTS))
curr_tpl.S = next_tpl.S;
curr_tpl.E = next_tpl.E;
curr_tpl.c = next_tpl.c;

/* open a cursor to store tuples back
in the DB */
SQLPrepare(hstmt2,  "INSERT  INTO
r_coal VALUES (?,?,?)", SQL_NTS)

/* main memory temporal coalescing */
while     (SQLFetch(hstmt1)     !=
SQL_NO_DATA){ /* fetch all tuples */
  if (curr_tpl.c == next_tpl.c &&
  next_tpl.S <= curr_tpl.E){
    /* value-equivalent and
    overlapping*/
    if (next_tpl.E > curr_tpl.E)
    curr_tpl.E = next_tpl.E;
  } else{
   /* not value-equivalent or non-overlapping */
   SQLExecute(hstmt2) /* store back
   current tuple */
   curr_tpl.S = next_tpl.S;
   curr_tpl.E = next_tpl.E;
   curr_tpl.c = next_tpl.c;
  }
}
SQLExecute(hstmt2) /* store back current tuple */
```

Key Applications

Temporal coalescing defines a normal form for temporal relations and is a crucial and frequently used operator for applications that do not want to distinguish between snapshot equivalent relations. Applications that allow to distinguish between snapshot equivalent relations have temporal coalescing as an explicit operator similar to duplicate elimination in existing database systems.

Definition

Temporal compatibility captures properties of temporal languages with respect to the nontemporal languages that they extend. Temporal compatibility, when satisfied, ensures a smooth migration of legacy applications from a non-temporal system to a temporal system. Temporal compatibility dictates the semantics of legacy statements and constrains the semantics of temporal extensions to these statements, as well as the language design.

Historical Background

Since the very early days of temporal database research, the compatibility with legacy languages and systems has been considered, but the first comprehensive investigation was reported by Bair et al. [2]. Compatibility issues are common for work done in the context of systems and commercial languages, such as SQL or Quel. Theoretical or logic-based approaches usually do not explore compatibility notions since they tend to strictly separate temporal from nontemporal structures.

Foundations

Motivation

Most data management applications manage time-referenced, or temporal, data. However, these applications typically run on top of relational or object-relational database management systems (DBMSs), such as DB2, Oracle, SQL Server, and MySQL, that offer only little built-in support for temporal data management. Organizations that manage temporal data may benefit from doing so using a DBMS with built-in temporal support. Indeed, it has been shown that using a temporal DBSM in place of a non-temporal DBMS may reduce the number of lines of query language code by a factor of three, with the conceptual complexity of application development decreasing even further [13].

Then, what hinders an organization from adopting a temporal DBMS? A key observation is that an organization is likely to already have a portfolio of data management applications that run against a non-temporal DBMS. In fact, the organization is likely to have made very large investments in its legacy systems, and it depends on the functioning of these systems for the day-to-day operation of its business.

It should be as easy as possible for the organization to migrate to a temporal DBMS. It would be attractive if all existing applications would simply work without modification on the temporal DBMS. This would help protect the organization's investment in its legacy applications. The opposite, that of having to rewrite all legacy applications, is a daunting proposition.

However, this type of compatibility is only the first step. The next step is to make sure that legacy applications can coexist with new applications that actually exploit the enhanced temporal support of the new DBMS. These applications may query and modify the same (legacy) tables. It should thus be possible to add a new temporal dimension to existing tables, without this affecting the legacy applications that use these tables.

Next, the organization maintains a large investment in the skill set of its IT staff. In particular, the staff is skilled at using the legacy query language, typically SQL. The new, temporal query language should leverage this investment, by making it easy for the application programmers to write temporal queries against temporal relations.

Next four specific compatibility properties that aim to facilitate the migration from a non-temporal DBMS to a temporal DBMS are considered.

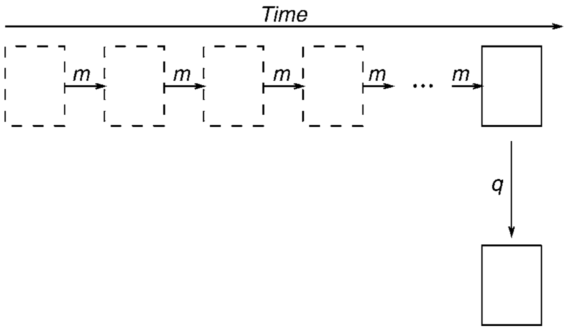
Upward Compatibility

The property of upward compatibility states that all language statements expressible in the underlying non-temporal query language must evaluate to the same result in the temporal query language, when evaluated on non-temporal data.

Figure 1 illustrates this property. In the figure, a conventional table is denoted with a rectangle. The current state of this table is the rectangle in the upper-right corner. Whenever a modification is made to this table, the previous state is discarded; hence, at any time, only the current state is available. The discarded prior states are denoted with dashed rectangles; the right-pointing arrows denote the modifications that took the table from one state to the next.

When a query *q* is applied to the current state of a table, a resulting table is computed, shown as the rectangle in the bottom right corner. While this figure only concerns queries over single tables, the extension to queries over multiple tables is clear.

As an example, consider a hypothetical temporal extension of the conventional query language SQL [9]. Upward compatibility states that (i) all instances of tables in SQL are instances of tables in this extension, (ii) all SQL modifications to tables result in the same tables when the modifications are evaluated according to the semantics of the extension, and (iii) all SQL queries result in the same tables when the queries are evaluated according to the extension.



Temporal Compatibility. Figure 1. Upward compatible queries.

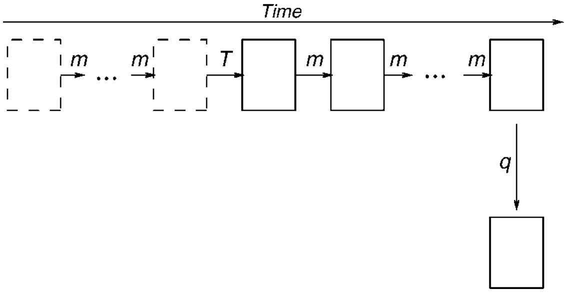
By requiring that a temporal extension to SQL is a strict superset (i.e., only *adding* constructs and semantics), it is relatively easy to ensure that the extension is upward compatible with SQL. TOSQL [1], TSQL [10], HSQL [11], IXSQL [7], TempSQL [5], and TSQL2 [12] were designed to satisfy upward compatibility.

While upward compatibility is essential in ensuring a smooth transition to a new temporal DBMS, it does not address all aspects of migration. It only ensures the operation of existing legacy applications and does not address the coexistence of these with new applications that exploit the improved temporal support of the DBMS.

Temporal Upward Compatibility

The property of temporal upward compatibility (TUC) addresses the coexistence of legacy and new applications. Assume an existing or new application needs support for the temporal dimension of the data in one or more of the existing tables that record only the current state. This is best achieved by changing the snapshot table to become a temporal table. It is undesirable to be forced to change the application code that accesses the snapshot table when that table is made temporal. TUC states that conventional queries on temporal data yield the same results as do the same queries on a conventional database formed by taking a timeslice at "now." TUC applies also to modifications, views, assertions, and constraints [2].

Temporal upward compatibility is illustrated in Fig. 2. When temporal support is added to a table, the history is preserved and modifications over time are retained. In the figure, the rightmost dashed state was the current state when the table was made temporal. All subsequent modifications, denoted again by



Temporal Compatibility. Figure 2. Temporal upward compatibility.

arrows, result in states that are retained, and thus are represented by solid rectangles. Temporal upward compatibility ensures that the states will have identical contents to those states resulting from modifications of the snapshot table. The query q is a conventional SQL query. Due to temporal upward compatibility, the semantics of this query must not change if it is applied to a temporal table. Hence, the query only applies to the current state, and a snapshot table results.

Most temporal languages were not designed with TUC in mind, and TOSQL [1], TSQL [10], HSQL [11], IXSQL [7], and TSQL2 [12] do not satisfy TUC. The same holds for temporal logics [4]. TempSQL [5] introduces a concept of different types of users, classical and system user. TempSQL satisfies TUC for classical users. ATSQL [3] was designed to satisfy TUC.

Snapshot Reducibility

This third property states that for each conventional query, there is a corresponding temporal query that, when applied to a temporal relation, yields the same result as the original snapshot query when applied separately to every snapshot state of the temporal relation.

Graphically, snapshot reducibility implies that for all conventional query expressions q in the snapshot model, there must exist a temporal query q^t in the temporal model so that for all db^t and for all c, the commutativity diagram shown in Fig. 3 holds.

This property requires that each query q (or operator) in the snapshot model has a counterpart q^t in the temporal model that is snapshot reducible with respect to the original query q. Observe that q^t being snapshot reducible with respect to q poses no syntactical restrictions on q^t. It is thus possible for q^t to be quite different from q, and q^t might be very involved. This is undesirable: the temporal model should be a straightforward extension of the snapshot model.

Most languages satisfy snapshot reducibility, but only because corresponding non-temporal and temporal statements do not have to be syntactically similar. This allows the languages to formulate for each nontemporal statement a snapshot reducible temporal statement, possibly a very different and complex statement.

Sequenced Semantics

This property addresses the shortcoming of snapshot reducibility: it requires that q^t and q be syntactically identical, modulo an added string.

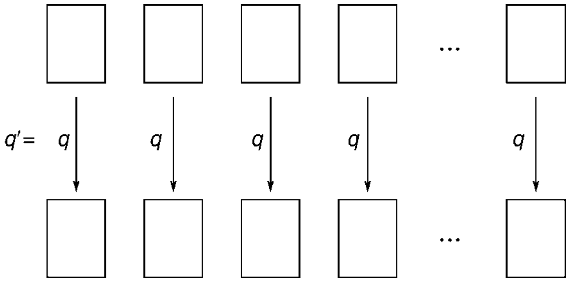
Figure 4 illustrates this property. This figure depicts a temporal query, q', that, when applied to a temporal table (the sequence of values across the top of the figure), results in a temporal table, which is the sequence of values across the bottom.

The goal is to ensure that an application programmer who is familiar with the conventional query language is able to easily formulate temporal generalizations of conventional queries using the temporal query language. This is achieved if a query q can be made temporal by simply adding a string to it. The syntactical similarity requirement of sequenced semantics makes this possible. Specifically, the meaning of q' is precisely that of applying the analogous *non-temporal* query q on each value of the argument table (which must be temporal), producing a state of the result table for each such application.

Most temporal languages do not offer sequenced semantics. As an exception, ATSQL [3] prepends the modifier SEQUENCED, together with the time dimension (valid time or transaction time, or both), to nontemporal statements to obtain their snapshot reducible generalizations. Temporal Logic [4] satisfies sequenced semantics as well: the original nontemporal statement yields sequenced semantics when evaluated over a corresponding temporal relation.

$$\begin{tikzcd}
db^t \arrow[r, "q^t"] \arrow[d, "\text{timeslice at } c"'] & q^t(db^t) \arrow[d, "\text{timeslice at } c"] \\
slice(db^t, c) \arrow[r, "q"'] & q(slice(db^t, c)) = slice(q^t(db^t), c)
\end{tikzcd}$$

Temporal Compatibility. Figure 3. Snapshot reducibility.



Temporal Compatibility. Figure 4. Sequenced semantics.

Key Applications

Temporal compatibility properties such as those covered here are important for the adoption of temporal database technology in practice. The properties are important because temporal technology is likely to most often be applied in settings where substantial investments have already been made in database management staff and applications. The properties aim at facilitating the introduction of temporal database technology in such settings.

Properties such as these are easily as crucial for the successful adoption of temporal database technology as is highly sophisticated support for the querying of time-referenced data.

Given the very significant decrease in code size and complexity for temporal applications that temporal database technology offers, it is hoped that other DBMS vendors will take Oracle's lead and incorporate support for temporal databases into their products.

Future Directions

Further studies of compatibility properties are in order. For example, note that temporal upward compatibility addresses the case where existing tables are snapshot tables that record only the current state. However, in many cases, the existing tables may already record temporal data using a variety of ad-hoc formats. The challenge is then how to migrate such tables to real temporal tables while maintaining compatibilities.

Next, it is felt that much could be learned from conducting actual case studies of the migration of real-world legacy applications to a temporal DBMS.

Temporal Conceptual Models

Vijay Khatri
Indiana University, Bloomington, IN, USA

Definition

A *conceptual model* provides a notation and formalism that can be used to construct a high-level, implementation-independent description of selected aspects of the "real world," termed a miniworld. This process is called conceptual modeling, and the resulting description is referred to as a *conceptual schema*. Conceptual modeling is an important part of systems analysis and design. A *temporal conceptual model* provides a notation and formalism with built-in support for capturing temporal aspects of a miniworld during conceptual design.

Historical Background

Temporal applications need to represent data semantics not only related to "what" is important for the application, but also related to "when" it is important. The history of temporal conceptual models can be viewed in terms of two generations. The *first generation temporal conceptual models*, e.g., [2,14], provide support for only *user-defined time*; see Fig. 1a for an example. In contrast to the first generation, the *second generation temporal conceptual models*, e.g., [5,9,16], provide varying degree of support for temporal aspects; see Fig. 1b for an example. Because the first generation temporal conceptual models provide support for representation of only user-defined time, they may be thought of as "almost" time-agnostic conceptual models; on the other hand, second generation temporal conceptual models that support temporal semantics, e.g., event, state, valid time, transaction time, may be construed as time-aware conceptual models.

Foundations

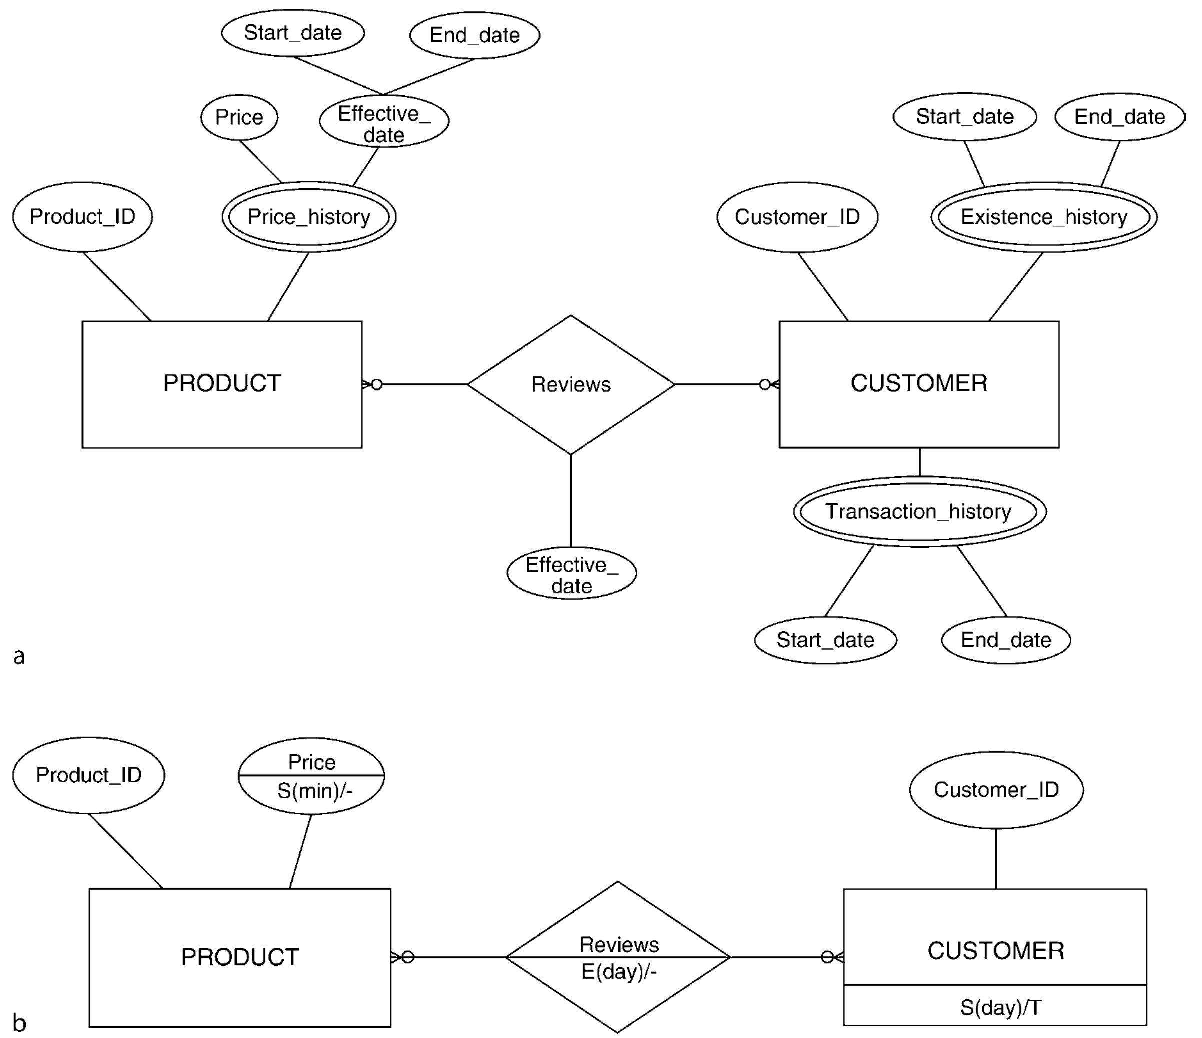
To highlight core concepts developed in the research related to temporal conceptual models, a framework of linguists is adopted that studies symbols with respect to three dimensions: syntactics, semantics and pragmatics [13]. The *syntactics* dimension includes formal relation between symbols, the *semantics* dimension involves the study of symbols in relation to the designatum (i.e., what the sign refers to) and the *pragmatics* dimension includes the relation between symbols and the interpreter.

In the following, a motivating example is employed to differentiate between first and second generation temporal conceptual models. Core concepts related to temporal conceptual models are described using syntactics, semantics and pragmatics.

Motivating Example

Figure 1a (first generation temporal conceptual model) provides an example of an ER schema that requires preserving the history of "prices" (of PRODUCT). Additionally, there is another entity type, CUSTOMER, whose existence needs to be modeled; the existence history needs to take into account both when the customer exists in the real world (Existence_history) and when the customer was added to the database (Transaction_history). Further, a CUSTOMER "reviews" PRODUCTs and the Effective_date on which the PRODUCT was reviewed needs to be captured as well. Because the first generation conceptual models do not provide a mechanism to represent temporal concepts, e.g., valid time, transaction time, event and state, these are all represented using only user-defined time. For example, the schema cannot differentiate Existence_history from Transaction_history, which are both represented simply as multi-valued attributes (double-lined ellipse). Additionally, the database analyst needs to make ad-hoc decisions related to granularity of a user-defined attribute such as Transaction_history. Start_date during implementation. As a result of the lack of a mechanism for directly mapping the miniworld to its representation, database designers are left to discover, design, and implement the temporal concepts in an ad-hoc manner.

The second generation temporal conceptual schema, referred to as the ST USM (geoSpatio-Temporal Unifying Semantic Model) schema [9] shown in Fig. 1b employs a textual string to represent temporal semantics. For example, "Price" is associated with valid time, which is represented as state ("S") with granularity of "min"(ute); further, the transaction time related to price is not relevant ("–"). The temporal semantics associated with "Price" are therefore represented by a textual string of valid time state ("S"), followed by a slash ("/"), followed by the specification of transaction time ("–"): "S (min)/–". Because both the existence (or valid) time and transaction time need to be recorded for the entity type, CUSTOMER, the annotation string for CUSTOMER is specified as "S(day)/T". Note that the granularity of transaction time is not specified



Temporal Conceptual Models. Figure 1. Examples of the two generations of temporal conceptual models.

because it is system-defined. A CUSTOMER "reviews" a PRODUCT at a certain point in time (event, E), captured to the granularity of day ("E (day)/–").

In summary, while the first generation temporal conceptual models provide a mechanism to represent only user-defined time, the second generation temporal conceptual models provide a mechanism to represent temporal data semantics. The readers are referred to Gregersen and Jensen [6] for a survey on various temporal conceptual models of the second generation.

Syntactics

Prior research has employed both graphical (see, for example, the TimeER Model [6]) and textual (see, for example, the Temporal Entity Relationship Model, TERM [11]) syntax to represent the temporal data semantics.

While some of graphical temporal conceptual models have changed the semantics of the constructs of conventional conceptual models (see, for example, [2]), others have proposed a new formalism for representing temporal aspects. The Temporal EER (TEER) Model [3] gave *new* meaning to *extant* ER modeling constructs such as the entity type, the attribute and the relationship; for example, each entity of an entity type is associated with a temporal element that represents the lifespan of the entity, i.e., the semantics of an entity type in a conventional conceptual model was changed. On the other hand, most of the graphical temporal conceptual models propose *new* constructs that represent the temporal aspects.

Prior research has employed two ways to graphically represent temporal aspects using new constructs; they are referred to as augmented (see, for example, the TimeER Model [6] and ST USM [9]) and standalone (see, for example, the Relationships, Attributes, Keys and Entities (RAKE) Model [4]). The *augmented approaches* construe second generation conceptual schemas as "constrained" first generation schemas. For example, ST USM employs a "shorthand" for temporal semantics that is represented as annotations (see, for example, Fig. 1b); however, the semantics of a second generation schema (ST USM schema) can be "unwrapped" using a first generation schema (USM schema) and a set of constraints. The readers are referred to [9] for examples of and procedure for "unwrapping" of the semantics of an annotated schema. In contrast, the *standalone approaches* suggest *new* constructs for representing the temporal aspects. The *augmented approaches* provide a mechanism for capturing temporal data semantics at the second level of abstraction; such approaches *deliberately* defer elicitation of the temporal data semantics ("when") from the first level of abstraction that focuses on "what" is important for the application. In contrast, the *standalone approaches* provide a single level of abstraction for representing both "what" and "when."

Having outlined different syntax adopted by various conceptual models, the temporal semantics that need to be captured in a temporal conceptual model are described next.

Semantics

Based on [8], definitions of different temporal aspects that need to be represented in a temporal conceptual model are outlined below.

An *event* occurs at a point in time, that is, it has no duration (for example, a special promotion for a product is scheduled on Christmas Eve this year (2007–12–24)), while a *state* has duration (for example, a certain price for a product is valid from 5:07 P.M. on 2005–11–11 to 5:46 P.M. on 2007–1–11).

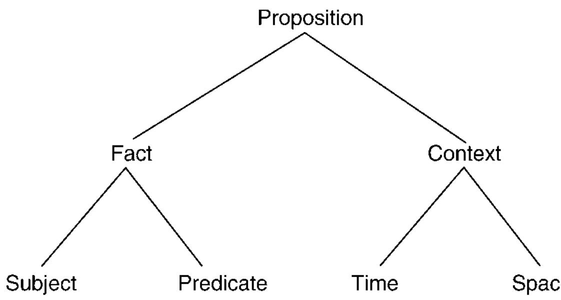
Facts can interact with time in two orthogonal ways, resulting in transaction time and valid time. *Transaction time* links a fact to the time that it becomes current in the database, and implies the storage of versions of data. The data semantics of transaction time associated with a fact require that the fact can exist in certain time periods in the past until *now* (state). *Valid time* is used to record the time at which a particular fact is true in the real world and implies the storage of histories related to facts. The data semantics of valid time associated with a fact imply that the fact can exist at certain points in time (events) or in certain time periods (states), in the past, the present, or the future.

Granularities, which are intrinsic to temporal data, provide a mechanism to hide details that are not known or not pertinent for an application. Day, minute, and second are examples of temporal granularities related to the Gregorian calendar. The price history for a manufacturing application may, for example, be associated with a temporal granularity of "day," while the representation of price history for a stock market application may require a temporal granularity of "minute" or even "second."

Pragmatics

Prior research suggests that "effective exchange of information between people and machines is easier if the data structures that are used to organize the information in the machine correspond in a natural way to the conceptual structures people use to organize the same information" [12]. Three criteria play a role in how an "interpreter" (users) interacts with "symbols" (conceptual schema): (i) "internal" representation; (ii) snapshot reducibility; (iii) upward compatibility. While snapshot reducibility and upward compatibility may be rooted in syntactics and semantics, they affect the pragmatic goal, comprehension.

Internal Representation All human knowledge is stored as abstract conceptual propositions. Based on propositions, Anderson and Bower's [1] Human Associative Model (HAM) represents information in the long-term memory as shown in Fig. 2. A *proposition*



Temporal Conceptual Models. Figure 2. Internal representation of human knowledge. (Adapted from HAM Model [1].)

is an assertion about the real world that is composed of a *fact* and *context* (associated with the fact). A *subject* and *predicate* correspond with a topic and a comment about the topic. For some applications, the context in which the fact is true can be the key to reasoning about the miniworld. This context in turn, is composed of *time* and *location* associated with the fact. Note that the "context" element is orthogonal to the "fact" element and specifies the temporal reality for which the fact is true. (This entry does not cover spatial aspects; see [9] for details on a spatio-temporal conceptual model.) An augmented approach that segregates "what" from "when" corresponds with the way humans naturally organize temporal information and should, thus, support comprehension of the schema.

Snapshot Reducibility Snapshot reducibility implies a "natural" generalization of the syntax and semantics of extant conventional conceptual models, e.g., the ER Model [2], for incorporating the temporal extension. Snapshot reducibility ensures that the semantics of a temporal model are understandable "in terms of" the semantics of the conventional conceptual model. Here, the overall objective is to help ensure minimum additional investment in a database analyst training.

For example, in a "conventional" conceptual model a *key attribute* uniquely identifies an entity (at a point in time). A *temporal key* implies uniqueness at *each point in time*. As may be evident, the semantics of a temporal key here are implied by the semantics of a key in a "conventional" conceptual model.

Upward Compatibility Upward compatibility refers to the ability to render a conventional conceptual schema temporal without impacting or negating that legacy schema, thus, protecting investments in the existing schemas. It also implies that both the legacy schemas and the temporal schemas can co-exist. Upward compatibility requires that the syntax and

Temporal Conceptual Models. Table 1. Summary of a sample of first and second generation temporal conceptual models

	Syntactics		Semantics			Pragmatics		
	Syntax	User-defined time	Valid time and transaction time	Event and state	Granularity	Consideration of internal representation	Upward compatibility	Snapshot reducibility
First Generation								
ER Model [2]	• "What": Graphical • "When": NA	Yes	No	No	No	NA	NA	NA
Second Generation								
TERM [11]	• "What": Textual • "When": Textual	Yes	Valid time only	Both	Yes	No	No	No
TERC+ [16]	• "What": Graphical • "When": Graphical	Yes	Valid time only	Both	No	No	Yes	Yes
TimeER [5]	• "What": Graphical • "When": Textual	Yes	Both	Both	No	No	Yes	Yes
ST USM [9]	• "What": Graphical • "When": Textual	Yes	Both	Both	Yes	Yes	Yes	Yes

semantics of the traditional conceptual model remain unaltered. An augmented approach that extends conventional conceptual models would ensure upward compatibility.

Summary

Because one of the important roles of conceptual modeling is to support user-database analyst interaction, the linguistics-based framework of evaluation is broader: it not only includes syntactics and semantics but also includes cognitive aspects in conceptual design (pragmatics). Table 1 summarizes the evaluation of a first generation and a few second generation temporal conceptual models.

Key Applications

There are several applications of this research, both for researchers and practitioners. (i) A temporal conceptual model can help support elicitation and representation of temporal data semantics during conceptual design. (ii) A temporal conceptual schema can, thus, be the basis for the logical schema and the database. (iii) A temporal conceptual modeling approach can be used as the basis for developing a design-support environment. Such a design support environment can be integrated with tools such as ERWin. (http://www.ca.com/us/products/product.aspx?id=260)

Future Directions

Future research should explore how the temporal schema can be used as the canonical model for information integration of distributed temporal databases. A temporal conceptual model should also be extended to incorporate schema versioning.

While an initial user study has been conducted [10], future research should further evaluate temporal conceptual modeling using, e.g., protocol analysis. Studies that address *how* problem solving occurs focus on "opening up the black box" that lies between problem-solving inputs and outputs; that is, such studies investigate what happens during individual problem solving (*isomorphic approach*) rather than simply observing the effects of certain stimuli averaged over a number of cases, as in traditional studies (*paramorphic approach*) [7]. The most common approach to opening up the black box is to examine the characteristics of the problem-solving process using protocol analysis.

Experimental Results

To evaluate the augmented temporal conceptual design approach, a user experiment [10] views conceptual schema comprehension in terms of matching the *external problem representation* (i.e., conceptual schema) with *internal task representation*, based on the theory of HAM and the theory of cognitive fit [15]. The study suggests that the similarity between annotated schemas (external representation) and the HAM model of internal memory results in cognitive fit, thus, facilitating comprehension of the schemas.

Temporal Constraints

Peter Revesz
University of Nebraska-Lincoln, Lincoln, NE, USA

Definition

Temporal Constraints describe relationships among variables that refer somehow to time. A set of temporal constraints can be stored in a temporal database, which is queried by temporal queries during problem solving. For example, a set of temporal constraints may form some requirements, all of which must be satisfied during some scheduling problem.

Most interesting temporal constraints derive from references to time in natural language. Such references typically compare two *time points*, two *sets of time points*, or two *time intervals*. The literature on temporal constraints and this entry focuses on the study of these types of comparative or *binary* constraints.

Historical Background

The seminal work on temporal intervals is by Allen [1]. Difference Bounded Matrices (see the Section on Scientific Fundamentals) were introduced by Dill [3]. A graph representation of difference constraints and efficient constraint satisfaction problem-based solutions for consistency of difference constraints were presented by Dechter et al. [2]. A graph representation of gap-order constraints and an efficient algebra on them is presented by Revesz [11]. A graph representation of set order constraints and algebra on them is described in [12]. Addition constraints are considered in [12].

Temporal Constraints. Table 1. Consistency for conjunctions of temporal constraints

Case	Temporal constraints	Integers	Rationals
1.	After, Before, Equal, Inequal, AoE, BoE	$O(v + e)$	$O(v + e)$
2.	Addition	$O(ve)$	$O(v + e)$
3.	Inequal, Difference	NP-complete	$O(v^3)$

The complexity of deciding the consistency of conjunctions of integer addition constraints in Table 1 is from [9].

Periodicity constraint within query languages are considered by Kabanza et al. [4] and Toman and Chomicki [15]. Constraint databases [12,8] were introduced by Kanellakis et al. [5] with a general framework for constraints that includes temporal constraints. Indefinite temporal constraint databases were introduced by Koubarakis [6]. Linear cardinality constraints on sets were considered by Kuncak et al. [7] and Revesz [13].

Deciding the consistency of conjunctions of rational (or real) difference and inequality constraints was proven tractable by Koubarakis, but the $O(v^3)$ complexity result in Table 1 is from Péron and Halbwachs [10]. The NP-completeness result in Table 1 follows from [14].

Foundations

Temporal constraints on time points express temporal relationships between two time points, which are called also *time instances*. More precisely, let x and y be integer or rational variables or constants representing time points, and let b be an integer constant. Then some common temporal constraints on time points include the following:

$$\begin{array}{ll}
\textit{After}: & x > y \\
\textit{Before}: & x < y \\
\textit{Equal}: & x = y \\
\textit{Inequal}: & x \neq y \\
\textit{After or Equal}\ \ (\textit{AoE}): & x \geq y \\
\textit{Before or Equal}\ \ (\textit{BoE}): & x \leq y \\
\textit{After by at least } b\ \ (\textit{Gap}-\textit{Order}): & \\
& x - y \geq b \ \text{ where } \ b \geq 0 \\
\textit{Difference}: & x - y \geq b \\
\textit{Potential}: & x - y \leq b \\
\textit{Addition}: & \pm x \pm y \geq b
\end{array}$$

In the above table, the first six constraints are called *qualitative* constraints, and the last four constraints are called *metric* constraints because they involve a measure b of time units. For example, "a copyright form needs to be filled out before publication" can be expressed as $t_{copyright} < t_{publication}$, where $t_{copyright}$ is the time point when the copyright form is filled out and $t_{publication}$ is the time point when the paper is printed. This constraint could be just one of the requirements in a complex scheduling problem, for example, the process of publishing in a book a collection of research papers. Another temporal constraint may express that "the publication must be at least 30 days after the time of submission," which can be expressed by the constraint $t_{publication} - t_{submission} \geq 30$.

Temporal constraints on sets of time points express temporal relationships between two sets of time points. The domain of a set X is usually assumed to be the finite and infinite subsets of the integers. Common temporal constraints between sets of time points include the following:

$$\begin{array}{ll} \textit{Equal}: & X = Y \\ \textit{Inequal}: & X \neq Y \\ \textit{Contains}\ \ (\textit{Set Order}): & X \subseteq Y \\ \textit{Disjoint}: & X \cap Y = \emptyset \\ \textit{Overlap with } b \textit{ elements}: & \\ & |X \cap Y| = b \end{array}$$

where X and Y are set variables or constants, $\emptyset$ is the empty set, b is an integer constant, and $||$ is the *cardinality* operator. For example, "The Database Systems class and the Geographic Information Systems class cannot be at the same time" can be expressed as $T_{Database} \cap T_{GIS} = \emptyset$, where $T_{Database}$ is the set of time points (measured in hour units) the Database System class meets, and T_{GIS} is the set of time points the Geographic Information Systems class meets.

Temporal constraints on time intervals express temporal relationships between two time intervals. These types of temporal constraints are known as *Allen's Relations* [Allen's Relations] because they were studied first by J. F. Allen [1].

Other types of temporal constraints: The various other types of temporal constraints can be grouped as follows:

- *n-ary temporal constraints.* These generalize the binary temporal constraints to n number of variables that refer to time. While *temporal databases* typically use binary constraints, *constraint databases* [5] use n-ary constraints [Constraint Databases], for example linear and polynomial constraints on n time point variables.
- *Temporal periodicity constraints.* Periodicity constraints [4,15] occur in natural language in phrases such as "every Monday." These constraints are discussed separately in [Temporal Periodicity Constraints].
- *Indefinite temporal constraints.* The nature of a temporal constraint can be two types: definite and indefinite. Definite constraints describe events precisely, while indefinite constraints describe events less precisely leaving several possibilities. For example, "Ed had fever between 1 P.M. and 9 P.M. but at no other times" is a definite constraint because it relays each time instance whether Ed had a fever or not. On the other hand, "Ed had fever for some time during 1 P.M. and 9 P.M." is an indefinite constraint because it allows the possibility that Ed had fever at 5 P.M. and at no other times, or another possibility that he had fever between 1 P.M. and 4 P.M. and at no other times. Hence it does not relay whether Ed had fever at 5 P.M. Conjunctions of temporal constraints can be represented in a number of ways. Consider a scheduling problem where one needs to schedule the events $e_1,\ldots,e_6$. Suppose that there are some scheduling requirements of the form "some (second) event occurs after another (first) event by at least b days." For example, each row of the following table, which is a temporal database relation, represents one such scheduling constraint.

Scheduling_Requirements

Second_Event	First_Event	After_By
0	e_1	5
0	e_2	2
e_1	e_3	−2
e_1	e_5	−9
e_2	e_1	−6
e_3	e_2	3
e_3	e_4	−3
e_4	e_3	−5
e_5	e_4	3
e_5	e_6	3
e_6	0	1

Many queries are easier to evaluate on some alternative representation of the above temporal database relation. Some alternative representations that may be used within a temporal database system are given below.

Conjunctions of Constraints

Let x_1,...,x_6 represent,respectively, the times when events e_1,...,e_6 occur. Then the *Scheduling_Requirements* relation can be represented also by the following conjunction of difference constraints:

$$
\begin{aligned}
&0 - x_1 \geq 5,\\
&0 - x_2 \geq 2,\\
&x_1 - x_3 \geq -2, x_1 - x_5 \geq -9, x_2 - x_1 \geq -6, x_3 -\\
&x_2 \geq 3, x_3 - x_4 \geq -3, x_4 - x_3 \geq -5, x_5 - x_4 \geq 3,\\
&x_5 - x_6 \geq 3,\\
&x_6 - 0 \geq 1
\end{aligned}
$$

Labeled Directed Graphs

In general, the graph contains $n + 1$ vertices representing all the n variables and 0. For each difference constraint of the form $x_i - x_j \geq b$, the graph contains also a directed edge from the vertex representing x_j to the vertex representing x_i. The directed edge is labeled by b.

Difference Bound Matrices

Conjunctions of difference constraints can be represented also by *difference bound matrices (DBMs)* of size $(n + 1) \times (n + 1)$, where n is the number of variables. For each difference constraint of the form $x_i - x_j \geq b$, the DBM contains the value b in its (j, i)th entry. The default value is $-\infty$. For example, above set of difference constraints can be represented by the following DBM:

	0	x_1	x_2	x_3	x_4	x_5	x_6
0	$-\infty$	$-\infty$	$-\infty$	$-\infty$	$-\infty$	$-\infty$	1
x_1	5	$-\infty$	-6	$-\infty$	$-\infty$	$-\infty$	$-\infty$

x_6	$-\infty$	$-\infty$	$-\infty$	$-\infty$	$-\infty$	3	$-\infty$

A major question about temporal constraint formulas is whether they are *consistent* or *satisfiable.* A formula is consistent or satisfiable if and only if it has at least one substitution for the variables that makes the formula true. Otherwise, it is called *inconsistent* or *unsatisfiable.* For example, if the conjunction of difference constraints that describe the *Scheduling_Requirements* table is inconsistent, then there is no schedule of the events e_1,...,e_6 such that all the requirements are satisfied.

Table 1 summarizes some computational complexity results, in terms of v the number of vertices and e the number of edges in the graph representation.

Most complexity results translate deciding the consistency to classical problems on graphs with efficient and well-known solutions. Decher et al. [2] provides a translation to constraint satisfaction problems, which use efficient search heuristics for large sets of constraints. Many operations on DBMs can be defined. These operators include *conjunction* or *merge* of DBMs, *variable elimination* or *projection* of a variable from a DBM, testing *implication* of a DBM by a disjunction of DBMs, and *transitive closure* of a DBM [12].

Temporal Constraints on Time Intervals.

In general, deciding the consistency of a conjunction of temporal constraints on intervals is NP-complete. Many computational complexity results for temporal constraints on time intervals follow from the complexity results for temporal constraint on time points. In particular, any conjunction of pointisable temporal constraints on time intervals can be translated to a conjunction of temporal constraints on time points. After the translation, the consistency can be tested as before.

Key Applications

Temporal constraints are used in scheduling, planning, and temporal database querying [Temporal Databases Queries]. Temporal database queries usually take the form of SQL or Datalog combined with temporal constraints. Examples include Datalog with gap-order constraints [11] and Datalog with periodicity constraints [15].

Future Directions

There are still many open problems on the use of temporal constraints in temporal database query languages. An important problem is finding efficient indexing methods for conjunctions of temporal constraints. The combination of temporal constraints with spatial constraints is an interesting area within spatiotemporal databases [Spatiotemporal Databases] and constraint databases [12].

Synonyms

Time series data mining; Sequence data mining; Temporal association mining

Definition

Temporal data mining refers to the extraction of implicit, non-trivial, and potentially useful abstract information from large collections of temporal data. Temporal data are sequences of a primary data type, most commonly numerical or categorical values and sometimes multivariate or composite information. Examples of temporal data are regular time series (e.g., stock ticks, EEG), event sequences (e.g., sensor readings, packet traces, medical records, weblog data), and temporal databases (e.g., relations with time-stamped tuples, databases with versioning). The common factor of all these sequence types is the total ordering of their elements. They differ on the type of primary information, the regularity of the elements in the sequence, and on whether there is explicit temporal information associated to each element (e.g., timestamps). There are several mining tasks that can be applied on temporal data, most of which directly extend from the corresponding mining tasks on general data types. These tasks include classification and regression (i.e., generation of predictive data models), clustering (i.e., generation of descriptive data models), temporal association analysis between events (i.e., causality relationships), and extraction of temporal patterns (local descriptive models for temporal data).

Historical Background

Analysis of time series data has been an old problem in statistics [4], the main application being forecasting for different applications (stock market, weather, etc.) Classic statistical models for this purpose include autoregression and hidden Markov models. The term temporal data mining came along as early as the birth of data mining in the beginning of the 1990s. Soon after association rules mining in large databases [1] has been established as a core research problem, several researchers became interested in association analysis in long sequences and large temporal databases (see [12] for a survey). One big challenge in temporal data mining is the large volume of the data, which make traditional autoregression analysis techniques inapplicable. Another challenge is the nature of the data which is not limited to numerical-valued time series, but includes sequences of discrete, categorical, and composite values (e.g., sets). This introduces new, interesting types of patterns, like causality relationships between events in time, partial periodic patterns, and calendric patterns.

Foundations

Classic data mining tasks, like classification, clustering, and association analysis can naturally be applied on large collections of temporal data. Special to temporal databases, are the extraction of patterns that are frequent during specific temporal intervals and the identification of temporal relationships between values or events in large sequences. In the following, the above problems are discussed in more detail.

Classification and Clustering

Classification of time series is often performed by nearest neighbor (NN) classifiers [13]. Given a time series $\vec{s}$ of unknown label and a database $\mathcal{D}$ of labeled samples, such a classifier (i) searches in $\mathcal{D}$ for the k most similar time series to $\vec{s}$ and (ii) gives $\vec{s}$ the most popular label in the set of k returned time series. This process involves two challenges: definition of an appropriate *similarity* function to be used by the NN classifier and scalability of classification. The dissimilarity (distance) between two time series is typically quantified by their Euclidean distance or the dynamic time warping (DTW) distance. Like classification, clustering of time series can be performed by applying an off-the-shelf clustering algorithm [7] (e.g., k-means), after defining an appropriate distance (i.e., dissimilarity) function.

For sequences of categorical data, Hidden Markov Models (HMM) can be used to capture the behavior of the data. HMM can be used for classification as follows. For each class label, a probabilistic state transition model that captures the probabilities of seeing one symbol (state) after the current one can be built. Then a sequence is given the label determined by the HMM that describes its behavior best.

Prediction

For continuous-valued sequences, like time series, regression is an alternative to classification. Regression does not use a fixed set of class labels to describe each sequence, but models sequences as functions, which are more appropriate for predicting the values in the future. Autoregression is a special type of regression, where future values are predicted as a linear combination of recent previous values, assuming that the series exhibits a periodic behavior. Formally, an autoregressive model of order p for a time series $\vec{s} = \{s_1, s_2, \ldots\}$ can be described as follows:

$$s_i = e_i + \sum_{j=1}^{p} \phi_j s_{i-j},$$

where $\phi_j (1 \leq j \leq p)$ are the parameters of autoregression, and e_i is an error term. The error terms are assumed to be independent identically-distributed random variables (i.i.d.) that follow a zero-mean normal distribution. The main trend of a time series is commonly described by a *moving average* function, which is a smoothed abstraction of the same length. Formally, the moving average of order q for a time series $\vec{s} = \{s_1, s_2, \ldots\}$ can be described as follows:

$$MA(\vec{s})_i = e_i + \sum_{j=1}^{q} \psi_j e_{i-j},$$

where $\psi_j (1 \leq j \leq q)$ are the parameters of the model. By combining the above two concepts, a time series $\vec{s}$ can be described by an autoregressive moving average (ARMA) model:

$$s_i = e_i + \sum_{j=1}^{p} \phi_j s_{i-j} + \sum_{j=1}^{q} \psi_j e_{i-j},$$

Autoregressive integrated moving average (ARIMA) is a more generalized model, obtained by integrating an ARMA model. In long time series, periodic behaviors tend to be local, so a common practice is to segment the series into pieces with constant behavior and generate an autoregression model at each piece.

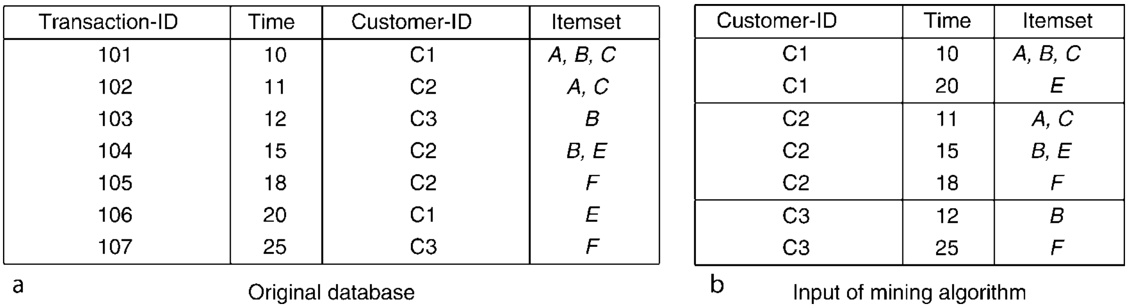
Association Analysis and Extraction of Sequence Patterns

Agrawal and Srikant [3] proposed one of the first methods for association analysis in timestamped transactional databases. A transactional database records timestamped customer transactions (e.g., sets of books bought at a time) in a store (e.g., bookstore) and the objective of the analysis is to discover causality relationships between sets of items bought by customers. An example of such a *sequential* pattern (taken from the paper) is "5% of customers bought 'Foundation,' then 'Foundation and Empire,' and then 'Second Foundation,' " which can be represented by {(Foundation),(Foundation and Empire),(Second Foundation)}. In general, sequential patterns are total orders of *sets of items* bought in the same transaction. For example, {(Foundation,Life),(Second Foundation)} models the buying of "Foundation" and "Life" at a single transaction followed by "Second Foundation" at another transaction. The patterns can be extracted by dividing the database that records the transaction history of the bookstore into groups, one per customer, and then treat each group as an ordered sequence. For example, the transactional database shown in Fig. 1a is transformed to the grouped table of Fig. 1b.

The algorithm for extracting sequential patterns from the transformed database is reminiscent to the Apriori algorithm for frequent itemsets in transactional databases [2]. It takes as input a minimum support threshold *min-sup* and operates in multiple passes. In the first pass, the items that have been bought by at least *min-sup* of the customers are put to a frequent items set L_1. Then, orderings of pairs of items in L_1 form a candidate set C_2 of level-2 sequential patterns, the supports of which are counted during the second pass of the transformed database and the frequent ones form L_2. A sequence adds to the support of a pattern if the pattern is contained in it. For example, the sequence $\{(A, C),(B, E),(F)\}$ of customer C2 in Fig. 1 adds to the support of pattern $\{(A),(F)\}$. In general, after L_k has been formed, the algorithm generates and counts candidate patterns of $k + 1$ items. These candidates are generated by joining pairs (s_1, s_2) of frequent k-sequences, such that the subsequence obtained by dropping the first item of s_1 is identical to the one obtained by dropping the last item of s_2. For example, $\{(A, B),(C)\}$ and $\{(B), (C, D)\}$ generate $\{(A, B), (C, D)\}$. Candidates resulting from the join phase are pruned if they have a subsequence that is not frequent.

Agrawal and Srikant also considered adding constraints when counting the supports of sequential patterns. For example, if "Foundation and Empire" is bought 3 years after "Foundation," these two books may be considered unrelated. In addition, they considered relaxing the rigid definition of a transaction by unifying transactions of the same customer that took place close in time. For example, if a customer buys a new book minutes after her previous transaction, this book should be included in the previous transaction (i.e., the customer may have forgotten to include it in her basket before). Parallel to Agrawal and Srikant, Mannila et al. [9] studied the extraction of frequent causality patterns (called episodes) in long event sequences. The main differences of this work are (i) the input is a single very long sequence of events (e.g., a stream of sensor indications), (ii) patterns are instantiated by temporal sliding windows along this stream of events, and (iii) patterns can contain sequential modules (e.g., *A* after *B*) or parallel modules (e.g., *A* and *B* in any order). An example of such an episode is "*C* first, then *A* and *B* in any order, then *D*". To compute frequent episodes Mannila et al. [9] proposed adaptations of the classic Apriori technique [2]. A more efficient technique for mining sequential patterns was later proposed by Zaki [14].

Han et al. [6] studied the problem of mining partial periodic patterns in long event sequences. In many



Transaction-ID	Time	Customer-ID	Itemset

b Input of mining algorithm

Temporal Data Mining. Figure 1. Transformation of a timestamped transactional database.

applications, the associations between events follow a periodic behavior. For instance, the actions of people follow habitual patterns on a daily basis (i.e., "wake-up," then "have breakfast," then "go to work," etc.). Given a long event sequence (e.g., the actions of a person over a year) and a time period (e.g., 24 h), the objective is to identify patterns of events that have high support over all the periodic time intervals (e.g., days). For this purpose, all subsequences corresponding to the activities of each periodic interval can be extracted from the long sequence, and a sequential pattern mining algorithm [3] can be applied. Based on this idea, an efficient technique for periodic pattern mining, which is facilitated by the use of a sophisticated prefix tree data structure, was proposed by Han et al. [6]. In some applications, the time period every when the patterns are repeated is unknown and has to be discovered from the data. Towards this direction, Cao et al. [5] present a data structure that automatically identifies the periodicity and discovers the patterns at only a small number of passes over the data sequence.

Temporal, Cyclic, and Calendric Association Rules

An association rule in a transactional database may not be strong (according to specific support and confidence thresholds) in the whole database, but only when considering the transactions in a specified time interval (e.g., during the winter of 2005). An association rule bound to a time interval, where it is strong, is termed temporal association rule [12]. Identification of such a rule can be performed by starting from short time intervals and progressively extending them to the maximum possible length where the rule remains strong.

Özden et al. [10] noticed that association rules in transactional databases (e.g., people who buy turkey they also buy pumpkins) may hold only in particular temporal intervals (e.g., during the last week of November every year). These are termed *cyclic* association rules, because they are valid periodically, at a specific subinterval of a cycle (e.g., year). Such rules can be discovered by identifying the periodic intervals of fixed granularity (e.g., week of the year), which support the associations.

Cyclic rules are assumed to be supported at *exact* intervals (e.g., the last day of January), and at *every* cycle (e.g., every year). In practice, a rule may be supported with some mismatch threshold (e.g., the last weekday of January) and only at the majority of cycles (e.g., 80% of the cycles). Accordingly, the "cyclic" rule concept was extended by Ramaswamy et al. [11] to the more flexible *calendric* association rule. A calendar is defined by a set of time intervals (e.g., the last 3 days of January, every year). For a calendric rule to be strong, it should have enough support and confidence in at least *min-sup*% of the time units included in the calendar. An algebra for defining calendars and a method for discovering calendric association rules referring to them can be found in Ref. [11].

Li et al. [8] proposed a more generalized framework for calendric association rules. Instead of searching based on a predetermined calendar, they automatically identify the rules and their supporting calendars, taken from a hierarchy of calendar concepts. The hierarchy is expressed by a relation of temporal generalizations of varying granularity, e.g., $R(year, month, day)$. A possible calendric pattern is expressed by setting to each attribute, either a specific value of its domain, or a wildcard value "$\ast$." For example, pattern ($\ast$, *Jan*, 30) means the 30th of January each year, while (2005, $\ast$, 30) means the the 30th day of each month in year 2005. By defining containment relationships between such patterns (e.g., ($\ast$, $\ast$, 30) contains all the intervals of (2005, $\ast$, 30)) and observing that itemset supports for them can be computed constructively (e.g., the support of an itemset in ($\ast$, $\ast$, 30) can be computed using its support in all (y, $\ast$, 30) for any year y), Li et al. [8] systematically explore the space of all calendric patterns using the Apriori principle to prune space (e.g., an itemset is not frequent in ($\ast$, $\ast$, 30) if it is infrequent in all (y, $\ast$, 30) for every year y).

Key Applications

Weather Forecasting

Temporal causality relationships between events can assist the prediction of weather phenomena. In fact, such patterns have been used for this purpose since the ancient years (e.g., "if swallows fly low, it is going to rain soon").

Market Basket Analysis

Extension of classic association analysis to consider temporal information finds application in market analysis. Examples include, temporal relationships between products that are purchased within the same period by customers ("5% of customers bought 'Foundation,' then 'Foundation and Empire' ") and calendric association rules (e.g., turkey is bought together with pumpkin during the last week of November, every year).

Stock Market Prediction

Time-series classification and regression is often used by financial analysts to predict the future behavior of stocks. The structure of the time series can be compared with external factors (such as pieces of news) to derive more complex associations that result in better accuracy in prediction.

Web Data Mining

The World Wide Web can be viewed as a huge graph where nodes correspond to web pages (or web sites) and edges correspond to links between them. Users navigate through the web defining sequences of page visits, which are tracked in weblogs. By analyzing these sequences one can identify frequent sequential patterns between web pages or even classify users based on their behavior (sequences of sites they visit and sequences of data they download).

Temporal Data Models

Christian S. Jensen[1], Richard T. Snodgrass[2]

[1]Aalborg University, Aalborg, Denmark

[2]University of Arizona, Tucson, AZ, USA

Synonyms

Valid-time data model; Transaction-time data model; Bitemporal data model; Historical data model

Definition

A "data model" consists of two components, namely a set of objects and a language for querying those objects [4]. In a temporal data model the objects vary over time, and the operations in some sense "know" about time. Focus has been on the design of data models where the time references capture valid time, or transaction time, or a combination of both (for bitemporal data).

Historical Background

Almost all real-world databases contain time-referenced data. Few interesting databases are entirely stagnant, and when the modeled reality changes, the database must be updated. Usually at least the start time of currently valid data are captured, though most databases also retain previous data.

Two decades of research into temporal databases have unequivocally shown that a *time-referencing table*, containing certain kinds of time-valued columns that capture one or more temporal aspects of data recorded in other columns, is completely different from this table, without the time-valued columns. Effectively designing, querying, and modifying time-referencing tables requires a different set of approaches and techniques. It is possible to handle such data within standard data models, generally at the expense of high data redundancy, awkward modeling, and unfriendly query languages. An alternative is a data model, probably an extension of an extant, non-temporal data model, that explicitly incorporates time, making it easier to express queries, modifications, and integrity constraints.

As an example, consider a primary key of the following relation, which records the current positions of employees, identified by their social security numbers: `EMP(EmpID, POSITION)`. The primary key is obviously `EmpID`. Now add `STARTTIME` and `STOPTIME` attributes. While a primary key of `(EmpID, STARTTIME)` seems to work, such a primary key will not prevent overlapping periods, which would allow an employee to have two positions at a point of time, which is problematic. Stating the primary key constraint properly requires a complex assertion containing a dozen lines of code with multiple sub-queries [3]. Referential integrity is even more challenging.

The last two decades have seen the introduction of a great many temporal data models, not just in the context of relational data, as in the above example, but also with object-oriented, logic-based, and semistructured data.

Foundations

Levels of Abstraction

Temporal data models exist at three abstraction levels: the *conceptual level*, in which the data models are generally extensions of the Entity-Relationship Model, the *logical level*, in which the data models are generally extensions of the relational data model or of an object-oriented data model, and, infrequently, the *physical level*, in which the data model details how the data are to be stored. In terms of prevalence, models at the logical level are by far the most numerous. However, it has been shown that several of the models that were originally proposed as logical data models are actually equivalent to the BCDM logical model, and should more properly be viewed as physical data models [2]. This entry is restricted to logical models, focusing on the objects that are subject to querying rather than the query languages. First examined is the association of time with data, as this is at the core of temporal data management.

Temporal Aspects of Data

A database models and records information about a part of reality, termed the modeled reality. Aspects of the modeled reality are represented in the database by a variety of structures, termed database entities. In general, times are associated with database entities. The term "fact" is used for any (logical) statement that can meaningfully be assigned a truth value, i.e., true or false.

The facts recorded by database entities are of fundamental interest, and a fundamental temporal aspect may be associated with these: the valid time of a fact is the times when the fact is true in the modeled reality. While all facts have a valid time by definition, the valid time of a fact may not necessarily be recorded in the database. For example, the valid time may not be known, or recording it may not be relevant. Valid time may be used for the capture of more application-specific temporal aspects. Briefly, an application-specific aspect of a fact may be captured as the valid time of another, related fact.

Next, the transaction time of a database entity is the time when the entity is current in the database. Like valid time, this is an important temporal aspect. Transaction time is the basis for supporting accountability and "traceability" requirements. Note that transaction time, unlike valid time, may be associated with any database entity, not only with facts. As for valid time, the transaction-time aspect of a database entity may or may not be captured in the database. The transaction-time aspect of a database entity has a duration: from insertion to deletion. As a consequence of the semantics of transaction time, deleting an entity does not physically remove the entity from the database; rather, the entity remains in the database, but ceases to be part of the database's current state.

Observe that the transaction time of a database fact, say *f*, is the valid time of the related fact, "*f* is current in the database." This would indicate that supporting transaction time as a separate aspect is redundant. However, both valid and transaction time are aspects of the content of all databases, and recording both of these is essential in many applications. In addition, transaction time, due to its special semantics, is particularly well-behaved and may be supplied automatically by the DBMS. Specifically, the transaction times of a fact stored in the database is bounded by the time the database was created at one end of the time line and by the current time at the other end.

The above discussion suggests why temporal data models generally offer built-in support for one or both of valid and transaction time.

Representation of Time

The valid and transaction time values of database entities are drawn from some appropriate time domain. There is no single answer to how to perceive time in reality and how to represent time in a database, and different time domains may be distinguished with respect to several orthogonal characteristics. First, the time domain may or may not stretch infinitely into the past and future. Second, time may be perceived as discrete, dense, or continuous. Some feel that time is really continuous; others contend that time is discrete and that continuity is just a convenient abstraction that makes it easier to reason mathematically about certain discrete phenomena. In databases, a finite and discrete time domain is typically assumed, e.g., in the SQL standards. Third, a variety of different structures have been imposed on time. Most often, time is assumed to be totally ordered.

Much research has been conducted on the semantics and representation of time, from quite theoretical topics, such as temporal logic and infinite periodic time sequences, to more applied questions such as how to represent time values in minimal space. Substantial research has been conducted that concerns the use of different time granularities and calendars in general, as well as the issues surrounding the support for indeterminate time values. Also, there is a significant body of research on time data types, e.g., time instants, time intervals (or "periods"), and temporal elements.

Data Model Objects

The management of temporal aspects has been achieved by building time into the data model objects. Here, the relational model is assumed, with a focus on valid time. One approach is to timestamp tuples with time instants, or points. Then a fact is represented by one tuple for each time point during which the fact is valid. An example instance for the EMP relation example is shown in Fig. 1.

A distinguishing feature of this approach is that (syntactically) different relations have different information content. Next, timestamps are atomic values that can be easily compared. Assuming a totally ordered time domain, the standard set of comparison predicates, =, ≠, <, >, ≤, and ≥, is sufficient to conveniently compare timestamps. The conceptual simplicity of time points comes at a cost, though. The model offers little support for capturing, e.g., that employee 2 was assigned to Sales during two contiguous periods [4,5] and [6,7], instead of during a single contiguous period [4,7].

It is important to note that the point model is not meant for physical representation, as for all but the most trivial time domains, the space needed when using the point model is prohibitive. The combination of conceptual simplicity and low computational complexity has made the point model popular for theoretical studies.

Another type of data model uses time periods as timestamps. This type of model associates each fact with a period that captures the valid time of the fact. Multiple tuples are needed if a fact is valid over disjoint periods. Figure 2 illustrates the approach.

The notion of snapshot equivalence, which reflects a point-based view of data, establishes a correspondence between the point-based and period-based models. Imagine that the last two tuples in the relation in Fig. 2 were replaced with the single tuple (2, Sales, [4,7]) to obtain a new relation. The resulting two relations are different, but snapshot equivalent.

1	Engineering	5
1	Engineering	6
2	Sales	4
2	Sales	5
2	Sales	6
2	Sales	7

Temporal Data Models. Figure 1. Point model.

Specifically, the new relation is a coalesced version of the original relation.

In some data models, the relations are taken to contain the exact same information. These models adopt a point-based view and are only period-based in the weak sense that they use time periods as convenient representations of (convex) sets of time points. It then also makes sense for such models to require that their relation instances be *coalesced*. This requirement ensures that relation instances that are syntactically different are also semantically different, and vice versa. In such models, the relation in Fig. 2 is not allowed.

In an inherently period-based model, periods carry meaning beyond denoting a set of points. In some situations, it may make a difference whether an employee holds a position for two short, but consecutive time periods versus for one long time period. Period-based models do not enforce coalescing and capture this distinction naturally.

Next, a frequently mentioned shortcoming of periods is that they are not closed under all set operations, e.g., subtraction. This has led to the proposal that temporal elements be used as timestamps instead. These are finite unions of periods.

With *temporal elements*, the same two semantics as for periods are possible, although models that use temporal elements seem to prefer the point-based semantics. Figure 3a and Figure 3b uses temporal elements to capture the example assuming the period-based semantics and point-based semantics, respectively. (As [4,5] ∪ [6,7] = [4,7], this latter period could have been used instead of [4,5] ∪ [6,7].)

1	Engineering	[5, 6]
2	Sales	[4, 5]
2	Sales	[6, 7]

Temporal Data Models. Figure 2. Period (or interval) model.

Note that the instance in Fig. 3b exemplifies the instances used by the point-based bitemporal conceptual data model (BCDM) when restricted to valid time. This model has been used for TSQL2. The BCDM timestamps facts with values that are sets of time points. This is equivalent to temporal elements because the BCDM adopts a discrete and bounded time domain.

Because value-equivalent tuples are not allowed (this corresponds to the enforcement of coalesced relations as discussed earlier), the full history of a fact is contained in exactly one tuple, and one tuple contains the full history of exactly one fact. In addition, relation instances that are syntactically different have different information content, and vice versa. This design decision reflects the point-based underpinnings of the BCDM.

With temporal elements, the full history of a fact is contained in a single tuple, but the information in a relation that pertains to some real-world object may still be spread across several tuples. To capture all information about a real-world object in a single tuple, attribute value timestamping has been introduced. This is illustrated in Fig. 4, which displays the sample instance using a typical attribute-value timestamped data model.

The instance records information about employees and thus holds one tuple for each employee, with a tuple containing all information about an employee. An obvious consequence is that the information about a position cannot be contained in a single tuple. Another observation is that a single tuple may record multiple facts. In the example, the first tuple records two facts: the position type for employee 1 for the two positions, Sales and Engineering.

It should also be noted that different groupings into tuples are possible for this attribute-value timestamping model. Figure 5 groups the relation instance in Fig. 4 on the `POSITION` attribute, indicating that it is now the positions, not the employees, that are the objects in focus.

Temporal Data Models. Figure 5. Attribute-value timestamped model, grouped on POSITION.

Data models that timestamp attribute values may be temporally grouped. In a temporally grouped model, all aspects of a real-world object may be captured by a single tuple [1].

At first sight, that attribute-value timestamped model given above is temporally grouped. However, with a temporally grouped model, a real-world object is allowed to change the value for its key attribute. In the example, this means that the instance in Fig. 6 should be possible. Now observe that when grouping this instance on EmpID or POSITION, or both, it is not possible to get back to the original instance. Thus, temporally grouped tuples are not well supported. Clifford et al. [1] explore the notion of temporally grouped models in considerable depth.

Query Languages

Having covered the objects that are subject to querying, the last major aspect of a logical data model is the query language associated with the objects. Such languages come in several variants.

Some are intended for internal use inside a temporally enhanced database management system. These are typically algebraic query languages. However, algebraic languages have also been invented for more theoretical purposes. For example, an algebra may be used for defining the semantics of a temporal SQL extension. A key point is that an algebra is much simpler than is such an extension. Little is needed in terms of language design; only a formal definition of each operator is needed.

[4, 7] 2	[4, 7] Sales

Temporal Data Models. Figure 6. Attribute-value timestamped model, temporally grouped.

Other query languages are targeted at application programmers and are thus typically intended to replace SQL. The vast majority of these are SQL extensions. Finally, languages have been proposed for the purpose of conducting theoretical studies, e.g., of expressive power.

Key Applications

Virtually all databases contain temporal information, and so virtually all database applications would benefit from the availability of data models that provide natural support for such time-varying information.

Future Directions

Rather than come up with a new temporal data model, it now seems better to extend, in an upward-consistent manner, existing non-temporal models to accommodate time-varying data.

Synonyms

Historical database; Time-oriented database

Definition

A temporal database is a collection of time-referenced data. In such a database, the time references capture some temporal aspect of the data; put differently, the data are timestamped. Two temporal aspects are prevalent. The time references may capture either the past and current states of the database, yielding a transaction-time database; they may capture states of the reality being modeled by the data, yielding a valid-time database; or they may capture both aspects of the data, yielding a bitemporal database.

Historical Background

"Time" is a fundamental concept that pervades all aspects of daily life. As one indicator, a recent study by Oxford University Press found that the word "time" is the most commonly used noun in the English language. The nouns "year" and "day" rank third and fifth in the study.

Moving to a database context, the capture and representation of time-varying information go back literally thousands of years. The Egyptians and Syrians carved records into stone walls and pyramids of inventories of grain over many years. But it has been only in the last few decades that the advent of increasingly inexpensive and voluminous digital storage has enabled the computerized management of increasingly large volumes of time-referenced data.

Temporal databases have been the subject of intense study since the early 1980s. A series of bibliographies on temporal databases enumerates the thousands of refereed papers that have been written on the subject (the series started with Boulour's paper [3]; the most recent in the series is by Wu et al. [17]). There have also been more specialized bibliographies [2,9,13].

The first temporal database conference was held in Sofie Antipolis, France in 1987 [1]. Two workshops, the Temporal Database Workshop in Arlington, Texas in 1993 and in Zürich, Switzerland in 1995 [8], were held subsequently. The premier conferences on the topic are the International Symposium on Temporal Representation and Reasoning (*TIME*) (held annually since 1994), the International Symposium on Spatial and Temporal Databases (*SSTD*) (held biannually), and the Spatio-Temporal Database Management (*STDBM*) series (three up through 2006).

A seminal book collecting important results to date in this field appeared in 1993 [16]. Several surveys have been written on the topic [4–7, 10–12, 14, 15]. Temporal databases were covered in detail in an advanced database textbook [18].

Foundations

Time impacts all aspects of database technology, including database design (at the conceptual, logical, and physical levels) and the technologies utilized by a database management system, such as query and modification languages, indexing techniques and data structures query optimization and query evaluation techniques, and transaction processing.

The entries related to temporal databases go into more detail about these aspects. The following provides an organization on those entries (which are indicated in *italics*).

General Concepts

- Philosophers have thought hard about time (*temporal concepts in philosophy*).
- Two general temporal aspects of data attract special attention: *valid time* and *transaction time*.
- The *time domain* can be differentiated along several aspects: its structure, e.g., linear or branching; discrete versus continuous; bounded or infinite.
- Just as multiple versions of data may be stored, independently, the schemas can be versioned (*schema versioning*).
- The concept of "now" is important (*now in temporal databases*).

Temporal Data Models

- *Temporal conceptual models* generally extend an existing conceptual model, such as one of the variants of the Entity-Relationship model.
- *Temporal logical models* generally extend the relational model or an object-oriented model (*temporal object-oriented models*) or XML (*temporal XML*).
- Data can be associated with time in several ways: with time points (*point-stamped temporal models*) or time periods (*period-stamped temporal models*); these may capture valid and/or transaction time; and the associations of the data with the time values may carry probabilities (*temporal probabilistic models*).
- The time values associated with the data are characterized by their *temporal granularity*, and they may possess *temporal indeterminacy* and *temporal periodicity*.
- Data models incorporate *temporal constraints*, *temporal integrity constraints*, and *temporal dependencies*.

Temporal Query Languages

- Most *temporal query languages* are based on the relational algebra or calculus. Not surprisingly, much attention has been given to the design of user-level temporal query languages, notably *SQL-based temporal query languages*. For such languages, different notions of *temporal compatibility* have been an important design consideration.
- *Qualitative temporal reasoning* and *temporal logic in database query languages* provide expressive query facilities.
- *Temporal vacuuming* provides a way to control the growth of an otherwise append-only transaction-time database.
- *TSQL2* and its successor SQL/Temporal provided a way for many in the temporal database community to coordinate their efforts in temporal query language design and implementation.
- *Temporal query processing* involves disparate architectures, from *temporal strata* outside the conventional DBMS to adding native temporal support within a DBMS.
- *Supporting transaction time* in an efficient manner in the context of transactions is challenging and generally requires changes to the kernel of a DBMS.
- *Temporal algebras* extend the conventional relational algebra. Some specific operators (e.g., *temporal aggregation*, *temporal coalescing*, *temporal joins*) have received special attention.
- Temporal storage structures and indexing techniques have also received a great deal of attention (*temporal indexing*).
- *Temporal visual languages* have also been designed that present graphical user interfaces, as contrasted with the textual form of the temporal query languages mentioned previously.

Temporal Applications

- *Temporal access control* uses temporal concepts in database security.
- *Temporal data mining* has recently received a lot of attention.
- *Time series* has also been an active area of research.
- Other applications include temporal constraint satisfaction, support for planning systems, and natural language disambiguation.

The concepts of temporal databases are also making their way into research on data warehousing, OLAP, and data streams.

Key Applications

As storage costs decrease, more databases are retaining historical data. The dual of such a decrease is that the cost of deletion is effectively increasing, as the application then has to explicitly make the decision on what to retain and what to delete, and the DBMS has to revisit the data on disk in order to move it. Some have asserted that it may be simpler to simply disallow deletion (except for purging of unneeded records, termed *temporal vacuuming*) within a DBMS, rendering all databases by default temporal databases.

Commercial products are starting to include temporal support. Most notably, the Oracle database management system has included temporal support from its 9i version. Lumigent's LogExplorer product provides an analysis tool for Microsoft SQLServer logs, to allow one to view how rows change over time (a nonsequenced transaction-time query) and then to selectively back out and replay changes, on both relational data and the schema (it effectively treats the schema as a transaction-versioned schema). aTempo's Time Navigator is a data replication tool for DB2, Oracle, Microsoft SQL Server, and Sybase that extracts information from a database to build a slice repository, thereby enabling image-based restoration of a past slice; these are transaction time-slice queries. IBM's DataPropagator can use data replication of a DB2 log to create both before and after images of every row modification to create a transaction-time database that can be later queried.

Future Directions

While much progress has been made in all of the above listed areas, temporal database concepts and technologies have yet to achieve the desired levels of simplification and comprehensibility. While many of the subtleties of temporal data and access and storage thereof have been investigated, in many cases quite thoroughly, a synthesis is still needed of these concepts and technologies into forms that are usable by novices.

Given the simplifications of data management afforded by built-in support of time in database management systems, it is hoped that DBMS vendors will continue to enhance the temporal support in their products.

Temporal Dependencies

JEF WIJSEN
University of Mons-Hainaut, Mons, Belgium

Definition

Static integrity constraints involve only the current database state. Temporal integrity constraints involve current, past, and future database states; they can be expressed by essentially unrestricted sentences in temporal logic. Certain syntactically restricted classes of temporal constraints have been studied in their own right for considerations of feasibility or practicality; they are usually called temporal dependencies. Most temporal dependencies proposed in the literature are dynamic versions of static functional dependencies.

Historical Background

Static dependencies (functional, multivalued, join, and other dependencies) have been investigated in depth since the early years of the relational model. Classical problems about dependencies concern logical implication and axiomatization. The study of a particular dependency class is often motivated by its practical importance in databases. This is undeniably the case for the notion of functional dependency (FD), which is fundamental in database design. A dynamic version of functional dependencies was first proposed by Vianu [7]. Since the mid 1990's, several other temporal variants of the notion of FD have been introduced.

Foundations

This section gives an overview of several temporal dependency classes proposed in the literature. With the exception of the notion of dynamic algebraic dependency (DAD) [2], all temporal dependencies here presented can be seen as special cases of the notion of constraint-generating dependency (CGD) [1]. The formalism of CGD, presented near the end, thus allows to compare and contrast different temporal dependency classes.

Functional Dependencies Over Temporal Databases

Since the semantics of temporal versions of FDs will be explained in terms of static FDs, the standard notion of FD is recalled next. All the following definitions are relative to a fixed set $U = \{A_1,...,A_n\}$ of *attributes*.

Definition A tuple over U is a set $t = \{A_1 : c_1,...,A_n : c_n\}$, *where each c_i is a constant. If $X \subseteq U$, then $t[X]$ denotes the restriction of t to X. A relation over U is a finite set of tuples over U.*

A functional dependency (FD) over U is an expression $X \rightarrow Y$ where $X,Y \subseteq U$. A relation I *over U satisfies the FD $X \rightarrow Y$ if for all tuples $s,t \in I$, if $s[X] = t[X]$, then $s[Y] = t[Y]$.*

When evaluating FDs over temporal relations, one may want to treat timestamp attributes different from other attributes. To illustrate this, consider the temporal relation *EmpInterval* with its obvious meaning.

EmpInterval

Name	Sex	Sal	Project	From	To
Ed	M	10K	Pulse	1	3
Ed	M	10K	Wizard	2	3
Ed	M	12K	Wizard	4	4

An employee has a unique sex and a unique salary, but can work for several projects. The salary, unlike the sex, may change over time. The relation *EmpInterval* is "legal" with respect to these company rules, because for any time point i, the *snapshot* relation $\{t[\mathit{Name}, \mathit{Sex}, \mathit{Sal}, \mathit{Project}] \mid t \in \mathit{EmpInterval}, t(\mathit{From}) \leq i \leq t(\mathit{To})\}$ satisfies *Name* →*Sex* and *Name* → *Sal*. Note that the relation *EmpInterval* violates the FD *Name* → *Sal*, because the last two tuples agree on *Name* but disagree on *Sal*. However, since these tuples have disjoint periods of validity, they do not go against the company rules.

Hence, the intended meaning of an FD expressed over a temporal relation may be that the FD must be satisfied at every snapshot. To indicate that *Name* →*Sal* has to be evaluated on snapshots, Jensen et al. [6] use the notation $\mathit{Name} \overset{\mathrm{T}}{\rightarrow} \mathit{Sal}$. The FD *Name* →*Sex* needs no change, because the sex of an employee should be unique not only at each snapshot, but also over time.

Chomicki and Toman [3] note that no special syntax is needed if tuples are timestamped by time points. For example, given the following point-stamped temporal relation, one can simply impose the classical FDs *Name* →*Sex* and *Name*, *T* →*Sal*.

EmpPoint

Name	Sex	Sal	Project	T
Ed	M	10K	Pulse	1
Ed	M	10K	Pulse	2
Ed	M	10K	Pulse	3
Ed	M	10K	Wizard	2
Ed	M	10K	Wizard	3
Ed	M	12K	Wizard	4

Vianu's Dynamic Functional Dependency [7]

Consider an employee table with attributes *Name*, *Sex*, *Merit*, and *Sal*, with their obvious meanings. The primary key is *Name*. Assume an annual companywide update of merits and salaries. In the relation shown next, every tuple is followed by its updated version. Old values appear in columns with a caron (ˇ), new values in columns with a caret (ˆ). For example, John Smith's salary increased from 10 to 12K. Such a relation that juxtaposes old and new values is called *action relation*.

⊢ old ⊣				⊢ new ⊣			
Nǎme	Sěx	Měrit	Sǎl	Nâme	Sêx	Mêrit	Sâl
John Smith	M	Poor	10K	John Smith	M	Good	12K
An Todd	F	Fair	10K	An Todd	F	Good	12K
Ed Duval	M	Fair	10K	Ed Duval	M	Fair	10K

The company's policy that "*Each new salary is determined solely by new merit and old salary*" can be expressed by the classical FD *Sǎl*, *Mêrit* →*Sâl* on the above action relation. In particular, since John Smith and An Todd agree on old salary and new merit, they must have the same new salary. Such FDs on action relations were introduced by Vianu [7] and called dynamic functional dependencies.

Definition For each $A_i \in U$, assume that $\check{A}_i$ and $\hat{A}_i$ are new distinct attributes. Define $\check{U} = \{\check{A}_1,\ldots,\check{A}_n\}$ and $\hat{U} = \{\hat{A}_1,\ldots,\hat{A}_n\}$. For $t = \{A_1 : c_1,\ldots,A_n : c_n\}$, define:

$$\check{t} = \left\{\check{A}_1 : c_1,\ldots,\check{A}_n : c_n\right\},\ \textit{a tuple over } \check{U};\ \textit{and}$$
$$\hat{t} = \left\{\hat{A}_1 : c_1,\ldots,\hat{A}_n : c_n\right\},\ \textit{a tuple over } \hat{U}$$

A *Vianu dynamic functional dependency* (VDFD) over U is an FD $X \rightarrow Y$ over $\check{U}\hat{U}$ such that for each $A \in Y$, XA contains at least one attribute from $\check{U}$ and one attribute from $\hat{U}$.

An update *over U is a triple $\langle I, \mu, J\rangle$, where I and J are relations over U and μ is a bijective mapping from I to J. The update $\langle I, \mu, J\rangle$* satisfies *the VDFD $X \rightarrow Y$ if the* action relation $\{\check{t} \cup \hat{s} \mid t \in I, s = \mu(t)\}$ *satisfies the FD $X \rightarrow Y$.*

The notion of VDFD directly extends to sequences of database updates. The interaction between dynamic VDFDs and static FDs is studied in [7].

Temporal Extensions of Functional Dependency Proposed by Wijsen [9, 10, 11, 12]

Instead of extending each tuple with its updated version, as is the case for VDFDs, one can take the union of the old relation and the new relation:

Name	Sex	Merit	Sal		
John smith	M	Poor	10K	⊤	
An todd	F	Fair	10K	old	
Ed duval	M	Fair	10K	⊥	⊤
John smith	M	Good	12K		new
An todd	F	Good	12K		⊥

The company's policy that "*Every change in merit (promotion or demotion) gives rise to a salary change*," is expressed by *Name*, *Sal* $\overset{\circ}{\rightarrow}$ *Merit* and means that the FD *Name*, *Sal* →*Merit* must be satisfied by the union of the old and the new relation. In particular, since Ed Duval's salary did not change, his merit cannot have changed either. Likewise, "*The sex of an employee cannot change*" is expressed by *Name* $\overset{\circ}{\rightarrow}$ *Sex*. The construct $\overset{\circ}{\rightarrow}$ naturally generalizes to database histories that involve more than two database states.

Definition A Wijsen dynamic functional dependency (WDFD) over *U* is an expression of the form $X \overset{\circ}{\rightarrow} Y$, where $X, Y \subseteq U$.

A database history *is a sequence* $\langle I_1,I_2,I_3,\ldots\rangle$, *where each* I_i *is a relation over U. This history* satisfies $X \overset{\circ}{\rightarrow} Y$ *if for every* $i \in \{1,2,\ldots\}$, $I_i \cup I_{i+1}$ satisfies $X \rightarrow Y$.

Although I_{i+1} can be thought of as the result of an update performed on I_i, there is no need to model a one-one relationship between the tuples of both relations, as was the case for VDFDs. VDFDs and WDFDs capture different types of constraints, even in the presence of some attribute that serves as a time-invariant tuple-identifier. This difference will be illustrated later on in the discussion of constraint-generating dependencies.

In practice, database histories will be be stored in relations with timestamped tuples. Like FDs, WDFDs can result in predictable (i.e., redundant) values. For example, if the following relation has to satisfy *Name*, *Sal* $\overset{\circ}{\rightarrow}$ *Merit*, then the value for the placeholder † must be equal to "Poor." Wijsen [9] develops temporal variants of 3NF to avoid data redundancy caused by WDFDs.

Name	City	Merit	Sal	From	To
Ed	Paris	Poor	10K	1	2
Ed	London	†	10K	3	4

WDFDs can be naturally generalized as follows: instead of interpreting FDs over unions of successive database states, the syntax of FD is extended with a binary relation on the time domain, called *time accessibility relation*, that indicates which tuple pairs must satisfy the FD.

Definition *A* time accessibility relation *(TAR) is a subset of* $\{(i,j) \mid 1 \leq i \leq j\}$. *A* generalized WDFD *over U is an expression* $X{\rightarrow}_{\alpha}Y$, *where* $X,Y \subseteq U$ *and* α *is a TAR. This generalized WDFD is satisfied by database history* $\langle I_1,I_2,I_3,\ldots\rangle$ *if for all* $(i,j) \in \alpha$, $s \in I_i$, $t \in I_j$, *if* $s[X] = t[X]$, *then* $s[Y] = t[Y]$.

If the TAR Next is defined by `Next` =$\{(1,1),(1,2),(2,2),(2,3),(3,3),(3,4),\ldots\}$, then $X{\rightarrow}_{\mathtt{Next}}Y$ and $X \overset{\circ}{\rightarrow} Y$ are equivalent. TARs can also capture the notion of time granularity. For example, `MonthTAR` can be defined as the TAR containing (i, j) whenever $i \leq j$ and time points *i*, *j* belong to the same month. Then, $Name{\rightarrow}_{\mathrm{MonthTAR}}$ *Sal* expresses that the salary of an employee cannot change within a month.

The temporal functional dependencies proposed in [11] extend this formalism with a notion of identity, denoted by λ, similar to object-identity. The identity is time-invariant and allows to relate old and new versions of the same object. For example, *Emp*: $\lambda{\rightarrow}_{\mathrm{Next}}Name$ means that the name of an employee object cannot change from one time to the next.

Trend dependencies [10,12] extend generalized WDFDs in still another way by allowing both equalities and inequalities. They can be seen as a temporal extension of the concept of *order dependency* introduced by Ginsburg and Hull [4]. For example, $(Name,=)\ {\rightarrow}_{\mathrm{Next}}(Sal,\leq)$ expresses that the salary of an employee cannot decrease. Technically, it is satisfied by a database history $\langle I_1,I_2,I_3,\ldots\rangle$ if for all $(i, j) \in$ Next, if $s \in I_i$ and $t \in I_j$ and $s(Name) = t(Name)$, then $s(Sal) \leq t(Sal)$.

Wang et al.'s Temporal Functional Dependency [8]

The dynamic versions of FDs introduced by Vianu and Wijsen can impose constraints on tuples valid at successive time points. Wang et al.'s notion of temporal functional dependency (TFD) concentrates on temporal granularity and compares tuples valid during the same granule of some temporal granularity. The main idea is captured by the following definitions that are simplified versions of the ones found in [8].

Definition *Assume a linear time domain* $(D, <)$. *Every nonempty subset of* D *is called a* granule. *Two distinct granules* G_1 *and* G_2 *are said to be* non-interleaved *if each point of either granule is smaller than all points of the other granule (i.e., either* $\forall d_1 \in G_1 \forall d_2 \in G_2 (d_1 < d_2)$ or $\forall d_1 \in G_1 \forall d_2 \in G_2 (d_2 < d_1)$). *A* granularity *is a set* $\mathcal{G}$ *of pairwise non-interleaved granules.*

Other granularity notions found in the literature often assume that granules are indexed by integers. Such index has been omitted here to simplify the formalism.

Common granularities are Month and Year. If granularity $\mathcal{G}$ is associated with temporal relation I, then all tuples of I must be timestamped by granules of $\mathcal{G}$. For example, all tuples in the following relation are timestamped by months. Practical labels, like Nov-2007, are used to denote granules of time points.

EmpMonth

Name	Sal	Position	T : Month
Ed	10K	Lecturer	Nov-2007
Ed	11K	Lecturer	Dec-2007
Ed	12K	Professor	Jan-2008

Definition *Assume a set* $U = \{A_1,\ldots,A_n\}$ *of attributes and a timestamp attribute* $T \notin U$. A timestamped tuple with granularity $\mathcal{G}$ *(or simply* $\mathcal{G}$-tuple) *over* U *is a set* $\{A_1\colon c_1,\ldots,A_n : c_n, T : G\}$, *where each* c_i *is a constant and* $G \in \mathcal{G}$. If $t = \{A_1 : c_1,\ldots,A_n : c_n, T : G\}$, *then define* $t[U] = \{A_1 : c_1,\ldots,A_n : c_n\}$ and $t(T) = G$. A timestamped relation with granularity $\mathcal{G}$ (or simply $\mathcal{G}$-relation) *over* U *is a finite set of* $\mathcal{G}$*-tuples over* U.

The TFD $\mathit{Name}\rightarrow_{\text{Month}}\mathit{Sal}$ expresses that the salary of an employee cannot change within a month. Likewise, $\mathit{Name}\rightarrow_{\text{Year}}\mathit{Position}$ expresses that the position of an employee cannot change within a year. Both dependencies are satisfied by the relation *EmpMonth* shown above. To check $\mathit{Name}\rightarrow_{\text{Year}}\mathit{Position}$, it suffices to verify whether for each year, the FD $\mathit{Name} \rightarrow \mathit{Position}$ is satisfied by the set of tuples whose timestamps fall in that year. For example, for the year 2007, the relation $\{t[\mathit{Name}, \mathit{Sal}, \mathit{Position}] \mid t \in \mathit{EmpMonth}, t(T) \subseteq 2007\}$ must satisfy $\mathit{Name} \rightarrow \mathit{Position}$. This is captured by the following definition.

Definition A temporal functional dependency (*TFD*) *over* U *is an expression* $X \rightarrow_{\mathcal{H}} Y$, *where* $X, Y \subseteq U$ *and* $\mathcal{H}$ *is a granularity. A* $\mathcal{G}$*-relation* I *over* U *satisfies* $X \rightarrow_{\mathcal{H}} Y$ *if for each granule* $H \in \mathcal{H}$, *the relation* $\{t[U] \mid t \in I, t(T) \subseteq H\}$ *satisfies the FD* $X \rightarrow Y$.

Wang et al. extend classical normalization theory to deal with data redundancy caused by TFDs. For example, since positions cannot change within a year, Ed must necessarily occupy the same position in Nov-2007 and Dec-2007. To avoid this redundancy, the information on positions must be moved into a new relation with time granularity Year, as shown above. After this decomposition, Ed's position in 2007 is only stored once.

Constraint-Generating Dependencies [1]

Classical dependency theory assumes that each attribute of a relation takes its values in some uninterpreted domain of constants, which means that data values can only be compared for equality and disequality. The notion of *constraint-generating dependency* (CGD) builds upon the observation that, in practice, certain attributes take their values in specific domains, such as the integers or the reals, on which predicates and functions, such as $\leq$ and $+$, are defined. CGDs can thus constrain data values by formulas in the first-order theory of the underlying domain.

A *constraint-generating k-dependency* takes the following form in tuple relational calculus:

$$\forall t_1 \forall t_2 \ldots \forall t_k ((R_1(t_1) \wedge \ldots \wedge R_k(t_k) \wedge C[t_1,\ldots,t_k]) \Longrightarrow C'[t_1,\ldots,t_k])$$

where C and C' are arbitrary constraint formulas relating the values of various attributes in the tuples $t_1,\ldots,t_k$.

CGDs naturally arise in temporal databases: timestamp attributes take their values from a linearly ordered time domain, possibly equipped with arithmetic. Baudinet et al. [1] specifically mention that the study of CGDs was inspired by the work of Jensen and Snodgrass on temporal specialization and generalization [5]. For example, assume a relation R with two temporal attributes, denoted VT and TT. Every tuple $t \in R$ stores information about some event, where $t(TT)$ is the (transaction) time when the event was recorded in the database, and $t(VT)$ is the (valid) time when the event happened in the real world. The following CGD expresses that every event should be recorded within c time units after its occurrence:

$$\forall t(R(t) \Longrightarrow (t(VT) < t(TT) \wedge t(TT) \leq t(VT) + c)).$$

Given appropriate first-order theories for the underlying domains, CGDs can capture the different temporal dependencies introduced above. Assume a point-stamped temporal relation $Emp(Name, Merit, Sal, VT)$ with its obvious meaning. Assume that $Name$ provides a unique and time-invariant identity for each employee. Then, the VDFD $S\check{a}l, \hat{M}erit \rightarrow \hat{S}al$ can be simulated by the following constraint-generating 4-dependency. In this formula, the tuples s and s' concern the same employee in successive database states (likewise for t and t').

$$\forall s \forall s' \forall t \forall t' \left(\begin{pmatrix} Emp(s) \wedge Emp(s') \\ \wedge s(Name) = s'(Name) \\ \wedge s'(VT) = s(VT) + 1 \\ \wedge Emp(t) \wedge Emp(t') \\ \wedge t(Name) = t'(Name) \\ \wedge t'(VT) = t(VT) + 1 \\ \wedge s(Sal) = t(Sal) \\ \wedge s'(Merit) = t'(Merit) \\ \wedge s(VT) = t(VT) \end{pmatrix} \begin{matrix} \Rightarrow s'(Sal) = \\ t'(Sal)) \end{matrix} \right)$$

The WDFD $Name, Sal \overset{\circ}{\rightarrow} Merit$ can be expressed as a constraint-generating 2-dependency:

$$\forall t \forall t' \left(\begin{pmatrix} Emp(t) \wedge Emp(t') \\ \wedge t(Name) = t'(Name) \\ \wedge t(Sal) = t'(Sal) \\ \wedge (t'(VT) = t(VT) \vee t'(VT) \\ = t(VT) + 1) \end{pmatrix} \Rightarrow \begin{matrix} t(Merit) = \\ t'(Merit) \end{matrix} \right)$$

Assume a binary predicate $Month$ on the time domain such that $Month(t_1, t_2)$ is true if t_1 and t_2 are two time instants within the same month. Then, $Name \rightarrow_{\text{Month}} Sal$ can be expressed as a constraint-generating 2-dependency:

$$\forall t \forall t' \left(\begin{pmatrix} Emp(t) \wedge Emp(t') \\ \wedge t(Name) = t'(Name) \\ \wedge Month(t(VT), t'(VT)) \end{pmatrix} \Rightarrow \begin{matrix} t(Sal) = \\ t'(Sal) \end{matrix} \right)$$

Dynamic Algebraic Dependencies [2]

Consider a database schema containing $Emp(Name, Merit, Sal)$ and $WorksFor(Name, Project)$. A company rule states that "*The Pulse project only recruits employees whose merit has been good at some past time.*" The relational algebra expression E_0 shown below gets the workers of the Pulse project; the expression F_0 gets the good workers. In a consistent database history, if the tuple t is in the answer to E_0 on the current database state, then t is in the answer to F_0 on some (strict) past database state.

$$E_0 = \pi_{Name}(\sigma_{Project=\text{"Pulse"}} WorksFor)$$
$$F_0 = \pi_{Name}(\sigma_{Merit=\text{"Good"}} Emp)$$

Definition *A relational algebra query E is defined as usual using the named relational algebra operators* $\{\sigma, \pi, \bowtie, \rho, \cup, -\}$. *A* dynamic algebraic dependency *(DAD) is an expression of the form EF, where E and F are relational algebra queries over the same database schema and with the same output schema. A finite database history* $\langle I_0, I_1, \ldots, I_n \rangle$, where $I_0 = \{\}$, satisfies *the DAD EF if for each* $i \in \{1, \ldots, n\}$, *for each* $t \in E(I_i)$, *there exists* $j \in \{1, \ldots, i-1\}$ *such that* $t \in F(I_j)$.

The preceding definition uses relational algebra. Nevertheless, every DAD EF can be translated into temporal first-order logic in a straightforward way. Let $Now(\vec{x})$ and $Past(\vec{x})$ be safe relational calculus queries equivalent to E and F respectively, with the same free variables $\vec{x}$. Then the DAD EF is equivalent to the closed formula:

$$\forall \vec{x}(Now(\vec{x}) \Rightarrow \blacklozenge\, Past(\vec{x})).$$

It seems that the expressive power of DADs relative to other dynamic constraints has not been studied in depth. Notice that the simple DAD $\forall x(R(x) \Rightarrow \blacklozenge S(x))$

Name	Sex	Sal	Project	Day	Month	Year
Ed	M	10K	Pulse	29-Aug-2007	Aug-2007	2007
Ed	M	10K	Pulse	30-Aug-2007	Aug-2007	2007
Ed	M	10K	Pulse	31-Aug-2007	Aug-2007	2007
Ed	M	10K	Wizard	30-Aug-2007	Aug-2007	2007

Ed	M	12K	Wizard	1-Sep-2007	Sep-2007	2007

is tuple-generating, in the sense that tuples in *R* require the existence of past tuples in *S*. The other temporal dependencies presented in this entry are not tuple-generating.

Bidoit and De Amo [2] study the existence of an operational specification that can yield all and only the database histories that are consistent. The operational specification assumes that all database updates are performed through a fixed set of update methods, called transactions. These transactions are specified in a transaction language that provides syntax for concatenation and repetition of elementary updates (insert a tuple, delete a tuple, erase all tuples).

Key Applications

An important motivation for the study of FDs in database courses is schema design. The notion of FD is a prerequisite for understanding the principles of "good" database design (3NF and BCNF). In the same line, the study of temporal functional dependencies has been motivated by potential applications in temporal database design. It seems, however, that one can go a long way in temporal database design by practicing classical, non-temporal normalization theory. As suggested in [3,8], one can put timestamp attributes on a par with ordinary attributes, write down classical FDs, and apply a standard 3NF decomposition. For example, assume a database schema $\{Name, Sex, Sal, Project, Day, Month, Year\}$.
The following FDs apply:

$$\begin{aligned} &Name \rightarrow Sex\\ &Name, Month \rightarrow Sal\\ &Day \rightarrow Month\\ &Month \rightarrow Year \end{aligned}$$

The latter two FDs capture the relationships that exist between days, months, and years. The standard 3NF synthesis algorithm finds the following decomposition – the last two components may be omitted for obvious reasons:

$$\begin{aligned} &\{Name, Project, Day\}\\ &\{Name, Sex\}\\ &\{Name, Sal, Month\}\\ &\{Day, Month\}\\ &\{Month, Year\} \end{aligned}$$

This decomposition, resulting from standard normalization, is also "good" from a temporal perspective. In general, the "naive" approach seems to prevent data redundancy in all situations where relationships between granularities can be captured by FDs. It is nevertheless true that FDs cannot capture, for example, the relationship between weeks and months. In particular, *Week* →*Month* does not hold since certain weeks contain days of two months. In situations where FDs fall short in specifying relationships among time granularities, there may be a need to timestamp by new, artificial time granularities in order to avoid data redundancy [8].

Synonyms

Time period set

Definition

A *temporal element* is a finite union of *n*-dimensional time intervals. Special cases of temporal elements include *valid-time elements*, *transaction-time elements*, and *bitemporal elements*, which are finite unions of valid-time intervals, transaction-time intervals, and bitemporal intervals, respectively.

Key Points

Assuming an *n*-dimensional time domain, an interval is the product of *n* convex subsets drawn from each of the constituent dimensions.

Given a finite, one-dimensional time domain, a temporal element may be defined equivalently as a subset of the time domain. If the time domain is unbounded and thus infinite, some subsets of the time domain are not temporal elements. These subsets cannot be enumerated in finite space. For non-discrete time domains, the same observation applies.

Temporal elements are often used as timestamps. Unlike time periods, they are closed under the set theoretic operations of union, intersection, and complement, which is a very desirable property when formulating temporal database queries.

The term "temporal element" has been used to denote the concept of a valid-time interval. However, "temporal" is generally used as generic modifier, so more specific modifiers are adopted here for specific kinds of temporal elements. The term "time period set" is an early term for a temporal element. The adopted term has been used much more frequently.

Temporal Evolution

▶ History in Temporal Databases

Temporal Expression

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

A *temporal expression* is a syntactic construct used, e.g., in a query that evaluates to a temporal value, i.e., an instant, a time period, a time interval, or a temporal element.

Key Points

Advanced by Gadia [1], a temporal expression is a convenient temporal query language construct.

First, any temporal element is considered a temporal expression. As Gadia uses a discrete and bounded time domain, any subset of the time domain is then a temporal expression. Next, an attribute value of a tuple in Gadia's data model is a function from the time domain to some value domain. Likewise, the attribute values of a tuple are valid during some temporal element. To illustrate, consider an (ungrouped) relation with attributes `Name` and `Position`. An example tuple in this relation is:

$$\begin{aligned}&(\langle[4,17]\ \mathit{Bill}\rangle,\\ &\quad\langle[4,8]\mathit{Assistant},\\ &\quad[9,13]\ \mathit{Associate}, [14,17]\mathit{Full}\rangle)\end{aligned}$$

Now let X be an expression that returns a function from the time domain to some value domain, such as an attribute value, a tuple, or a relation. Then the temporal expression $[[X]]$ returns the domain of X. Using the example from above, the temporal expression [[`Position`]] evaluates to [4,17] and the temporal expression [[`Position <> Associate`]] evaluates to $[4,8] \cup [14,17]$.

The terms "Boolean expression" and "relational expression" may be used for clearly identifying expressions that evaluate to Boolean values and relations.

Temporal Generalization

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

Temporal generalization comes in three guises. Consider a temporal database in which data items are timestamped with valid and transaction time. Temporal generalization occurs when weakening constraints hitherto applied to the timestamps. Used in this sense, temporal generalization is the opposite of temporal specialization.

Next, a temporal relation is generalized when new timestamps are being associated with its tuples. In larger information systems where data items flow between multiple temporal relations, items may accumulate timestamps by keeping their previous timestamps and gaining new timestamps as they are entered into new temporal relations. Thus, a tuple in a particular relation has multiple timestamps: a valid timestamp, a *primary* transaction timestamp, which records when the tuple was stored in this relation, one or more *inherited* transaction timestamps that record when the tuple was stored in previous relations, and one or more additional timestamps that record when the tuple was manipulated elsewhere in the system.

Finally, a more involved notion of temporal generalization occurs when a derived relation inherits the transaction timestamps from the relation(s) it is derived from.

By describing the temporal generalization that occurs in an information system, important semantics are captured that may be utilized for a variety of purposes. For example, a temporal relation may be queried, with specific restrictions, from a temporal relation that receives tuples with some delay from that relation. Another use is to increase the efficiency of query processing.

Key Points

The first notion of temporal generalization is simply the opposite of temporal specialization.

As an example of the second notion of temporal generalization, consider the following complex yet realistic scenario of a collection of temporal relations maintained by the transportation department of a state government. An *employee relation* is maintained on the workstation of each manager in this department, recording schedules, budgets, and salary levels for the employees under that manager. For the entire department, a single *personnel relation* is maintained on the administrative computer under the data processing group, which also maintains a *financial relation*. The bank, responsible for salary payments, maintains an *accounts relation*. Data items in the form of timestamped tuples move from the employee relation to the personnel relation and then to the financial relation and ultimately to the accounts relation, accumulating transaction timestamps each time they enter a new database. Each timestamp has a relationship with the other transaction timestamps and with the valid timestamp. These can be stated in the schema and utilized during querying to ensure accurate results.

As an example of the third notion of temporal generalization, consider process control in a manufacturing plant. Values from sensors that capture process characteristics such as pressure and temperature may be stored in temporal relations. This data may subsequently be processed further to derive new data that capture relevant aspects of the process being monitored at a higher level of abstraction. The original data, from which the new data was derived, may be stored together with the new data, to capture the lineage, or provenance, of that data. As a result, the new data inherits timestamps from the original data.

Time granularity; Temporal type

Definition

In the context of databases, a temporal granularity can be used to specify the temporal qualification of a set of data, similar to its use in the temporal qualification of statements in natural languages. For example, in a relational database, the timestamp associated with an attribute value or a tuple may be interpreted as associating that data with one or more granules of a given temporal granularity (e.g., one or more *days*). As opposed to using instants from a system-specific time domain, the use of user-defined granularities enables both more compact representations and temporal qualifications at different levels of abstraction. Temporal granularities include very common ones like *hours*, *days*, *weeks*, *months*, and *years*, as well as the evolution and specialization of these granularities for specific contexts or applications: *trading days*, *banking days*, *academic semesters*, etc.. Intuitively, a temporal granularity is defined by grouping sets of instants from a time domain into so-called *granules* in a rather flexible way with some mild conditions. For example, the granularity *business days* is defined as the infinite set of granules, each including the time instants composing one working day. A label, for example a date for a day granule, is often used to refer to a particular granule of a granularity. Answering queries in terms of a granularity different from the one used to store data in a database is not simply a matter of syntactic granularity conversion, but it involves subtle semantics issues.

Historical Background

Temporal granularities have always had a relevant role in the qualification of statements in natural languages, and they still play a major role according to a 2006 study by Oxford University. The study includes words "day," "week," "month," and "year" among the 25 most common nouns in the English language. Temporal granularities have also been used for a long time in computer applications, including personal information management, project management, scheduling, and more. Interestingly, in many situations, their use is limited to a very few common ones, their semantics is often simplified and sometimes confusing, and their management is hard-coded in applications with ad-hoc solutions. The database community seems to be a major driver in formalizing temporal granularities. One of the earliest formalizations was proposed in [5]. At the same time the AI community was investigating formalisms to represent calendar unit systems [9,10]. In the early 1990s, the relevant role played by time granularity and calendars in temporal databases, as well as the need to devise algorithms to manage granular data, became widely recognized by the research community, and some significant progress has been made [4, 11, 13, 15]. Some support for granularities was also included in the design of the temporal query language TSQL2. A comprehensive formal framework for time granularities to be applied in several areas of database research emerged in the mid-1990s, and has been progressively refined in the following years through the investigation of its applications in data mining, temporal database design, query processing, and temporal constraint reasoning [3]. This framework is based on a set-theoretic approach (partly inspired by [5]) and on an algebraic representation, and it includes techniques to compute basic as well as more complex operations on granules and granularities. The basic notions found a large consensus in the database community [1]. The use of logic to specify formal properties and to reason about granularities as defined in the above framework was investigated in [6]. Programming oriented support for integrating multiple calendars was provided in [12]. In the logic community, an independent line of research on representation and reasoning with multiple granularities investigated classical and non-classical logic extensions based on multi-layered time domains, with applications to the specification of real-time reactive systems. This approach is extensively described in [8]. More recently, the use of automata to represent granularities and to perform basic operations on them has been proposed [7]. This work, partly inspired by previously proposed string-based representation of granularities [15], has the benefit of providing compact representation of granularities. Moreover, decision procedures for some basic problems, such as granularity equivalence and minimization, can be applied directly on that representation.

Foundations

What follows is an illustration of the main formal definitions of temporal granularities and their relationships according to the set-theoretic, algebraic approach.

Definitions

A temporal granularity can be intuitively described as a sequence of time granules, each one consisting of a set of time instants. A granule can be composed of a single instant, a set of contiguous instants (time-interval), or even a set of non-contiguous instants. For example, the `September 2008 business-month`, defined as the collection of all the business days in September 2008, can be used as a granule. When used to describe a phenomena or, in general, when used to timestamp a set of data, a granule is perceived as a non-decomposable temporal entity. A formal definition of temporal granularity is the following.

Assume a time domain T as a set of totally ordered time instants. A *granularity* is a mapping G from the integers (the *index set*) to the subsets of the time domain such that:

(1) If $i < j$ and $G(i)$ and $G(j)$ are non-empty, then each element in $G(i)$ is less than all the elements in $G(j)$.

(2) IIf $i < k < j$ and $G(i)$ and $G(j)$ are non-empty, then $G(k)$ is non-empty.

Each non-empty set $G(i)$ in the above definition is called *granule*.

The first condition in the granularity definition states that granules in a granularity do not overlap and that their index order is the same as their time domain order. The second condition states that the subset of the index set for the granules is contiguous. Based on the above definition, while the time domain can be discrete, dense, or continuous, a granularity defines a countable set of granules; each granule is identified by an integer. The index set can thereby provide an "encoding" of the granularity in a computer. Two granules $G(i)$ and $G(j)$ are *contiguous* if there does not exist $t \in T$ such that $\forall s \in G(i)(s < t)$ and $\forall s \in G(j)(s > t)$. Independently, there may be a "textual representation" of each non-empty granule, termed its *label*, that is used for input and output. This representation is generally a string that is more descriptive than the granule's index. An associated mapping, the *label mapping*, defines for each label a unique corresponding index. This mapping can be quite complex, dealing with different languages and character sets, or can be omitted if integers are used directly to refer to granules. For example, "August 2008" and "September 2008" are two labels each referring to the set of time instants (a granule) corresponding to that month.

A granularity is *bounded* if there exist lower and upper bounds k_1 and k_2 in the index set such that $G(i) = \emptyset$ for all i with $i < k_1$ or $k_2 < i$.

The usual collections days, months, weeks and years are granularities. The granularity describing all years starting from 2000 can be defined as a mapping that takes an arbitrary index i to the subset of the time domain corresponding to the year 2000, $i + 1$ to the one corresponding to the year 2001, and so on, with all indexes less than i mapped to the empty set. The years from 2006 to 2010 can also be represented as a granularity G, with $G(2006)$ identifying the subset of the time domain corresponding to the year 2006, $G(2007)$ to 2007, and so on, with $G(i) = \emptyset$ for each $i < 2006$ and $i > 2010$.

The union of all the granules in a granularity G is called the *image* of G. For example, the image of `business-days-since-2000` is the set of time instants included in each granule representing a business-day, starting from the first one in 2000. The single interval of the time domain starting with the greatest lower bound of the image of a granularity G and ending with the least upper bound ($-\infty$ and $+\infty$ are considered valid lower/upper bounds) is called the *extent* of G. Note that many commonly used granularities (e.g., `days`, `months`, `years`) have their image equal to their extent, since each granule is formed by a set of contiguous elements of the time domain and each pair of contiguous indexes is mapped to contiguous granules.

Granularity Relationships

In the following, some commonly used relationships between granularities are given.

A granularity G *groups into* a granularity H, denoted $G \unlhd H$, if for each index j there exists a (possibly infinite) subset S of the integers such that $H(j) = \cup_{i \in S} G(i)$. For example, `days` groups into `weeks`, but `weeks` does not group into `months`.

A granularity G is *finer than* a granularity H, denoted $G \preceq H$, if for each index i, there exists an index j such that $G(i) \subseteq H(j)$. If $G \preceq H$, then H is *coarser than* G ($H \succeq G$).

For example, `business-days` is finer than `weeks`, while `business-days` does not group into `weeks`; `business-days` is finer than `years`, while `weeks` is not.

A granularity G *groups periodically into* a granularity H if:

1) $G \unlhd H$.
2) There exist $n, m \in \mathbf{Z}^+$, where n is less than the number of non-empty granules of H, such that for all $i \in \mathbf{Z}$, if $H(i) = \cup^k_{r=0} G(j_r)$ and $H(i+n) \neq \emptyset$, then $H(i+n) = \cup^k_{r=0} G(j_r + m)$.

The *groups periodically into* relationship is a special case of *groups into* characterized by a periodic repetition of the "grouping pattern" of granules of G into granules of H. Its definition may appear complicated, but it is actually quite simple. Since G groups into H, any non-empty granule $H(i)$ is the union of some granules of G; for instance, assume it is the union of the granules $G(a_1)$, $G(a_2)$,...,$G(a_k)$. The periodicity property (condition 2 in the definition) ensures that the n^{th} granule *after* $H(i)$, i.e., $H(i + n)$, if non-empty, is the union of $G(a_1 + m)$, $G(a_2 + m)$,...,$G(a_k + m)$. This results in a periodic "pattern" of the composition of n granules of H in terms of granules of G. The pattern repeats along the time domain by "shifting" each granule of H by m granules of G. Many common granularities are in this kind of relationship. For example, `days` groups periodically into `business-days`, with $m = 7$ and $n = 5$, and also groups periodically into `weeks`, with $m = 7$ and $n = 1$; `months` groups periodically into `years` with $m = 12$ and $n = 1$, and `days` groups periodically into `years` with $m = 14{,}697$ and $n = 400$. Alternatively, the relationship can also be described, by saying, for example, years is periodic (or 1-periodic) with respect to months, and years is periodic (or 400-periodic) with respect to days. In general, this relationship guarantees that granularity *H* can be finitely described in terms of granules of *G*. More details can be found in [3].

Given a granularity order relationship *g-rel* and a set of granularities, a granularity *G* in the set is a *bottom granularity* with respect to *g-rel*, if *G g-rel H* for each granularity *H* in the set.

For example, given the set of all granularities defined over the time domain ($\mathbf{R}$;$\leq$), and the granularity relationship $\preceq$ (finer than), the granularity corresponding to the *empty* mapping is the bottom granularity with respect to $\preceq$. Given the set of all granularities defined over the time domain ($\mathbf{Z}$;$\leq$), and the granularity relationship $\trianglelefteq$ (groups into), the granularity mapping each index into the corresponding instant (same integer number as the index) is a bottom granularity with respect to $\trianglelefteq$. An example of a set of granularities without a bottom (with respect to $\preceq$ or $\trianglelefteq$) is {weeks, months}.

Calendars are typically used to describe events or time-related properties over the same span of time using different granularities. For example, the Gregorian calendar comprises the granularities days, months, and years. Considering the notion of bottom granularity, a formal definition of calendar follows.

A *calendar* is a set of granularities that includes a bottom granularity with respect to $\trianglelefteq$ (groups into).

Defining New Granularities through Algebraic Operators

In principle, every granularity in a calendar can be defined in terms of the bottom granularity, possibly specifying the composition of granules through the relationships defined above. Several proposals have appeared in the literature for a set of algebraic operators with the goal of facilitating the definition of new granularities in terms of existing ones. These algebras are evaluated with respect to expressiveness, user friendliness, and ability to compute operations on granularities directly on the algebraic representation. Some of the operations that are useful in applications are inter-granule conversions; for example, to compute which day of the week was the k-th day of a particular year, or which interval of days was r-th week of that year, as well as conversions involving different calendars. In the following, the main operators of one of the most expressive calendar algebras [3] are briefly described. Two operators form the backbone of the algebra:

1. The *grouping* operator systematically combines a few granules of the source granularity into one granule in the target granularity. For example, given granularity days, granularity weeks can be generated by combining 7 granules (corresponding to Monday – Sunday) week = *Group*$_7$(day) if we assume that day(1) corresponds to Monday, i.e., the first day of a week.
2. The *altering-tick* operator deletes or adds granules from a given granularity (via the help of a second granularity) to form a new one. For example, assume each 30 days are grouped into a granule, forming a granularity 30-day-groups. Then, an extra day can be added for each January, March, and so on, while two days are dropped from February. The February in leap years can be similarly changed to have an extra day, hence properly representing month.

Other auxiliary operators include:

- *Shift* shifts the index forward or backward a few granules (e.g., the granule used to be labeled 1 may be re-labeled 10) in order to provide proper alignment for further operations.
- *Combine* combines all the granules of one granularity that fall into (using finer-than relationship) a second granularity. For example, by combining all the business days in a week, business-week is obtained.
- *Subset* generates a new granularity by selecting an interval of granules from a given granularity. For example, choosing the days between year 2000 and 2010, leads to a granularity that only contains days in these years.
- *Select* generates new granularities by selecting granules from the first operand in terms of their relationship with the granules of the second operand. For example, selecting the first day of each week gives the Mondays granularity.

More details, including other operators, conditions of applicability, as well as comparison with other algebra proposals can be found in [3]. The algebra directly supports the inter-granule and inter-calendar conversions mentioned above. Some more complex operations on granularities (e.g., temporal constraint propagation in terms of multiple granularities) and the verification of formal properties (e.g., equivalence of algebraic granularity representations) require a conversion in terms of a given bottom granularity. An efficient automatic procedure for this conversion has been devised and implemented [2]. The automaton-based approach may be a valid alternative for the verification of formal properties.

Key Applications

Temporal granularities are currently used in several applications, but in most cases their use is limited to very few standard granularities, supported by system calendar libraries and ad-hoc solutions are used to manipulate data associated with them. This approach often leads to unclear semantics, hidden mistakes, low interoperability, and does not take advantage of user-defined granularities and complex operations. The impact of a formal framework for temporal granularities has been deeply investigated for a number of application areas among which logical design of temporal databases, querying databases in terms of arbitrary granularities, data mining, integrity constraint satisfaction, workflows [3]. For example, when temporal dependencies in terms of granularities can be identified in the data (e.g., "salaries of employees do not change within a fiscal year"), specific techniques have been devised for the logical design of temporal databases that can lead to significant benefits. In query processing, it has been shown how to support the retrieval of data in terms of temporal granularities different from the ones associated to the data stored in the database, provided that assumptions on the data semantics are formalized, possibly as part of the database schema. Time distance constraints in terms of granularities (e.g., *Event2 should occur within two business days after the occurrence of Event1*) have been extensively studied, and algorithms proposed to check for consistency and solutions. Applications include the specification of classes of frequent patterns to be identified in time series, the specification of integrity contraints in databases, and the specification of constraints on activities durations and on temporal distance between specific events in workflows.

Temporal granularities also have several applications in other areas like natural language processing, temporal reasoning in AI, including scheduling and planning, and in computer logic, where they have been mainly considered for program specification and verification.

Future applications may include advanced personal information management (PIM). Time and location-aware devices coupled with advanced calendar applications, supporting user-defined granularities, may offer innovative personalized scheduling and alerting systems.

Experimental Results

Several systems and software packages dealing with temporal granularities have been developed, among which MultiCal, Calendar algebra implementation, GSTP Project, and TauZaman. Information about these systems can be easily found online.

Temporal Homogeneity

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

Assume a temporal relation where the attribute values of tuples are (partial) functions from some time domain to value domains. A tuple in such a relation is *temporally homogeneous* if the domains of all its attribute values are identical. A temporal relation is temporally homogeneous if all its tuples are temporally homogeneous. Likewise, a temporal database is temporally homogeneous if all its relations are temporally homogeneous.

In addition to being specific to a type of object (tuple, relation, database), homogeneity is also specific to a time dimension when the time domain is multidimensional, as in "temporally homogeneous in the valid-time dimension" or "temporally homogeneous in the transaction-time dimension."

Key Points

The motivation for homogeneity arises from the fact that no timeslices of a homogeneous relation produce null values. Therefore, a homogeneous relational model is the temporal counterpart of the snapshot relational model without nulls. Certain data models assume temporal homogeneity, while other models do not.

A tuple-timestamped temporal relation may be viewed as a specific attribute-value timestamped relation. An attribute value *a* of a tuple with timestamp *t* is represented by a function that maps each value in *t* to *a*. Thus, models that employ tuple timestamping are necessarily temporally homogeneous.

Temporal Indeterminacy

Curtis Dyreson
Utah State University, Logan, UT, USA

Synonyms

Fuzzy time; Imprecise time

Definition

Temporal indeterminacy refers to "don't know when" information, or more precisely, "don't know *exactly* when." The modifier 'temporally indeterminate' indicates that the modified object has an associated time, but that the time is not known precisely. The time when an event happens, when a time interval begins or ends, or even the duration of a period may be indeterminate. For example, the event of a car accident might be "sometime last week," the interval an airplane flight takes may be from "Friday to Saturday," or the duration a graduate student takes to write a dissertation may be "four to fifteen years."

The adjective ‘temporal’ allows parallel kinds of indeterminacy to be defined, such as spatial indeterminacy. There is a subtle difference between indeterminate and imprecise. In this context, indeterminate is a more general term than imprecise since precision is commonly associated with making measurements. Typically, a precise measurement is preferred to an imprecise one. Imprecise time measurements, however, are just one source of temporally indeterminate information.

Historical Background

Despite the wealth of research on adding incomplete information to databases, there are few efforts that address incomplete temporal information [6]. Much of the previous research in incomplete information databases has concentrated on issues related to null values, the applicability of fuzzy set theory, and the integration of various combinations of probabilistic reasoning, temporal reasoning, and planning.

In the earliest work on temporal indeterminacy, an indeterminate instant was modeled with a set of possible chronons [12]. Dutta next introduced a fuzzy set approach to handle events that can be interpreted to have multiple occurrences [5]. For example the event “Margaret’s salary is high” may occur at various times as Margaret’s salary fluctuates to reflect promotions and demotions. The meaning of “high” is incomplete, it is not a crisp predicate. In Dutta’s model all the possibilities for high are represented in a *generalized* event and the user selects some subset according to his or her interpretation of “high.” Generalized bitemporal elements were defined somewhat differently in a later paper by Kouramajian and Elmasri [11]. Bitemporal elements combine transaction time and valid time in the same temporal element, and can include a noncontiguous (i.e., indeterminate) set of noncontiguous possible times. Gadia et al. proposed an interesting model that intertwines support for value and temporal incompleteness [8]. By combining the different kinds of incomplete information, a wide spectrum of attribute values are simultaneously modeled, including values that are completely known, values that are unknown but are known to have occurred, values that are known if they occurred, and values that are unknown even if they occurred. Dyreson and Snodgrass proposed using probabilistic events to model temporal indeterminacy. In their model a time is represented as a probability distribution [7]. Probabilistic times were also comprehensively addressed by Dekhtyar et al. [4].

Reasoning with incomplete information can be computationally expensive. Koubarakis was the first to focus attention on the issue of cost [9,10]. He showed that by restricting the kinds of constraints allowed in representing the indeterminacy, polynomial time algorithms can be obtained. Koubarakis proposed a temporal data model with global and local inequality constraints on the occurrence time of an event. Another constraint-based temporal reasoner is LaTeR, which has been successfully implemented [2]. LaTeR similarly restricts the kinds of constraints allowed (to conjunctions of linear inequalities), but this class of constraints includes many of the important temporal predicates [3].

Temporal indeterminacy has also been addressed in non-relational contexts, for instance in object-oriented databases [1].

Foundations

There are (at least) three possible sources of indeterminacy in a statement with respect to time: (i) a discrepancy between the *granularity* of the temporal qualification and the occurrence time; (ii) an underspecification of the occurrence time when the granularities of the temporal qualification and the occurrence time coincide; and (iii) relative times.

As a first approximation, a statement is *temporally indeterminate* if the granularity of its reference to time (in the examples, the granularity of days) is coarser than the granularity of the time at which the denoted event(s) occur. Temporal indeterminacy as well as relativity of reference to time is mainly a qualification of a statement rather than of the event it denotes (that is, temporal indeterminacy characterizes the relationship between the granularity of the time reference of a statement and the granularity of an event’s occurrence time). It does not depend on the time at which the statement is evaluated. The crucial and critical point is the determination of the time granularity of the event occurrence time.

Generally, a statement whose reference to time has a granularity (e.g., days) which is temporally determinate with respect to every coarser granularity (e.g., months) and temporally indeterminate with respect to every finer granularity (e.g., seconds). But this general rule has exceptions since it does not take into account information about the denoted occurrence time. In particular, for a *macro-event* there exists a (finest) granularity at which its occurrence time can be specified, but with respect to finer granularities, the event as a whole does not make sense, and must, if possible, be decomposed into a set of components.

But not all cases of temporally indeterminate information involve a discrepancy between the granularity of the reference to time and the granularity of the occurrence time. Consider the sentence: "The shop remained open on a Sunday in April 1990 all day long." 'Days' is the granularity of both the time reference and the occurrence time. Nevertheless, this statement is temporally indeterminate because the precise day in which the shop remained open is unknown (it is known only that it is one of the Sundays in April 1990).

Statements that contain a relative reference to time are also temporally indeterminate, but the reverse does not hold: temporally-indeterminate statements can contain relative as well as absolute references to time. The statements "Jack was killed sometime in 1990" and "Michelle was born yesterday" contain absolute and relative references to time, respectively, but they are both temporally indeterminate.

The following example illustrates how temporal indeterminacy can be represented in a relational database. Consider the employment relation shown in Fig. 1 which is cobbled together from the (somewhat hazy) memories of several employees. Each tuple shows a worker's name, salary, department, and time employed (i.e., the valid time). The first tuple represents Joe's employment in Shoes. It is temporally indeterminate since the exact day when Joe stopped working in Shoes is not known precisely; the ending valid time is recorded as sometime in January 2005 and represented as the indeterminate event "`1 Jan 2005~31 Jan 2005`." Joe then went to work in Admin, which is also temporally indeterminate. Joe started working in Admin "After leaving Shoes" which is a temporal constraint on an indeterminate time. The third tuple represents Sue's employment history. She began working in Shoes sometime in the first half of January 2005 ("`1 Jan 2005~15 Jan 2005`") with a uniform probability for each day in that range (which is more information than is known about Joe's termination in Shoes, the probability is missing from that indeterminate event). Finally, Eve began working in Admin on some Monday in January 2005, but it is not known which Monday.

Querying temporal indeterminacy is more challenging than representing it. The two chief challenges are efficiency and expressiveness. Consider a query to find out who was employed on January 10, 2005 as expressed in a temporal version of SQL (e.g., TSQL2) below.

```
SELECT Name
FROM Employee E
WHERE VALID(E) overlaps "10 Jan 2005"
```

There are two well-defined limits on querying incomplete information: the *definite* and the *possible*. The definite answer includes only information that is known. On a tuple-by-tuple basis, determining which employment tuple definitely overlaps January 10, 2005 is straightforward: *none* definitely do. In contrast, every tuple *possibly* overlaps that day. It is efficient to compute both bounds on a tuple-by-tuple basis, but not very expressive. It would be more expressive to be able to find other answers that lie between the bounds. Probabilistic approaches seek to refine the set of potential answers by reasoning with probabilities. For instance, can it be computed who was *probably* employed (exceeding a probability of 0.5)? The probability that Sue began working before January 10, 2005 is 0.67 (the probability mass is uniformly distributed among all the possibilities). Since the probability mass function for Joe's termination in Shoes is missing, he can not be included in the employees who were probably employed.

Name	Dept.	Sal.	Valid time
Joe	Shoes	40K	[1 Jan 2003 – 1 Jan 2005~31 Jan 2005]
Joe	Admin	100K	[After leaving shoes – now]
Sue	Shoes	50K	[1 Jan 2005~15 Jan 2005 (uniform) – now]
Eve	Admin	90K	[A Monday in January 2005 – now]

Temporal Indeterminacy. Figure 1. A relation with temporal indeterminacy.

Most of the existing approaches have focused on improving the efficiency of computing probabilistic answers; the *usability* of probabilistic approaches has not yet been determined. It might be very difficult for users to interpret and use probabilities (should a user interpret "probably" as exceeding 0.75 or 0.5) so other approaches (e.g., fuzzy set approaches) may be needed to improve usability. A second research issue concerns reasoning with *intra-tuple* constraints. The definite answer given above is inaccurate. Even though it is not known exactly when Joe stopped working in Shoes or started working in Admin, it is known that he was employed in one or the other on January 10, 2005. The intra-tuple constraint in the second tuple represents this knowledge. Though intra-tuple constraints provide greater reasoning power, reasoning with them often has high computational complexity. Research continues in defining classes of constraints that are meaningful and computationally feasible. Finally, temporal indeterminacy has yet to be considered in new kinds of queries (e.g., roll-up in data warehouses and top-k queries) and new temporal query languages (e.g., τXQuery and TOWL).

Key Applications

The most common kinds of temporal indeterminacy are valid-time indeterminacy and user-defined time indeterminacy. Transaction-time indeterminacy is rarer because transaction times are always known exactly. Temporal indeterminacy can occur in logistics, especially in planning scenarios where project completion dates are typically inexact. In some scientific fields it is quite rare to know an exact time, for instance, archeology is replete with probabilistic times generated by radio-carbon dating, tree-ring analyses, and by the layering of artifacts and sediments. Indeterminacy can arise even when precise clocks are employed. In a network of road sensors, an "icy road" has an indeterminate lifetime as the change from non-icy to icy is gradual rather than instantaneous; "icy road" has a fuzzy starting and ending time.

Temporal Integrity Constraints

Jef Wijsen
University of Mons-Hainaut, Mons, Belgium

Synonyms

Dynamic integrity constraints

Definition

Temporal integrity constraints are integrity constraints formulated over temporal databases. They can express dynamic properties by referring to data valid at different time points. This is to be contrasted with databases that do not store past or future information: if integrity constraints can only refer to data valid at the current time, they can only express static properties. Languages for expressing temporal integrity constraints extend first-order logic with explicit timestamps or with temporal connectives. An important question is how to check and enforce such temporal integrity constraints efficiently.

Historical Background

The use of first-order temporal logic for expressing temporal integrity constraints dates back to the early 1980s (see for example [2]). Since the late 1980s, progress has been made in the problem of checking temporal integrity [3, 9, 11] without having to store the entire database history. This entry deals with general temporal integrity constraints.

Foundations

Integrity constraints, whether they are temporal or not, are an important component of each database schema. They express properties that, ideally, must be satisfied by the stored data at all times. If a database satisfies all the integrity constraints, it is called *consistent*. Integrity constraints are commonly expressed in a declarative way using logic. Declarative integrity constraints generally do not specify how to keep the database consistent when data are inserted, deleted, and modified. An important task is to develop efficient procedures for checking and enforcing such constraints.

Temporal databases store past, current, and future information by associating time to database facts. An integrity constraint can be called "temporal" if it is expressed over a temporal database. By relating facts valid at different points in time, temporal integrity constraints can put restrictions on how the data can change over time. This is to be contrasted with databases that do not store past or future facts: if integrity constraints can only refer to a single database state, they cannot capture time-varying properties of data.

1. Defining Temporal Integrity

While temporal integrity constraints can in principle be expressed as Boolean queries in whichever temporal query language, it turns out that temporal logic on timepoint-stamped data are the prevailing formalism for defining and studying temporal integrity.

1.1 Temporal, Transition, and Static Constraints Since first-order logic is the lingua franca for expressing non-temporal integrity constraints, it is natural to express temporal integrity constraints in temporal extensions of first-order logic. Such temporalized logics refer to time either through variables with a type of time points, or by temporal modal operators, such as:

Operator	Meaning
$\bullet p$	Property *p* was true at the previous time instant.
$\blacklozenge p$	Property *p* was true sometime in the past.
$\circ p$	Property *p* will be true at the next time instant.
$\Diamond p$	Property *p* will be true sometime in the future.

Satisfaction of such constraints by a temporal database can be checked if the question "Does (did/will) $R(a_1,...,a_m)$ hold at t?" can be answered for any fact $R(a_1,...,a_m)$ and time instant t. Alternatively, one can equip facts with time and ask: "Is $R(a_1,...,a_m \mid t)$ true?". Thus, one can abstract from the concrete temporal database representation, which may well contain interval-stamped facts [7]. Every time point t gives rise to a *(database) state* containing all facts true at t.

The following examples assume a time granularity of days. The facts *WorksFor*(John Smith, Pulse) and *Earns*(John Smith, 20K), true on 10 August 2007, express that John worked for the Pulse project and earned a salary of 20K at that date. The alternative encoding is *WorksFor*(John Smith, Pulse | 10 Aug 2007) and *Earns*(John Smith, 20K | 10 Aug 2007).

Although temporal integrity constraints can generally refer to any number of database states, many natural constraints involve only one or two states. In particular, *transition constraints* only refer to the current and the previous state; *static constraints* refer only to the current state.

The first-order temporal logic (FOTL) formulas (1)–(4) hereafter illustrate different types of integrity constraints. The constraint *"An employee who is dropped from the Pulse project cannot work for that project later on"* can be formulated in FOTL as follows:

$$\neg\exists x(\mathit{WorksFor}(x,\mathrm{Pulse}) \wedge \blacklozenge(\neg \mathit{WorksFor}(x,\mathrm{Pulse}) \wedge \bullet\, \mathit{WorksFor}(x,\mathrm{Pulse}))) \tag{1}$$

This constraint can be most easily understood by noticing that the subformula $\blacklozenge(\neg\,\mathit{WorksFor}(x,\ \mathrm{Pulse}) \wedge \bullet\, \mathit{WorksFor}(x,\ \mathrm{Pulse}))$ is true in the current database state for every employee x who was dropped from the Pulse project sometime in the past (this subformula will recur in the discussion of integrity checking later on). This constraint can be equivalently formulated in a two-sorted logic, using two temporal variables t_1 and t_2:

$$\neg\exists x\exists t_1\exists t_2((t_1 < t_2) \wedge \mathit{WorksFor}(x,\mathrm{Pulse}|t_2) \\ \wedge \neg \mathit{WorksFor}(x,\mathrm{Pulse}|t_1) \wedge \mathit{WorksFor}(x,\mathrm{Pulse}|t_1-1))$$

The constraint "*Today's salary cannot be less than yesterday's*" is a transition constraint, and can be formulated as follows:

$$\neg\exists x\exists y\exists z(\mathit{Earns}(x,y) \wedge \bullet(\mathit{Earns}(x,z) \wedge y < z)) \tag{2}$$

Finally, static constraints are illustrated. The most fundamental static constraints in the relational data model are primary keys and foreign keys. The constraint "*No employee has two salaries*" implies that employee names uniquely identify *Earns*-tuples in any database state; it corresponds to a standard primary key. The constraint "*Every employee in the WorksFor relation has a salary*" means that in any database state, the first column of *WorksFor* is a foreign key that references (the primary key of) *Earns*. These constraints can be formulated in FOTL without using temporal connectives:

$$\forall x\forall y\forall z(\mathit{Earns}(x,y) \wedge \mathit{Earns}(x,z) \rightarrow y = z) \tag{3}$$

$$\forall x\forall y(\mathit{WorksFor}(x,y) \rightarrow \exists z \mathit{Earns}(x,z)) \tag{4}$$

Formulas (3) and (4) show a nice thing about using FOTL for expressing temporal integrity: static constraints read as non-temporal constraints expressed in first-order logic.

1.2 Different Notions of Consistency The syntax and semantics of the temporal logic used in the previous section are defined next. Different notions of temporal constraint satisfaction are discussed.

Assume a countably infinite set **dom** of constants. In the following syntax, R is any relation name and each s_i is a variable or a constant:

$$C, C' ::= R(s_1,\ldots,s_m)|s_1 = s_2 \\ |C \wedge C'|\neg C|\exists x(C)|\circ C|\diamond C|\bullet C|\blacklozenge C$$

The connectives $\bullet$ and $\blacklozenge$ are called *past operators*; $\circ$ and $\diamond$ are *future operators*. A *past formula* is a formula without future operators; a *future formula* is a formula without past operators. Other modal operators, like the past operator **since** and the future operator **until**, can be added to increase expressiveness. The set of time points is assumed to be infinite, discrete and linearly ordered with a smallest element. Thus, the time scale can be depicted as follows:

Discreteness of time is needed in the interpretation of the operators $\circ$ and $\bullet$. Formulas are interpreted relative to an infinite sequence $H = \langle H_0, H_1, H_2, \ldots\rangle$, where each H_i is a finite set of facts formed from relation names and constants of **dom**. Intuitively, H_i contains the facts true at time t_i. Such a sequence H is called an *infinite (database) history* and each H_i a *(database) state*. The following rules define inductively what it means for a closed formula C to be *satisfied* by H, denoted $H \models_{\mathrm{inf}} C$.

$H, i \models_{\mathrm{inf}} R(a_1, \ldots, a_m)$	iff	$R(a_1, \ldots, a_m) \in H_i$
$H, i \models_{\mathrm{inf}} a_1 = a_2$	iff	$a_1 = a_2$
$H, i \models_{\mathrm{inf}} C \wedge C'$	iff	$H, i \models_{\mathrm{inf}} C$ and $H, i \models_{\mathrm{inf}} C'$
$H, i \models_{\mathrm{inf}} \neg C$	iff	not $H, i \models_{\mathrm{inf}} C$
$H, i \models_{\mathrm{inf}} \exists x(C)$	iff	$H, i \models_{\mathrm{inf}} C[x \mapsto a]$ for some $a \in$ **dom**, where $C[x \mapsto a]$ is obtained from C by replacing each free occurrence of x with a
$H, i \models_{\mathrm{inf}} \bullet C$	iff	$i > 0$ and $H, i-1 \models_{\mathrm{inf}} C$
$H, i \models_{\mathrm{inf}} \blacklozenge C$	iff	$H, j \models_{\mathrm{inf}} C$ for some j such that $0 \leq j < i$
$H, i \models_{\mathrm{inf}} \circ C$	iff	$H, i+1 \models_{\mathrm{inf}} C$
$H, i \models_{\mathrm{inf}} \Diamond C$	iff	$H, j \models_{\mathrm{inf}} C$ for some $j > i$

Note that the truth of each subformula is expressed relative to a *single* "reference" time point i (along with H). This characteristic allows efficient techniques for integrity checking [6] and seems crucial to the success of temporal logic. Finally:

$$H \models_{\mathrm{inf}} C \text{ iff } H, j \models_{\mathrm{inf}} C \text{ for each } j \geq 0$$

Consistency of infinite database histories is of theoretical interest. In practice, only a finite prefix of H will be known at any one time. Consider, for example, the situation where H_0 is the initial database state, and for each $i \geq 0$, the state H_{i+1} results from applying an update to H_i. Since every update can be followed by another one, there is no last state in this sequence. However, at any one time, only some *finite history* $\langle H_0,\ldots,H_n\rangle$ up to the most recent update is known, and it is of practical importance to detect constraint violations in such a finite history. It is reasonable to raise a constraint violation when the finite history obtained so far cannot possibly be extended to an infinite consistent history. For example, the constraints

$$\neg\exists x(\mathit{Hire}(x) \wedge \neg\Diamond(\mathit{Promote}(x) \wedge \Diamond\mathit{Retire}(x)))$$
$$\neg\exists x(\mathit{Retire}(x) \wedge \Diamond\mathit{Retire}(x))$$

express that all hired people are promoted before they retire, and that no one can retire twice. Then, the finite history $\langle\{\mathit{Hire}(\mathrm{Ed})\},\{\mathit{Hire}(\mathrm{An})\},\{\mathit{Retire}(\mathrm{Ed})\}\rangle$ is inconsistent, because of the absence of *Promote*(Ed) in the second state. It is assumed here that the database history is append-only and that the past cannot be modified.

Two different notions, denoted $\vDash_{\mathrm{pot}}$ and $\vDash_{\mathrm{fin}}$, of satisfaction for finite histories are as follows:

1. $\langle H_0,\ldots,H_n\rangle \vDash_{\mathrm{pot}} C$ if $\langle H_0,\ldots,H_n\rangle$ can be extended to an infinite history $H = \langle H_0,\ldots,H_n, H_{n+1},\ldots\rangle$ such that $H \vDash_{\mathrm{inf}} C$.
2. $\langle H_0,\ldots,H_n\rangle \vDash_{\mathrm{fin}} C$ if $\langle H_0,\ldots,H_n\rangle$ can be extended to an infinite history $H = \langle H_0,\ldots,H_n, H_{n+1},\ldots\rangle$ such that $H, i \vDash_{\mathrm{inf}} C$ for each $i \in \{0, 1,\ldots,n\}$.

Obviously, the first concept, called *potential satisfaction*, is stronger than the second one: $\langle H_0,\ldots,H_n\rangle \vDash_{\mathrm{pot}} C$ implies $\langle H_0,\ldots,H_n\rangle \vDash_{\mathrm{fin}} C$. Potential satisfaction is the more natural concept. However, Chomicki [3] shows how to construct a constraint *C*, using only past operators (● and ♦), for which $\vDash_{\mathrm{pot}}$ is undecidable. On the other hand, $\vDash_{\mathrm{fin}}$ is decidable for constraints *C* that use only past operators, because the extra states H_{n+1}, H_{n+2},... do not matter in that case. It also seems that for most practical past formulas, $\vDash_{\mathrm{pot}}$ and $\vDash_{\mathrm{fin}}$ coincide [6]. Chomicki and Niwiński [4] define restricted classes of future formulas for which $\vDash_{\mathrm{pot}}$ is decidable.

1.3 Expressiveness of Temporal Constraints The only assumption about time used in the constraints shown so far, is that the time domain is discrete and linearly ordered. Many temporal constraints that occur in practice need additional structure on the time domain, such as granularity. The constraint "*The salary of an employee cannot change within a month*" assumes a grouping of time instants into months. It can be expressed in a two-sorted temporal logic extended with a built-in predicate `month`(t_1, t_2) which is true if t_1 and t_2 belong to the same month:

$$\neg\exists x\exists y_1\exists y_2\exists t_1\exists t_2(\mathrm{month}\ (t_1, t_2) \wedge \mathit{Earns}(x, y_1|t_1)$$
$$\wedge\ \mathit{Earns}(x, y_2|t_2) \wedge y_1 \neq y_2).$$

Arithmetic on the time domain may be needed to capture constraints involving time distances, durations, and periodicity. For example, the time domain 0, 1, 2,... may be partitioned into weeks by the predicate `week`(t_1, t_2) defined by: `week`(t_1, t_2) if $t_1\backslash 7 = t_2\backslash 7$, where \ is the integer division operator. If $0 \leq t_2 - t_1 \leq 7$, then one can say that t_2 is *within a week from* t_1 (even though `week`(t_1, t_2) may not hold).

Temporal databases may provide two temporal dimensions for valid time and transaction time. Valid time, used in the preceding examples, indicates when data are true in the real world. Transaction time records the history of the database itself. If both time dimensions are supported, then constraints can explicitly refer to both the history of the domain of discourse and the system's knowledge about that history [10]. Such types of constraints cannot be expressed in formalisms with only one notion of time.

Temporal logics have been extended in different ways to increase their expressive power. Such extensions include fixpoint operators and second-order quantification over sets of timepoints. On the other hand, several important problems, such as potential constraint satisfaction, are undecidable for FOTL and have motivated the study of syntactic restrictions to achieve decidability [4].

This entry focuses on temporal integrity of databases that use (temporal extensions of) the relational data model. Other data models have also been extended to deal with temporal integrity; time-based cardinality constraints in the Entity-Relationship model are an example.

1.4 Constraints on Interval-stamped Temporal Data All constraints discussed so far make abstraction of the concrete representation of temporal data in a (relational) database. They only assume that the database can tell whether a given fact holds at a given point in time. The notion of finite database history (let alone infinite history) is an abstract concept: in practice, all information can be represented in a single database in which facts are timestamped by time intervals to indicate their period of validity. An interval-stamped relation is shown below.

Emp	*Sal*	*FromTo*
John Smith	10K	[1 May 2007, 31 Dec 2007]
John Smith	11K	[1 Jan 2008, 31 Dec 2008]

Following [10], constraints over such interval-stamped relations can be expressed in first-order logic extended with a type for time intervals and with Allen's interval relations. The following constraint, stating that "*Salaries of employees cannot decrease*," uses temporal variables i_1, i_2 that range over time intervals:

$$\forall x \forall y \forall z \forall i_1 \forall i_2 (Earns(x, y|i_1) \wedge Earns(x, z|i_2) \\ \wedge \text{before}(i_1, i_2) \Rightarrow y \leq z).$$

Nevertheless, it seems that many temporal integrity constraints can be most conveniently expressed under an abstract, point-stamped representation. This is definitely true for static integrity constraints, like primary and foreign keys. Formalisms based on interval-stamped relations may therefore provide operators like *timeslice* or *unfold* to switch to a point-stamped representation. Such "snapshotting" also underlies the *sequenced* semantics [8], which states that static constraints must hold independently at every point in time.

On the other hand, there are some constraints that concern only the concrete interval-stamped representation itself. For example, the interval-stamped relation *Earns* shown below satisfies constraint (3), but may be illegal if there is a constraint stating that temporal tuples need to be coalesced whenever possible.

2. Checking and Enforcing Temporal Integrity

Consider a database history to which a new state is added whenever the database is updated. Consistency is checked whenever a tentative update reaches the database. If the update would result in an inconsistent database history, it is rejected; otherwise the new database state is added to the database history. This scenario functions well if the entire database history is available for checking consistency. However, more efficient methods have been developed that allow checking temporal integrity without having to store the whole database history.

To check integrity after an update, there is generally no need to inspect the entire database history. In particular, static constraints can be checked by inspecting only the new database state; transition constraints can be checked by inspecting the previous and the new database state. Techniques for temporal integrity checking aim at reducing the amount of historical data that needs to be considered after a database update. In "history-less" constraint checking [3,9,11], all information that is needed for checking temporal integrity is stored, in a space-efficient way, in the current database state. The past states are then no longer needed for the purpose of integrity checking (though they may be needed for answering queries).

The idea is similar to Temporal Vacuuming and can be formalized as follows. For a given database schema **S**, let FIN_HISTORIES(**S**) denote the set of finite database histories over **S** and STATES(**S**) the set of states over **S**. Given a database schema **S** and a set **C** of temporal constraints, the aim is to compute a schema **T** and a computable function E : FIN_HISTORIES(**S**) → STATES(**T**), called *history encoding*, with the following properties:

- for every $H \in$ FIN_HISTORIES(**S**), the consistency of H with respect to **C** must be decidable from $E(H)$ and **C**. This can be achieved by computing a new set **C**′ of (non-temporal) first-order constraints over **T** such that for every $H \in$ FIN_HISTORIES(**S**), $H \models_{\text{temp}} \mathbf{C}$ if and only if $E(H) \models \mathbf{C}'$, where $\models_{\text{temp}}$ is the desired notion of temporal satisfaction (see the section on "Different Notions of Consistency"). Intuitively, the function E encodes, in a non-temporal database state over the schema **T**, all information needed for temporal integrity checking.
- E must allow an incremental computation when new database states are added: for every $\langle H_0,\ldots, H_n\rangle \in$ FIN_HISTORIES(**S**), the result $E(\langle H_0,\ldots, H_n\rangle)$ must be computable from $E(\langle H_0,\ldots,H_{n-1}\rangle)$ and H_n. In turn, $E(\langle H_0,\ldots,H_{n-1}\rangle)$ must be computable from $E(\langle H_0,\ldots,H_{n-2}\rangle)$ and H_{n-1}. And so on.

Formally, there must be a computable function $\Delta : \mathrm{STATES}(\mathbf{T}) \times \mathrm{STATES}(\mathbf{S}) \rightarrow \mathrm{STATES}(\mathbf{T})$ and an initial database state $J_{\mathrm{init}} \in \mathrm{STATES}(\mathbf{T})$ such that $E(\langle H_0 \rangle) = \Delta(J_{\mathrm{init}}, H_0)$ and for every $n > 0$, $E(\langle H_0,\ldots,H_n \rangle) = \Delta(E(\langle H_0,\ldots,H_{n-1} \rangle), H_n)$. The state J_{init} is needed to get the computation off the ground.

Note that the history encoding is fully determined by the quartet ($\mathbf{T}$, J_{init}, Δ,$\mathbf{C}'$), which only depends on $\mathbf{S}$ and $\mathbf{C}$ (and not on any database history).

Such history encoding was developed by Chomicki [3] for constraints expressed in Past FOTL (including the **since** modal operator). Importantly, in that encoding, the size of $E(H)$ is polynomially bounded in the number of distinct constants occurring in H, irrespective of the length of H. Chomicki's *bounded history encoding* can be illustrated by constraint (1), which states that an employee cannot work for the Pulse project if he was dropped from that project in the past. The trick is to maintain an auxiliary relation (call it *DroppedFromPulse*, part of the new schema $\mathbf{T}$) that stores names of employees who were dropped from the Pulse project in the past. Thus, *DroppedFromPulse*(x) will be true in the current state for every employee name x that satisfies $\blacklozenge(\neg \mathit{WorksFor}(x, \mathrm{Pulse}) \wedge \bullet \mathit{WorksFor}(x, \mathrm{Pulse}))$ in the current state. Then, constraint (1) can be checked by checking $\neg \exists x(\mathit{WorksFor}(x, \mathrm{Pulse}) \wedge \mathit{DroppedFromPulse}(x))$, which, syntactically, is a static constraint. Note incidentally that the label "static" is tricky here, because the constraint refers to past information stored in the current database state. Since history-less constraint checking must not rely on past database states, the auxiliary relation *DroppedFromPulse* must be maintained incrementally (the function Δ): whenever an employee named x is dropped from the Pulse project (i.e., whenever the tuple *WorksFor*(x, Pulse) is deleted), the name x must be added to the *DroppedFromPulse* relation. In this way, one remembers who has been dropped from Pulse, but forgets when.

History-less constraint checking thus reduces dynamic to static constraint checking, at the expense of storing in auxiliary relations (over the schema $\mathbf{T}$) historical data needed for checking future integrity. Whenever a new database state is created as the result of an update, the auxiliary relations are updated as needed (using the function Δ). This technique is suited for implementation in active database systems [5,11]: a tentative database update will trigger an abort if it violates consistency; otherwise the update is accepted and will trigger further updates that maintain the auxiliary relations.

The approach described above is characterized by ad hoc updates. A different approach is operational: the database can only be updated through a predefined set of update methods (also called transactions). These transactions are specified in a transaction language that provides syntax for embedding elementary updates (insertions and deletions of tuples) in program control structures. Restrictions may be imposed on the possible execution orders of these transactions. Bidoit and de Amo [1] define dynamic dependencies in a declarative way, and then investigate transaction schemes that can generate all and only the database histories that are consistent.

Although it is convenient to use an abstract temporal representation for specifying temporal constraints, consistency checks must obviously be performed on concrete representations. Techniques for checking static constraints, like primary and foreign keys, need to be revised if one moves from non-temporal to interval-timestamped relations [8]. Primary keys can be enforced on a non-temporal relation by means of a unique-index construct. On the other hand, two distinct tuples in an interval-timestamped relation can agree on the primary key without violating consistency. For example, the consistent temporal relation shown earlier contains two tuples with the same name John Smith.

Key Applications

Temporal data and integrity constraints naturally occur in many database applications. Transition constraints apply wherever the legality of new values after an update depends on the old values, which happens to be very common. History-less constraint checking seems particularly suited in applications where temporal conditions need to be checked, but where there is no need for issuing general queries against past database states. This may be the case in monitor and control applications [12].

Temporal Joins

Dengfeng Gao
IBM Silicon Valley Lab, San Jose, CA, USA

Definition

A temporal join is a join operation on two temporal relations, in which each tuple has additional attributes indicating a time interval. The temporal join predicates include conventional join predicates as well as a temporal constraint that requires the overlap of the intervals of the two joined tuples. The result of a temporal join is a temporal relation.

Besides binary temporal joins that operate on two temporal relations, there are n-ary temporal joins that operate on more than two temporal relations. Besides temporal overlapping, there are other temporal conditions such as "before" and "after" [1]. This entry will concentrate on the binary temporal joins with overlapping temporal condition since most of the previous work has focused on this kind of joins.

Historical Background

In the past, temporal join operators have been defined in different temporal data models; at times the essentially same operators have even been given different names when defined in different data models. Further, the existing join algorithms have also been constructed within the contexts of different data models. Temporal join operators were first defined by Clifford and Croker [4]. Later many papers studied more temporal join operators and the evaluation algorithms. To enable the comparison of join definitions and implementations across data models, Gao et al. [7] proposed a taxonomy of temporal joins and then use this taxonomy to classify all previously defined temporal joins.

Foundations

Starting from the core set of conventional relational joins that have long been accepted as "standard" [11]: Cartesian product (whose "join predicate" is the constant expression TRUE), theta-join, equijoin, natural join, left and right outerjoin, and full outerjoin, a temporal counterpart that is a natural, temporal generalization of the set can be defined. The semantics of the temporal join operators are defined as follows.

To be specific, the definitions are based on a single data model that is used most widely in temporal data management implementations, namely the one that timestamps each tuple with an interval. Assume that the time-line is partitioned into minimal-duration intervals, termed *chronons* [5]. The intervals are denoted by inclusive starting and ending chronons.

Two temporal relational schemas, R and S, are defined as follows.

$$R = (A_1,\ldots, A_n, \mathrm{T}_s, \mathrm{T}_e)$$
$$S = (B_1,\ldots, B_m, \mathrm{T}_s, \mathrm{T}_e)$$

The A_i, $1 \leq i \leq n$, and B_i, $1 \leq i \leq m$, are the *explicit attributes* that are found in corresponding snapshot schemas, and T_s and T_e are the timestamp start and end attributes, recording when the information recorded by the explicit attributes holds (or held or will hold) true. T will be used as a shorthand for the interval $[T_s, T_e]$, and *A* and *B* will be used as a shorthand for $\{A_1,...,A_n\}$ and $\{B_1,...,B_n\}$, respectively. Also, *r* and *s* are defined to be instances of *R* and *S*, respectively.

Consider the following two temporal relations. The relations show the canonical example of employees, the departments they work for, and the managers who supervise those departments.

Employee

EmpName	Dept	T
Ron	Ship	[1,5]
George	Ship	[5,9]
Ron	Mail	[6,10]

Manages

Dept	MgrName	T
Load	Ed	[3,8]
Ship	Jim	[7,15]

Tuples in the relations represent facts about the modeled reality. For example, the first tuple in the Employee relation represents the fact that Ron worked for the Shipping department from time 1 to time 5, inclusive. Notice that none of the attributes, including the timestamp attributes T, are set-valued – the relation schemas are in 1NF.

Cartesian Product

The temporal Cartesian product is a conventional Cartesian product with a predicate on the timestamp attributes. To define it, two auxiliary definitions are needed.

First, *intersect* (*U*,*V*), where *U* and *V* are intervals, returns TRUE if there exists a chronon *t* such that $t \in U \wedge t \in V$, and FALSE otherwise. Second, *overlap* (*U*,*V*) returns the maximum interval contained in its two argument intervals. If no non-empty intervals exist, the function returns. To state this more precisely, let *first* and *last* return the smallest and largest of two argument chronons, respectively. Also let U_s and U_e denote the starting and ending chronons of *U*, and similarly for *V*.

$$overlap(U,V) = \begin{cases} [last(U_s, V_s), first(U_e, V_e)] \text{ if } last(U_s, V_s) \\ \qquad\qquad\qquad \leq first(U_e, V_e) \\ \emptyset \qquad\qquad\qquad\qquad \text{otherwise.} \end{cases}$$

The temporal Cartesian product, $r \times^{\mathrm{T}} s$, of two temporal relations *r* and *s* is defined as follows.

$$r \times^{\mathrm{T}} s = \{z^{(n+m+2)} \mid \exists x \in r\ \exists y \in s\ (intersect\ (x[\mathrm{T}], y[\mathrm{T}]) \wedge z[A] = x[A] \wedge z[B] = y[B] \wedge$$
$$z[\mathrm{T}] = overlap(x[\mathrm{T}], y[\mathrm{T}]) \wedge z[\mathrm{T}] \neq \phi)\}$$

The first line of the definition ensures that matching tuples *x* and *y* have overlapping timestamps and sets the explicit attribute values of the result tuple *z* to the concatenation of the explicit attribute values of *x* and *y*. The second line computes the timestamp of *z* and ensures that it is non-empty. The *intersect* predicate is included only for later reference – it may be omitted without changing the meaning of the definition.

Consider the query "Show the names of employees and managers where the employee worked for the company while the manager managed some department in the company." This can be satisfied using the temporal Cartesian product.

Employee × $^{\mathrm{T}}$ Manages

EmpName	Dept	Dept	MgrName	T
Ron	Ship	Load	Ed	[3,5]
George	Ship	Load	Ed	[5,8]
George	Ship	Ship	Jim	[7,9]
Ron	Mail	Load	Ed	[6,8]
Ron	Mail	Ship	Jim	[7,10]

The *overlap* function is necessary and sufficient to ensure *snapshot reducibility*, as will be discussed in detail later. Basically, the temporal Cartesian product acts as though it is a conventional Cartesian product applied independently at each point in time. When operating on interval-stamped data, this semantics corresponds to an intersection: the result will be valid during those times when contributing tuples from *both* input relations are valid.

Theta-Join

Like the conventional theta-join, the temporal theta-join supports an unrestricted predicate *P* on the explicit attributes of its input arguments. The temporal theta-join, $r \bowtie^{\mathrm{T}}_{\mathrm{P}} s$, of two relations *r* and *s* selects those tuples from $r \times^{\mathrm{T}} s$ that satisfy predicate $P(r[A],s[B])$. Let σ denote the standard selection operator.

The temporal theta-join, $r \bowtie^{\mathrm{T}}_{\mathrm{P}} s$, of two temporal relations *r* and *s* is defined as follows.

$$r \bowtie^{\mathrm{T}}_{\mathrm{P}} s = \sigma_{P(r[A],s[B])}(r \times^{\mathrm{T}} s)$$

Equijoin

Like snapshot equijoin, the temporal equijoin operator enforces equality matching between specified subsets of the explicit attributes of the input relations.

The temporal equijoin on two temporal relations *r* and *s* on attributes $A' \subseteq A$ and $B' \subseteq B$ is defined as the theta-join with predicate $P \equiv r[A'] = s[B']$:

$$r \bowtie^{\mathrm{T}}_{r[A']=s[B']} s \ .$$

Natural Join

The temporal natural join bears the same relationship to the temporal equijoin as does their snapshot counterparts. Namely, the temporal natural join is simply a temporal equijoin on identically named explicit attributes, followed by a subsequent projection operation.

To define this join, the relation schemas are augmented with explicit join attributes, C_i, $1 \leq i \leq k$, which are abbreviated by *C*.

$$R = (A_1,..,A_n, C_1,..,C_k, \mathrm{T}_s, \mathrm{T}_e)$$
$$S = (B_1,...,B_m, C_1,...,C_k, \mathrm{T}_s, \mathrm{T}_e)$$

The temporal natural join of *r* and *s*, $r \bowtie^{\mathrm{T}} s$, is defined as follows.

$$\begin{aligned}&r \bowtie^{\mathrm{T}} s = \{z^{(n+m+k+2)} \mid \exists x \in r \exists y \in s(x[C] = y[C] \wedge\\ &z[A] = x[A] \wedge z[B] = x[B] \wedge z[C] = y[C] \wedge\\ &z[\mathrm{T}] = overlap(x[\mathrm{T}],y[\mathrm{T}]) \wedge z[\mathrm{T}] \neq \phi)\}\end{aligned}$$

The first two lines ensure that tuples *x* and *y* agree on the values of the join attributes *C* and set the explicit attribute of the result tuple *z* to the concatenation of the non-join attributes *A* and *B* and a single copy of the join attributes, *C*. The third line computes the timestamp of *z* as the overlap of the timestamps of *x* and *y*, and ensures that *x*[T] and *y*[T] actually overlap.

The temporal natural join plays the same important role in reconstructing normalized temporal relations as does the snapshot natural join for normalized snapshot relations [10]. Most previous work in temporal join evaluation has addressed, either implicitly or explicitly, the implementation of the temporal natural join (or the closely related temporal equijoin).

Outerjoins and Outer Cartesian Products

Like the snapshot outerjoin, temporal outerjoins and Cartesian products retain *dangling tuples*, i.e., tuples that do not participate in the join. However, in a temporal database, a tuple may dangle over a portion of its time interval and be covered over others; this situation must be accounted for in a temporal outerjoin or Cartesian product.

The temporal outerjoin may be defined as the union of two subjoins, analogous to the snapshot outerjoin. The two subjoins are the temporal left outerjoin and the temporal right outerjoin. As the left and right outerjoins are symmetric, only the left outerjoin is defined here.

Two auxiliary functions are needed. The *coalesce* function collapses value-equivalent tuples – tuples with mutually equal non-timestamp attribute values [9] – in a temporal relation into a single tuple with the same non-timestamp attribute values and a timestamp that is the finite union of intervals that precisely contains the chronons in the timestamps of the value-equivalent tuples. *(Finite unions of time intervals are termed *temporal elements* [6].)* The definition of *coalesce* uses the function *chronons* that returns the set of chronons contained in the argument interval.

$$\begin{aligned}&coalesce(r) = \{z^{(n+2)} \mid \exists x \in r(z[A] = x[A] \Rightarrow chronons(x[\mathrm{T}]) \subseteq z[\mathrm{T}] \wedge\\ &\forall x'' \in r\ (x[A] = x''[A] \Rightarrow (chronons(x''[\mathrm{T}]) \subseteq z[\mathrm{T}]))) \wedge\\ &\forall t \in z[\mathrm{T}] \exists x'' \in r(z[A] = x''[A] \wedge t \in chronons(x''[\mathrm{T}]))\}\end{aligned}$$

The first two lines of the definition coalesce all value-equivalent tuples in relation *r*. The third line ensures that no spurious chronons are generated.

Now a function *expand* is defined that returns the set of maximal intervals contained in an argument temporal element, T. Prior to defining *expand* an auxiliary function *intervals* is defined that returns the set of intervals contained in an argument temporal element.

$$intervals(T) = \{[t_s, t_e] | t_s \in T \wedge t_e \in T \wedge$$
$$\forall t \in chronons([t_s, t_e])(t \in T)\}$$

The first two conditions ensures that the beginning and ending chronons of the interval are elements of T. The third condition ensures that the interval is contiguous within T.

Using *intervals*, *expand* is defined as follows.

$$expand(T) = \{[t_s, t_e] | [t_s, t_e] \in intervals(T) \wedge$$
$$\neg \exists [t_s', t_e'] \in intervals(T)(chronons([t_s, t_e]) \subset chronons([t_s', t_e']))\}$$

The first line ensures that a member of the result is an interval contained in T. The second line ensures that the interval is indeed maximal.

The temporal left outerjoin is now ready to be defined. Let R and S be defined as for the temporal equijoin. $A' \subseteq A$ and $B' \subseteq B$ are used as the explicit join attributes.

The temporal left outerjoin, $r \quad_{r[A']=s[B']} s$ of two temporal relations r and s is defined as follows.

$$r \quad_{r[A']=s[B']} s = \{z^{(n+m+2)} | \exists x \in coalesce(r) \exists y \in coalesce(s)$$
$$(x[A'] = y[B'] \wedge z[A] = x[A] \wedge z[\mathrm{T}] \neq \phi \wedge$$
$$((z[B] = y[B] \wedge z[\mathrm{T}] \in \{expand(x[\mathrm{T}] \cap y[\mathrm{T}])\}) \vee$$
$$(z[B] = \mathrm{null} \wedge z[\mathrm{T}] \in \{expand(x[\mathrm{T}]) - expand(y[\mathrm{T}])\}))) \vee$$
$$\exists x \in coalesce(r) \forall y \in coalesce(s)$$
$$(x[A'] \neq y[B'] \Rightarrow z[A] = x[A] \wedge z[B] = \mathrm{null} \wedge$$
$$z[\mathrm{T}] \in expand(x[T]) \wedge z[\mathrm{T}] \neq \phi)\}$$

The first four lines of the definition handle the case where, for a tuple x deriving from the left argument, a tuple y with matching explicit join attribute values is found. For those time intervals of x that are not shared with y, tuples with null values in the attributes of y are generated. The final three lines of the definition handle the case where no matching tuple y is found. Tuples with null values in the attributes of y are generated.

The temporal outerjoin may be defined as simply the union of the temporal left and the temporal right outerjoins (the union operator eliminates the duplicate equijoin tuples). Similarly, a temporal outer Cartesian product is a temporal outerjoin without the equijoin condition ($A' = B' = \phi$).

Temporal Joins. Table 1. Temporal join operators

Operator	Initial Citation	Taxonomy Operator	Restrictions
Θ-JOIN	[2]	Theta-join	None
EQUIJOIN	[2]	Equijoin	None
NATURAL-JOIN	[2]	Natural Join	None
TIME-JOIN	[2]	Cartesian Product	1
T-join	[8]	Cartesian Product	None
Cartesian product	[3]	Outer Cartesian Product	None
TE-JOIN	[13]	Equijoin	2
TE-OUTERJOIN	[13]	Left Outerjoin	2
EVENT-JOIN	[13]	Outerjoin	2
Valid-Time Theta-Join	[14]	Theta-join	None
Valid-Time Left Join	[14]	Left Outerjoin	None
GTE-Join	[15]	Equijoin	2, 3

Restrictions:
1 = restricts also the valid time of the result tuples
2 = matching only on surrogate attributes
3 = includes also intersection predicates with an argument surrogate range and a time range

Table 1 summarizes how previous work is represented in the taxonomy. For each operator defined in previous work, the table lists the defining publication, researchers, the corresponding taxonomy operator, and any restrictions assumed by the original operators.

In early work, Clifford [4] indicated that an INTERSECTION-JOIN should be defined that represents the categorized non-outer joins and Cartesian products, and he proposed that an UNION-JOIN be defined for the outer variants.

Reducibility

The following shows how the temporal operators reduce to snapshot operators. Reducibility guarantees that the semantics of snapshot operator is preserved in its more complex, temporal counterpart.

For example, the semantics of the temporal natural join reduces to the semantics of the snapshot natural join in that the result of first joining two temporal

$$\begin{tikzcd}
\underline{\text{Temporal relations}} & & \underline{\text{Snapshot relations}} \\
r,\, r' \arrow[rr, "\tau_t^{\mathrm{T}}"] \arrow[d, "\bowtie^{\mathrm{T}}"'] & & \tau_t^{\mathrm{T}}(r),\, \tau_t^{\mathrm{T}}(r') \arrow[d, "\bowtie"] \\
r \bowtie^{\mathrm{T}} r' \arrow[r, "\tau_t^{\mathrm{T}}"] & \tau_t^{\mathrm{T}}(r \bowtie^{\mathrm{T}} r') = & \tau_t^{\mathrm{T}}(r) \bowtie \tau_t^{\mathrm{T}}(r')
\end{tikzcd}$$

Temporal Joins. Figure 1. Reducibility of temporal natural join to snapshot natural join.

relations and then transforming the result to a snapshot relation yields a result that is the same as that obtained by first transforming the arguments to snapshot relations and then joining the snapshot relations. This commutativity diagram is shown in Fig. 1 and stated formally in the first equality of the following theorem.

The timeslice operation τ^{T} takes a temporal relation r as argument and a chronon t as parameter. It returns the corresponding snapshot relation, i.e., with the schema of r, but without the timestamp attributes, that contains (the non-timestamp portion of) all tuples x from r for which t belongs to $x[\mathrm{T}]$. It follows from the next theorem that the temporal joins defined here reduce to their snapshot counterparts.

Theorem 1

Let t denote a chronon and let r and s be relation instances of the proper types for the operators they are applied to. Then the following hold for all t:

$$\begin{aligned}
\tau_{\mathrm{t}}^{\mathrm{T}}(r \bowtie^{\mathrm{T}} s) &= \tau_{\mathrm{t}}^{\mathrm{T}}(r) \bowtie \tau_{\mathrm{t}}^{\mathrm{T}}(s) \\
\tau_{\mathrm{t}}^{\mathrm{T}}(r \times^{\mathrm{T}} s) &= \tau_{\mathrm{t}}^{\mathrm{T}}(r) \times \tau_{\mathrm{t}}^{\mathrm{T}}(s) \\
\tau_{\mathrm{t}}^{\mathrm{T}}(r \bowtie_{\mathrm{P}}^{\mathrm{T}} s) &= \tau_{\mathrm{t}}^{\mathrm{T}}(r) \bowtie_P \tau_{\mathrm{t}}^{\mathrm{T}}(s) \\
\tau_{\mathrm{t}}^{\mathrm{T}}(r \mathbin{⟕}^{\mathrm{T}} s) &= \tau_{\mathrm{t}}^{\mathrm{T}}(r) \mathbin{⟕} \tau_{\mathrm{t}}^{\mathrm{T}}(s) \\
\tau_{\mathrm{t}}^{\mathrm{T}}(r \mathbin{⟖}^{\mathrm{T}} s) &= \tau_{\mathrm{t}}^{\mathrm{T}}(r) \mathbin{⟖} \tau_{\mathrm{t}}^{\mathrm{T}}(s)
\end{aligned}$$

Due to the space limit, the proof of this theorem is not provided here. The details can be found in the related paper [7].

Evaluation Algorithms Algorithms for temporal join evaluation are necessarily more complex than their snapshot counterparts. Whereas snapshot evaluation algorithms match input tuples on their explicit join attributes, temporal join evaluation algorithms typically must in addition ensure that temporal restrictions are met. Furthermore, this problem is exacerbated in two ways. Timestamps are typically complex data types, e.g., intervals, requiring inequality predicates, which conventional query processors are not optimized to handle. Also, a temporal database is usually larger than a corresponding snapshot database due to the versioning of tuples.

There are two categories of evaluation algorithms. Index-based algorithms use an auxiliary access path, i.e., a data structure that identifies tuples or their locations using a join-attribute value. Non-index-based algorithms do not employ auxiliary access paths. The large number of temporal indexes have been proposed in the literature [12]. Gao et al. [7] provided a taxonomy of non-index-based temporal join algorithms.

Key Applications

Temporal joins are used to model relationships between temporal relations with respect to the temporal dimensions. Data warehouses usually need to store and analyze historical data. Temporal joins can be used (alone or together with other temporal relational operators) to perform the analysis on historical data.

Temporal Logic in Database Query Languages

Jan Chomicki[1], David Toman[2]

[2]University of Waterloo, Waterloo, ON, Canada

Definition

The term “temporal logic” is used in the area of formal logic, to describe systems for representing and reasoning about propositions and predicates whose truth depends on time. These systems are developed around a set of *temporal connectives*, such as *sometime in the future* or *until*, that provide implicit references to time instants. First-order temporal logic is a variant of temporal logic that allows first-order predicate (relational) symbols, variables and quantifiers, in addition to temporal connectives. This logic can be used as a natural *temporal query language* for point-stamped temporal databases. A query (a temporal logic formula) is evaluated with respect to an *evaluation point (time instant)*. Each such point determines a specific database snapshot that can be viewed as a relational database. Thus, the evaluation of temporal logic queries resembles the evaluation of first-order (relational calculus) queries equipped with an additional capability to “move” the evaluation point using *temporal connectives*. In this way, it becomes possible to refer in a single query to multiple snapshots of a given temporal database. The answer to a temporal logic query evaluated with respect to all time instants forms a point-stamped temporal relation.

Historical Background

Temporal logic was developed (originally under the name of *tense logic* by Arthur Prior in the late 1950s), for representing and reasoning about natural languages. It was introduced to computer science by Amir Pnueli [8] as a tool for formal verification of software systems. The first proposal for using a temporal logic in the database context was by Sernadas [9]. Subsequently, de Castilho et al. [3] initiated the study of temporal-logic integrity constraints in relational databases. Tuzhilin and Clifford [12] considered temporal logic as a query language for temporal databases.

Foundations

Temporal Logic is a variant of *modal* logic, tailored to expressing statements whose truth is relative to an underlying time domain which is commonly a *linearly ordered* set of time instants. The modalities are expressed using natural-language statements of the form *sometime in the future*, *always in the future*, etc. and are captured in the syntax of the logic using *temporal connectives*.

Temporal logics are usually rooted in *propositional logic*. However, for the purposes of querying (single-dimensional, valid time) point-stamped temporal databases, *linear-time first-order temporal logic (FOTL)*, an extension of first-order logic (relational calculus) with *temporal connectives*, is used. More formally, given a relational schema ρ (of a snapshot of a point-stamped temporal database), the syntax of FOTL queries is defined as follows:

$$Q ::= r(x_{i_1},\ldots,x_{i_k}) \mid x_i = x_j \mid Q \wedge Q \mid \neg Q \mid \exists x.Q \mid Q \textbf{ since } Q \mid Q \textbf{ until } Q$$

for $r \in \rho$. The additional **since** and **until** connectives are the *temporal connectives*. The connectives completely *encapsulate* the structure of time: FOTL only refers to time *implicitly* using these connectives. In contrast, temporal relational calculus (TRC) uses *explicit* temporal variables and attributes to refer to time. Note that there are no restrictions on the nesting of the temporal connectives, the Boolean connectives, and the quantifiers.

The meaning of all temporal logic formulas is defined relative to a particular time instant called the *evaluation point*. Intuitively, the evaluation point can be viewed as representing the *current instant* or *now*. The standard first-order parts of FOTL formulas are then evaluated in the snapshot of the temporal database determined by the evaluation point. The temporal connectives make it possible to change the evaluation point, i.e., to "move" it to the past or to the future. In this way the combination of first-order constructs and temporal connectives allows to ask queries that refer to multiple snapshots of the temporal database. For example the query Q_1 **since** Q_2 asks for all answers that make Q_2 true sometime in the past and Q_1 true between then and now. Similarly, queries about the future are formulated using the **until** connective. More formally, answers to FOTL queries are defined using a *satisfaction relation* that, for a given FOTL query, links a temporal database and an evaluation point (time instant) with the valuations that make the given query true with respect to the snapshot of that database at that particular evaluation point. This definition, given below, extends the standard definition of satisfaction for first-order logic.

Definition [FOTL Semantics] Let *DB* be a point-stamped temporal database with a data domain D, a point-based time domain T_P, and a (snapshot) schema ρ.

The *satisfaction relation* $DB, \theta, t \models Q$, where Q is an FOTL formula, θ a valuation, and $t \in \mathrm{T}_P$, is defined inductively with respect to the structure of the formula Q: as shown in Figure 2. where $\mathbf{r}_j^{DB(t)}$ is the instance of the relation r_j in the snapshot $DB(t)$ of the database DB at the instant t.

The answer to an FOTL query Q over DB is the set of tuples:

$$Q(DB) := \{(t, \theta(x_1),\ldots,\theta(x_k)) : DB, \theta, t \models Q\},$$

where $x_1,\ldots,x_k$ are the free variables of Q.

Note that answers to FOTL queries are (valid-time) point-stamped temporal relations.

Other commonly used temporal connectives, such as $\diamond$ (*sometime in the future*), $\square$ (*always in the future*), $\blacklozenge$ (*sometime in the past*), and $\blacksquare$ (*always in the past*) can be defined in terms of **since** and **until** as follows:

$$\diamond X_1 := \text{true } \textbf{until } X_1 \qquad \blacklozenge X_1 := \text{true } \textbf{since } X_1$$
$$\square X_1 := \neg\diamond\neg X_1 \qquad \blacksquare X_1 := \neg\blacklozenge\neg X_1$$

For a discrete linear order, the $\circ$ (*next*) and $\bullet$ (*previous*) operators are defined as follows:

$$\circ X_1 := \text{false } \textbf{until } X_1 \qquad \bullet X_1 := \text{false } \textbf{since } X_1$$

The connectives **since**, $\blacklozenge$, $\blacksquare$, and $\bullet$ are called *past temporal connectives* (as they refer to the past) and **until**, $\diamond$, $\square$, and $\circ$ *future temporal connectives*.

Example. The sensor information about who enters or exits a room is kept in the relations *Entry* (Fig. 1a) and *Exit* (Fig. 1b). Consider the query Q_a: "*For every time instant, who is in the room Bell 224 at that instant?*" It can be written in temporal logic as:

$$\exists r.\ ((\neg Exit(r,p)) \textbf{ since } Entry(r,p)) \wedge r = \text{"Bell 224"}$$

The answer to Q_a in the given database is presented in Fig. 1c, under the assumption that time instants correspond to minutes.

a

Entry		
Time	Room	Person
8 : 30	Bell 224	John
9 : 00	Bell 224	Mary
11 : 00	Capen 10	John

b

Exit		
Time	Room	Person
10 : 30	Bell 224	John
10 : 00	Bell 224	Mary
12 : 00	Capen 10	John

c

Time	Person
8 : 31	John
...	...
10 : 30	John
9 : 01	Mary
...	...
10 : 00	Mary

Temporal Logic in Database Query Languages. Figure 1. The *Entry*, the *Exit*, and the *Who is in Bell 224* relations.

$DB, \theta, t \models r_j(x_{i1},\ldots,x_{ik})$	if $(\theta(x_{i1}),\ldots,\theta(x_{ik})) \in r_j^{DB(t)}$
$DB, \theta, t \models x_i = x_j$	if $\theta(x_i) = \theta(x_j)$
$DB, \theta, t \models Q_1 \wedge Q_2$	if $DB, \theta, t \models Q_1$ and $DB, \theta, t \models Q_2$
$DB, \theta, t \models \neg Q_1$	if not $DB, \theta, t \models Q_1$
$DB, \theta, t \models \exists x_i.Q_1$	if there is a $\in D$ *such that* $DB, \theta[x_i \mapsto a], t \models Q_1$
$DB, \theta, t \models Q_1$ **since** Q_2	if $\exists t_2.t_2 < t$ and $DB, \theta, t_2 \models Q_2$ and $(\forall t_1.t_2 < t_1 < t$ implies $DB, \theta, t_1 \models Q_1)$
$DB, \theta, t \models Q_1$ **until** Q_2	if $\exists t_2.t_2 > t$ and $DB, \theta, t_2 \models Q_2$ and $(\forall t_1.t_2 > t_1 > t$ implies $DB, \theta, t_1 \models Q_1)$

Temporal Logic in Database Query Languages. Figure 2. The satisfaction relation for FOTL.

Extensions

Several natural extensions of FOTL are obtained by modifying various components of the language:

Multiple temporal contexts (multi-dimensional TLs). Standard temporal logics use a single *evaluation point* to relativize the truth of formulas with respect to time. However, there is no principled reason to not use more than one evaluation point simultaneously. The logics taking this path are called *multidimensional temporal logics* or, more precisely, *n-dimensional* temporal logics (for $n \geq 1$). The satisfaction relation is extended, for a particular n, in a natural way, as follows:

$$DB, \theta, t_1,\ldots,t_n \models Q$$

where $t_1,\ldots,t_n$ are the evaluation points. In a similar fashion the definitions of *temporal connectives* are extended to this setting. Two-dimensional connectives, for example, seem to be the natural basis for temporal logic-style query language for the bitemporal data model. Unfortunately, there is no consensus on the selection of two-dimensional temporal operators.

An interesting variant of this extension are *interval temporal logics* that associate truth with *intervals* – these, however, can be considered *pairs* of time points [5,13].

More complex time domains. While most temporal logics assume that the time domain is equipped with a linear order only, in many practical settings the time domain has additional structure. For example, there may be a way to refer to *duration* (the distance of two time points). The linear-order temporal connectives are then generalized to *metric temporal connectives*:

$$DB, \theta, t \models Q_1 \ \mathbf{since}_{\sim m}\ Q_2 \quad \text{if } \exists \mathrm{t}_2.\mathrm{t} - \mathrm{t}_2 \sim \mathrm{m}$$
and
$$DB, \theta, t_2 \models Q_2$$
and
$$(\forall t_1.t_2 < t_1 < t \text{ implies } DB, \theta, t_1 \models Q_1)$$

$$DB, \theta, t \models Q_1 \ \mathbf{until}_{\sim m}\ Q_2 \text{ if } \exists \mathrm{t}_2.\mathrm{t}_2 - \mathrm{t} \sim \mathrm{m}$$
and
$$DB, \theta, t_2 \models Q_2$$
and
$$(\forall t_1.t_2 < t_1 < t \text{ implies } DB, \theta, t_1 \models Q_1)$$

for $\sim \in \{<, \leq, =, \geq, >\}$. Intuitively, these connectives provide means of placing constraints on how far in the past/future certain subformulas must be true. The resulting logic is then the *Metric First-order Temporal Logic*, a first-order variant of *Metric Temporal Logic* [7].

Example. To demonstrate the expressive power of Metric Temporal Logic, consider the query Q_b: "*For every time instant, who has been in the room Bell 224 at that instant for at least 2 hours?*":

$$\exists r.\ ((\neg Exit(r,p))\ \mathbf{since}_{\geq 2:00}\ Entry(r,p)) \wedge r = \text{"Bell 224"}$$

More powerful languages for defining temporal connectives. Another extension introduces a more powerful *language* for specifying temporal connectives over the underlying linearly-ordered time domain. Vardi and Wolper show that temporal logics with connectives defined using first-order formulas cannot express various natural conditions such as "every other day". To remedy this shortcoming, they propose temporal connectives defined with the help of *regular expressions* (ETL [15]) or *fixpoints* (temporal μ-calculus [14]). Such extensions carry over straightforwardly to the first-order setting.

More complex underlying query languages. Last, instead of relational calculus, temporal connectives can be added to a more powerful language, such as Datalog. The resulting language is called Templog [2]. With suitable restrictions, query evaluation in this language is decidable and the language itself is equivalent to Datalog$_{1S}$ [2].

Expressive Power

The **since** and **until** temporal connectives can be equivalently defined using *formulas* in the underlying theory of linear order as follows:

$$\begin{aligned} X_1 \textbf{ since } X_2 \quad &:= \exists t_2.t_0 > t_2 \wedge X_2 \wedge \forall t_1 \\ &\quad (t_0 > t_1 > t_2 \rightarrow X_1) \\ X_1 \textbf{ until } X_2 \quad &:= \exists t_2.t_0 < t_2 \wedge X_2 \wedge \forall t_1 \\ &\quad (t_0 < t_1 < t_2 \rightarrow X_1) \end{aligned}$$

where X_1 and X_2 are *placeholders* that will be substituted with other formulas to be evaluated at the time instants t_1 and t_2, respectively. This observation indicates that every FOTL query can be equivalently expressed in TRC. The explicit translation parallels the inductive definition of FOTL satisfaction, uniformly parameterizing the formulas by t_0. In this way, an atomic formula $r(x_1,\ldots,x_k)$ (where r is a non-temporal snapshot relation) becomes $R(t_0, x_1,\ldots,x_k)$ (where R is a point-timestamped relation), and so on. For a particular t_0, evaluating $r(x_1,\ldots,x_k)$ in $DB(t_0)$, the snapshot of the database DB at t_0, yields exactly the same valuations as evaluating $R(t_0, x_1,\ldots,x_k)$ in DB. The embedding of the temporal connectives uses the definitions above. For example, the embedding of the **since** connective looks as follows:

$$\begin{aligned} &\text{Embed}(Q_1 \textbf{ since } Q_2) = \exists t_2(t_0 > t_2 \wedge \\ &\quad \forall t_0(t_2 = t_0 \rightarrow \text{Embed}(Q_2)) \wedge \\ &\quad \forall t_1(t_0 > t_1 > t_2 \rightarrow \forall t_0(t_1 = t_0 \rightarrow \text{Embed}(Q_1)))). \end{aligned}$$

Note that t_0 is the only free variable in Embed(Q_1), Embed(Q_2), and Embed(Q_1 **since** Q_2). Thus, in addition to applying the (first-order) definition of the temporal connective, the embedding performs an additional *renaming* of the temporal variable denoting the evaluation point for the subformulas, because the only free variable outside of the expanded temporal connectives must be called t_0.

Additional temporal connectives can be defined using the same approach, as formulas in the underlying theory of the temporal domain. However, for linear orders – the most common choice for such a theory – Kamp [6] has shown that all the connectives that are first-order definable in terms of linear order can be readily formulated using **since** and **until**.

In addition, it is easy to see on the basis of the above embedding that all FOTL queries (and their subqueries) define point-stamped temporal relations. This *closure property* makes FOTL amenable to specifying operators for temporal relational algebra(s) over the point-stamped temporal model. On the other hand, many, if not most, other temporal query languages, in particular various temporal extensions of SQL, are based on TRC and use temporal variables and attributes to explicitly access timestamps. These languages do not share the above closure property. Surprisingly, and in contrast to the propositional setting, one can prove that query languages based on FOTL are strictly weaker than query languages based on TRC [1,11]. The query

SNAPSHOT EQUALITY: "are there two distinct time instants at which a unary relation R contains exactly the same values?"

cannot be expressed in FOTL. On the other hand, SNAPSHOT EQUALITY can be easily expressed in TRC as follows:

$$\exists t_1, t_2.t_1 < t_2 \wedge \forall x.R(t_1, x) \;\Leftrightarrow\; R(t_2, x).$$

Intuitively, the subformula "$\forall x.R(t_1, x) \;\Leftrightarrow\; R(t_2, x)$" in the above query requires the simultaneous use of *two* distinct evaluation points t_1 and t_2 in the scope of a universal quantifier, which is not possible in FOTL. The result can be rephrased by saying that FOTL and other temporal query languages closed over the point-stamped temporal relations fail to achieve (the temporal variant of) Codd's completeness. In particular, there cannot be a temporal relational algebra over the (single-dimensional) point-stamped temporal model that can express all TRC queries.

In addition, this weakness is inherent to other languages with *implicit access* to timestamps, provided the underlying time domain is a linear order. In particular:

1. Adding a finite number of additional temporal connectives defined in the theory of linear order (including constants) is not sufficient for expressing SNAPSHOT EQUALITY [11];
2. Introducing *multidimensional temporal connectives* [4], while sufficient to express SNAPSHOT EQUALITY, is still not sufficient to express all TRC queries [10]. This also means that in the bitemporal model, the associated query languages cannot simultaneously preserve closure with respect to bitemporal relations and be expressively equivalent to TRC;
3. Using temporal connectives that are defined by fixpoints and/or regular expressions (see the earlier discussion) is also insufficient to express SNAPSHOT EQUALITY. Due to their non-first-order nature, the resulting query language(s) are incomparable, in terms of their expressive power, to TRC [1].

The only currently known way of achieving first-order completeness is based on using temporal connectives defined over a time domain whose structure allows the definition of pairing and projections (e.g., integer arithmetic). In this way temporal connectives can use pairing to simulate an unbounded number of variables and in turn the full TRC. However, such a solution is not very appealing, as the timestamps in the intermediate temporal relations do not represent time instants, but rather (encoded) tuples of such instants.

Key Applications

The main application area of FOTL is in the area of temporal integrity constraints. It is based on the observation that a sequence of relational database states resulting from updates may be viewed as a snapshot temporal database and constrained using Boolean FOTL formulas. Being able to refer to the past states of the database, temporal logic constraints generalize dynamic constraints. Temporal logic is also influential in the area of design and analysis of temporal query languages such as temporal relational algebras.

Temporal Logical Models

Arie Shoshani

Synonyms

Historical data models

Definition

Temporal logical models refer to the logical structure of data that captures the temporal behavior and operations over such structures. The term "logical" is used to distinguish such temporal structures form the physical storage organization and implementation. For example, the behavior of temporal events and operations over them can be described logically in a way that is independent of the physical structure (e.g., linked lists) or indexing of the events. Temporal logical models include concepts of data values that are collected or are changed over time, such as continuous physical phenomena, a series of discrete events, and interval data over time. The challenge is one of having a single comprehensive model that captures this diversity of behavior.

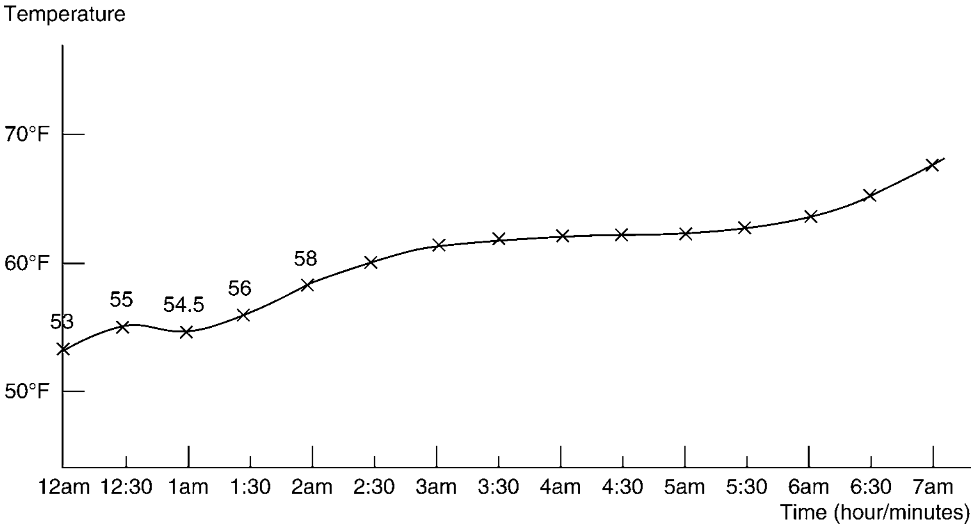
Historical Background

In the 1980s, several researchers focused on dealing with temporal data, both on the modeling concepts and on physical organization and indexing of temporal data. This led to the temporal database field to be established, and several books were written or edited on the subject (for example [4,5,12]). Since then, the subject continues to appear in specific application domains, or in combination with other concepts, such as spatio-temporal databases, and managing streaming data.

Foundations

The Treatment of Time in Database Systems

Time is a natural part of the physical world and an indispensable part of human activity, yet many database models treat temporal behavior as an afterthought. For example, weather (temperature, clouds, and storms) is a continuous phenomenon in time, yet it is treated as discrete events per day or per hour. In contrast, some human activities are fundamentally discrete events, such as salary which may change annually, but are treated as continuous concepts, where the salary is the same for the duration between the discrete events of salary changes. The main reason for the inconsistent treatment of time is that temporal objects and their semantics are not explicit in the data model. Consider for example, temperature measurements at some weather station as shown in Fig. 1. These are represented in conventional database systems (such as relational data models) as a two-part concept of time-of-measurement and value-of-measurement attributes, but the fact that the measurements are taken at evenly spaced intervals (e.g., every half an hour) and that the temperature represents a continuous



Temporal Logical Models. Figure 1. Continuous behavior of temperature measurements.

phenomenon is not captured. Consequently, if one asks what the temperature was at 12:35A.M, no such value exists. Furthermore, the interpolation function associated with getting this value is unknown. It could be a simple weighted averaging of the two nearest values, or a more sophisticated curve interpolation function.

Temporal Data Behavior

Temporal logical models are models designed to capture the behavior of temporal data sequences. First, some examples that illustrate the concepts that need to be captured by the model are presented.

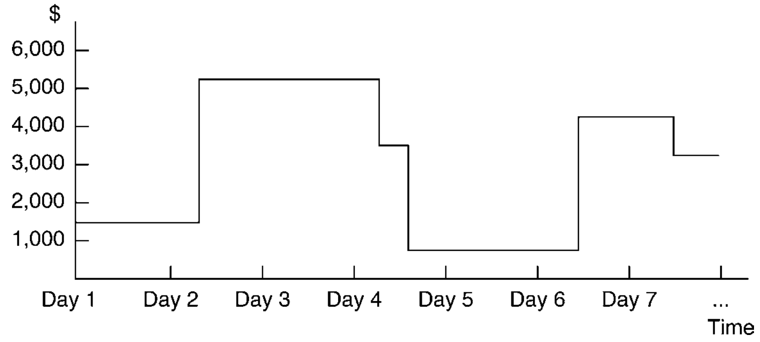
Example 1: wind velocity. Usually, the measurements of wind velocity are taken by devices at regular time periods, for example every hour. These are referred to as "time series." In this example, the measured quantity is not a single value, but has a more complex structure. It measures the direction of the wind and the velocity of the wind, which can be represented as a three-dimensional vector. The measured phenomenon is continuous, of course, but for this application it is determined by the database designers that a certain time granularity for queries is desired, such as values by minutes. Since the values are collected only hourly, an interpolation function must be provided and associated with this time sequence. The behavior is similar to the temperature behavior shown in Fig. 1, except that the measured values are three-dimensional vectors for each time point.

Example 2: bank account. The amount of money in the bank account changes when transactions take place. Money can be added or taken out of the account at irregular times. The value of the account is the same for the duration of time between transactions. This is shown in Fig. 2, where the granularity of the time points is in minutes. Note that the days shown should have precise dates in the database. Another aspect in this example is that in the case of a deposit of a check, funds may not be available until the check clears. Thus, there are two times associated with the deposit, the time of the transaction, and the time when funds are made available.

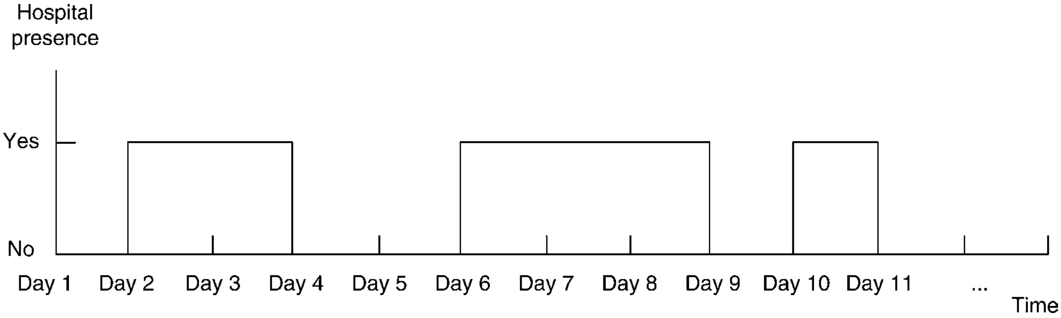
Example 3: hospitalization visits. Hospital visits of an individual occur typically at irregular times, and each can last a period of time, usually measured in days. The value associated with the hospital visit time sequence is Boolean; that is, only the fact that a visit took place or did not. This is an example where the concept of an interval must be represented in the data model. This is shown in Fig. 3, where the granularity is a day, and the interval durations span days. Here again, the days shown will have to have precise dates in the database.

Example 4: store revenue. Suppose that a store owner wishes to keep in a database the total revenue per day. The time sequence is regular, i.e., a time series (not counting days when the store is closed). The values per day do not represent continuous phenomena, but rather they are discrete in time, collected every day at the end of that day. This is the same as representing discrete events, such as the time of an accident, etc. In general, it does not make sense to apply interpolation to such a time sequence. However, if some data are missing, an interpolation rule could be used to infer the missing values. This is shown in Fig. 4. This is a time series, because only the days of business are shown (Monday – Friday).

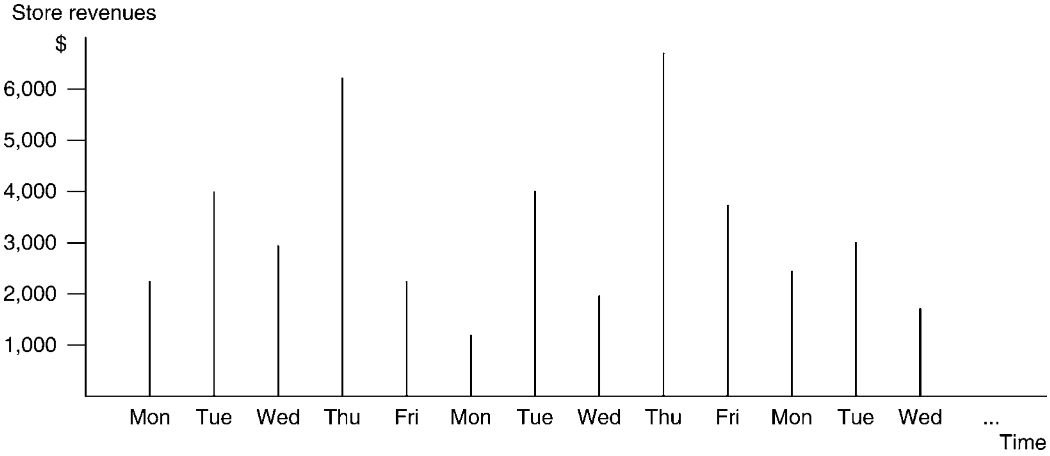
In the example above, only a single time sequence is shown, but there could be a collection of related time sequences. For example, time sequences of the quantity of each item sold in a store. For each item, there is a



Temporal Logical Models. Figure 2. Step-wise constant behavior of a bank account.



Temporal Logical Models. Figure 3. Interval behavior of hospital visits.



Temporal Logical Models. Figure 4. Discrete behavior of store revenues.

time sequence. However, all time sequences in this case have the same behavior, and they are collected in tandem per day. Such groups of related time sequences are referred to as "time sequence collections" [11]. As is discussed later, this concept is important for operations performed over collections of time sequences.

Behavioral Properties of Temporal Sequences

As is evident from the above examples, there are certain properties that can be specified to capture the logical behavior of temporal sequences. If such properties were supported by database systems, it is only necessary in such systems to store temporal data as time-value pairs in the general case, or simply ordered sequences of values for time series. These properties are discussed next, along with the possible category values they can assume.

Time-granularity: value and unit

The time-granularity indicates the time points for which data values can exist in the model. It is the smallest unit of time measure between time points in the time sequence. For example, if deposits and withdrawals to a bank account can be recorded with a minute precision, then the time granularity is said to be a minute. However, in cases where data values can be interpolated, an interpolation-granularity needs to be specified as well. For example, the temperatures shown in Fig. 1 are recorded every half an hour, and therefore the time granularity is 30 minutes, but given that values can be interpolated up to a minute precision, it is necessary to specify that the interpolation-granularity is a minute. This point is discussed further below in the section on "interpolation rule." Note that for regular time sequences (time series), it is often necessary to describe the origin of the time sequence, and the time granularity is relative to that origin. A formal treatment of time granularity can be found in [1].

1) Regularity: regular (time series), irregular

As mentioned above time series are regular sequences. They can be described by specifying the "time-step" between the time points. The time-step together with the "life span" (described next) specify fully the time points for which data values are expected to be provided. Because of its regular nature, it is not necessary to store the time points in the databases – these can be calculated. However, this is a physical implementation choice of the system, and the time values can be stored explicitly to provide faster access. Time series are prevalent in many applications, such as statistics gathering, stock market, etc.

Irregular time sequences are useful for event data that occurs in unpredictable patterns, such as bank withdrawals, visits to the library, or making a phone call. A typical phenomena in such sequences, is that most of the time points have no values associated with them. For example, suppose that the time granularity for recording phone calls is a minute. The time sequence of phone calls will typically be mostly empty (or null). For this reason, irregular time sequences are usually represented as time-value pairs in the database.

Life span: begin-time, end-time

The life span indicates for what period of time the time sequence is valid. The begin-time is always necessary, and has to be specified with the same precision of the time granularity. For example, if for the temperature time series in Fig. 1, the begin-time was January 1, 1:15 A.M, and the granularity was 30 minutes, then the time points will be 1:15 A.M, 1:45 A.M, 2:15 A.M, etc.

The life span end-time can be specified as "open-ended." That means that this time series is active.

Behavior type: continuous, step-wise-constant, interval, discrete.

These types were illustrated in the examples of the previous section. For example 1, on wind velocity, the type is continuous. For example 2, the amount available in a bank account, the type is step-wise-constant. For example 3, of hospital visits, the type is interval. For example 4, the store revenues per day, the type is discrete. Note that the interval type can be considered as a special case of step-wise-constant type having the Boolean values (0 or 1). Another thing worth noting is that discrete time sequences cannot be associated with an interpolation rule. The interpolation rules for the other types are discussed next.

Interpolation rule: interpolation-granularity, interpolation-function.

The interpolation-granularity has to be specified in order for the underlying system to enforce the data points for which interpolation can be applied in response to queries. Note that the interpolation-granularity has to be in smaller units than the time-granularity, and the number of interpolation-granularity points in a time-granularity unit must be an integer. For example, while temperature in the example of Fig. 1 has time-granularity of 30 minutes, the interpolation-granularity can be 5 minutes.

The interpolation-function for the step-wise-constant and interval types are straightforward, and are implied by the type. But, for a continuous type, an interpolation-function must be specified. It should be possible to provide the system with such a function for each continuous time sequence. If no interpolation-function is provided, the system can use a default function.

Value type: binary, numeric, character, multi-valued, etc.

This property of temporal sequences is no different from specifying attribute types in conventional database systems. The case of a binary type is special to interval events, and is not always supported by conventional system. Also, multi-valued or multi-component attributes are special requirements for more sophisticated time sequences that exist in scientific data, such as the wind velocity in example 2.

Transaction vs. valid time: transaction, valid

Similar to the bank account in example 2 where the deposit time was different from the time when funds are available, there are many examples where temporal data are recorded in the database before the data values are valid. This concept was explored extensively in [13], and referred to as "transaction time" and "valid time." Actually, there are situations where the transaction time can occur after the valid time for retroactive cases. For example, a salary raise can be added to a database in March of some year, but is retroactive to January of that year. This concept has led to an extensive literature on representing it as an extension of query languages, including a temporal extension to the SQL query language, referred to as TSQL [12]. It is worth noting that other concepts of multiple temporal dimensions were also introduced in the literature, in addition to transaction and valid times. For example, [3] introduced the concept of "event time" – times of the events that initiates and terminates the interval validity, and "availability time" – the time interval during which facts are available.

If multiple temporal dimensions are needed in the model, they can be thought of as multiple correlated time sequences. However, in general, each time dimension can have different properties. For example, the transaction time sequence for bank deposits can have a granularity of a minute, while the valid time for the available funds can be daily.

Operation over Temporal Data

Because of the inherent time order of temporal data, operations over them, such as "when," "preceding," "following," etc. are based on the time order. Similarly, the concept of a "time window" is natural. Various researchers have developed precise semantics to query languages by adding temporal operators to existing query languages, including relational query languages, such as SQL, relational algebras, such as QUEL, functional query languages, such as DAPLEX, deductive query languages, such a Datalog, and entity-relationship languages. Many such examples can be found in the books on temporal databases [4,5]. In order to explain the various operators, they are classified into the following four categories.

Predicate Operators Over Time Sequences Predicate operators refer to either specific times or a time interval. For specific times, the obvious predicates include "before," "after," "when," etc. But, in addition, there are operators that refer to the life span, such as "first, and "last." For time intervals, operators such as "during" or "interval" are used. Also, when specifying an interval, the keyword "now" is used to refer to time sequences that are active, such as "interval" (Jan 01, 2007, now). Note that the time values used must be expressed at the granularity of the time sequence (or the interpolation-granularity if interpolation is allowed). In some time sequences, it is useful to use an integer to refer to the nth time instance, such as t-33 to mean the 33rd time point in the time sequence. However, this is not included in most proposed query languages.

Another purpose of predicate operators is to get back the time periods where some condition on the data values hold. For example, suppose that a time sequences represents temperature at some location. The query "get periods where temperature >100" (the units are Prof.F) will return a (Boolean) interval time sequence, where the temperature was greater than 100. Note that "periods" is treated as a keyword.

Aggregation Operators Over Time Windows The usual statistical operators supported by database systems (sum, count, average, min, max) can be applied to a specific time window (t_begin, t_end), to the entire time sequence (first, last), or to the combinations (first, t_end), (t_begin, last). In general, "first" or "last" can be substituted by an instance number, such as "t-33" mentioned above. Here, again, the time has to be specified in the granularity of the time sequence.

Another way to apply operators over windows is to combine that with the "group by" concept. This is quite natural for temporal sequence that involve calendar concepts of month, day, minute, second, etc. For example, suppose that a time sequence represents daily sales. One can have a query "sum sales by month." This is the same as asking for multiple windows, each over the days in each month.

Aggregation Operators Over Time Sequence Collections In a typical database, time sequences are defined over multiple object instances. For example, one can have in an organization the salary history of all of its employees. Asking for the "average salary over all employees" over time requires the average operation to be applied over the entire collection of time sequences. This operation is not straight forward if all salary raises do not occur at the same time. This operation will generate a time sequence whose time points are the union of all the time points of the time sequences, where the average values are performed piecewise on the resulting intervals.

Similar to the case of aggregation over time windows, where the "group by" operation can be applied, it is possible to group by object instances in this case. For example, if employees are organized by departments, one can ask for "average salary over all employees per department."

Composition of Time Sequences Composition refers to algebraic operations over different time sequences. For example, suppose that in addition to salary history recorded for each employee in an organization, the history of commissions earned is recorded. In order to obtain "total income," the salary and the commission time sequences have to be added for each employee. This amounts to the temporal extension of algebraic operations on multiple attributes in non-temporal query languages.

Combinations of the Above Operators It is conceptually reasonable to combine the above operators in query languages. For example, it should be possible to have the aggregation and composition operators applied only to a certain time window, such as getting the "average salary over all employees for the last three years." Furthermore, it should be possible to apply a temporal operator to the result of another temporal operator. This requires that the result of operations over time sequences is either a time sequence or a scalar. If it is a time sequence, temporal operators can be applied. If it is a scalar (a single value) it can be applied as a predicate value. This requirement is consistent with other languages, such as the relational language, where the operation on relations always generates a relation or a scalar.

Additional Concepts There are many concepts introduced in the literature that capture other logical aspects of temporal operations and semantics. This broad literature cannot be covered here; instead, several concepts are mentioned next. Temporal specialization and generalization are explored in [6]. Unified models for supporting point-based and interval-based semantics are developed in [2,14]. It is argued in [8] that temporal data models have to include explicitly the concept of ordered data, and a formal framework for that is proposed. A single framework for supporting both time series and version-based temporal data are developed in [9]. There are also many papers that discuss how to efficiently support temporal operations (such as aggregation), see for example [7,10]. Finally, in the context of streaming data, temporal aggregation operations on time windows have in explored – see entries on "stream data management" and "stream mining."

Key Applications

Temporal data are ubiquitous. It naturally exists in applications that have time series data, such as stock market historical data, or history of transactions in bank accounts. In addition, it is a basic requirement of scientific databases collecting data from instruments or performing simulation over time steps. In the past, many databases contained only the current (most updated) data, such as current salary of employees, current inventories in a store or a warehouse, etc. The main reason for that was the cost of storage and efficiency of processing queries. One could not afford keeping all the historical data. More recently, as the cost of storage is plummeting, and compute engines are faster and can operate in parallel, historical data are routinely kept. While it is still worth keeping a version of current data for some applications for efficiency of access, many applications now use historical data for pattern and trend analysis over time, especially in data warehouse applications.

Future Directions

While a lot of research was done on temporal data, the concepts and operations over such data are only partially supported, if at all, in commercial and open source database system. Some support only the concept of date_time (it is complex enough, crossing time zones and century boundaries), but the support for properties of time sequences and operations over them are still not generally available. Building such database systems is still a challenge.

Temporal Object-Oriented Databases

Carlo Combi
University of Verona, Verona, Italy

Definition

In a strict sense, a temporal object-oriented database is a database managed by an object-oriented database system able to explicitly deal with (possibly) several temporal dimensions of data. The managed temporal dimensions are usually valid and/or transaction times. In a wider sense, a temporal object-oriented database is a collection of data having some temporal aspect and managed by an object-oriented database system.

Historical Background

Research studies on time, temporal information, and object-oriented data started at the end of 1980s and continued in the 1990s. From the seminal work by Clifford and Croker on objects in time [4], several different topics have been discussed. Segev and Rose studied both the modeling issues and the definition of suitable query languages [12]; Wuu and Dayal showed how to use an object-oriented data model to properly represent several temporal aspects of data [14]; Goralwalla et al. studied the adoption and extension of an object-oriented database system, TIGUKAT, for managing temporal data, and finally proposed a framework allowing one to classify and define different temporal object-oriented data models, according to the choices adopted for representing time concepts and for dealing with data having temporal dimensions [8]. Schema evolution in the context of temporal object-oriented databases has been studied by Goralwalla et al. and by Edelweiss et al. [6,9]. Bertino et al. studied the problem of formally defining temporal object-oriented models [1] and, more recently, they proposed an extension of the ODMG data model, to deal with temporalities [2]. Since the end of 1990s, research has focused on access methods and storage structures, and on temporalities in object relational databases, which, in contrast to object-oriented databases, extend the relational model with some object-oriented features still maintaining all the relational structures and the related, well studied, systems. As for the first research direction, for example, Norvag studied storage structures and indexing techniques for temporal object databases supporting transaction time [10]. Recently, some effort has been done on extending object-relational database systems with some capability to deal with temporal information; often, as in the case of the work by Zimanyi and colleagues, studies on temporalities in object-relational databases are faced in the context of spatio-temporal databases, where temporalities have to be considered together with the presence of spatial information [15]. In these years, there were few survey papers on temporal object-oriented databases, even though they were considered as a part of survey papers on temporal databases [11,13]. Since the 1990s, temporal object-oriented databases have also been studied in some more application-oriented research efforts: among them are temporal object models and languages for multimedia and for medical data, as, for example, in [5,7].

Foundations

Object-oriented (OO) methodologies and technologies applied to the database field have some useful features – abstract data type definition, inheritance, complex object management – in modeling, managing, and storing complex information, as that related to time and to temporal information. Objects and times have, in some sense, a twofold connection: from a first point of view, complex, structured types could be suitably defined and used to manage both complex time concepts and temporal dimensions of the represented information; on the other side, object-oriented data models and languages may be suitably extended with some built-in temporal features. In the first case, the object-oriented technology is performed to show that complex concepts, as those related to time and temporal information, can be suitably represented and managed through types, generalization hierarchies, and so on. In the second case, the focus is slightly different and is on extending object-oriented models and languages to consider time-related concepts as first-class citizens: so, for example, each object, besides an object identifier, will have a lifespan, managed by the system.

Even though different approaches and proposals in the literature do not completely agree on the meaning of different terms used by the "object-oriented" community, there is a kind of agreement on the basic concepts of any object-oriented data model. An *object* may represent any entity of the real world, e.g., a patient, a therapy, a time interval. The main feature of an object is its *identity*, which is immutable, persists during the entire existence of the object, and is usually provided by the database system through an identifier, called OID (Object IDentifier). An object is characterized by a state, described by properties (*attributes* and *associations* with other objects) and by a behavior, defined by *methods*, describing modalities, by which it is possible to interact with the object itself. Objects are created as instances of a *type*; a *class* is the collection (also named *extent*) of all the objects of a given type stored into the database at a certain moment. A *type* describes (i) the structure of properties through attributes and associations, and (ii) the behavior of its instances through methods applicable to objects instances of that type.

To introduce the faced topics, a simple clinical database is used, storing data on symptoms and therapies of patients and will graphically represent its schema through the well-known UML notation for class diagrams, adopting the primitive types provided by the ODMG data model [3].

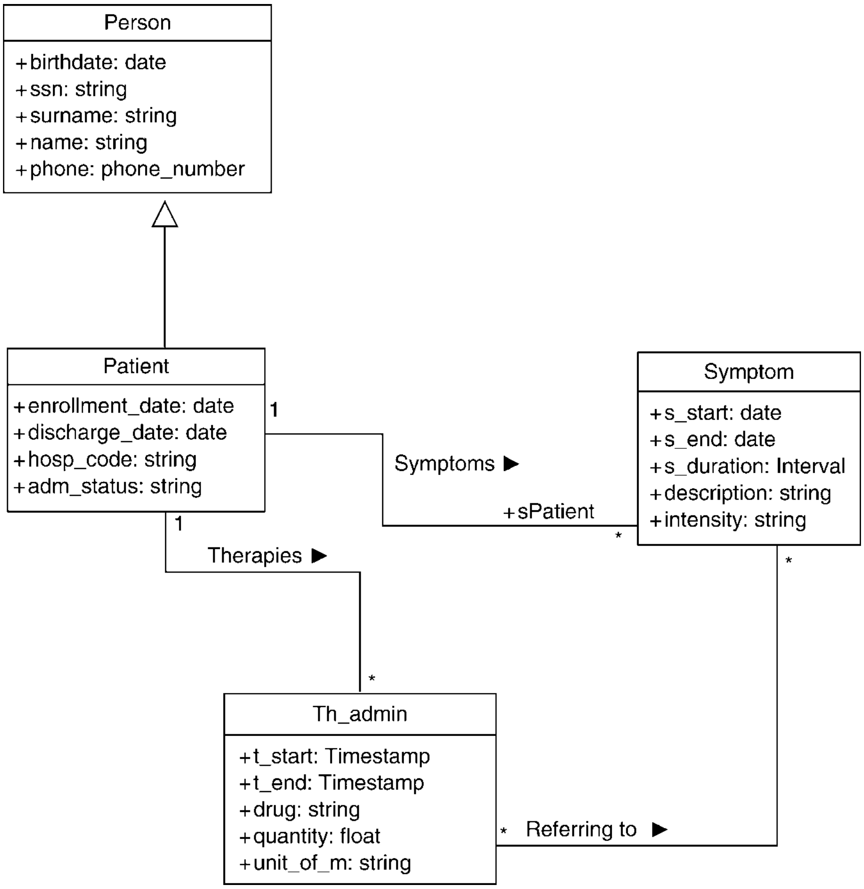
Time and Abstract Data Types

Through suitable abstract data types (ADTs), it is possible to represent several and different features of time primitives; more specifically ADTs can be suitably used to represent anchored (i.e., time points and time periods) and unanchored (i.e., durations) temporal primitives. Usually, any OO database system allows one to define ADTs, which can be possibly used to represent complex temporal concepts; moreover, any database system usually provides several built-in primitive and complex data types, allowing the user to represent the most usual time concepts.

Considering, for example, the clinical database depicted in Fig. 1, it is possible to observe different data types for time; according to the ODMG data model, the types Date and Timestamp represent time points corresponding to days and to seconds, respectively, while the type Interval stands for spans of time, i.e., distances between two time points.

According to this approach, as underlined by Wuu and Dayal [14], different types of time could be defined, starting from some general concept of time, through aggregation and generalization. For example, the ODMG type Timestamp could be viewed as a specialization of a supertype Point, having two operations defined, i.e., those for comparisons (= and >), as its behavior. Various time types can be defined as subtypes of Point. The two operations defined for Point are inherited, and could be suitably redefined for different subtypes. Indeed, properties of specific ordering relationships determine different time structures, e.g., total vs. partial, or dense vs. discrete. Moreover, through the basic structured types provided by the model, it is possible to build new types for time concepts. As an example, it could be important to specify a type allowing one to represent periods of time; this way, it is possible to represent in a more compact and powerful way the periods over which a therapy has been administered, a symptom was holding, a patient was hospitalized. Thus, in the database schema a new type Period will be used as part of types Patient, Th_admin, and Symptom, as depicted in Fig. 2.

ADTs may be used for managing even more complex time concepts [5], allowing one to deal with times given at different granularities or with indeterminacy in a uniform way.



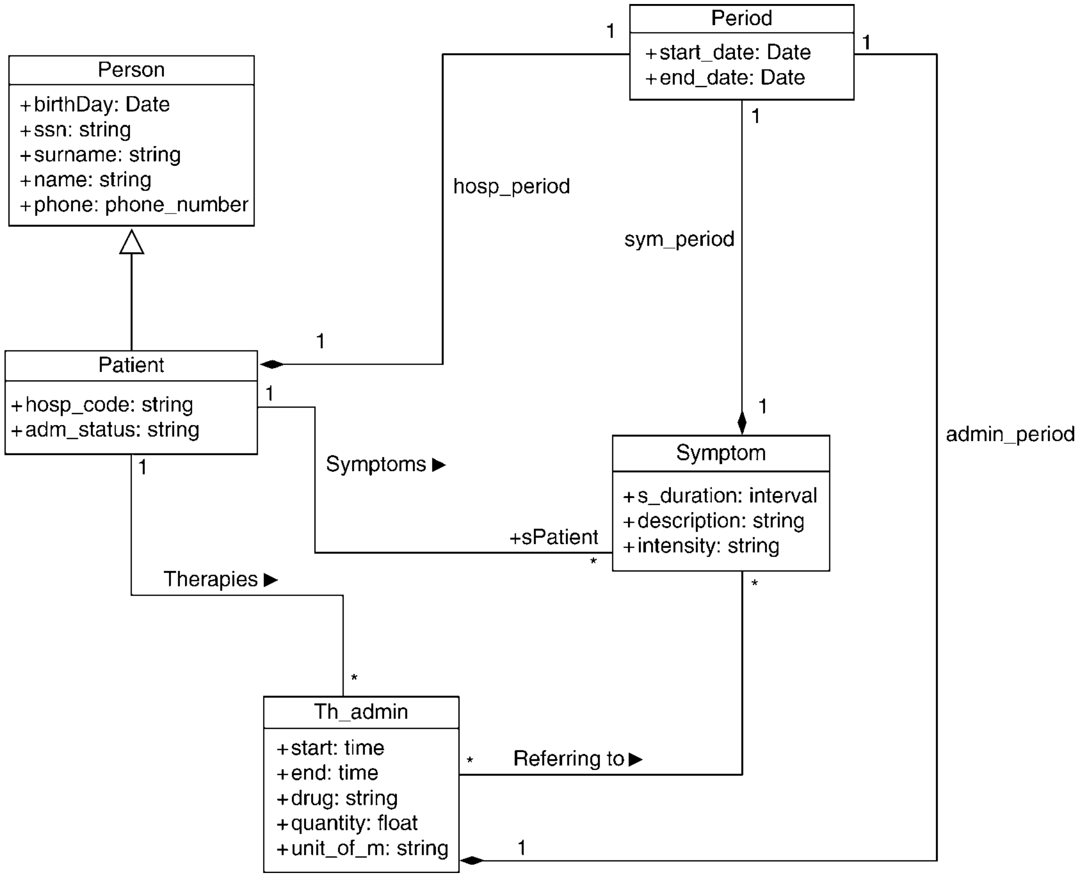
Temporal Object-Oriented Databases. Figure 1. Object-oriented schema of the database about patients' symptoms and therapies, using ODMG standard time types.

Temporal Object Data Models

Up to this point, the proposed solutions just use ADTs to represent complex time concepts; the sound association of time to objects for representing temporal data, i.e., time evolving information, according to the well-known temporal dimensions, such as valid and/or transaction times, is left to the user. Focusing, without loss of generality, on valid time, in the given example the semantics of valid time must be properly managed by the application designer, to check that symptoms occurred and therapies were administered when the patient was alive, that therapies related to symptoms were administered after that symptoms appeared, that there are no different objects describing the same symptom with two overlapping periods, and so on.

Managing this kind of temporal aspects in object databases has been the main focus of several research studies [13]: the main approaches adopted in dealing with the temporal dimension of data in object-oriented data models are (i) the direct use of an object-oriented data model (sometimes already extended to deal with other features as version management), and (ii) the modeling of the temporal dimensions of data through ad-hoc data models. The first approach is based on the idea that the rich (and extensible) type system usually provided by OO database systems allows one to represent temporal dimensions of data as required by different possible application domains. The second approach, instead, tries to provide the user with a data model where temporal dimensions are first-class citizens, avoiding the user the effort of modeling from scratch temporal features of data for each considered application domain.

General OO Models Using OO Concepts for Modeling Temporal Dimensions Among the proposed object-oriented systems able to deal with temporal

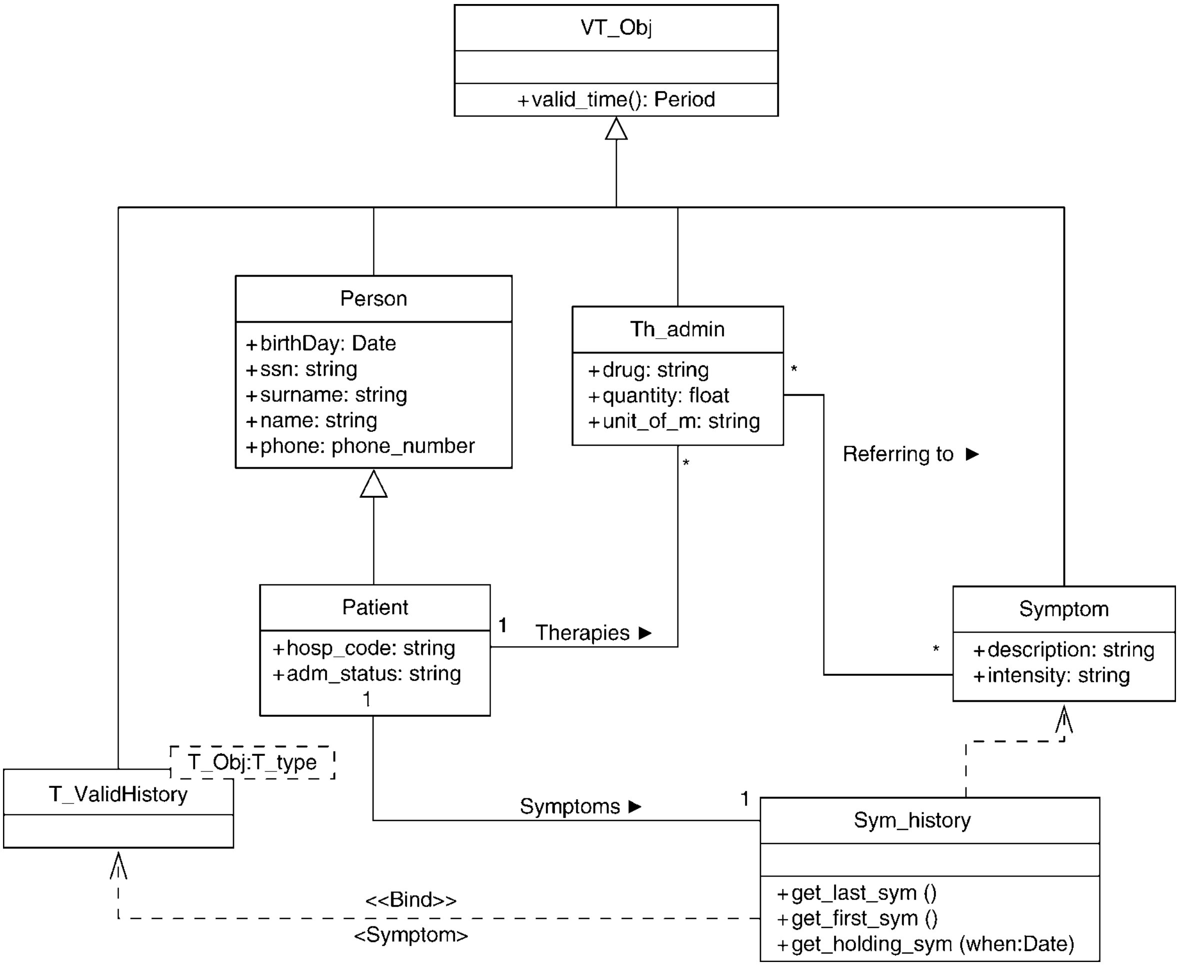


Temporal Object-Oriented Databases. Figure 2. Object-oriented schema of the database about patients' symptoms and therapies, introducing the type Period.

information, OODAPLEX and TIGUKAT adopt the direct use of an object-oriented data model [7,14]. In these systems suitable data types allow the database designer to model temporal information. For example, TIGUKAT models the valid time at the level of objects and of collections of objects. More particularly, for each single application it is possible to use the rich set of system-supported types, to define the real semantics of valid (or transaction) time.

According to this approach, the example database schema could be modified, to manage also the valid time semantics: as depicted in Fig. 3, objects having the valid time dimension are explicitly managed through the type VT_Obj, the supertype of all types representing temporal information, while the type Sym_History, based on the (template) type T_valid History is used to manage the set of objects representing symptoms.

OO Models Having Explicit Constructs for Temporal Dimensions of Data Besides the direct use of an OO data model, another approach which has been widely adopted in dealing with the temporal dimension of data by object-oriented data models consists of temporally-oriented extensions, which allow the user to explicitly model and consider temporal dimensions of data. As an example of this approach, Fig. 4 depicts the schema related to patients' symptoms and therapies: the temporal object-oriented data model underlying this schema allows one to manage the valid time of objects, often referred to as *lifespan* in the object-oriented terminology (this aspect is represented through the stereotype temporal and the operation lifespan() for all types); moreover, the temporal model allows the designer to specify that attributes within types can be time-varying according to different granularities: for example, the intensity of a symptom



Temporal Object-Oriented Databases. Figure 3. Object-oriented schema of the database about patients' symptoms and therapies, modeling temporal dimensions through suitable types.

may change over time. Finally, temporalities can be represented even for associations, specifying the granularity to consider for them. Several constraints can be defined, and implicitly verified, when defining a temporal object-oriented data model. For example, in this case, any object attribute could be constrained to hold over some subinterval of the lifespan of the considered object: $\forall o \in$ Symptom (o.intensity.$VT() \subseteq o$.lifespan()), where $VT()$ returns the overall period over which the (varying) values of a temporal attribute have been specified. In a similar way, a temporal relationship is allowed only when both the related objects exist. As for the inheritance, objects could be allowed to move from some supertype to a subtype during their existence; the constraint here is that their lifespan as instances of a subtype must be a subinterval of their lifespan as instances of a supertype: $\forall o \in$ Patient (o.lifespan() $\subseteq$ ((Person)o).lifespan())

Temporal Object Query Languages

According to the approaches for object-oriented data models dealing with temporal information, even when querying temporal data, it is possible to either adopt a generic object-oriented query language and use directly its constructs for temporal data or extend an (atemporal) query language with some ad-hoc keywords and clauses to deal with temporal data in a more powerful and expressive way [3,5,12]. For both the approaches, the main focus is on querying data: data definition and data manipulation are usually performed through the object-oriented language provided by the database system [5].

Temporal Object-Oriented Database Systems

Usually, temporal object-oriented database systems, offering a temporal data model and a temporal query language, are realized on top of object-oriented database systems, through a software layer able to translate temporalities in data and queries into suitable data structures and statements of the underlying OO system [5]. According to this point of view, only recently some studies have considered technical aspects at the physical data level; among them it is worth mentioning here the indexing of time objects and storage architectures for transaction time object databases [10].

Key Applications

Clinical database systems are among the applications of temporal object-oriented databases, i.e., the real world databases where the structural complexity of data needs for the object-oriented technology. Indeed, clinical database systems have to manage temporal data, often with multimedia features, and complex relationships among data, due both to the healthcare organization and to the medical and clinical knowledge. Attention in this field has been paid on the management of clinical data given at different granularities and with indeterminacy [5,7]. Another interesting application domain is that of video database systems, where temporal aspects of object technology have been studied for the management of temporal aspects of videos. Complex temporal queries have been studied in this context, involving spatio-temporal constrains between moving objects.

Future Directions

New and more intriguing topics have attracted the attention of the temporal database community in these last years; however, the results obtained for temporal object-oriented databases could be properly used in different contexts, such as that of temporal object-relational databases, which seem to attract also the attention of the main companies developing commercial database systems, and that of semi-structured temporal databases, where several OO concepts could be studied and extended to deal with temporalities for partially structured information (as that represented through XML data).

Temporal Periodicity

Paolo Terenziani
University of Turin, Turin, Italy

Definition

Informally, *periodic events* are events that repeat regularly in time (e.g., each Tuesday), and *temporal periodicity* is their temporal *periodic pattern* of repetition. A pattern is *periodic* if it can be represented by specifying a finite portion of it, and the duration of each repetition. For instance, supposing that day 1 is a Monday, the pair <*'day 2,' '7 days'*> may implicitly represent all Tuesdays.

A useful generalization of periodic patterns are *eventually* periodic ones, i.e., patterns that can be expressed by the union of a periodic pattern and a finite non-periodic one.

The above notion of periodic events can be further extended. For instance, Tuzhilin and Clifford [14] distinguish between *"strongly"* periodic events, that occur at equally distant moments in time (e.g., a class, scheduled to meet once a week, on Wednesday at 11A.M), *"nearly periodic"* events, occurring at regular periods, but not necessarily at equally distant moments of time (e.g., a meeting, that has to be held once a week, but not necessarily on the same day), and *"intermittent"* events, such that if one of them occurred then the next one will follow some time in the future, but it is not clear when (e.g., a person visiting "periodically" a pub). Most of the approaches discussed in the following cope only with "strongly" periodic events.

Finally, it is worth highlighting that "(periodic) temporal granularity," "calendar," and "calendric system" are notions closely related to temporal periodicity.

Historical Background

Temporal periodicity is pervasive of the world all around us. Many natural and artificial phenomena take place at periodic time, and temporal periodicity seems to be an intrinsic part of the way humans approach reality. Many real-world applications, including process control, data access control, data broadcasting, planning, scheduling, multimedia, active databases, banking, law and so on need to deal with periodic events. The problem of how to store and query periodic data has been widely studied in the fields of databases, logic, and artificial intelligence.

In all such areas it is widely agreed that, since many different data conventions exist, a pre-defined set of periodicities would not suffice. For instance, Snodgrass and Soo [12] have emphasized that the use of a calendar depends on the cultural, legal, and even business orientation of the users, and listed many examples of different calendric systems. As a consequence, many approaches to *user-defined* temporal periodicity have been proposed. The core issue is the definition of expressive *formal languages* to *represent* and *query* user-defined temporal periodicity. In particular, an *implicit* representation [2] is needed, since it allows one to cope with data holding at periodic times in a compact way instead of explicitly listing all the instances (extensions) of the given periodicity (e.g., all "days" in a possibly infinite frame of time). Additionally, also the *set-theoretic operations* (intersection, union, difference) on definable periodicities can be provided (e.g., in order to make the formalism a suitable candidate to represent periodic data in temporal databases). Operationally, also *mapping functions* between periodicities are an important issue to be taken into account.

Within the database community, the problem of providing an implicit treatment of temporal periodicity has been intensively investigated since the late 1980s. Roughly speaking, such approaches can be divided into three mainstreams (the terminology is derived from Baudinette et al. [2] and Niezette and Stevenne [9]):

(1) *Deductive rule*-based approaches, using deductive rules. For instance, Chomicki and Imielinsky [4] dealt with periodicity via the introduction of the successor function in Datalog;
(2) *Constraint*-based approaches, using mathematical formulae and constraints (e.g., [6]);
(3) *Symbolic* approaches, providing symbolic formal languages to cope with temporal periodicity in a compositional (and hopefully *natural* and *commonsense*) way (consider, e.g., [9,8]).

Tuzhilin and Clifford [14] have proposed a comprehensive survey of many works in such mainstreams, considering also several approaches in the areas of logics and of artificial intelligence.

Foundations

In the following, the main features of the three mainstreams mentioned above are analyzed.

Deductive Rule-Based Approaches

Probably the first milestone among *deductive rule-based* approaches is the seminal work by Chomicki and Imielinski [4], who used Datalog_{1S} to represent temporal periodicity. Datalog_{1S} is the extension to Datalog with the successor function. In their approach, *one* temporal parameter is added to Datalog_{1S} predicates, to represent time. For instance, in their approach, the schedule of backups in a distributed system can be represented by the following rules:

$$\mathrm{backup}(T + 24, X) \leftarrow \mathrm{backup}(T, X)$$

$$\mathrm{backup}(T, Y) \leftarrow \mathrm{dependent}(X, Y),\ \mathrm{backup}(T, X)$$

The first rule states that a backup on a machine should be taken every 24 hours. The second rules requires that all backups should be taken simultaneously on all dependent machines (e.g., sharing files). Of course, Datalog_{1S} programs may have infinite least Herbrand models, so that infinite query answers may be generated. However, in their later works Chomicki and Imielinski have provided a finite representation of them.

Another influential rule-based approach is based on the adoption of Templog, an extension of logic programming based on temporal logic. In this language, predicates can vary with time, but the time point they refer to is defined implicitly by temporal operators rather than by an explicit temporal argument [2]. Specifically, three temporal operators are used in Templog: *next*, which refers to the next time instant, *always*, which refers to the present and all the future time instants, and *eventually*, which refers to the present or to some future time instant.

Constraint-Based Approaches

While deductive rule-based approaches rely on deductive database theory, the approaches of the other mainstreams apply to relational (or object-oriented) databases.

Kabanza et al. [6] have defined a *constraint-based* formalism based on the concept of *linear repeating points* (henceforth lpr's). A lrp is a set of points {x(n)} defined by an expression of the form x(n) = c + kn where *k* and *c* are integer constants and *n* ranges over the integers.

A *generalized tuple* of temporal arity *k* is a tuple with *k* temporal attributes, each one represented by a lrp, possibly including *constraints* expressed by linear equalities or disequalities between temporal attributes. Semantically, a generalized tuple denotes a (possibly infinite) set of (ordinary) tuples, one tuple for each value of the temporal attributes satisfying the lrp's definitions and the constraints. For instance, the generalized tuple

$$(a_1,\ldots, a_n|[5+4n_1, 7+4n_2]\Lambda\, X_1 = X_2 - 2)$$

(with data part $a_1,\ldots,a_n$) represents the infinite set of tuples with temporal attributes X_1 and X_2, such that $X_1 = 5 + 4n_1$, $X_2 = 7 + 4n_2$, $X_1 = X_2–2$, for some integers n_1 and n_2, i.e.,

$$\{\ldots(a_1,\ldots,a_n|[1,3]), (a_1,\ldots,a_n|[5,7]),\\ (a_1,\ldots,a_n|[9,10]),\ldots\}$$

A *generalized relation* is a finite set of generalized tuples of the same schema.

In Kabanza et al. [6], the algebraic operations (e.g., intersection) have been defined over generalized relations as mathematical manipulations of the formulae coding lrp's.

A comparative analysis of deductive rule-based and constraint-based approaches has been provided, e.g., by Baudinet et al. [2], showing that they have the same *data expressiveness* (i.e., the set of temporal databases that can be expressed in such languages is the same). Specifically, as concerns the temporal component, they express *eventually periodic* sets of points (which are, indeed, points that can be defined by *Presburger Arithmetics* – see below). In such an approach, the *query* expressiveness and the computational complexity of such formalisms have also been studied.

Symbolic Approaches

In constraint-based approaches, temporal periodicity is represented through mathematical formulae. Several authors have suggested that, although expressive, such approaches do not cope with temporal periodicity in a "commonsense" (in the sense of "human-oriented") way, arguing in favor of a *symbolic* representation, in which complex periodicities can be compositionally built in terms of simpler ones (see, e.g., the discussions in [9,13]). A milestone in the area of symbolic approaches to temporal periodicity is the early approach by Leban et al. [8]. In Leban's approach, *collections* are the core notion. A *collection* is a *structured* set of *intervals* (elsewhere called *periods*). A base collection, partitioning the whole timeline (e.g., the collection of seconds), is used as the basis of the construction. A new partition P' of the timeline (called *calendar* in Leban's terminology) can be built from another partition P as follow:

$$P' =< P; s_0, \ldots s_{n-1} >$$

where $s_0,\ldots,s_{n-1}$ are natural numbers greater than 0. Intuitively, $s_0,\ldots,s_{n-1}$ define the number of periods of P whose unions yield periods of P′, intending that the union operation has to be repeated cyclically. For example, Weeks = {Days;7} defines weeks as aggregations of seven days. Analogously, months (not considering leap years for the sake of brevity) can be defined by the expression Months = {Days; 31,28,31,30,31,30,31,31,30,31,30,31}.

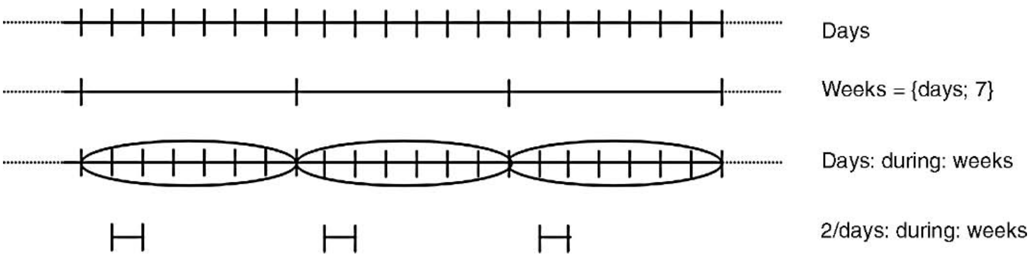
Two classes of operators, *dicing* and *slicing*, are defined in order to operate on collections.

The dicing operators provide means to further divide each period in a collection within another collection. For example, given the definitions of *Days* and *Weeks*, Day:during:Weeks breaks up weeks into the collection of days they contain. Other dicing operators are allowed (taken from a subset of Allen's relations [1]). Slicing operators provide a way of selecting periods from collections. For instance, in the expression 2/Day:during:Weeks the slicing operator "2/" is used in order to select the second day in each week. Different types of slicing operators are provided (e.g., -n/selects the *n-th* last interval from each collection).

Collection expressions can be arbitrarily built by using a combination of these operators (see, e.g., The examples in Figure 1).

While Leban's approach was mainly aimed to represent periodicity within knowledge bases (i.e., in artificial intelligence contexts), later on it has played an increasingly important role also in the area of temporal databases. Recently, Terenziani [8] has defined a temporal extension to relational databases, in which the valid time of periodic tuples can be modeled through (an extension of) Leban's language, and symbolic manipulation is used in order to perform algebraic operations on the temporal relations.

Another early symbolic approach which has been widely used within the database and artificial



Temporal Periodicity. Figure 1. Operators in Leban's language.

intelligence areas is the one by Niezette and Stevenne [9], who provided a formalism as well as the algebraic operations on it, mostly as an upper layer built upon *linear repeating points* [6]. A comparison between such a formalism and Leban's one, as well as an analysis of the relationships between the periodicities defined by such languages and *periodic granularities* has been provided by Bettini and De Sibi [3]. A recent influential symbolic approach, based on the notion of periodic granularities, has been proposed by Ning et al. [10].

An important issue concerns the formal analysis of the expressiveness (and of the semantics) of the implicit representation formalisms proposed to cope with temporal periodicity. *Presburger Arithmetics*, i.e., the first-order theory of addition and ordering over integers, is a natural reference to evaluate the expressiveness (and semantics) of such languages, because of its simplicity, decidability, and expressiveness, since it turns out that all sets definable in Presburger Arithmetics are *finite*, *periodic*, or *eventually periodic*. A recent comparison of the expressiveness of several constraint-based and symbolic approaches, based on Presburger Arithmetics, has been provided by Egidi and Terenziani [15].

While the above-mentioned approaches in [9,6,13] mainly focused on extending the relational model to cope with temporal periodicity, Kurt and Ozsoyoglu [7] devoted more attention to the definition of a *periodic temporal object oriented SQL*. They defined the temporal type of *periodic elements* to model strictly periodic and also eventually periodic events. Periodic elements consist of both an aperiodic part and a periodic part, represented by the repetition pattern and the period of repetition. They also defined the set-theoretic operations of union, intersection, complement and difference, which are closed with respect to periodic elements.

Moreover, in the last years, periodicity has also started to be studied in the context of moving objects. In particular, Revesz and Cai [11] have taken into account also periodic (called *cyclic* periodic) and eventually periodic (called *acyclic* periodic) *movements* of objects. They have proposed an extended relational data model in which objects are approximated by unions of *parametric rectangles*. Movement is coped with by modeling the x and y dimensions of rectangles through functions of the form f(t mod p), where t denotes time, p the repetition period, and mod the module function. Revesz and Cai have also defined the algebraic operations on the data model.

Key Applications

Temporal periodicity plays an important role in many application areas, including process control, data access control, office automation, data broadcasting, planning, scheduling, multimedia, active databases, banking, and so on. Languages to specify user-defined periodicities in the *queries* have been already supported by many approaches, including commercial ones. For instance, Oracle provides a language to specify periodicity in the queries to *time series* (e.g., to ask for the values of IBM at the stock exchange *each Monday*). Even more interestingly, such languages can be used in the *data*, in order to express (finite and infinite) *periodic valid times* in an implicit and compact way. However, such a move involves an in-depth revision and extension of "standard" database theory and technology, which have been partly addressed within the temporal database research community, but have not yet been fully implemented in commercial products.

Synonyms

Temporal assignment

Definition

In a query or update statement, *temporal projection* pairs the computed facts with their associated times, usually derived from the associated times of the underlying facts.

The generic notion of temporal projection may be applied to various specific time dimensions. For example, *valid-time projection* associates with derived facts the times at which they are valid, usually based on the valid times of the underlying facts.

Key Points

While almost all temporal query languages support temporal projection, the flexibility of that support varies greatly.

In some languages, temporal projection is implicit and is based the intersection of the times of the underlying facts. Other languages have special constructs to specify temporal projection.

The term “temporal projection” has been used extensively in the literature. It derives from the `retrieve` clause in Quel as well as the `SELECT` clause in SQL, which both serve the purpose of the relational algebra operator (generalized) projection, in addition to allowing the specification of derived attribute values.

The related concept called “temporal assignment” roughly speaking is a function that maps a set of time values to a set of values of an attribute. One purpose of a temporal assignment would be to indicate when different values of the attribute are valid.

Historical query languages

Definition

A temporal query language is a database query language that offers some form of built-in support for the querying and modification of time-referenced data, as well as enabling the specification of assertions and constraints on such data. A temporal query language is usually quite closely associated with a temporal data model that defines the underlying data structures to which the language applies.

Historical Background

When the relational data model was proposed by Codd, he also proposed two query languages: the relational calculus and the relational algebra. Similarly, temporal data models are closely coupled with temporal query languages.

Most databases store time-referenced, or temporal, data. The ISO standard Structured Query Language SQL [4] is often the language of choice when developing applications that utilize the information captured in such databases. In spite of this, users realize that temporal data management is often challenging with SQL. To understand some of the difficulties, it is instructive to attempt to formulate the following straightforward, realistic queries, assertions, and modifications in SQL. An intermediate SQL programmer can express all of them in SQL for a database without time-referenced data in perhaps 5 minutes. However, even SQL experts find these same queries challenging to do in several *hours* when the data are time-referenced [6].

- An `Employee` table has three attributes: `Name`, `Manager`, and `Dept`. Temporal information is retained by adding a fourth attribute, `When`, of data type `PERIOD`. Attribute `Manager` is a foreign key for `Employee.Name`. This means that at each point in time, the `Manager` value of a tuple also occurs as a `Name` value (probably in a different tuple). This cannot be expressed via SQL's foreign-key constraint, which fails to take time into account. Formulating this constraint as an assertion is challenging.
- Consider the query "List those employees who are not managers." This can easily be expressed in SQL, using `EXCEPT` or `NOT EXISTS`, on the original, non-temporal relation with three attributes. Things are just a little harder with the `When` attribute; a `WHERE` predicate is required to extract the current employees. To formulate the query "List those employees who were not managers, and indicate when," `EXCEPT` and `NOT EXISTS` do not work because they do not consider time. This simple temporal query is hard to formulate, even for SQL experts.
- Consider the query "Give the number of employees in each department." Again, this is a simple SQL query using the `COUNT` aggregate when formulated on non-temporal data. To formulate the query on temporal data, i.e., "Give *the history of* the number of employees in each department," is very difficult without built-in temporal support in the language.
- The modification "Change the manager of the Tools department for 2004 to Bob" is difficult in SQL because only a portion of many validity periods are to be changed, with the information outside of 2004 being retained.

Most users know only too well that while SQL is an extremely powerful language for writing queries on the current state, the language provides much less help when writing temporal queries, modifications, and assertions and constraints.

Hence there is a need for query languages that explicitly "understand" time and offer built-in support for the management of temporal data. Fortunately, the outcomes of several decades of research in temporal query languages demonstrate that it is indeed possible to build support for temporal data management into query languages so that statements such as the above are easily formulated.

Foundations

Structure may be applied to the plethora of temporal query languages by categorizing these languages according to different concerns.

Language Extension Approaches

One attempt at bringing structure to the diverse collection of temporal query languages associates these languages with four approaches that emphasize how temporal support is being added to a non-temporal query language [1].

Abstract Data Types for Time From a design and implementation perspective, the simplest approach to improving the temporal data management capabilities of an existing query language is to introduce time data types with associated predicates and functions. This approach is common for query languages associated with temporal object-oriented databases [7].

Data types for time points, time intervals (periods), and for durations of time may be envisioned, as may data types for temporal elements, i.e., finite unions of time intervals. The predicates associated with time-interval data types are often inspired by Allen's 13 interval relationships. With reference to these, different sets of practical proposals for predicates have been proposed.

However, while being relatively easy to achieve, the introduction of appropriate time data types results only in modest improvements of the temporal data management capabilities of the query language.

Use of Point Timestamps An interval timestamp associated with a tuple in a temporal relational data model is often intended to capture the fact that the information recorded by the tuple is valid at each time point contained in the interval. This way, the interval is simply a compact representation of a set of time points. Thus, the same information can be captured by a single tuple timestamped with an interval and a set of identical tuples, each timestamped with a different time point from the interval (with no time points missing).

One attraction of intervals is that their representing is of fixed size. Another is that they appear to be very intuitive to most users — the notion of an interval is conceptually very natural, and people use it frequently in their daily thinking and interactions. In some respects, the most straightforward and simplest means of capturing temporal aspects is to use interval-valued timestamps.

However, the observation has also been advanced that the difficulty in formulating temporal queries on relations with interval-timestamped tuples stem exactly from the intervals – Allen has shown that there are 13 possible relations between a pair of intervals. It has been argued that a language such as SQL is unprepared to support something (an interval) that represents something (a convex set of time points) that it is not.

Based on this view, it is reasonable to equip an SQL extended with interval-valued timestamps with the ability to *unfold* and *fold* timestamps. The unfold function maps an interval-stamped tuple (or set of tuples) to the corresponding set of point-stamped tuples (set of tuples), and the fold function collapses a set of point-stamped tuples into the corresponding interval-stamped tuple(s). This way, it is possible to manipulate both point- and interval-stamped relations in the same language. If deemed advantageous when formulating a statement, one can effectively avoid the intervals by first unfolding all argument relations. Then the statement is formulated on the point-stamped relations. At the end, the result can be folded back into an interval-stamped format that lends itself to presentation to humans.

A more radical approach to designing a temporal query language is to completely abandon interval timestamps and use only point timestamps. This yields a very clean and simple design, although it appears that database modification and the presentation of query results to humans must still rely on intervals and thus are "outside" the approach.

The strength of this approach lies in its generalization of queries on non-temporal relations to corresponding queries on corresponding temporal relations. The idea is to extend the non-temporal query with equality constraints on the timestamp attribute of the temporal relation, to separate different temporal database states during query evaluation, thereby naturally supporting sequenced semantics.

Syntactic Defaults This approach introduces what may be termed syntactic defaults along with the introduction of temporal abstract data types, the purpose being to make the formulation of common temporal queries more convenient. Common defaults concern the access to the current state of a temporal relation and the handling of temporal generalizations of common non-temporal queries, e.g., joins. The temporal generalization of a non-temporal join is one where two tuples join if their timestamps intersect and where the timestamp of the result tuple is the intersection of the timestamps. Essentially, the non-temporal query is computed for each point in time, and the results of these queries are consolidated into a single result. The nature of the consolidation depends on the data type of the timestamps; if intervals are used, the consolidation involves coalescing.

The most comprehensive approach based on syntactic defaults is the TSQL2 language [5], but many of the earlier query languages that the creators of this language were attempting to consolidate also follow this approach. As an example, TSQL2 includes a default valid clause that computes the intersection of the valid times of the tuples in the argument relations mentioned in a statement's from clause, which is then returned in the result. So as explained above, the timestamp of a tuple that results from joining two relations is the intersection of the timestamps of the two argument tuples that produce the tuple. When there is only one argument relation, the valid clause produces the original timestamps.

Such defaults are very effective in enabling the concise formulation of common queries, but they also tend to complicate the semantics of the resulting temporal query language.

Semantic Defaults The use of semantic defaults is motivated in part by the difficulties in systematically extending a large and unorthogonal language such as SQL with syntactic defaults that are easy to understand and that do not interact in unintended ways. With this approach, so-called *statement modifiers* are added to a non-temporal query language, e.g., SQL, in order to obtain built-in temporal support [8].

It was argued earlier that statements that are easily formulated in SQL on non-temporal relations can be very difficult to formulate on temporal relations. The basic idea is then to make it easy to systematically formulate temporal queries from non-temporal queries. With statement modifiers, a temporal query is then formulated by first formulating the "corresponding" non-temporal query (i.e., assuming that there are no timestamp attributes on the argument relations) and then applying a statement modifier to this query.

For example, to formulate a temporal join, the first step is to formulate the corresponding non-temporal join. Next, a modifier is placed in front of this query to indicate that the non-temporal query is to be rendered temporal by computing it at each time point. The modifier ensures that the argument timestamps overlap and that the resulting timestamp is the intersection of the argument intervals. The attraction of using statement modifiers is that these may be placed in front of any non-temporal query to render that query temporal.

Statement modifiers are capable of specifying the semantics of the temporal queries unambiguously, independently of the syntactic complexity of the queries that the modifiers are applied to. This renders semantic defaults scalable across the constructs of the language being extended. With modifiers, the users thus need not worry about which predicates are needed on timestamps and how to express timestamps to be associated with result tuples. Further, the use of statement modifiers makes it possible to give more meaning to interval timestamps; they need no longer be simply compact representations of convex sets of time points.

Additional Characterizations of Temporal Query Languages

Several additional dimensions exist on which temporal query languages can be characterized. One is *abstractness*: is the query language at an abstract level or at a concrete level. Examples of the former are Temporal Relational Calculus and First-order Temporal Logic; an example of the latter is TSQL2.

Another dimension is *level*: is the query language at a logical or a physical level? A physical query language assumes a specific representation whereas a logical query language admits several representations. Examples of the former are examined in McKenzie's survey of relational algebras [3]; an example of the latter is the collection of algebraic operators defined on the Bitemporal Conceptual Data Model [2], which can be mapped to at least five representational models.

A third dimension is whether the query language supports a *period-stamped temporal model* or a *point-stamped temporal model*.

Other entries (indicated in *italics*) examine the long and deep research into temporal query languages in a more detailed fashion. *Qualitative temporal reasoning* and *temporal logic in database query languages* provide expressive query facilities. *Temporal vacuuming* provides a way to control the growth of a database. *TSQL2* and its successor SQL/Temporal provided a way for many in the temporal database community to coordinate their efforts in temporal query language design and implementation. *Temporal query processing* involves disparate architectures, from *temporal strata* outside the conventional DBMS to adding native temporal support within the DBMS. *Supporting transaction time* generally requires changes within the kernel of a DBMS. *Temporal algebras* extend the conventional relational algebra. Some specific operators (e.g., *temporal aggregation*, *temporal coalescing*, *temporal joins*) have received special attention. Finally, the

Oracle database management system includes support for valid and transaction time, both individually and in concert, in its extension of.

Future Directions

Given the substantial decrease in code size (a factor of three [6]) and dramatic decrease in conceptual complexity of temporal applications that temporal query languages offer, it is hoped that DBMS vendors will continue to incorporate temporal language constructs into their products.

Temporal Query Processing

Michael Böhlen
Free University of Bolzano-Bozen, Bolzano, Italy

Definition

Temporal query processing refers to the techniques used by database management system to process temporal statements. This ranges from the implementation of query execution plans to the design of system architectures. This entry surveys different system architectures. It is possible to identify three general system architectures that have been used to systematically offer temporal query processing functionality to applications [6]: The *layered* approach uses an off-the-shelf database system and extends it by implementing the missing functionality in a layer between the database system and the applications. The *monolithic* approach integrates the necessary application-specific extensions directly into the database system. The *extensible* approach relies on a database system that allows to plug user-defined extensions into the database system.

Historical Background

In order to deploy systems that offer support for temporal query processing new systems must be designed and implemented. Temporal extensions of database systems are quite different from other database system extensions. On the one hand, the complexity of the newly added types, often an interval, is usually quite low. Therefore, existing access structures and query processing techniques are often deemed sufficient to manage temporal information [7,8,11]. On the other hand the temporal aspect is ubiquitous and affects all parts of a database system. This is quite different if extensions for multimedia, geographical or spatio-temporal data are considered. Such extensions deal with complex objects, for example, objects with complex boundaries, moving points, or movies, but their impact on the various components of a database system is limited.

A first overview of temporal database system implementations appeared in 1996 [2]. While the system architecture was not the focus, the overview describes the approached followed by the systems. Most systems follow the layered approach, including ChronoLog, ARCADIA, TimeDB, VT-SQL, and Tiger. A comprehensive study of a layered query processing architecture was done by Slivinskas et al. [10]. The authors use the Volcano extensible query optimizer to optimize and process queries. A monolithic approach is pursued by HDBMS, TDBMS, T-REQUIEM, and T-squared DBMS. A successful implementation of an index structure for temporal data has been done with the help of Informix's datablade technology [1].

Foundations

Figure 1 provides an overview of the different architectures that have been used to systematically provide temporal database functionality: the layered, monolithic, and extensible architectures. The gray parts denote the temporal extensions. The architecture balances initial investments, functionality, performance and lock-ins.

Functionalities

The different operators in a temporal database system have different characteristics with respect to query processing.

Temporal selection, temporal projection and temporal union resemble their non-temporal counterparts and they do not require dedicated new database functionality. Note though that this only holds if the operators may return uncoalesced relation instances [3] and if no special values, such as *now*, are required. If the operators must returned coalesced relations or if *now* must be supported the support offered by conventional database systems is lacking.

Temporal Cartesian product (and temporal joins) are also well supported by standard database systems. In many cases existing index structures can be used to index interval timestamps [7].

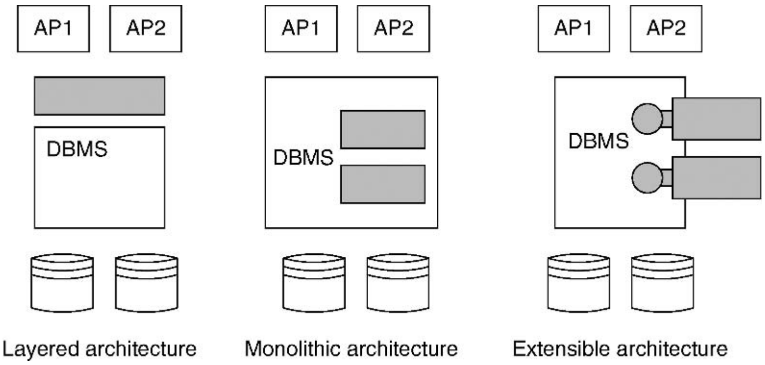
Temporal difference is more subtle and not well-supported by traditional database systems. It is possible to formulate temporal difference in, e.g., SQL, but it is cumbersome to do so. Algebraic formulations and efficient implementations have been studied by Dunn et al. [4].

Temporal aggregation is even worse than temporal difference. Formulating a temporal aggregation in SQL is a challenge for even advanced SQL programmers and yields a statement that current database systems cannot evaluate efficiently [11].

Temporal coalescing and temporal integrity constraints [11] are other examples of operations that current database system do not handle efficiently. *Temporal coalescing* is an algebraic operator and a declarative SQL implementation is inefficient.

The Layered Architecture

A common approach to design an extended database systems with new data types and operations for time-referenced data are to use an off-the-shelf database system and implement a layer on top providing data types



Temporal Query Processing. Figure 1. Illustration of architectural choices for temporal database systems and services for temporal applications. The database system with such a component is then used by different applications having similar data type and operation requirements. Database systems enhanced in this way exploit the standard data types and data model, often the relational model, as a basis. They define new data types and possibly a new layer that provides application specific support for data definition and query language, query processing and optimization, indexing, and transaction management. Applications are written against the extended interface.

The layered approach has the advantage of using standard components. There is a clear separation of responsibilities: application-specific development can be performed and supported independent of the database system development. Improvements in the database system component are directly available in the whole system with almost no additional effort. On the other hand, the flexibility is limited. Development not foreseen in the database system component has to be implemented bypassing the database system. The more effort is put into such an application-specific data management extension, the more difficult it gets to change the system and take advantage of database system improvements. Also (legacy) applications might access the database system over different interfaces. For such applications accessing the extended database system through a special purpose layer is not always an option.

The reuse of a standard database system is an advantage but at the same time also a constraint. The layer translates and delegates temporal requests to sequences of nontemporal request. If some of the functionality of the database systems should be extended or changed, e.g., a refined transaction processing for transaction time, this cannot be done easily with a layered approach. For the advanced temporal functionality the layered architecture might not offer satisfactory performance.

The Monolithic Architecture

Many systems that use a monolithic architecture have originally been designed as stand-alone applications without database functionality. The designers of a monolithic architecture then extend their system with database system functionality. They add query functionality, transaction management, and multi-user capabilities, thereby gradually creating a specialized database system. The data management aspects traditionally associated with database system and the application-specific functionality are integrated into one component.

Instead of adding general database system functionality to an application it is also possible to incorporate the desired application domain semantics into the database system. Typically, this is done by database companies who have complete control over and knowledge of their source code or by open source communities.

Because of the tight integration of the general data management aspects and the application specific functionality, monolithic systems can be optimized for the specific application domain. This results in good performance. Standard and specialized index structures can be combined for good results. Transaction management can be provided in a uniform way for standard as well as new data types. However, implementing a monolithic system is difficult and a big (initial) effort, since all aspects of a database system have to be taken into account. Another drawback is that enterprises tend to be reluctant to replace their database system, which increases the threshold for the adoption of the temporal functionality. With monolithic systems, there is is a high risk of vendor lock-ins.

The Extensible Architecture

Extensible database systems can be extended with application-specific modules. Traditional database functionality like indexing, query optimization, and transaction management is supported for new data types and functions in a seamless fashion.

The first extensible system prototypes have been developed to support non-standard database system applications like geographical, multimedia or engineering information systems. Research on extensible systems has been carried out in several projects, e.g., Ingres [12], Postgres[13], and Volcano [5]. These projects addressed, among other, data model extensions, storage and indexing of complex objects as well as transaction management and query optimization in the presence of complex objects. Today a number of commercial approaches are available, e.g., datablades from Informix, cartridges from Oracle, and extenders from DB2. A limitation is that the extensions only permit extension that were foreseen initially. A comprehensive temporal support might require support that goes beyond data types and access structures.

The SQL99 standard [9] specifies new data types and type constructors in order to better support advanced applications.

The extensible architecture balances the advantages and disadvantages of the layered and monolithic architectures, respectively. There is a better potential to implement advanced temporal functionality with a satisfactory performance than in the layered architecture. However, functionality not foreseen by the extensible database system might still be difficult to implement.

Key Applications

All applications that want to provide systematic support for time-varying information must choose one of the basic system architectures. The chosen architecture balances (initial) investments, future lock-ins, and performance.

Future Directions

The architecture determines the initially required effort to provide support for time-varying information and may limit functionality and performance. Changing from one architecture to another is not supported. Such transitions would be important to support the graceful evolution of temporal database applications.

Synonyms

Two-sorted first-order logic

Definition

Temporal Relational Calculus (TRC) is a temporal query language extending the relational calculus. In addition to data variables and quantifiers ranging over a data domain (a universe of *uninterpreted constants*), temporal relational calculus allows *temporal variables* and quantifiers ranging over an appropriate time domain [1].

Key Points

A natural temporal extension of the relational calculus allows explicit variables and quantification over a given time domain, in addition to the variables and quantifiers over a data domain of uninterpreted constants. The language is simply the two-sorted version (variables and constants are temporal or non-temporal) of first-order logic over a data domain D and a time domain T.

The syntax of the two-sorted first-order language over a database schema $\rho = \{R_1,...,R_k\}$ is defined by the grammar rule:

$$\begin{aligned} Q ::= R(t_i, x_{i_1},..., x_{i_k}) \mid t_i < t_j \mid x_i = x_j \mid \\ Q \wedge Q \mid \neg Q \mid \exists x_i.Q \mid \exists t_i.Q \end{aligned}$$

In the grammar, t_i's are used to denote temporal variables and x_i's to denote data (non-temporal) variables. The atomic formulae $t_i < t_j$ provide means to refer to the underlying ordering of the time domain. Note that the schema ρ contains schemas of *time-stamped temporal relations*.

Given a point-timestamped database DB and a two-sorted valuation θ, the semantics of a TRC query Q is defined in the standard way (similarly to the semantics of relational calculus) using the *satisfaction relation* $DB, \theta \vDash Q$:

$$\begin{array}{ll} DB, \theta \vDash R_j(t_i, x_{i_1},..., x_{i_k}) & \text{if } R_j \in \rho \text{ and } (\theta(\mathrm{t_i}), \\ & \theta(x_{i_1}),..., \theta(x_{i_k})) \in R_j^{DB} \\ DB, \theta \vDash t_i < t_j & \text{if } \theta(t_i) < \theta(t_j) \\ DB, \theta \vDash x_i = x_j & \text{if } \theta(x_i) = \theta(x_j) \\ DB, \theta \vDash Q_1 \wedge Q_2 & \text{if} DB, \theta \vDash Q_1 \text{ and} \\ & DB, \theta \vDash Q_2 \\ DB, \theta \vDash \neg Q_1 & \text{if not } DB, \theta \vDash Q_1 \\ DB, \theta \vDash \exists t_i.Q_1 & \text{if there is } s \in T \text{ such} \\ & \text{that } DB, \theta[t_i \mapsto s] \vDash Q_1 \\ DB, \theta \vDash \exists x_i.Q_1 & \text{if there is } a \in D \text{ such} \\ & \text{that } DB, \theta[x_i \mapsto a] \vDash Q_1 \end{array}$$

where R_j^{DB} is the interpretation of the predicate symbol R_j in the database DB.

The *answer to a query Q over DB* is the set $Q(DB)$ of valuations that make Q true in DB. Namely, $Q(DB) := \{\theta_{|FV\ (Q)} : DB,\ \theta \vDash Q\}$ where $\theta_{|FV\ (Q)}$ is the restriction of the valuation θ to the free variables of Q.

In many cases, the definition of TRC imposes additional restrictions on valid TRC queries:

Restrictions on free variables: Often the number of free temporal variables in TRC queries can be restricted to guarantee closure over the underlying data model (e.g., a single-dimensional timestamp data model or the bitemporal model). Note that this restriction applies only to queries, not to subformulas of queries. **Range restrictions**: Another common restriction is to require queries to be range restricted to guarantee domain independence. In the case of TRC (and many other abstract query languages), these restrictions depend crucially on the chosen *concrete encoding* of temporal databases. For example, no range restrictions are needed for temporal variables when queries are evaluated over interval-based database encodings, because the complement of an interval can be finitely represented by intervals.

The schemas of atomic relations, $R_j(t_i, x_{i_1},..., x_{i_k})$, typically contain a single temporal attribute/variable, often in fixed (e.g., first) position: This arrangement simply reflects the choice of the underlying temporal data model to be the single-dimensional valid time model. However, TRC can be similarly defined for multidimensional temporal data models (such as the bitemporal model) or for models without a predefined number of temporal attributes by appropriately modifying or relaxing the requirements on the structure of relation schemas.

An interesting observation is that a variant of TRC, in which temporal variables range over *intervals* and that utilizes *Allen's interval relations* as basic comparisons between interval values, is equivalent to TRC over two-dimensional temporal relations, with the two temporal attributes standing for interval endpoints.

Synonyms

Temporal restriction

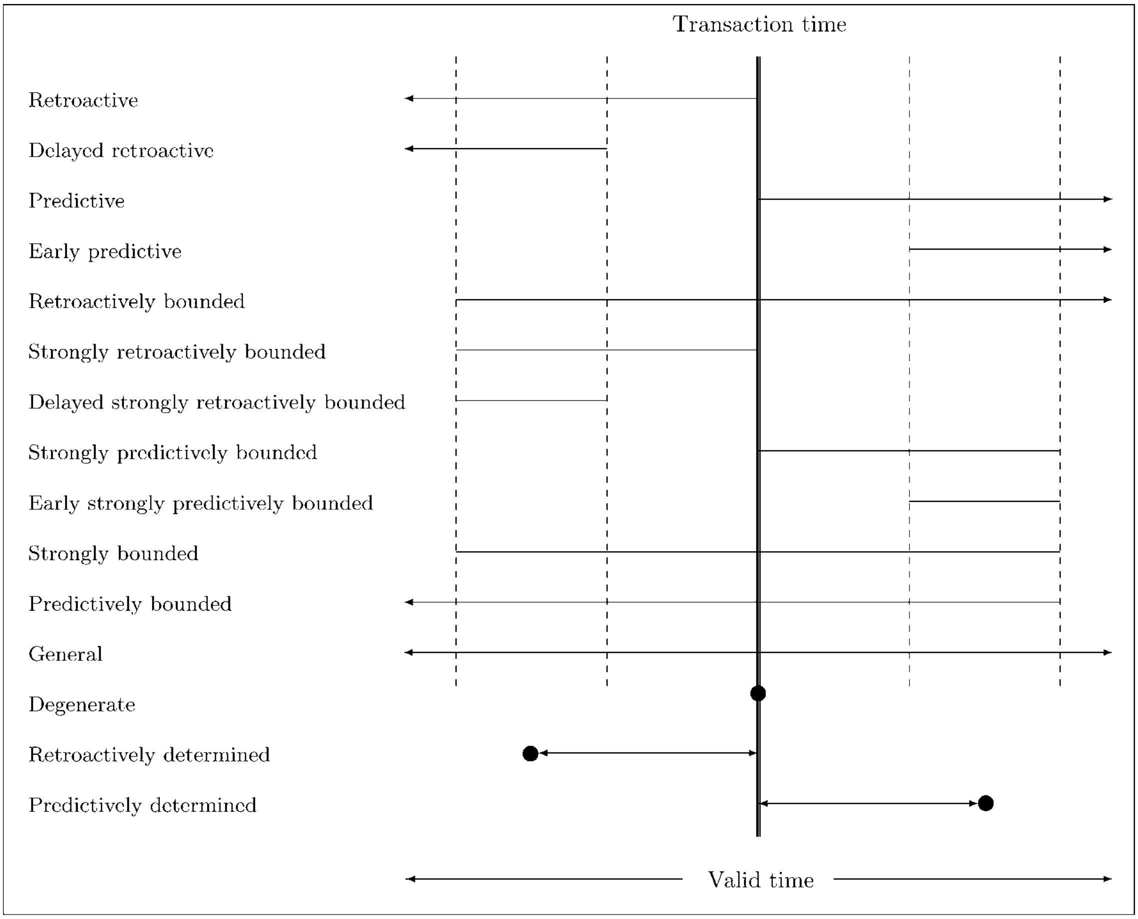
Definition

Temporal specialization denotes the restriction of the interrelationships between otherwise independent (implicit or explicit) timestamps in temporal relations. An example is a relation where tuples are always inserted after the facts they record were valid in reality. In such a relation, the transaction time of a tuple would always be after the valid time. Temporal specialization may be applied to relation schemas, relation instances, and individual tuples.

Key Points

Data models exist where relations are required to be specialized, and temporal specializations often constitute important semantics about temporal relations that may be utilized for, e.g., improving the efficiency of query processing.

Temporal specialization encompasses several kinds of specialization. One is based on the relationships



Temporal Specialization. Figure 1. Temporal Specialization based on isolated events – restrictions on the valid timestamp relative to the transaction timestamp. Adapted from Jensen and Snodgrass (1994).

between isolated events, and one based on inter-event relationships. Two additional kinds consider intervals instead of events, and one is based on the so-called completeness of the capture of the past database states.

The taxonomy based on *isolated events*, illustrated in Fig. 1, considers the relationship between a single valid time and a single transaction time. For example, in a *retroactive* relation, an item is valid before it is operated on (inserted, deleted, or modified) in the database. In a *degenerate* relation, there is no time delay between sampling a value and storing it in the database. The valid and transaction timestamps for the value are identical.

The interevent-based taxonomy is based on the *interrelationships* among multiple event timestamped items, and includes non-decreasing, non-increasing, and sequential. Regularity is captured through the categories of transaction time event regular, valid time event regular, and temporal event regular, and strict versions of these. The interinterval-based taxonomy uses Allen's relations.

To understand the last kind of specialization, which concerns the *completeness* of the capture of past states, recall that a standard transaction — time database captures all previously current states – each time a database modification occurs, a new previously current state is created. In contrast a valid-time database captures only the current database state. In-between these extremes, one may envision a spectrum of databases with incomplete support for transaction time. For example, consider a web archive that takes a snapshot of a collection of web sites at regular intervals, e.g., every week. If a site was updated several times during the same week, states would be missing from the database. Such incomplete databases are considered specializations of more complete ones.

Concerning the synonym, the chosen term is more widely used than the alternative term. The chosen term indicates that specialization is done with respect to the temporal aspects of the data items being timestamped. It is natural to apply the term temporal generalization to the opposite of temporal specialization. "Temporal restriction" has no obvious opposite term.

Temporal layer; Layered architecture; Temporal middleware; Wrapper

Definition

A temporal stratum is an architecture for implementing a temporal DBMS. The stratum is a software layer that sits on top of an existing DBMS. The layer translates a query written in a temporal query language into one or more queries in a conventional query language (typically SQL). The translated queries can then be executed by the underlying DBMS. The DBMS returns the result of the query/queries to the user directly or via the stratum. The core idea of the stratum is to provide new temporal query functionality to the users without changing the underlying DBMS. A temporal stratum can be implemented as a simple translator (temporal SQL to standard SQL) or as an advanced software component that also does part of the query processing and optimization. In the latter case, the temporal stratum can implement query processing algorithms that take the special nature of temporal data into consideration. Examples are algorithms for temporal join, temporal coalescing, and temporal aggregation.

Historical Background

Applications that store and query multiple versions of data have existed for a very long time. These applications have been implemented using, for example, triggers and log-like tables. Supporting multiple versions of data can be time consuming to build and computationally intensive to execute, since the major DBMS vendors only have limited temporal support. See [8] for details.

Parallel to the work in the software industry the research community has proposed a large number of temporal data models and temporal query languages. For an overview see [7]. However, most of this research is not supported by implementations. A notable exception to this is the Postgres DBMS that has built-in support for transaction time [6]. Postgres has later evolved into the popular open-source DBMS PostgreSQL that does not have transaction-time support. Most recently, the Immortal DB research prototype [2] has looked at how to built-in temporal support in the Microsoft SQL Server DBMS.

The DBMS vendors have not been interested in implementing the major changes to the core of their DBMSs that are needed to add temporal support to the existing DBMSs. In addition, the proposal to add temporal support to SQL3, called "SQL/Temporal" part 7 of the ISO SQL3 standard, has had very limited support. The temporal database research community has therefore been faced with a challenge of how to experimentally validate their proposals for new temporal data models and temporal query languages since it is a daunting task to build a temporal DBMS from scratch.

To meet this challenge it has been proposed to implement a temporal DBMS as a software layer on top of an existing DBMS. This has been termed a temporal stratum approach. Some of the first proposals for a temporal stratum mainly consider translating a query in a temporal query language to one or more queries in SQL [9].

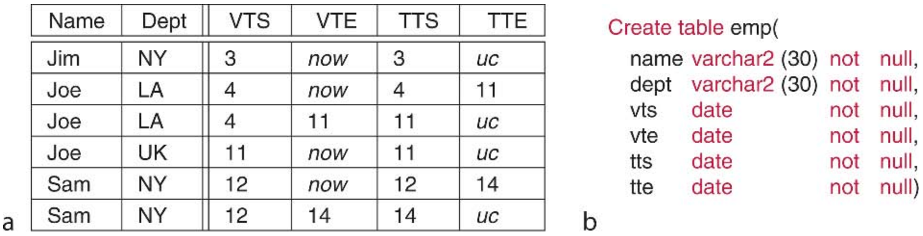
The temporal database research community has shown that some temporal queries are very inefficient to execute in plain SQL, either formulated directly in SQL or translated via a simple temporal stratum from a temporal query language to SQL. For this reason it has be researched how to make the temporal stratum approach more advanced such that it uses the underlying DBMS when this is efficient and does the query execution in the layer when the underlying DBMS is found to be inefficient [5,4].

Scientific Fundamentals

A bitemporal database supports both valid time and transaction time. In the following it is assumed that all tables have bitemporal support. Figure 1a shows the bitemporal table `emp`. The table has two explicit columns, `name` and `dept`, and four implicit timestamp columns: `VTS`, `VTE`, `TTS`, and `TTE`. The first row in the table says that Jim was in the New York department from the third (assuming the month of September 2007) and is still there, indicated by the variable *now*. This information was also entered on the third and is still considered to be the best valid information, indicated by the variable *uc* that means until changed.

It is straightforward to implement a bitemporal table in a conventional DBMS. The implicit attributes are simply made explicit. For the `emp` table an SQL table with six columns are created. This is shown in Fig. 1b. Existing DBMSs do not support variables and therefore the temporal stratum has to convert the variables *now* and *uc* to values in the domain of columns `VTE` and `TTE`. It has been shown that it is the most convenient to use the maximum value (9999-12-31) in the `date` domain for both *now* and *uc* [10].

Primary key and unique key constraints are quite complicated to implement in a temporal stratum.



Name	Dept	VTS	VTE	TTS	TTE
Jim	NY	3	*now*	3	*uc*
Joe	LA	4	*now*	4	11
Joe	LA	4	11	11	*uc*
Joe	UK	11	*now*	11	*uc*
Sam	NY	12	*now*	12	14
Sam	NY	12	14	14	*uc*

```
Create table emp(
  name varchar2 (30) not  null,
  dept varchar2 (30) not  null,
  vts  date          not  null,
  vte  date          not  null,
  tts  date          not  null,
  tte  date          not  null)
```

Temporal Strata. Figure 1. (a) The Bitemporal Table `emp` (b) SQL Implementation.

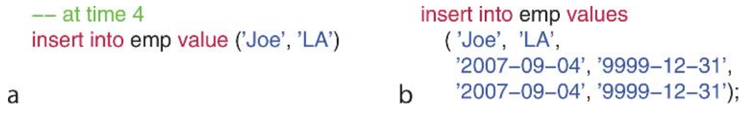
A temporal query language such as ATSQL [1] has to be temporal upwards compatible, i.e., all non-temporal SQL statements have to work as before. For primary keys this means that a primary key on a bitemporal table cannot be directly mapped to a primary key in the underlying DBMS. As an example, if the `emp` only has to store the current version of where employees are, the `name` column can be used as a primary key. However, since `emp` has bitemporal support there are now three rows in the example table where the name is "Joe." Due to space constraints, an example is not listed here. Please see [8] for a concrete example.

To look at how modifications are handled in a temporal stratum, first consider the temporal insert statement shown in Fig. 2a. This is a temporal upward compatible insert statement (it looks like a standard SQL statement). The mapping to SQL is shown in Fig. 2b. The columns `vts` and `tts` are set to the current date (fourth of September 2007). The *now* and *uc* variables are set to the maximum `date`. The result is the second row in Fig. 1a.

At time 11 Joe is updated from being in the LA department to the UK department. The temporal upwards compatible update statement for this is shown in Fig. 3a. This update statement is mapped to an SQL update of the existing row and two SQL insert statements. The update ends the current belief by updating the `TTE` column to the current date. The first SQL insert statement stores for how long it was believed that Joe was in the LA department. The second SQL insert statement stores the new belief that Joe is in the UK department. The temporal update corresponds to the updated second row plus the third and fourth row in Fig. 1a. A delete statement is mapped like the SQL update statement and the first SQL insert statement in Fig. 3b. In Fig. 1a a temporal insert of Sam at time 12 and a temporal delete of Sam at time 14 are shown as rows number 5 and 6. Note that the SQL delete statement is never used for mapping temporal modification statements. For a complete coverage of implementing temporal modification statements in a temporal stratum, please see [10].

It is possible to see past states of the database. In particular the following will look at the `emp` table as of the 13th. This is called a time slicing, i.e., the database is rewound to 13th to see the content of the database as of this date.

The ATSQL query in Fig. 4a is a sequenced query that selects the explicit attribute and the valid-time attributes (`vts` and `vte`). The equivalent SQL query translated by a temporal stratum is shown in Fig. 4b. The result of the query is shown in Fig. 4c (using *now*



```
-- at time 4
insert into emp value ('Joe', 'LA')
```

```
insert into emp values
  ( 'Joe',  'LA',
    '2007-09-04', '9999-12-31',
    '2007-09-04', '9999-12-31');
```

Temporal Strata. Figure 6. Temporal aggregation

instead of the maximum date). The temporal SQL query is only slightly simpler than the equivalent standard SQL query.

To see the benefits of a temporal stratum it is necessary to look at more complicated queries. In the following, the focus is on temporal aggregation queries. Alternative complicated queries are temporal join or temporal coalescing.

Assume that a boss wants to see how many employees a company has had over (valid) time looking at the database as of the 13th. The result shown in Fig. 4c is used as an input for this query. For convenience it is assumed that this timeslice query is converted to a view call `empAt13`.

The content of the database is illustrated in Fig. 5, where the vertical dotted lines indicates the time where the result has to be split. The temporal query that expresses this is shown in Fig. 6a and the result of the query is shown in Fig. 6b. Note that the result is not coalesced.

To execute this query the temporal stratum has to find the constant periods, i.e., the periods where the count is the same. Here the temporal stratum can do either direct conversion to standard SQL or do part of the query processing in the stratum. The direct converted query is listed in Fig. 7. The standard SQL is very complicated compared to the equivalent temporal SQL query in Fig. 6a. The benefit for the user should be obvious. In line 1 of Fig. 7, the count and the valid-time start and end associated with the count are selected. In line 2 the view `empat13` from Fig. 4b is used. In addition, the `const_period` is introduced in lines 2–39. In line 40, only those periods that overlap the group currently being considered are included. In line 41, the groups are formed based on the valid-time start and valid-time end. Finally, in line 42 the output is listed in the valid-time start order.

The next question is then the efficiency of executing the query in the underlying DBMS or doing part of the query processing in the temporal stratum. It has been experimentally shown that for temporal aggregation, it can be up to ten times more efficient to do part of the query processing in a temporal stratum [5].

A different approach to adding temporal support to an existing DBMS is to use an extensible DBMS such as IBM Informix, Oracle, or DB2. This is the approach taken in [11]. Here temporal support is added to IBM Informix. Compared to a stratum approach it is not possible in the extension approach to use a new temporal SQL. The temporal extension are accessed by the user via new operators or function calls.

Key Applications

There is no support for valid-time or transaction-time in existing DBMSs. However, in Oracle 10g there is a flashback option [3] that allows a user to see the state

```
select count(name), const_period.vts as vts, const_period.vte as vte
from   empat13, (select t1.vts as vts, t1.vte as vte
                 from   empat13 t1
                 where  not exists ( select *
                                    from   empat13 t2
                                    where (t1.vts < t2.vts and t2.vts < t1.vte) or
                                          (t1.vts < t2.vte and t2.vte < t1.vte))
                 union
                 select t1.vts as vts, t2.vts as vte
                 from   empat13 t1, empat13 t2
                 where  t1.vts < t2.vts and t2.vts < t1.vte
                 and    not exists (select *
                                    from   empat13 t3
                                    where  (t1.vts < t3.vts and t3.vts < t2.vts) or
                                           (t1.vts < t3.vte and t3.vte < t2.vts))
                 union
                 select t1.vts as vts, t2.vte as vte
                 from   empat13 t1, empat13 t2
                 where  t1.vts < t2.vte and t2.vte < t1.vte
                 and    not exists (select *
                                    from   empat13 t3
                                    where  (t1.vts < t3.vts and t3.vts < t2.vte) or
                                           (t1.vts < t3.vte and t3.vte < t2.vte))
                union
                select t1.vte as vts, t2.vts as vte
                from   empat13 t1, empat13 t2
                where  t1.vte < t2.vts
                and    not exists (select *
                                   from   empat13 t3
                                   where  (t1.vte < t3.vts and t3.vts < t2.vts) or
                                          (t1.vte < t3.vte and t3.vte < t2.vts))
                union
                select t1.vte as vts, t2.vte as vte
                from   empat13 t1, empat13 t2
                where  t2.vts < t1.vte and t1.vte < t2.vte
                and    not exists (select *
                                   from   empat13 t3
                                   where  (t1.vte < t3.vts and t3.vts < t2.vte) or
                                          (t1.vte < t3.vte and t3.vte < t2.vte))) const_period
where empat13.vts <= const_period.vts and const_period.vte <= empat13.vte
group by const_period.vts, const_period.vte
order by const_period.vts
```

of the entire database or a single table as of a previous instance in time. As an example, the flashback query in Fig. 8 will get the state of the `emp` table as of the 1st of September 2007 at 08.00 in the morning. The result can be used for further querying.

Future Directions

The Sarbanes-Oxley Act is a US federal law that requires companies to retain all of there data for a period of five or more years. This law may spur additional research with temporal databases and in particular temporal database architecture such as a temporal stratum.

Temporal Vacuuming

John F. Roddick[1], David Toman[2]

Data expiration

Definition

Transaction-time temporal databases are inherently append-only resulting, over time, in a large historical sequence of database states. Data vacuuming allows for a strategic, and irrevocable, deletion of obsolete data.

Historical Background

The term *vacuuming* was first used in relation to databases in the Postgres database system as a mechanism for moving old data to archival storage [10]. It was later refined by Jensen and Mark in the context of temporal databases to refer to the removal of *obsolete* information [4] and subsequently developed into a comprehensive and usable adjunct to temporal databases [6,8,11]. Data expiration has also been investigated in the context of data warehouses by Garcia-Molina et al. [2] and others [9].

Foundations

In many applications, data about the past needs be retained for further use. This idea can be formalized, at least on the conceptual level, in terms of an append-only transaction-time temporal database or a history. However, a naive and unrestricted storage of all past data inevitably leads to unreasonable demands on storage and subsequently impacts negatively on efficiency of queries over such histories. Hence techniques that allow selective removal of *no longer needed* data have been developed and, at least in prototype systems, deployed.

The parts of the historical data that are to be retained/deleted are specified in terms of *vacuuming specifications*. These specifications state, for example, that data beyond certain absolute or relative time point is *obsolete* (as opposed to merely *superceded*) and thus can be removed. For example, the regulation

▶ *"Taxation data must be retained for the last 5 years"*

can be considered a specification of what data individuals must retain concerning their taxation returns and what can be discarded. However, one must be careful when designing such specifications as once a part of the history is deleted, it can no longer be reconstructed from the remaining data. Consider the alternative regulation

► *"Taxation data must be retained for past years, except for the last year."*

While this specification seems to suggest that the data of the last year can be discarded, doing so would lead to a problem in the following year (as this year's return won't be the last one any more). Hence, this specification is intuitively not well formed and must be avoided. Vacuuming specifications can be alternatively phrased in terms of what may be deleted, rather than what should be retained. For example, rather than

► *"Taxation data must be retained for the last 5 years"*

it would be better to rephrase it as

► *"Taxation data over 5 years old may be deleted."*

The reason for this is that vacuuming specifications indicate specific deletion actions and there is thus less chance of misinterpretation.

Another issue with vacuuming specifications relates to the granularity of data that is removed from the history. For example, if data items (such as tax receipts) are temporally correlated with other items that may appear in different, perhaps much older, parts of the history (such as investments), those parts of the history may have to be retained as well. Such considerations must be taken into account when deciding whether the specifications are allowed to refer to the complete history or whether selective vacuuming of individual data items is permitted. In both cases, issues of data integrity need to be considered.

Formal Vacuuming Specifications

A transparent way to understand the above issues is to consider the result of applying a vacuuming specification to a history (i.e., the *retained* data) to be a view defined on the original history.

Definition. Let $H = \langle S_0, S_1, \ldots, S_k \rangle$ be a history. The instances S_i represent the state of the data at time i and all states share a common fixed schema. $\mathbf{T}_H$ and $\mathbf{D}_H$ are used to denote the *active* temporal and data domains of H, respectively. A *vacuuming specification* is a function (a view) $E : H \rightarrow H'$, where H' is called the *residual history* (with some, potentially different but fixed schema).

The idea behind this approach is that the instance of the view represents the *result* of applying the vacuuming specification to the original history and *it is this instance that has to be maintained* in the system. While such view(s) usually map histories to other histories (sometimes called the *residual histories*), in principle, there is no restriction on the schema of these views nor on the language that defines the view. This approach allows us to address the two main questions concerning a vacuuming specification:

- **Is a given specification well formed?** The first question relates to anomalies such as the one outlined in the introductory example. Since only the instance of the view and not the original history itself is *stored*, a new instance of the view must be definable in terms of the current instance of the view $E(H)$ whenever a new state of the history S is created by progression of time. This condition can be formalized by requiring:
$$E(H; S) = \Delta(E(H), S)$$
for some function (query) Δ where $H;S$ is the extension of H with a new state S. To start this process, a constant, $\emptyset$, is technically needed to represent the instance of the view in the beginning (i.e., for an empty initial history). The condition above essentially states that the view E must be *self-maintainable* in terms of the pair $(\emptyset,\Delta)$. The pair $(\emptyset,\Delta)$ is called a *realization* of E.
- **What queries does a specification support?** The second question concerns which queries can be correctly answered over the residual histories. Again, for a query Q to be answerable, it must be the case that
$$Q(H) = Q'(E(H))$$
for some function (query) Q' and all histories H. Q' is a *reformulation* of Q with respect to E. This requirement states that queries preserved by the vacuuming process are exactly those that can be answered only using the view E.

In addition, for the approach to be *practical*, the construction of Δ and $\emptyset$ from E and of Q' from Q and E, respectively, must be effective.

Definition. A vacuuming specification represented by a self-maintainable view E is a *faithful history encoding for a query* Q if Q is answerable using the view E.

Given a vacuuming specification E over a history H that is self-maintainable using $(\emptyset,\Delta)$ and a query Q' that answers Q using E; the triple $(\emptyset,\Delta,Q')$ is then called the *expiration operator* of Q for H.

Space/Storage Requirements

Understanding vacuuming specifications in terms of self-maintainable materialized views also provides a natural tool for comparing different specifications with respect to *how well they remove unnecessary data*. This can be measured by studying the size of the instances of E with respect to several parameters of H:

- The size of the history itself, $|H|$,
- The size of the active data domain, $|\mathbf{D}_H|$, and
- The length of the history, $|\mathbf{T}_H|$.

In particular, the dependency of $|E(H)|$ on $|\mathbf{T}_H|$ is important as the progression of time is often the major factor in the size of H. It is easy to see that vacuuming specification with a *linear* bound in terms of $\mathbf{T}_T$ always exists: it is, e.g., the identity used to define both E and Q'. However, such a specification is not very useful and better results can be probably achieved using standard *compression algorithms*. Therefore the main interest is in two main cases defined in terms of $|\mathbf{T}_H|$:

1. Specifications bounded by O(1), and
2. Specifications bounded by $O(log(|\mathbf{T}_H|))$.

In the first case the vacuuming specification provides a *bounded encoding of a history*. Note that in both cases, the size of $E(H)$ will still depend on the other parameters, e.g., $|\mathbf{D}_H|$. This, however, must be expected, as intuitively, the more H refers to different constants (individuals), the larger $E(H)$ is likely to be (for example, to store the *names* of the individuals).

Vacuuming in Valid-Time Databases. In contrast to transaction-time temporal databases (or histories), valid-time temporal databases allow *arbitrary* updates of the temporal data. Hence information about future can be recorded and data about the past can be modified and/or deleted. This way, vacuuming specifications reduce to appropriate updates of the valid time temporal database.

Moreover, when allowing arbitrary updates of the database, it is easy to show that the only *faithful history encoding*s are those that are lossless (in the sense that H can be reconstructed from the instance of E).

Example. Consider a valid time temporal database H with a schema $\{R\}$ and a query Q asking *"return the contents of the last state of R recorded in H."* Then, for a vacuuming specification E to be a *faithful encoding* of H (w.r.t. Q), it must be possible to answer Q using only the instance of E after updating of H. Now consider a sequence of updates of the form *"delete the last state of R in H."* These updates, combined with Q, can *reconstruct* the contents of R for an arbitrary state of H. This can only be possible if E is lossless.

This, however, means that any such encoding must occupy roughly the same storage as the original database, making vacuuming useless. Similar results can be shown even for valid time databases in which updates are restricted to insertions.

Approaches to Vacuuming

The ability to vacuum data from a history depends on the expressive power of the query language in which queries over the history are formulated and on the number of the actual queries. For example, allowing an arbitrary number of *ad-hoc* queries precludes any possibility effective vacuuming of data, as finite relational structures can be completely characterized by first-order queries. Thus, for common temporal query languages, this observation leaves us with two essential options:

1. An *administrative* solution is adopted and a given history is vacuumed using a set of *policies* independent of queries. Ad-hoc querying of the history can be allowed in this case. However, queries that try to access already expired values (i.e., for which the view is not faithful history encoding) have to fail in a predefined manner, perhaps by informing the application that the returned answer may be only approximate, or
2. A query driven data expiration technique is used. Such a technique, however, can only work for a fixed set of queries *known in advance.*

Administrative Approaches to Vacuuming

One approach to vacuuming data histories, and, in turn, to defining *expiration operators*, can be based on *vacuuming specifications* that define query/application-independent policies. However, when data are removed from a history in such a way, the system should be able to characterize queries whose answers are not affected. A particular way to provide vacuuming specifications (such as through the ideas of Skyt et al. [6,8]) is using *deletion* (ρ) and *keep* (κ)

expressions. These would be invoked from time to time, perhaps by a vacuuming daemon. The complete specification may contain both deletion and keep specifications. For example:

$$\rho(EmpDep) : \sigma_{TT_{end} \leq NOW-1yr}(EmpDep)$$
$$\kappa(EmpDep) : \sigma_{EmpStatus='Retain'}(EmpDep)$$
$$\rho(EmpDep) : \sigma_{VT_{end} \leq NOW-7yrs}(EmpDep)$$

This specification states that unless the Employee has a status of “Retain,” all corrected data should be vacuumed after 1 year and all superceded data vacuumed after 7 years. For safety, keep specifications always override delete specifications (note that the ordering of the individual deletion and keep expressions is significant).

Vacuuming in Practice. Vacuuming specifications are generally given as either part of the relation definition or as a stand-alone vacuuming specification. In TSQL2, for example, a CREATE TABLE command such as:

```
CREATE TABLE EmpDep (
    Name              CHAR(30) NOT NULL,
    Dept              CHAR(30) NOT NULL,
AS TRANSACTION YEAR(2) TO DAY
VACUUM NOBIND (DATE ‘now - 7 days’);
```

specifies *inter alia* that only queries referencing data valid within the last 7 days are permissible [3] while

```
CREATE TABLE EmpDep ( ... )
  VACUUM DATE ‘12 Sep 2007’;
```

specifies that only query referencing any data entered on or after 12 September 2007 are permissible. The VACUUM clause provides a specification of what temporal range constitutes a valid query with the NOBIND keyword allowing DATE to be the date that the query was executed (as opposed to the date that the table was created).

An alternative is to allow tuple-level expiration of data. In this case, the expiration date of data are specified on insert. For example, in the work of Schmidt et al. [5] users might enter:

```
INSERT INTO EmpDep
VALUES (‘Plato’, ‘Literature’, ...)
EXPIRES TIMESTAMP ‘2007-09-12 23:59:59’;
```

to indicate that the tuple may be vacuumed after the date specified.

Application/Query-Driven Approaches

There are many applications that collect data over time but for which there are no *natural* or *a priori* given vacuuming specifications. However, it is still important to control the size of the past data needed. Hence, it is a natural question whether appropriate specifications can be derived *from the (queries in the) applications* themselves (this requires an *a priori* fixed *finite* set of queries – in the case of ad-hoc querying such a specification cannot exist. Formally, given a query language $\mathcal{L}$, a computable mapping of queries $Q \in \mathcal{L}$ to triples $(\emptyset, \Delta, Q')$, such that $(\emptyset, \Delta, Q')$ is an expiration operator for Q over H, has to be constructed. Figure 1 summarizes the results known for various temporal query languages and provides references to the actual techniques and proofs.

Key Applications

The major application domains for vacuuming are historical databases (that, being append only, need a mechanism to limit their size), logs (particularly those collected for more than one purpose with different statutes and business processes), monitoring applications (with rollback requirements) and garbage collection (in programming languages). Also, as *data streams* are essentially *histories*, the techniques and results

Temporal Vacuuming. Figure 1. Space bounds for residual histories.

developed for vacuuming and data expiration can be applied to query processing over data streams. In particular, expiration operators for a given query yield immediately a *synopsis* for the same query in a streaming setting. This observation also allows the transfer of the space complexity bounds.

Future Directions

Most approaches have concentrated on specifying what data to retain for given queries to continue to be answered perfectly. There are two other possibilities:

- Given a particular vacuuming specification and a query that is not supported fully by this specification, can the degree can this query be answered by the residual history be determined? Some suggestions are given by Skyt and Jensen [7] who propose that queries that may return results affected by vacuuming should also provide suggestions for an alternative, similar query.
- Given a requirement that certain queries should not be answered (e.g., for legal reasons), what would be the vacuuming specifications that would guarantee this, in particular in the conjunction with the issue of approximate answers above?

Both of these are areas for further research. Finally, most vacuuming research assumes a static schema definition (or at least, an overarching applicable schema definition). Having the versioning of schema while also handling the vacuuming of data is also an open problem.

Definition

Database technology has evolved in order to be typically oriented towards a large set of non-expert users. While attempting to meet this need, textual query languages, such as SQL, have been replaced by visual query languages, which are based on visual representations of the database and direct manipulation mechanisms. Moreover, data characterized by the temporal dimension play an important role in modern database applications. Temporal Visual Languages are user-oriented languages that meet the specific requirements of querying and visualizing temporal data in an interactive and easy-to-use visual form.

Historical Background

The availability of graphical devices at low cost and the advent of the direct manipulation paradigm [10] have given rise in the last years to a large diffusion of visual user interfaces. Regarding the database area, databases are designed, created, and possibly modified by experts, but there are different kinds of users whose job requires access to databases, specifically for extracting information. However, traditional query languages for databases, such as SQL, are not very approachable for these users, for both their intrinsic syntactical complexity and the lack of a global view of the data of interest together with their interrelationships. Thus, visual interfaces for databases, in particular, the so-called Visual Query Systems (VQS) [4], have arisen as an evolution of the traditional query languages.

VQS include both a language to express queries in a visual form and a query strategy. They are oriented to a wide spectrum of users who generally ignore the inner structure of the accessed database and are characterized by several notable features, such as the availability of interactive visual mechanisms that facilitate the typical process of query formulation and refinement, without requiring users to have a previous knowledge of the database schema and to learn the syntax and semantics of a query language.

Moreover, it has been pointed out that modern database applications deal with temporal data such as banking, medical records, airline reservations, financial data, decision support systems, etc. Several proposals of temporal query languages have been carried out in the past years, where special clauses and predicates are added to the original language in order to deal with the temporal aspects. These languages increase the usability problems of the originating query languages, including quite complex syntax and a steep learning curve. For instance, considering specifically the temporal relational languages, the user must be familiar with concepts such as *tuple* and *attribute time-stamping*, temporal joins, as well as syntax and semantics of temporal predicates. As efforts were made to find new visual query mechanisms for accessing conventional databases, this should also be done for temporal databases.

In order to address this need, some proposals of temporal visual query languages have arisen in the last years. Initial proposals have mainly concentrated on the activity of query formulation, where temporal visual operators are interactively applied over diagrammatic representations of the database schemas exhibiting temporal features. However, most of these visual languages are not provided with formal syntax and semantics [13] and do not address the visual interaction with the query result. Trying to overcome this limitation, a variety of techniques for visualizing time-oriented data have been proposed [12], but they do not support query capabilities for extracting further information. In recent years, research efforts have been made in order to develop temporal visual interfaces in which the end-user could apply visual mechanisms for querying and visualizing temporal data in a single structure.

Foundations

Elements in temporal databases such as objects and their attributes may be temporal, meaning that the history of the successive values of a property is recorded or that the history of an object as a whole may be kept in the database. The valid time of a data element may be a single instant, a time interval or a set of disjoint time intervals.

The process of visual query formulation can be seen as constituted by three phases [13]: the user selects the part of the database he wants to operate on (location phase); then, he defines the relations/restrictions within the selected part in order to produce the query result (manipulation phase); finally, he operates on the query result (visualization phase). The same phases apply to a visual temporal query formulation.

In the *location phase* the goal is the precise definition of the fragment of the database schema involved in the query, known as *query subschema*. Many approaches of temporal visual languages adopt the visualization of the database schemas as Entity-Relationship (ER) diagrams extended with temporal entities (classes) and temporal relationships. Following this approach, the selection of the subschema of interest may be done by selecting the classes, attributes, and relationships of interest [10], including the temporal ones. As an evolution of this ER-based approach a direct manipulation strategy has been proposed in [13], which adopts a "graphical notebook" metaphor for interacting with the database schema. Usability tests showed that this approach was enjoyed by the users, since they prefer to interact with something more familiar.

In the *manipulation phase*, the query subschema can be manipulated in several ways, according to the available query operators on which the detailed conditions of the query must be specified. A database query has two orthogonal components: *selection* and *projection.* In an analogy to a SQL SELECT-FROM-WHERE statement, the SELECT clause gives the data *projection* of the query result, the FROM clause states the *query subschema* of the location phase and the WHERE clause establishes the *selection* conditions on the database in order to retrieve the required data. Temporal queries encompass the possible combinations of current/temporal selection and current/temporal projection over time and data, resulting into nine different combinations beginning from data selection/data projection up to mixed selection/mixed projection [13]. For instance a query '*when did the employee Joseph move from department 1 to department 2, and what salary did he get at the new job?* ' is a data selection (Joseph and the two departments) and mixed projection (date of movement – time; new salary – data).

The question in temporal query processing is how to relate the (temporal-) data of the query to (temporal-) data of the database. This relationship is stated by comparing time-spans of the data lifetime that has been specified in the query with the corresponding lifetimes of objects or attributes in the database. This comparison may include special forms for expressing temporal restrictions or relations between the query and the database.

Temporal visual languages can use a set of visual representations for time and temporal relations, depending on the type of request: snapshot or slice [14]. Snapshot queries deal with facts that were valid at a particular time instant, whereas slices queries return facts that were valid over some period of time. Regarding snapshot queries, instants are visually represented as circles or small vertical bars. If *p* is a time instant (point) of the query and *t* is the valid time of an object (or attribute), the temporal relations between them can be visually represented as icons (Fig. 1).

Regarding slice queries, the temporal relations between time intervals are based on Allen's Calculus of temporal intervals [3], which gives a complete set of possible relations between two (temporal) intervals. If both the database time *tv* and the query time *p* are intervals, the relational primitives of Allen can be visually represented as icons (Fig. 2). Instead of using icons for expressing temporal relations, a more intuitive

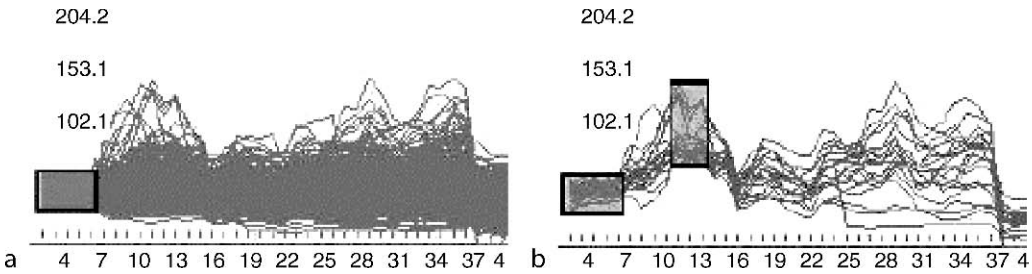
form of expressing such relations is to visually represent intervals as horizontal slide bars in order to dynamically specify the predicates of Allen. For instance, Silva et al. [13] have proposed a mobile slider, as illustrated in Fig. 3.

However, one of the most difficult problems in designing a temporal visual language is to achieve both high expressive power and ease-of-use. For example, the two representations illustrated above cannot deal with situations involving more than two intervals. In this case, the logical expressions between temporal relations (involving conjunctions and disjunctions) should be addressed in this manipulation phase. Some proposals address such a need by adopting visual metaphors for complex representation of temporal relations [6, 8] in a temporal query formulation. Considering that the endpoints may be imprecise or variable, Chittaro and Combi [6] propose three alternative visual representations of flexible temporal intervals in order to deal with variable endpoints. Hibino and Rudensteiner [8] propose a bar with alternative endpoints, e.g., for specifying the temporal relation between two intervals starting at the same time but without restriction on the end, giving rise the logical expression *begins(A,B)* ∨ *equals(A,B)* ∨ *begins(B,A)*.

Moreover, other complex temporal relations such as temporal patterns should be also addressed. For instance, users might be interested in data related to events of arbitrary duration or events separated by arbitrary time gaps. The temporal visual language defined in [7] address such a need by presenting visual metaphors for expressing event-based queries, where constraints on events and inter-event time-spans are visually specified in different ways.

Finally in the *visualization phase*, the historical data retrieved from the query result is visualized for



Temporal Visual Languages. Figure 4. History with "TimeBox" [9].

interactive exploration and analysis. The most widely known visualization technique of time-oriented data are the interactive timeline [12], where the time is regarded as an ordinal axis in a bi-dimensional (2D) visualization and data are located at different positions along this time axis. Timelines and other visualization techniques can be categorized according to the generic criteria that address ontologies about the time, such as the temporal primitives that make up the time axis (time points and intervals), the temporal order (linear, cyclic or branching), etc. For instance, timeline visualization takes advantage of the linear ordered nature of time. An additional criterion is if time-oriented visualization supports the snapshot or slice views [12]. Other relevant criterion is the data tied to time axis [2], such as the data type which indicates if the data are abstract or spatial; the number of involved variables (univariate or multivariate) related to the data (temporal attributes and relationships); and its abstraction level (e.g., raw vs. aggregated data).

It is worth noting that for an effective exploration of data, visual techniques must be integrated with suitable interaction techniques, following the principle of visualization information mantra, defined in [11]: *overview first, zoom and filter, then details-on-demand*, where visual tools exploring the *dynamic query* approach [1] are well-known implementations of this principle. This means that starting from an overview of a large dataset, one may zoom and filter this overview to extract a data subset. Then, more details can be obtained from the selected data subset. In dynamic queries, the manipulation and visualization phases proceed iteratively in a visual query formulation. This means that, after visualization of a preliminary result, the user may interact with this result in order to refine the query.

Within this context, the visualization phase in temporal visual languages focuses on visual query and exploration of temporal trends and patterns within historical results from a preliminary query by using suitable interactive visualization techniques. When exploring such data, suitable interaction techniques such as the direct manipulation and brushing can be integrated with visual query capabilities. For instance, *TimeSearcher* [9] allow users to visually query and explore patterns in time-series data by using visual widgets for data filtering called "*TimeBoxes*." *TimeBoxes* are rectangular query locators that specify the region(s) in which the users are interested. They are placed and directly manipulated on a 2D timeline, with the region boundaries providing the query parameters, as illustrated in Fig. 4. The extent of the *Timebox* on the time (x) axis specifies the time period of interest, while the extent on the value (y) axis specifies a constraint on the range of data values of interest. In this case, a query is dynamically created by drawing a box on the timeline. Multiple timeboxes can be combined to specify conjunctive queries. Only data sets that match all of the constraints implied by the timeboxes are visualized.

Key Applications

Temporal Visual Languages may be integrated with Spatial Visual Languages for Geographic Information Systems. Other typical applications are virtual reality, moving objects, or multimedia systems, such as video and audio data. It can be also an important concern in Visual Analytics.

In the medical field, there are many different applications needing temporality of patient records, images, examination events, and so on.

The classic application fields of Temporal Databases are systems of planning data, or systems of historic data, such as banking account, economic data, meteorological data, business histories, and many others. Also in Decision Support Systems, such as OLAP – Online Analytical Processing, time is the most important dimension.

Another promising application is related to the document management, which is based on time-changing texts, such as legal data or instructional texts. For instance, a judgment support system based on jurisprudence must consider the temporal context of past judgments.

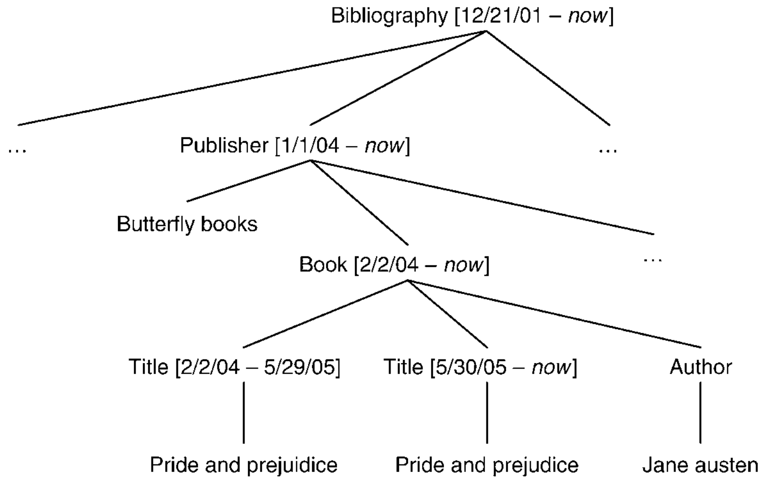
Temporal semi-structured data

Definition

Temporal XML is a *timestamped instance* of an XML data model or, more literally, an XML document in which *specially-interpreted* timestamps are present. In general, an XML data model instance is a tree or graph in which each node corresponds to an element, attribute, or value, and each edge represents the lexical nesting of the child in the parent's content. In temporal XML, a timestamp is added to some nodes or edges in the instance. The timestamp represents the lifetime of the node or edge in one or more temporal dimensions, usually valid time or transaction time. As an example, Fig. 1 shows a fragment of a temporal XML data model. The bibliographic data in the figure contains information about publishers, books, and authors. The figure also has timestamps that represent *when* each piece of data was entered into the data collection (i.e., the timestamps represent the *transaction-time* lifetime of each element). The bibliography began on Dec 21. 2001, and remains current (until *now*). Information about the Butterfly Books publisher was entered on Jan 1, 2004, and it started publishing a book by Jane Austen on Feb 2, 2004. The title of that book was originally misspelled, but was corrected on May 29, 2005. Alternatively, temporal XML is literally an XML document or data collection in which specially-interpreted timestamps, formatted



Temporal XML. Figure 1. A temporal XML fragment.

in XML, are included. Such a document yields a temporal XML data model instance when parsed.

Historical Background

XML is becoming an important language for data - representation and exchange, especially in web applications. XML is used to "mark-up" a data collection or document adding meaning and structure. The mark-up consists of elements inserted into the data. Usually an XML document is modeled as a tree in which each interior node corresponds to an element in the document and each leaf to a text value, attribute, or empty element. Temporal XML adds timestamps to the nodes and/or edges in the data model instance. The timestamps represent the lifetime of the nodes (edges).

Grandi has created a good bibliography of research in this area [8]. Chawathe et al. were the first to study time in an XML-like setting [2]. They encoded times in edge labels in a semi-structured database and extended the Lorel query language with temporal constructs. Dyreson et al. extended their research with collapsing and coalescing operators [5]. Grandi and Mandreoli presented techniques for adding explicit valid-time timestamps in an XML document [9]. Amagasa et al. next developed a temporal extension of the XML data model [1]. Following that, a range of temporal XML topics was investigated, from storage issues and indexing [3,11,12,13,14] to querying [6,7,12]. The timestamping of XML documents (or parts thereof) has also been considered in the more general context of versioning of XML documents [11,15]. Finally, schemes for validating and representing times in XML documents have also been considered [4,10].

Foundations

It is important to distinguish between "the representation in XML of a time" and "temporal XML." Times are common in many XML documents, especially documents that record the history of an enterprise. There is nothing special about the representation or modeling of these times. They would be modeled just the same as any other snippet of XML, e.g., represented within a <time> element. Temporal XML, on the other hand, is different. It models both the components within a document or data collection and their lifetimes. An instructive way to think about the difference is that temporal XML weds metadata in the form of timestamps to data contained in a document, i.e., to the elements or parts of the document that are annotated by the timestamps. Research in temporal XML builds on earlier research in temporal (relational) databases. Though many of the concepts and ideas carry over to temporal XML research, the ideas have to be adapted to the tree-like model of XML.

Many temporal XML data models impose a transaction-time constraint on the times along every path in a model instance: the timestamp of a child must be during (inclusive) the timestamp of its parent [1,4]. Said differently, no child may outlive its parent in transaction time. The reason for this constraint is that every snapshot of a temporal data model instance must be a single, complete, valid non-temporal XML data model instance. A non-temporal instance has a single root. But if in a temporal instance a child outlives its parent then, in some snapshot(s), the child represents a second root since it has no parent, thus violating a model property. In valid time it is more common to relax this constraint and model a temporal data collection as a sequence of forests where a child that outlives its parent is interpreted to mean that the child is the root in some snapshot(s) of some tree in the forest [10]. For instance, the valid time of Jane Austen's book Pride and Prejudice would extend from its time of publication (1813) to *now*, far exceeding the lifetime of its publication by Butterfly Books.

Another interesting situation is when a child moves among parents over time (for instance, in the data collection shown in Fig. 1 if the book Pride and Prejudice were published by two different publishers). A directed graph data model is better suited to modeling such movement as a node (e.g., the book) can have multiple incoming edges (e.g., an edge from each publisher) [5]. Various constraints have been proposed for relationships among the timestamps on nodes and edges in the graph.

Timestamps on nodes/edges in a data model instance changes query evaluation. At the core of all XML query languages (and different from SQL or relational query languages) are path expressions that navigate to nodes in a data model instance. In a temporal data model instance, a query has to account for the timestamps along each path that it explores. In general, a node is only available during the intersection of times on every node and edge in the path to it (though a node in a graph data model can be reached along multiple paths). Temporal XML queries can be evaluated using a sequenced semantics [7], that is, simultaneously evaluated in every snapshot or non-sequenced [6,14] where differences between versions can be extracted and paths between versions are directly supported by the data model.

Key Applications

Temporal XML can be used to model an evolving document or data collection. In many situations, "old" documents or document versions are still of use. For instance, in an industrial domain an airplane parts manufacturer has to retain part plan histories to produce parts for older planes, while in the legal domain a tax firm has to keep a complete history of tax laws for audits. Currently, the de facto method for storing old documents is an *archive*. An archive is a warehouse for deleted or modified documents. Archives can be site-specific or built for a number of sites, e.g., the Internet Archive. But the method to retrieve documents from an archive varies widely from site to site, which is problematic because then queries also have to vary. Moreover, archives typically only support retrievals of entire document versions, not a full range of temporal queries or version histories of individual elements. In contrast, temporal XML provides a basis for supporting a full range of temporal queries. Temporal XML can also be explicitly used to represent, store or view historical data, including structured data, or to encode multi-version documents. Multi-version documents are compact representations of XML documents which maintain their identity through modifications and amendments. A temporally consistent individual version or range of consecutive versions (timeslice) can be extracted by means of a temporal query. Temporal XML has also been proposed as a medium of communication with temporal relational databases in the context of traditional enterprise applications.

Future Directions

The future of temporal XML is tied to the continued growth of XML as an important medium for data storage and exchange. Currently, many sites promote XML by publishing data formatted in XML (e.g., genomic and proteomic data can be obtained in three, different XML formats from the National Center for Biotechnology Information (NCBI)). Building a temporal XML data collection by accumulating snapshots gathered from these sites is vital to answering queries such as "What new data has emerged over the past six months?" As search engines become more XML-aware, they could also benefit enormously from making time a relevant component in ranking resources, e.g., a search for "mp3 players" should lower the ranking of discontinued products. The growth of the Semantic Web may lead to XML being supplanted by new languages for knowledge representation such as the Ontology Web Language (OWL). Temporal extensions of these languages will not be far behind. OWL already has one such extension: the Time-determined Ontology Web Language (TOWL).

Term Proximity

Vassilis Plachouras
Yahoo! Research Barcelona, Spain

Synonyms

Lexical affinities; Lexical relations

Definition

Term proximity is a form of term dependence based on the distance of terms in a document. A retrieval system using term proximity assigns a higher score to documents in which the query terms appear close to each other.

Key Points

Term proximity is a feature that partially captures the dependence of terms in documents. Information retrievals models are often based on the assumption that terms occur independently of other terms in a document. This assumption is only an approximation to allow the simple mathematical development of retrieval models. There have been, however, several efforts to introduce dependence of terms [4]. Most of the efforts to use term proximity in the past did not result in substantial improvements. Metzler and Croft [2] argued that this can be attributed to the small size of the test collections used in the past, as well as to the fact that previous models required estimating term dependencies for both the classes of relevant and non-relevant documents.

Metzler and Croft [2] proposed a model based on Markov Random Fields for term dependence using term proximity. They modeled full independence, sequential dependence that is equivalent to phrase search, and full dependence, where the dependence between any pair of query terms is computed. Mishne and de Rijke [3] also proposed a model in which every n-gram of the query is considered as a phrase, and it is evaluated on an index consisting of single terms. Their results show that improvements in early precision are obtained in the setting of Web search. In both models, term proximity is based on lexical relations [1]. Terms are said to be in a lexical relation if they appear often within a certain number of tokens of each other.

Term Statistics for Structured Text Retrieval

Mounia Lalmas
Queen Mary, University of London, London, UK

Synonyms

Within-element term frequency; Inverse element frequency

Definition

Classical ranking algorithms in information retrieval make use of term statistics, the most common (and basic) ones being within-document term frequency, *tf*, and document frequency, *df*. *tf* is the number of occurrences of a term in a document and is used to reflect how well a term captures the topic of a document, whereas *df* is the number of documents in which a term appears and is used to reflect how well a term discriminates between relevant and non-relevant documents. *df* is also commonly referred to as inverse document frequency, *idf*, since it is inversely related to the importance of a term. Both *tf* and *idf* are obtained at indexing time. Ranking algorithms for structured text retrieval, and more precisely XML retrieval, require similar terms statistics, but with respect to elements.

Key Points

To calculate term statistics for elements, one could simply replace documents by elements and calculate so-called within-element term frequency, *etf*, and inverse element frequency, *ief*. This however raises an issue because of the nested nature of XML documents in particular. For instance, suppose that a section element is composed of two paragraph elements. The fact that a term appears in the paragraph necessitates that it also appears in the section. This overlap can be taken into account when calculating the *ief* value of a term.

In structured retrieval, in contrast to "flat" document retrieval, there are no a priori fixed retrieval units. The whole document, a part of it (e.g., one of its section), or a part of a part (e.g., a paragraph in the section), all constitute potential answers to queries. The simplest approach to allow the retrieval of elements at any level of granularity is to index all elements. Each element thus corresponds to a document, and *etf* and *ief* for each element are calculated based on the concatenation of the text of the element and that of its descendants (e.g., [4]).

With respect to the calculation of the inverse element frequency, *ief*, the above approach ignores the issue of nested elements. Indeed, the *ief* value of a term will consider both the element that contains that term and all elements that do so in virtue of being ancestors of that element. Alternatively, *ief* can be estimated across elements of the same type (e.g., [3]) or across documents (e.g., [1]). The former greatly reduces the impact of nested elements on the *ief* value of a term, but does not eliminate it as elements of the same type can be nested within each other. This approach can be extended to consider the actual path of an element, leading to so-called inverted path frequency. For example, in [2], this is defined as the combination of the *ief* values (as above calculated) with respect to each of the element types forming the path. The latter case, i.e., calculating *ief* across documents, is the same as using inverse document frequency, which completely eliminates the effect of nested elements.

Term Weighting

Ibrahim Abu El-Khair
Minia University, Minia, Egypt

Definition

Term weighting is a procedure that takes place during the text indexing process in order to assess the value of each term to the document. Term weighting is the assignment of numerical values to terms that represent their importance in a document in order to improve retrieval effectiveness [8]. Essentially it considers the relative importance of individual words in an information retrieval system, which can improve system effectiveness, since not all the terms in a given document collection are of equal importance. Weighing the terms is the means that enables the retrieval system to determine the importance of a given term in a certain document or a query. It is a crucial component of any information retrieval system, a component that has shown great potential for improving the retrieval effectiveness of an information retrieval system [7].

Historical Background

The use of word frequency dates back to G. K. Zipf and his well known law [14] for word distribution. The law indicates that there is a correlation between the frequency of a word and its rank, and their product is a constant.

$$r^*f = c$$

where: r is the rank of the word
f is the frequency of the word
c is a parameter/constant that depends on the text being analyzed.

Zipf indicates that this law is a way to express the within-document frequency weighting.

The use of word frequency as an indication of its significance in a given document was established almost 10 years later based on observations made by Luhn [4] when he was conducting an explanatory research on creating automatic abstracts in scientific documents. Based on these observations, Luhn proposed that the frequency of word occurrence in a document can be considered a useful measure of the word's significance in that document. The premise is that the author of a certain document repeats certain words as he/she presents his/her argument elaborating the subject of the document.

Looking at the word distribution in any given document shows that there are significant words and insignificant words. Luhn used Zipf's law as his null hypothesis [14] to enable him to specify two cut-off points to exclude all insignificant words, an upper point and a lower point. The upper cut-off eliminated the common words, and the lower point eliminated the rare words; both of which he considered extraneous in the document content. After Luhn excluded words above and below these two cut off points, the most useful range of words remained.

The 1960's saw several key developments in the field of information retrieval in general and the most notable were related to the development of the SMART system by Gerard Salton and his students, first at Harvard University and later at Cornell University. This system utilized weights for index terms based on their frequency [10]. The probabilistic approach to retrieval, with term weights based on probability of relevance, appeared in 1960 and since then it has been tested heavily with many variations [12].

The decade of the 1970's saw a breakthrough in the calculation of term weights used in retrieval systems. By then, it was confirmed that the significance of a certain term in a given document is determined using the term frequency of that term in the document. Sparck Jones [11] argued that the term frequency by itself is not sufficient enough to measure the importance of a term in a collection of documents. She suggested correlating the term frequency with its relative collection frequency, making the collection frequency a variable in retrieval. A significant development in the probabilistic based retrieval was also achieved in 1976 by Robertson and Sparck Jones [6].

Foundations

Storing, organizing, and retrieving information are the main functions of an information retrieval system. With the vast amounts of electronic information now available it is very hard to find the ideal information retrieval system that enables users to get what they want from a specific collection of documents. A considerable amount of research has addressed improvement in the effectiveness of retrieval systems, most of which is focused on finding appropriate indexing techniques. The indexing process in any retrieval system deals with assigning a set of index terms that represents the content of each document within a collection. Choosing the proper index terms is a primary issue in information retrieval systems, as they should be indicative of the content of a given document.

One of the most important procedures in the indexing process is assigning a value, or weight, to an index term in a document. It is a crucial component of any retrieval system, and one that has shown great potential for improving retrieval effectiveness [7]. By assigning a numerical value to a term representing its importance in the document, retrieval effectiveness can be improved [8]. Term weighting indicates how important each individual word is to the document and within the document collection.

The process of assigning term weights is affected by three major factors: term frequency, inverse document frequency, and document length.

Term Frequency

Following Luhn's observations [4], it is known that the significance of a certain term in a given document can be represented by the term frequency of that term in the document. Simply, if there is a document in which the word "database" occurs a hundred times, that document would potentially be more useful in response to a query containing "database" as a query term than a document in which the word appears only one or two times. Of course, the use of this factor alone in calculating the term weights in a collection of documents does not guarantee adequate retrieval performance. For example, there are very common words, sometimes referred to as stop words, which appear in the text but carry little meaning, serving only a syntactic function but not indicating subject matter [3]. They have a very high frequency and tend to diminish the impact of frequency differences among less common words, affecting the weighting process [2].

Inverse Document Frequency

The term frequency indicates the importance of the term in a given document, but knowing the term importance in a collection of documents is also significant. Term frequency was criticized as a method of determining term significance because in its simplest form, it treats all terms equally based on raw count, which does not take into account the term's discriminating power. To resolve this problem Sparck Jones [11] suggested the use of the relative collection frequency or inverse document frequency (IDF), making the frequency of the term in the collection as a whole a variable in retrieval. IDF places greater emphasis on the value of a term as a means of distinguishing one document from another than on its value as an indication of the content of the document itself.

Document Length

With the presence of long documents in the document collection handled by any retrieval system, it became harder to determine the importance of a term based only on the term frequency or the inverse document frequency or both. Even though the combination of them is a good weighting function, it overlooks the document length factor. Longer documents will have higher term frequencies because the terms tend to be repeated several times in the document, and thus will be high in the ranking during the retrieval process. Long documents are also likely to contain more unique terms which may affect the retrieval as well. More terms in a given document increases the possibility of matching between this document and multiple queries [7]. Applying a good normalization technique reduces the effect of long documents and makes the weighting function more effective. Another element to be taken into consideration with the document length factor is the removal of stop words, which changes the document length and subsequently affects the weighting process [2].

Term Weighting Schemes

The following is a brief and basic explanation of some of the major term weighting schemes available. It should be noted that each scheme has many variations and modifications that are not discussed.

TF*IDF A weighting function that depends on the term frequency (TF) in a given document calculated with its relative collection frequency or inverse document frequency (IDF). The term frequency emphasizes term significance in a given document, and inverse document frequency emphasizes term significance in the collection as a whole (TF*IDF).

BM25 A weighting function based on the traditional *Probabilistic Retrieval Model*. The basic principle is that a specific document could be judged relevant to a specific query, based on the assumption that the terms are distributed differently and independently in relevant and non relevant documents. The weight of a given term is calculated on the basis of the presence or absence of query terms in each document in the collection. Terms that have appeared in previously retrieved relevant documents for a given query should be given a higher weight than if they had not appeared in those relevant documents [12].

Language Modeling Language modeling (LM) is an extension of the probabilistic retrieval approach. It is a probabilistic mechanism for generating text, first applied by Andrei Markov at the beginning of the twentieth century to model letter sequences in works of Russian literature. It was also used by Claude Shannon in his models of letter sequences and word sequences, which he used to illustrate the implications of coding and information theory. At the end of the 1970's, LM was used successfully in speech recognition, which was its main application for many years [1]. In 1998 Ponte and Croft [5] were the first to apply language modeling to information retrieval. Their approach was to infer a language model for each document and estimate the probability of generating the query according to each of these models, and then rank the documents according to these probabilities. The results indicated an improvement in retrieval over the traditional TF*IDF, and there was further improvement when they used a smoothing function with their new approach.

Key Applications

Term weighting is a key process in any information retrieval system. It is the means that enables the system to determine the importance of any term in a certain document or a query.

Experimental Results

Experimentation in information retrieval has been an active area for over 40 years, and much of this research has focused on term weighting. Different schemes and variations with different retrieval models have been tested in order to find weighting schemes that perform effectively. In general, the schemes above and their variations have been tested extensively and evaluated (see the corresponding references). Many other weighting schemes were developed and used but without becoming widely adopted, either because the results were not effective enough or because of the complexity of the calculations or both. The Term Discrimination Value (TDV) model of indexing [9] is an example which is now seldom used because of its complexity and weak results.

Until the 1990s, experiments in the field of information retrieval in general and term weighting in particular were conducted on relatively small collections. With the beginning of TREC (http://trec.nist.gov) (Text REtrieval Conference) in 1992, large test collections became available for use by the IR community, making the results of experiments more credible and generalizable. Research in term weighting benefited, establishing the effectiveness of term weighting schemes such as BM25.

Test Collection

Ben Carterette
University of Massachusetts Amherst, Amherst, USA

Synonyms

Corpus

Definition

A test collection is a standard set of data used to measure search engine performance. It comprises a set of queries, ideally randomly sampled from some space, a set of documents to be searched, and a set of judgments indicating the relevance of each document to each query in the set.

Key Points

The use of test collections for performance evaluation began with Cleverdon and Mills [1] and is today known as the Cranfield methodology. Test collections today are much larger than Cleverdon's Cranfield collection, consisting of millions of documents and tens of thousands of relevance judgments. The advantage of having standardized test collections is that experimental results can be compared across research groups and over time.

The National Institute of Standards and Technology (NIST), through their annual Text REtrieval Conferences (TREC), has led the way in providing test collections for information retrieval research. NIST has assembled large-scale test collections for many different retrieval tasks and types of documents and made these available to researchers so that the state of the art in retrieval can be constantly improved.

Text classification

Definition

Text classification is to automatically assign textual documents (such as documents in plain text and Web pages) into some predefined categories based their content. Formally speaking, text classification works on an instance space X where each instance is a document d and a fixed set of classes $C = \{C_1,C_2,...,C_{|C|}\}$ where $|C|$ is the number of classes. Given a training set D_l of training documents $\langle d,C_i\rangle$ where $\langle d,C_i\rangle \in X \times C$, using a learning method or learning algorithm, the goal of document classification is to learn a classifier or classification function γ that maps instances to classes: $\gamma : X \rightarrow C$ [7].

Historical Background

Text classification, which is to classify documents into some predefined categories, provides an effective way to organize documents. Text classification dates back to the early 1960s, but only in the early 1990s did it become a major subfield of the information systems discipline. Recently, with the explosive growth of online textual data, text classification attracts more and more attention. A knowledge engineering approach is one of the most popular solutions before the late 1980s, which relies on manually defined rules encoding expert knowledge on how to classify documents under the given categories. After that, machine learning based methods became pervasive. These methods automatically build some automatic text classifiers by learning from a set of manually classified documents. The following sections will focus on machine learning based methods.

Foundations

Text categorization consists of several important components including document representation, dimensionality reduction, classification algorithms and performance evaluation, which are to be introduced in the followings sections. Readers are referred to [11] for more details.

Document Representation

Documents or Web pages cannot be directly interpreted by a classifier. Therefore, a proper representation approach is necessary to represent documents. Generally, a document d is usually represented as a vector of term weights $d = \langle w_1,w_2,...,w_{|V|}\rangle$, where V is the set of terms (sometimes called features) that occur at least once in the training document set D_l. This way is known as Vector Space Model (VSM) [7]. Different representation approaches vary in two issues: (i) different ways of understanding what a term is; (ii) different ways of computing term weights. For issue (i), a straightforward way is to identify terms with words. This is often called either the set-of-words or the bag-of-words approach to document representation, depending on whether weights are binary or not [11]. Although some previous work has found that representations more sophisticated than this are not significantly more effective [1], researchers still struggle to find better ways in the following four directions: (i) Represent a document by phrases [6]; (ii) Use the senses of words to represent a document [4]; (ii) Augment document representation by hidden concepts in a document; (iv) Employ language models, such as n-gram models [9], multigram models. For issue (ii), the weight can be binary (1 denoting presence and 0 absence of the term in the document) or nonbinary. For the nonbinary value of a term *t*, it can be either the Term Frequency (TF) of the term in a document or TFDIF as computed according to the following equation where $N(t,d)$ is the number of times the word *t* appears in *d*, $|D|$ is the size of the corpus, $n_{t,D}$ is the number of documents in D containing the word *t*:

$$w_t = N(t,d)*log(|D|/n_{t,D})$$

Sometimes, the document vectors are normalized by cosine normalization [11]. Using either binary or nonbinary values, either normalized or the original values depends on the classifier learning algorithm.

Generally, the bag-of-words representation is built based on the text in each document alone. However, it is not uncommon that some documents have certain relationships among them so that the text in one document can help enrich the text of its related documents to improve the classification results. The relationships among documents are quite obvious in the context of Web-page classification. For example, in [2], Glover et al. enrich Web pages by considering inbound links and words surrounding them. They come to the conclusion that the full-text of a Web page is not good enough for representing the Web pages for classification. They create virtual documents by incorporating anchor text and extended anchor text. The experimental results demonstrate that the virtual documents, especially when constructed through extended anchor text are of great help. In [13], the authors enhance the notion of virtual documents by complementing hyperlinks with implicit links which are extracted from query logs. Besides utilizing the links among documents, there are also works enriching documents by inserting features extracted from an existing knowledge base.

Dimensionality Reduction

In document classification, it is unavoidable to face the problem of high dimensionality. The original feature space consisting of the unique terms that occur in a moderate-sized document collection can reach hundreds of thousands of terms. Such high dimensionality prohibits the application of many classification algorithms such as neural networks and Bayes belief models [15]. Furthermore, some features in the native space do not contribute much to the document classification. Therefore, it is beneficial to conduct dimensionality reduction (DR). DR techniques consist of two groups, term selection and term generation. Term selection methods select a subset of terms from the native space while term generation methods obtain new features by combining or transforming the original ones. The methods belonging to the former group include Document Frequency (DF), Mutual Information (MI), Chi-Square and so on. The latter group of methods include Term Clustering, and Latent Semantic Indexing (LSI). A detailed analysis and comparison of these methods is presented in [11,15].

Related to feature selection, some works have tried to remove noise from documents. It is easy to imagine that some text in a document, especially in a Web page, is not related to the main topic of the documents. When judging the category of a document, only the main topic of the document should be considered and the irrelevant text should be removed. These works are different from conventional feature selection in that they process each document independently and the resultant feature space can still have high dimensionality. For example, in [5], Kolcz et al. use summarization as a feature selection method and apply a simple extraction-based technique with several heuristic rules. Different from Kolcz et al's work on pure-text document classification, [12] proposes to improve the Web-page classification performance by removing the noise through some summarization techniques.

Classification Algorithms

During the past few decades, a large number of categorization algorithms have been proposed for document classification such as naïve bayes [8], k-nearest neighbor, decision trees, regression models, neural networks, support vector machines [3], boosting and rule learning algorithms. The authors of [14] made a thorough comparison among these classifiers. In this section, two widely used text classification algorithms, Naive Bayes (NB) and Support Vector Machine (SVM) are briefly introduced.

Naïve Bayesian Classifier (NB) The Naïve Bayesian Classifier (NB) is a simple but effective text classification algorithm which has been shown to perform very well in practice [8]. The basic idea of NB is to use the joint probabilities of words and categories to estimate the probabilities of categories given a document. As described in [8], most researchers employ NB method by applying Bayes' rule:

$$P(C_j|d_i;\hat{\theta}) = \frac{P(C_j|\hat{\theta})\prod_{k=1}^{|V|}P(w_k|C_j;\hat{\theta})^{N(w_k,d_i)}}{\sum_{r=1}^{|C|}P(C_r|\hat{\theta})\prod_{k=1}^{|V|}P(w_k|C_r;\hat{\theta})^{N(w_k,d_i)}}$$

where $P(C_j|\hat{\theta})$ can be calculated by counting the frequency with each category C_j occurring in the training data; $|C|$ is the number of categories; $p(w_i|C_j)$ stands for probability that word w_i occurs in class C_j which may be small in training data, so the Laplace smoothing is chosen to estimate it; $N(w_k,d_i)$ is the number of occurrences of a word w_k in d_i; $|V|$ is the number of words in the training data.

Support Vector Machine (SVM) SVM is well founded in terms of computational learning theory and has been successfully applied to text categorization [3]. SVM operates by finding a hyper-surface in the space of possible inputs. The hyper-surface attempts to split the positive examples from the negative examples by maximizing the distance between the nearest of the positive and negative examples to the hyper-surface. Intuitively, this makes the classification correct for testing data that is near but not identical to the training data. There are various ways to train SVMs. The SVM^{light} system provided by Joachims [3] is one of the widely adopted and efficient implementations.

Performance Measures

Precision, recall and F1-measure are the most popular measures to evaluate the performance of document classification [10]. Precision (P) is the proportion of actual positive class members returned by the system among all predicted positive class members returned by the system. Recall (R) is the proportion of predicted positive members among all actual positive class members in the data. F1 is the harmonic average of precision and recall as shown below:

$$F1 = 2 \times P \times R/(P + R)$$

To evaluate the average performance across multiple categories, there are two conventional methods: micro-average and macro-average. Micro-average gives equal weight to every document; while macro-average gives equal weight to every category, regardless of its frequency [14].

Key Applications

Text classification has many applications [9], including email classification, text genre classification, topic identification, subjective sentiment classification and Web query classification.

Data Sets

There are several open data sets for text categorization. See the following for details:

Text Clustering

Hua Li
Microsoft Research Asia, Beijing, China

Definition

Text clustering is to automatically group textual documents (for example, documents in plain text, web pages, emails and etc) into clusters based on their content similarity. The problem of text clustering can be defined as follows. Given a set of n documents noted as *DS* and a pre-defined cluster number *K* (usually set by users), *DS* is clustered into *K* document clusters$DS_1, DS_2,\ldots,DS_k$, $(i.e, \{DS_1, DS_2,\ldots,DS_k\} = DS)$ so that the documents in a same document cluster are similar to one another while documents from different clusters are dissimilar [14].

Historical Background

Text clustering was initially developed to improve the performance of search engines through pre-clustering the entire corpus [2]. Text clustering later has also been investigated as a post-retrieval document browsing technique [1,2,7].

Foundations

Text clustering consists of several important components including document representation, text clustering algorithms and performance measurements. The readers should refer to [6,8,13] for more details.

Document Representation

The original representation of textual documents (like plain texts, web pages, emails and etc) could not be interpreted by text clustering algorithms directly. A proper document representation method is necessary for any text clustering algorithms. Vector Space Model [6] is generally used to represent a document *d* as a vector of term weights $d =< w_1, w_2,\ldots,w_{|V|} >$, where *V* is the set of terms (also named as features sometimes) that occur at least once in the document set *DS*. Different representation approaches vary in two issues: (i) different ways of understanding what a term is; (ii) different ways of computing term weights. For issue (i), a straightforward way is to identify terms with words. This is often called either the set-of-words or the bag-of-words approach to document representation, depending on whether weights are binary or not [11]. Some previous work has found that representations more sophisticated than this are not significantly more effective [5]. For issue (ii), the weight can be binary (1 denoting the presence and 0 absence of the term in the document) or non-binary. For the non-binary value, it can be either the Term Frequency (*TF*) of the term in a document or *TFIDF* as computed according to the following equation where *N(t, d)* is the number of the times the word *t* appears in *d*, $|D|$ is the size of the document corpus, $n_{t,D}$ is the number of documents in *D* containing the term *t*:

$$w_t = N(t, d) * \log(|D|/n_{t,D})$$

Cosine normalization is sometimes used to normalize the document vectors [11]. It would depend on the text clustering algorithms to choose proper term weight strategies.

Text Clustering Algorithms

Two categories can be used to organize all various clustering algorithms (most of the general clustering algorithms could be applied to text clustering tasks) developed in the past a few years: hierarchical and paritional approaches. The hierarchical algorithms generate successive clusters in a nested sequence. The partitional ones produce all clusters at one time.

In the following section, three popular clustering algorithms would be briefly introduced for readers to get primary impressions of basic clustering algorithms. Single-Link clustering [3] is one basic approach among hierarchical clustering algorithms category (http://en.wikipedia.org/wiki/Cluster_analysis). *K*-Means clustering [9] is one of the typical partitional algorithms which minimizes square error to generate clusters. Co-clustering [4] is a graphic theory based partitional clustering approach which is very popular in recent years. For more clustering algorithms, the readers can refer to [6].

Single-Link Clustering In the Single-Link clustering, the distance between two clusters is defined as the minimum of the distances of all linkages drawn from the two clusters, where the linkage is the criterion to determine the distance of pairs of patterns/points between two clusters while patterns/points are associated with them. One shortcoming of the Single-Link clustering is that it would suffer from a chaining effect [10] which has a tendency to produce clusters that are straggly or elongated [6].

The three main steps of Single-Link Clustering algorithm are as follows [6]:

1. With each pattern/point in its own cluster, construct a list of inter-pattern/point distances for all distinct N ordered pairs of patterns/points, and sort this list in ascending order.
2. Step through the sorted list of distances, forming for each distinct dissimilarity value d_k a graph on the patterns where pairs of patterns closer than d_k are connected by a graph edge.
   a If all the patterns are members of a connected graph, stop.
   b Otherwise, repeat 2.
3. The output of the algorithm is a nested hierarchy of graphs which can be cut at a desired dissimilarity level to form a clustering. The clusters would be identified by simply connected components in the corresponding graph.

***K*-Means Clustering** *K*-Means clustering algorithm is one of the simple but very efficient clustering algorithms, which allows it to run through large datasets. The main advantages of *K*-Means are (i) simplicity and efficiency; (ii) does not yield the same result with different run as the resulting clusters depend on the initial random assignments. The main disadvantage is that as it minimizes intra-cluster variance, *K*-means does not ensure the result has a global minimum of variance (http://en.wikipedia.org/wiki/Cluster_analysis).

K-Means algorithm is to cluster n objects (here textual documents) based on attributes (the document representation as vector space model) into K ($K < n$) partitions. It assigns each object to the cluster which has the nearest center. The center is defined as the average of all the objects in the cluster, which starts from a set of random initial centers. It assumes that the object attributes form a vector space and the objective for the algorithm to achieve is to minimize total intra-cluster variance or, the squared error function (http://en.wikipedia.org/wiki/Cluster_analysis):

$$V = \sum_{i=1}^{k} \sum\nolimits_{x_j \in S_i} (x_j - \mu_i)^2$$

where $S_i, i = 1, 2, \ldots, k$ are K clusters and μ_i is the center of cluster S_i.

The main steps of K-Means clustering algorithm are as follows [9]:

1. Setup the cluster number K;
2. Randomly generate K clusters and calculate the cluster centers, or directly generate K random points as cluster centers;
3. Assign each other points to the nearest cluster center;
4. Recalculate the new cluster centers after new points are clustered into the clusters;
5. Repeat 3 and 4 until some convergence criterion is met;

Co-Clustering In Co-Clustering method, the document collection would be modeled as a bipartite graph between document and words. That makes the clustering problem could be posed as a graph partitioning problem. Then Co-Clustering is developed as a spectral algorithm which could simultaneously yield a clustering of documents and words based on this document and word graph. The Co-Clustering algorithm uses the second left and right singular vectors of an appropriately scaled word-document matrix to yield good bipartitionings [4].

Performance Measurements

There are generally two types of measurements used to evaluate the performance of different text clustering algorithms. One is internal quality measure and the other is external quality measure. The authors of [12] had made a thorough introduction of various clustering algorithms measurements. The readers could refer to their work for more details. Here a brief introduction for both internal and external quality measurements would be introduced in the following.

Internal Quality Measure The internal quality measure is used to compare different sets of clusters without referring to external knowledge (like human labeled/known classes/categories). One approach of this kind of internal quality measurement is to calculate the "overall similarity" based on the pair-wise similarity of documents in a cluster [12].

External Quality Measure The external quality measure as naming is to leverage external knowledge as known classes (categories) to make comparisons with the generated clusters from the clustering algorithms. Entropy [12] is one external measure which provides a measure of "goodness" for un-nested clusters or for the clusters at one level of a hierarchical clustering. F-measure is another good example of external quality measure, which is more oriented toward measuring the effectiveness of a hierarchical clustering.

The readers should be aware that there are still many other different quality measures than those ones introduced here. The more important thing is that the performance of different clustering algorithms could vary substantially depending on which measure is applied [12].

Key Applications

Text clustering has many applications, including search results clustering, topic detection and tracking, email clustering, and etc.

Text Compression

Paolo Ferragina, Igor Nitto

Lossless data compression

Definition

Text Compression involves changing the representation of a file so that the (binary) compressed output takes less space to store, or less time to transmit, but still the original file can be reconstructed *exactly* from its compressed representation.

Key Points

The benefit of compressing texts in computer applications is threefold: it reduces the amount of memory to store a text, it reduces the time for transmitting the text over a computer network and, recently, it has been deployed to speed up algorithmic computations because they can better exploit the memory hierarchy available in modern PCs by reducing the disk access time, by increasing virtually the bandwidth and size of disk (or memory, cache), and by coming at a negligible cost because of the significant speed of current CPUs.

A text in uncompressed format, also called *raw* or *plain* text, is a sequence of symbols drawn from an alphabet Σ and represented in $\lceil \log_2 |\Sigma| \rceil$ bits each. Text compressors aim at storing a text in space less than its raw encoding by exploiting the redundancies possibly contained in it. Such redundancies might occur in the form of repetitions or frequently occurring patterns, which are not unlikely in texts generated by humans. Text compression is a *lossless* process because it allows restoring the original text from its compressed form by means of a proper *decompression* algorithm. Most of current approaches in text compression [4] can be classified into: *symbolwise*, *dictionary-based* and *transform-based*.

Symbolwise compressors encode the text one-symbol at time, by emitting a (variable length) codeword per individual symbol. They are further divided into two sub-families: *statistical* and *symbol-ranking*. Statistical compressors include some of the best compressors currently known, like PPM and DMC. They rely on two basic tools for the encoding task: a statistical model of the text and a statistical encoder. The statistical model serves to predict the probability of the next symbol given the previous portion of the text. If the prediction is conditioned on the last k occurred symbols, for some fixed constant k (typically ranging from 5 to 10), the model is said of *order k*. The model can be *static*, *semi-static*, or *dynamic*, according to the way the symbol probabilities are estimated from the scanning of the input text. The static construction assumes a fixed probability distribution for every input text. This is the simplest form of model construction but, since the model is independent of the input, it may poorly predict its symbols. The semi-static construction avoids this limitation by building the model via a preliminary scan of the input text. Unfortunately, a semi-static model must be passed to the decompressor as a part of the compressed file, thus increasing its size. As a result, statistical models are typically dynamic in that they are constructed *adaptively* as the input text is processed. This shares with the semi-static approach the advantage of being tailored on the input, but it additionally avoids the need of passing the model to the decompressor. The probability distribution provided by the model, whichever construction process is adopted, is eventually passed to the statistical encoder that determines the bit codeword associated to the next symbol. The principle used by all statistical encoding methods is to assign shorter codewords (even fraction of bits) to most probable symbols in order to minimize the average length of a codeword (this is typically called the *golden rule*). This is the essence of Huffman and Arithmetic encodings, also known as entropy encoders for their dependence on the entropy of symbols frequencies, a theoretical lower-bound on the number of bits emitted by any statistical encoder. The concatenation of all generated codewords gives the final compressed file of a statistical compressor.

Symbol-ranking compressors are still based on statistical prediction but, rather than estimating the probability distribution of the next symbol, they maintain the alphabet in a dynamic list, where symbols are sorted by decreasing likelihood of occurrence. Each symbol of the text is encoded with its rank in the list. If the prediction process is accurate enough, the distribution of ranks will be skewed around small values, and the resulting sequence will be well compressible through a statistical encoder. Symbol-ranking techniques have been rarely used as “stand-alone” compression methods but, like the well-known *Move-To-Front* (MTF) and *Inversion Frequency* encodings, they are often employed as a fundamental stage of more sophisticated compressors like the *Wheeler-Burrows* Transform (BWT), below.

While symbolwise compressors can encode only one symbol at a time, dictionary-based compressors can represent a *group* of symbols with one unique codeword. These compressors maintain a dictionary of strings, called *phrases*, each one identified by a distinct codeword. The input text is parsed into dictionary phrases which are then replaced by their corresponding (shorter) codewords. As for statistical models, dictionary construction schemes can also be classified into static, semi-static and dynamic; but the most significant difference is that, in the semi-static case, deciding which phrases to include in the dictionary is computationally difficult: in fact, computing the dictionary that maximizes compression is an NP-hard problem. An example of static dictionary is the Run-Length-Encoding method (`RLE`), in which the phrases are all possible runs of equal symbols, typically adopted in FAX transmissions and as a fundamental stage of the `BWT`-based compressors. An example of semi-static dictionary is the Huffword compressor, in which the dictionary is formed by all tokens extracted from an input text and phrases are Huffman-encoded according to their frequency of occurrence. Examples of dynamic-dictionary methods are the well-known `LZ77` and `LZ78` compressors which are implemented in many commercial softwares like `winzip`, `pkzip`, `ARJ`, the `.GIF` image format, etc..

The last class of compression algorithms considered is the one that *transforms* the input text in order to make it easier to compress by simpler coding schemes. The transformation must be reversible, lossless (e.g., a permutation of the input symbols), and efficiently computable and invertible. One notable example is the *Burrows-Wheeler* transform (BWT), which can be built and inverted in time linear in the length of the input text. The output of the `BWT` is a string in which symbols following the same context are grouped together, giving raise to clusters of nearly identical symbols. This feature makes redundancy in the input more accessible to simple coding schemes. The famous compression utility `bzip2`, currently available on most Linux distributions, is indeed based on the `BWT` and uses a proper combination of `MTF`, `RLE` and a statistical encoder to significantly squeeze the `BWT`-output. Besides its usage in pure text compression, the `BWT` has three other remarkable properties: it can be used to design a *compression booster* [1], that is, a tool for improving the performance of other compressors in a well-defined and measurable way; it can be used to derive novel and powerful transform-based compressors for various other data types [2,3], like `XML`, dictionaries and graphs (just to cite a few); and it is at the core of modern Compressed Full-text Indexes [3], that is, compressed representations of the input string which are efficiently searchable via arbitrary patterns.

Natural language generation (NLG)

Definition

Text generation is a subfield of natural language processing. It leverages knowledge in computational linguistics and artificial intelligence to automatically generate natural language texts, which can satisfy certain communicative requirements.

Historical Background

Research work in the text generation field first appeared in the 1970s. Goldman's work on natural language generation from a deep conceptual base appeared in [2]. In the 1980s, more significant work was contributed in this field: McDonald saw text generation as a decision making problem [6], Appelt on language planning (1981), McKeown [8]. In the 1990s, a generic architecture for text generation was discussed, Reiter [10], Hovy [3]. Still today, variations on the generic architecture is a still a widely discussed question, Mellish et al. [9].

Foundations

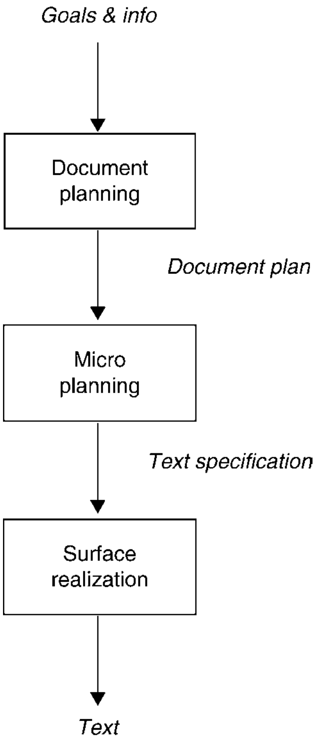
Text Generation, or Natural language generation (NLG), is usually compared with another subfield of natural language processing – natural language understanding (NLU), which is generally considered as the inverse process of the former. Because in a highly abstract level, NLG task synthesizes machine representation of information into natural language texts, while NLU task parses and maps natural language texts into machine representations. However, upon inspection at a more concrete level, they can hardly be seen as "opposite," because they are very different in problem sets, and by internal representations.

Text Generation System Architecture

Input and Output The input of text generation system is information represented in non-linguistic format, such as numerical, symbolical, graphical, etc. The output is understandable natural language in text format, such as messages, documents, reports, etc.

Architectures

The Generic Architecture Despite difference in application backgrounds and realization details, many of the current text generation systems followed a general architecture, which is known as the *Pipelined Architecture* or *Consensus Architecture*, usually described as in Fig. 1([11]; Edward Hovy also had a similar representation for this architecture).



Text Generation. Figure 1. A classical architecture for text generation.

As seen in the Fig. 1, the "Pipelined Architecture" describes a general strategy of tackling text generation problem from macro to micro, from inner structure organization to outer surface realization. Thus, language components such as paragraphs, sentences, and words will be coherently arranged together to meet certain communicative requirements.

The following are the detailed descriptions of the above stages:

Stage 1: Document Planning
Also known as Text Planning, Discourse Planning or Macro Planning). This includes:

- Content determination: Also know as content selection and organization, which is to discover and determine the major topics the text should cover, given a set of communicative goals and representations of information or knowledge.
- Document structuring: Determining the overall structure of the text/document. This structure categorizes and organizes sentence-leveled language components into clusters. The relationship

between different components inside a cluster can be explanatory, descriptive, comparative, causal, sequential, etc.

Stage 2: Micro Planning
Also know as Sentence Planning. This is to convert a document plan into a sequence of sentence or phrase specifications, including:

- Aggregation: To combine several linguistic structures (e.g., sentences, paragraphs) into a single and coherent structure. An example: Tomorrow will be cold. Tomorrow will be windy.
  →Tomorrow will be cold and windy.
- Lexicalization: To choose appropriate words from possible lexicalizations based on the communicative background. Examples: (i) buy, purchase, take, etc, (ii) a lot of, large amounts of, etc.
- Referring expression generation: To choose or introduce different means of reference for sentences, such as pronouns (*pronominalization*). There is usually more than one way to identify a specific object, for example: "Shakespeare, " "the poet and playwright, " "the Englishman, "and "he/him" can all point to the same object. Example: Andrew wanted to sing at the birthday party.
  →He wanted to sing at the birthday party.
  →The boy wanted to sing at the birthday party.

Stage 3: Surface realization
Also know as Speech Synthesis. This is to finally synthesize the text according the text specifications made in the previous stages.

- Structure realization: To mark up the text's surface structure, such as an empty line, or the boundaries between paragraphs, etc.
- Linguistic realization: To smooth the text by inserting function words, reorder word sequences, and select appropriate inflections and tenses of words, etc.

Other Architectures: Although the *Pipelined Architecture* provides a considerably articulate routine for text generation, it also provides predetermined restrictions for each stage in the process. Thus, the flexibility it can provide is limited, and is especially true for those sub-tasks in micro planning and surface realization stages. For example, the need for lexical selection can happen at any stage of the process. Thus, variations of the generic architecture and other methodologies have been discussed by many researchers (a recent discussion, Chris Mellish et al. [9]).

Key Applications

1. Routine documentation or information generation: examples of information are weather forecast descriptions, transportation schedules, accounting spreadsheets, expert system knowledge bases, etc. Examples of documentation are technical reports and manuals, business letters, medical records, doctor prescriptions, etc.
2. Literary writing: such as stories, poems, lyrics, couplets, etc. (Chinese couplet writer: generating a couplet sentence according to a given one. http://duilian.msra.cn).

Text Index Compression

Inverted index; List; File compression

Definition

Text index compression is the problem of designing a reduced-space data structure that provides fast search of a text collection, seen as a set of documents. In Information Retrieval (IR) the searches to support are usually for whole words or phrases, either to retrieve the list of all documents where they appear (full-text searching) or to retrieve a ranked list of the documents where those words or phrases are most relevant according to some criterion (relevance ranking). As inverted indexes (sometimes also called inverted lists or inverted files) are by far the most popular type of text index in IR, this entry focuses on different techniques to compress inverted indexes, depending on whether they are oriented to full-text searching or to relevance ranking.

Historical Background

Text indexing techniques have been known at least since the 1960's (see, for example, the book *Automatic Information Organization and Retrieval*, 1968, by Gerard Salton, one of the pioneers in the area). Initially departing from the analog manual indexing process, where a short list of keywords was associated to each document from a collection, the increase in computational and storage capabilities quickly led to the so-called "full-text model", where every text word would be searchable (except for a few so-called "stopwords", which are too frequent and do not carry any meaning nor discriminative power, e.g., articles and prepositions). The so-called "inverted indexes" (or inverted lists, or inverted files), which are also modeled upon the traditional inverted index found at the end of books, have been since then the canonical model for indexing text collections. Most of the indexes used nowadays in Information Retrieval (IR) are variants of the inverted index. These mainly differ depending on the precise type of task that is to be carried out: Sometimes the application needs to find all the documents (and even exact positions within them) where some search terms appear; sometimes only a few "good" documents are wanted because the end user is a human.

Depending on the type of inverted index, it might take as little as 10% of extra space over the text size, or as much as 100% and even more. Nowadays the space, at least in secondary storage media, is extremely cheap and virtually unlimited. However, there are also extremely large text collections (for example the Web) where paying a significant amount of extra space for the index is not irrelevant. However, the most compelling reason to reduce the index size is the large gaps in the memory hierarchy: It is several orders of magnitude faster to transfer data from the main memory than from secondary storage. Hence, a reduction in space translates into an almost proportional increase in throughput at query processing, as the extra processing time for decompression is almost negligible. In networked environments, which are also becoming common to cope with the large demands in storage space and processing power, the same considerations apply with respect to network transfer time. For decades, CPU speeds have been increasing at an exponential rate, whereas disk speeds have not improved much. Moreover, new memory levels (caches) have appeared between the CPU and the main computer memory. This has only made it more and more attractive to design text indexes that fit in little space, even at the expense of needing more sophisticated decompression mechanisms. See [14,15] for a recent exhaustive coverage of the topic.

Foundations

An *inverted index* is formed by two main parts:

1. *Vocabulary.* Is the set of all the different *words* in the collection. The definition of what is a word may depend on the application. Not only does it involve delimiting them, but also determining which normalization processes will be carried out on them, e.g., upper/lower case conversion, removal of stopwords, stemming, etc. Once defined, the word becomes the unit of retrieval: one can search for words or for sequences of words (*phrases*), but not

for, say, a part of the word (although there are some exceptions in text retrieval systems offering extended functionalities which are not covered here, see e.g., [3]).

2. *Postings.* Is a list of "occurrences" of each vocabulary word in the collection. Depending on the application, the index might store the list of document identifiers where the word appears, or the list of exact positions (byte offsets or word offsets), or the list of document identifiers plus a "weight" associated to it, which computes according to some formula the importance of the word in that document, or the list of word positions plus data on the field where the word appears, or even color or font size of each occurrence.

For concreteness, this entry will assume that a policy for defining and normalizing words has been fixed, and will focus on the two most important type of posting lists: one storing exact word positions within documents (useful for full-text retrieval), and another storing document identifiers and weights (useful for relevance ranking). Because of the different processing needs, these lists might be stored in different orders. This is relevant because ordering is the key to inverted list compression.

A widely accepted statistical rule in IR [6] establishes that the vocabulary grows sublinearly with the collection size, more precisely as $v = O(n^{\beta})$ for some $0 < \beta < 1$ that depends on the collection. Different experiments show that β is actually around 0.5 [3], which means in practice that, even for very large collections, it is feasible to maintain the vocabulary in the main memory of the computer. For this reason, most of the efforts in index compression have focused on compressing the postings.

Inverted Indexes for Full-Text Retrieval

In full-text retrieval, queries are words or phrases and the task is to find *all* the documents where the word or phrase appears, possibly giving also the position(s) of the occurrences within each retrieved document. The most convenient index organization for word queries is a scheme storing basically all the answers to all the v possible queries: For each vocabulary word, the list of all the documents where it appears is stored in increasing order of document identifier. If exact occurrence positions are desired, and one does not want to sequentially scan the retrieved documents in order to find them, then the index must also store all the occurrence positions of each word within each document, also in increasing order. Because of the other types of queries that are usually necessary to support, it is usually advantageous to store the list of document identifiers contiguously and separated from the list of positions, so that the document identifiers alone can be retrieved with fewer disk accesses.

The important point is that the postings consist of *lists of increasing numbers* (document identifiers or occurrence positions). Moreover, for word queries, those lists are accessed from the beginning to the end. An obvious idea is to encode the *differences* between consecutive entries in the list. The longer the list, the smallest the differences between consecutive values. Because the number of occurrences of vocabulary words is usually highly skewed [3] (following a Zipf–Mandelbrot distribution [8]), there will be very long (and thus very compressible) lists and many short lists, where the long lists will contain a significant fraction of the whole data. Hence, a technique that represents those differences in a way that smaller numbers use a shorter representation should achieve compression. This requires that a different amount of bits is used to represent different numbers, as opposed to the classical data representation where a fixed number of bits is allocated for every possible number.

A first idea would be to use exactly the bits that the number uses, for example the binary representation of 9 is 1001_2, and hence one would like to represent it using 4 bits. The problem, of course, is that one cannot decode the individual numbers from the concatenation of their representations if one uses this method. For example, 10011101 could be 9,1,5 or 9,13. A large part of the research in inverted index compression refers to the design of *self-delimiting codes*, which (i) can be uniquely decoded from the concatenation of the codes, (ii) give shorter codes to smaller numbers, (iii) preferably can be efficiently decoded.

Several self-delimiting coding schemes are described in the book *Managing Gigabytes* [14], one of the best references on text index compression. Let $x > 0$ be a number to encode and $|x|$ the number of bits needed to code it (i.e., the highest bit set in the binary representation of x is at position $|x|$). Some of the most famous codes are described next.

1. Elias' γ-code emits $|x| - 1$ 0's followed by the $|x|$ bits representing x. For example, the code for

$x = 23 = 10111_2$ is 0000 10111 (which are here artificially separated in two parts). To decode the first number from a bit stream, one finds the next 1, and if one skipped $\ell - 1$ 0's before it, on reads the next ℓ bits starting from that 1. Those ℓ bits form x. This works because the representation of x always starts with a 1 (i.e., its most significant bit). Elias' γ representation of x takes $2|x| - 1 = 1 + 2\lfloor \log_2 x \rfloor$ bits. The representations of the first numbers are as follows: $1 = 1_2 \rightarrow 1$, $2 = 10_2 \rightarrow 010$, $3 = 11_2 \rightarrow 011$, $4 = 100_2 \rightarrow 00100$,...

2. Elias' δ-code first codes $|x|$ using Elias' γ-code, and then emits the $|x| - 1$ least significant bits of x (as one knows that the most significant bit is a 1). For example, the code for $x = 23 = 10111_2$, $|x| = 5 = 101_2$, is 00 101 0111. The length of the δ-code of x is $2||x|| - 1 + |x| - 1 = 1 + 2\lfloor \log_2(1 + \lfloor \log_2 x \rfloor) \rfloor + \lfloor \log_2 x \rfloor$. These codes are theoretically appealing because the space they require is $\log_2 x + O(\log \log x)$, which is asymptotically the same as just writing x. For example, it is not hard to prove that, using this scheme to encode all the word offsets of the occurrences, the whole index needs $nH_0 + O(n \log \log n)$ bits, where n is the number of words in the text collection and H_0 is its zero-order entropy seen as a sequence of words [9]. Thus the space is similar to that obtained when compressing the text using a good word-based zero-order compressor [4].
3. Rice codes are parameterized by a value r. The lowest r bits of x are represented in binary form (even if $|x| < r$), preceded by the unary representation of $\lfloor x/2^r \rfloor$. A different r value (the one yielding least space) can be chosen for each inverted list. An extension are Golomb codes, where instead of the quotient and remainder of the division by 2^r, any divisor d can be used. These are usually reported to achieve the least space consumption [14].

There are many other self-delimiting codes, such as Fibonacci codes [7], variable-byte codes [13], Dense codes [4], Simple codes [2], and many others. Some trade a slight loss in space for a large gain in decoding time.

Searching for Phrases Using Inverted Indexes

The described encodings of inverted lists must be decoded from the beginning, which as explained is appropriate to answer queries consisting of a single word. Phrase queries, however, are more complicated to deal with. If the index stores only document identifiers, all it can do is to intersect the list of documents of the different words, and then it is necessary to sequentially search the candidate documents for the exact phrases. If the index, instead, stores occurrence positions, it can look for the consecutive occurrences of the involved words within the same document. (This is especially convenient if the index stores word offsets rather than byte offsets of occurrences. Storing byte offsets, on the other hand, is more convenient to highlight the occurrences in the text.)

In both cases, a list intersection-like capability is necessary. Incidentally, note that another popular operation in inverted indexes is the conjunctive query, that is, find the documents where all the query words appear. Those are obviously solved by intersecting the lists of document identifiers as explained. Disjunctive queries (find the documents where some of the words appear) are solved by merging lists of document identifiers. Although there is not an especially clever way of merging lists other than traversing them all sequentially, much research has been done on the problem of efficiently intersection increasing lists of numbers. Although sequential intersection is an option as well, one can do better when one list is much shorter than the other, as it is frequently the case of the highly skewed length distributions that arise in natural language text collections [8].

Describing those techniques is not in the scope of this entry. A recent example of this research, which indeed takes compression into account, can be seen in [12]. In all cases the main idea is that one can search the longer list for the elements in the shorter list. This implies that some degree of random access is necessary in the encoded lists. For this sake, the natural choice [14] is to insert some absolute list values at regular intervals in the compressed list data, so that the search can be first carried out on those sampled values and only one chunk between consecutive samples must be decompressed. There is also some recent research on how those absolute values should be physically organized [5], as it turns out to be more convenient to store all the samples in contiguous form.

Note that, independently of the encoding technique used, the success of the compression depends on what is indexed. If one indexes the occurrences of all the text words, the space used by the index will be at best around 40% of that of the original (uncompressed) text, which can be reduced to around 20% by removing the stopwords. If only document identifiers are recorded, the space can be typically 10–20% depending on the size of the documents. A technique to achieve even less space, at the expense of higher time to solve queries, is called *block addressing* [10]. The idea is to cut the text into blocks, so that the index stores the blocks where each word appears. The index is used to filter out some blocks upon queries, and the others have to be sequentially traversed. Hence, the block size yields a space/time tradeoff, where reasonable performance on moderate-sized collections can be achieved with as little as 5% of index space overhead.

Finally, it is interesting to mention that there exist compressed indexes for what is (also) called "full-text searching", in the sense that the text is seen as a sequence of symbols and the index is able of retrieving any text substring (not only words or phrases) [9]. Those indexes were classically much larger than the text, and recent developments have shown that they can be compressed to sizes competitive to those of inverted indexes for word and phrase retrieval. Their search times are still larger than those for inverted indexes, although research is being carried out on applying them over a text regarded as a sequence of words (not letters). In this case they can also search only for words and phrases, but their space becomes even better than using inverted indexes, and performance for phrase searching is competitive.

Inverted Indexes for Relevance Ranking

Inverted indexes are also used to rank documents by "relevance" to a given query, so as to return a small set of those ranking higher. There are many formulas for computing relevance [3], yet the most popular ones build on two components: one is the *term frequency* $tf_{w,d}$, which is the number of times word w appears in document d, and the other is the *inverse document frequency* idf_w, which is the logarithm of the inverse of the fraction of the documents where word w appears. Note that, while idf_w is just one value per vocabulary word (and hence easy to maintain in main memory with the vocabulary), there is one $tf_{w,\ d}$ value per entry in the inverted index: For each word, the index stores the documents where it appears and the associated term frequency for each.

Because the relevance formula gives more weight to terms with higher term frequency, it is sensible to store the document identifiers of each word by decreasing term frequency value, rather than by increasing document identifier. This enables efficient algorithms that examine only a short prefix of the inverted lists [11]. The problem is that, although the decreasing term frequencies can be stored differentially, this is not possible anymore with the document identifiers accompanying them. Fortunately, because of Zipf–Mandelbrot law [8], it turns out that many of the term frequencies are small values, and therefore there are long runs of equal term frequencies, especially at the tail of the lists. Within those runs, one can still reorder the documents by increasing document identifier and encode them differentially. Recently, it has been shown that reducing the precision of the exact term frequency values is not only advantageous for compression purposes (which is obvious) but also for retrieval effectiveness [1].

Key Applications

Any application managing natural language text collections that have to be searched, and which are massive enough to discard sequential search as a solution, needs some kind of index. Index compression not only saves space, but more importantly, disk and network transfer time. A canonical example application are Web search engines.

Future Directions

Inverted index technology, even including compression, is rather mature. Still, it faces enormous efficiency challenges, especially those coming from Web search engines. The most active research fields related to inverted index compression are on encodings that permit fast decoding (e.g., [2]), and the interactions between information discarded to boost compression and the resulting retrieval quality of the index (e.g., [1]). The possibility of applying "true full-text indexes" [9] to natural language text is also extremely interesting, as it brings in radically new compression methods as well as algorithms for solving phrase queries. Yet, this trend is rather preliminary, and much research is needed to compete with inverted indexes in secondary memory scenarios.

Other challenges in inverted indexes, only mildly related to compression, are distributed indexes (how to split the collection and/or the indexes across multiple machines to boost performance), dynamic indexes (how to efficiently update the index when the collection changes), and extensions (how to cope with more complex queries, for example allowing approximate searches).

Experimental Results

Experiments can be found in the most recent cited papers, as most of them are of practical nature.

URL to Code

Probably the best known public domain implementation of compressed indexes was the *MG System* (http://www.cs.mu.oz.au/mg), closely related to the book *Managing Gigabytes* [14]. This system is now almost 10 years old, and is being replaced by its successor, *Zettair* (http://www.seg.rmit.edu.au/zettair).

Document index and retrieval

Definition

Text indexing is a preprocessing step for text retrieval. During the text indexing process, texts are collected, parsed and stored to facilitate fast and accurate text retrieval. Text retrieval (also called document retrieval) is a branch of information retrieval in which the information is stored primarily in the form of text. Text retrieval is defined as the matching of some stated user query against a set of texts. As the result of text retrieval, texts are ranked and presented to the user according to their relevance with user query. User queries can range from a few words to multi-sentence full descriptions, which represent the user's information need.

Historical Background

Text indexing is the most fundamental part of a retrieval system. Over the past two decades, the corpus size of typical retrieval system has increased dramatically. The Text REtrieval Conference (TREC) (http://trec.nist.gov/) that started in 1992 only provides document collection consisting of less than 1 million texts in the 1990s. Today, the largest TREC test collection, named GOV2, is a 2004 crawl of the.gov top-level domain. GOV2 consists of approximately 25 million web pages (428GB of text). Moreover, a web search engine is believed to have far more items in its index. For example, in 2005, Yahoo claimed to have more than 20 billion items in its index, which is several orders larger than GOV2. The retrieval system is often required to return relevant document/text for a user query in a few seconds. Without an index, it is impossible for a retrieval system to achieve this task.

There are many indexing techniques. Among them, inverted index, suffix array, and signature are three typical examples. Signature files were popular in the 1980s, but since this scheme is inferior to inverted files in terms of speed, size and functionality, it is used less nowadays. Suffix trees are faster for phrase searches, but they are not easy to build and maintain. Finally, due to its simplicity and efficiency, inverted index is currently the most popular indexing scheme and is used for many applications.

Text retrieval is the core part of a retrieval system. There have been several decades of research on text retrieval, which has resulted in a fruitful range of beautiful, effective text retrieval models, such as Boolean model, vector model, and probabilistic model.

The Boolean model is one of the earliest models. Despite its simplicity, the Boolean retrieval model was popular among many large commercial information providers until the early 1990s. A noticeable advantage of the Boolean model is that in Boolean models, queries are represented in the form of a Boolean expression of terms, that is, an expression in which terms are combined with the operators AND, OR, and NOT. Many users prefer the Boolean query model because Boolean queries are precise and offer users greater control and transparency over the retrieved text. But the Boolean model also suffers from some major drawbacks. For example, the Boolean model judges a document to be either relevant or non-relevant in respect to a given query without any notion of grading scale, which does not achieve good performance in practice.

Different from the Boolean model, the vector model largely uses free text queries, which consist of one or more words but do not use operators to build up the query expressions. Query and documents are presented as a weighted vector over a fixed dictionary, and the documents are ranked by their Cos similarity with query. The vector model is better than Boolean model in that it is able to deal with cases in which documents only partially match the query. The famous tf-idf scheme for the vector model is very influential in the research of text retrieval.

Besides the simple Boolean model and vector model, probabilistic models have achieved great success regarding the text retrieval task. Probabilistic models are mainly guided by Probability Ranking Principle (PRP): "If a reference retrieval system's response to each request is a ranking of the documents in the collection in order of decreasing probability of relevance to the user who submitted the request, where the probabilities are estimated as accurately as possible on the basis of whatever data have been made available to the system for this purpose, the overall effectiveness of the system to its user will be the best that is obtainable on the basis of those data."

The Binary Independence Retrieval (BIR) model is one of the earliest probabilistic models for text retrieval. The model has other names, such as the Okapi model and the classical probabilistic model. Similar to the Boolean model, the BIR model documents are represented as binary vectors indexed over a fixed vocabulary. The representation ignores the number of times the term occurs, and is only able to capture whether or not a term occurs in a document. The 2-Poisson model was proposed to overcome this limitation. Under this model, documents are represented as vectors of term frequencies. Probabilistic models are not only solid from theoretical perspective, but also perform well in practice. An empirical, handcrafted approximation of the 2-Poisson model, called BM25, showed good performance over many data collections. It was first introduced at TREC in 1995, and is still a strong baseline for current text retrieval research.

The probabilistic language model, which was first applied to speech recognition and machine translation, has also been successfully applied to information retrieval in 1998 [4]. Since then, research to improving the language model has been an active area. Also, the probabilistic language model is a state-of-the-art text retrieval models for its robust, highly effective performance in the practice.

In all these models, documents are represented as a bag of words, where the exact ordering of the terms in a document is ignored but the number of occurrences of each term is material.

There are other models that go beyond the bag of words assumption, such as the Markov Random Field model, n-Gram language models, and the Indri Inference network model. The Markov Random Field model [2,3] for information retrieval, which was proposed in 2005 and improved in 2007, is demonstrated to be consistently and significantly better than probabilistic language model in several document collections, which shows that it is beneficial to incorporate dependency and features into text retrieval model.

Foundations

Among many text indexing schemes, the inverted index is the most popular. It could well support bag of words based text retrieval methods, like the tf-idf vector model, the BM25 model, and probabilistic language model. The process of building an inverted index is briefly described here. The major steps include:

1. Collecting the interested texts to form the text collection. For example, if the interested texts are the web pages on the internet, web pages should be crawled to form the text collection.
2. Tokenizing the text, which turns each document into a list of tokens. Generally, a text is represented as a continuous character stream. In this step, text is parsed and segmented into terms, digits, and email address and punctuations, such as ",", ".", "!", "?" and "-", are removed.
3. Doing linguistic preprocessing, which typically includes removing stemming and stop words, and then producing a list of indexing terms. Stemming refers to the process of reducing terms to their stems or root variants. For example, "computer," "computing," "compute" are reduced to "comput." For English, the most popular stemmer is Martin Porter's stemming algorithm. Stop words removal eliminates stop words from the documents. Common stop words include "a," "the," "of," "is" etc.
4. Creating the inverted index, which mainly consists of a dictionary and postings. The dictionary includes all the terms and the number of times they appear in the text collection. The postings include the text in which the terms appear. Thus the postings of a query could be obtained through the intersection operator of the query terms' postings.

With the support of the inverted index, many text retrieval models could be implemented efficiently. Here, the tf-idf vector model and probabilistic language model are taken as examples:

In the tf-idf vector model, either the query or document is represented as the weighted vector, with each component calculated as the product of term frequency (TF) and inverse document frequency (IDF) of the corresponding term. Term frequency is the number of times the term appears in a query or a document. The inverse document frequency of the term t is defined as

$$idf(t) = \log\left(\frac{N}{n_t}\right)$$

where N is the total number of texts in the collection and n_t is the number of documents with term t. The query vector is represented as $q = (tf_a(t_1) \cdot idf(t_1), tf_a(t_2) \cdot idf(t_2), \ldots, tf_a(t_n) \cdot idf(t_n))$, and the document vector is represented as $d = (tf_d(t_1) \cdot idf(t_1), tf_d(t_2) \cdot idf(t_2), \ldots, tf_d(t_n) \cdot idf(t_n))$. Then, documents are ranked by their Cos similarity with the query. The Cos similarity between the query and document is calculated as below:

$$sim(q, d) = \frac{\sum_{i=1}^{n} q_i \times d_i}{\sqrt{\sum_{i=1}^{n} q_i^2} \times \sqrt{\sum_{i=1}^{n} d_i^2}}$$

The TF and IDF together discriminate along two dimensions – informativeness (IDF) and aboutness (TF). The IDF component is used to discriminate between informative and non-informative query terms. Terms with high IDF occur rarely in the collection, and thus are considered more informative. The incorporation of TF component is based on the intuition that documents that contain more mentions of a term are more "about" this term.

The probabilistic language model for information retrieval is based upon the idea that a document is a good match to a query if the document model is likely to generate the query. Therefore, language model documents are ranked by query generation probability $p(q|d)$. There are several variant realizations for the language model. Among them, the query likelihood model [4] is the original and basic method for using language models in IR. The most common way to evaluate query generation probability $p(q|d)$ is using the multinomial unigram language model. Under this model, $p(q|d)$ is approximated as

$$p(q|d) = \prod_{w \in q} p(w|d)$$

Due to the data sparseness, the generation probability of query term absent in the document will be zero. Generally a smoothing technique is applied to overcome this problem. Please refer [6] for more details.

Key Applications

Text retrieval has many applications. It is used in digital libraries to help people quickly find desired books or articles. It could also be used in desktop search to help people instantly find documents, such as e-mail or other files, in a computer. Moreover, it is the fundamental basis of all internet search engines.

Future Directions

Most past research on text retrieval is based on the bag of words assumption, which has resulted in very fruitful models. These models have achieved rather good performance in the past, but appear to have reached a plateau; thus, their improvement has dwindled for several years. Recently, some text retrieval models (for example, Markov Random Field model for information retrieval) have tried to go beyond the bag of words assumption, and have achieved consistent and significant improvement. This indicates that it would be beneficial to incorporate dependency and features of documents into the text retrieval model; thus, more dedicated models may be developed in the future to improve retrieval performance further.

Data Sets

For testing the effectiveness of text indexing and retrieval strategies, TREC text datasets (http://trec.nist.gov/) are commonly used in the research community.

Text Indexing Techniques

Edleno Silva De Moura
Federal University of Amazonas, Manaus, Brazil

Definition

Text indexing is the act of processing a text in order to extract statistics considered important for representing the information available and/or to allow fast search on its content. Text indexing operations can be performed not only on natural language texts, but virtually on any type of textual information, such as source code of computer programs, DNA or protein databases and textual data stored in traditional database systems.

Historical Background

Efforts for indexing electronic texts are found in literature since the beginning of computational systems. For example, descriptions of Electronic Information Search Systems that are able to index and search text can be found in the early of 1950s [3].

In a seminal work, Gerard Salton wrote, in 1968, a book containing the basis for the modern information retrieval systems [5], including a description of a model largely adopted up to now for indexing texts, known as Vector Space Model. Other successful models for indexing texts were proposed since then, such as, for instance, Probabilistic Models and Language Models, which are discussed in detail in [2].

Text indexing operations have also received attention in the last decades as a basic operation in a large variety of applications. They are used in several basic algorithms related to data management, such as data integration and data disambiguation. Bioinformatics is another area where text indexing has been largely applied. In these cases, biological databases containing data such as DNA or protein information are indexed as texts in order to provide fast access to their content.

Foundations

The implementation of text indexing operations requires data structures for allowing fast access to the indexed information. The most used data structure for this purpose is known as *inverted index* or *inverted file*. An inverted index is a data structure composed of: (i) a vocabulary that contains all the distinct words indexed found in the text and (ii), for each word t of the vocabulary, a list that contains statistics about the occurrences of t in the text. Such list is known as the inverted list of t.

Inverted indexes allow fast search for statistics related to the distinct words found in a text. They are designed for using words as the search unit, which restricts their use in applications where words are not clearly defined or in applications where the system does not use words as the search unit. The statistics stored in an inverted index may vary according to the target application. Two non-exclusive alternatives usually found in literature are to record the position of all word occurrences in the text and to record general statistics about the word occurences in text units. Indexing all the word occurrences is useful in applications where positional information should be taken into account, such as when it is necessary to allow search for phrases or proximity queries. Inverted indexes that store word statistics are usually deployed in systems that adopt information retrieval models, such as the Vector Space Model, and in this case the text is divided into units of information, usually doucments. For instance, in web search engines, these units are the pages crawled from the web, while the whole set of pages compose the indexed text.

A third alternative to produce inverted indexes with intermediate space overhead and allow search for phrases and positional queries is to use a scheme known as block addressing [4]. Block addressing is a technique to reduce the space requirements of an inverted index. It was first proposed in a system called *Glimpse* [4]. The idea is that the text is logically divided into blocks, and the occurrences do not point to exact word positions but only to the blocks where the word appears. Space is saved because there are less blocks than text positions (and hence the pointers are shorter), and also because all the occurrences of a given word in a single text block are referenced only once.

Searching in a block addressing index is similar to search in a full inverted one. The pattern is searched in the vocabulary and a list of blocks where the pattern appears is retrieved. However, to obtain the exact pattern positions in the text, a sequential search over the qualifying blocks becomes necessary. The index is therefore used as a filter to avoid a sequential search over some blocks, while the others need to be checked. Hence, the reduction in space requirements is obtained at the expense of higher search costs.

The use of a block addressing scheme when indexing texts results in a tradeoff between index size and the computational costs for processing queries. The larger are the block units, the smaller is the final index overhead in terms of space. On the other hand, the larger are the block units, the larger are the portions of text that should be sequentially traversed when searching for a pattern in the text.

Although this combination of sequential search and index seems to produce less efficient search systems at first, block addressing indexes may achieve interesting combinations of cost for search time and space overhead. Block addressing was analyzed in [1], where it is analytically proved and experimentally verified that a block addressing index may yield sub-linear space overhead and, at the same time, sub-linear query time. Traditional inverted indexes pointing to words or documents achieve only the second goal. Empirical experiments performed in [?] indicate that in practice, $O(n^{0.85})$ space and query time can be obtained for exact queries in natural language texts.

Other data structures also adopted for indexing texts with the goal of allowing fast access to them are *signature files* and *suffix trees* [2,7]. Signature files are indexes that use a hash function to map the words found in a text to bit masks. The text is divided into blocks, and each block b is indexed by storing the result of a bit-wise OR operation over all the masks of the words that occur in b. This final mask represents the block in the signature file index. The search operation is performed through a bit-wise AND between the searched word and each block mask in the collection. Potential matches are reported whenever the bit-wise AND operation results in a number equal to the mask of the searched word. Note that false matches may arise, and thus the matched blocks should be inspected for confirming the occurrence of the word or not. Therefore, the signature file works as a filter for reducing the amount of text traversed in search operations.

The search in signature files is usually less efficient than the search when using inverted indexes. Further, inverted indexes support a larger set of search operations than signature files. For typical document indexing applications, signature files do not perform well compared to inverted indexes, being much larger and they are more expensive to build and update [8]. Thus, the use of inverted indexes in text indexing operations is more frequent than the use of signature files.

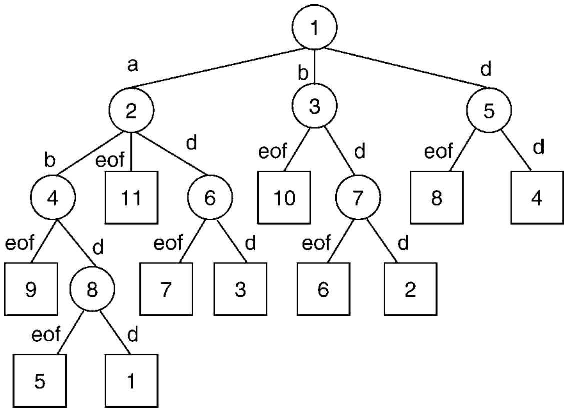
Another approach for indexing text databases regards the text as a long string. Suffix trees can index the text as a set of symbols according to the desired granularity of the search operations. For instance, by using suffix trees, it is possible to take all the characters of the text as index entries. This flexibility allows indexing texts that are written in languages where the words are not clearly separated from each other, such as it happens in some Asian languages, or even in texts where the concept of word does not exist, such as in DNA or protein databases.

Each position in the text is called a *suffix*. A suffix is defined by a starting position and extends to the right as far as needed or to the end of the text. Depending on the character sequences that are to be searched, the user must define the *index points*, i.e., which positions of the text will be indexed. In text databases, it is customary to index only word beginnings, but in many applications for text indexing it is necessary to index all the characters of the text. Suffix trees are data structures designed for indexing text using the suffix model, thus considering each entry point indexed in the text as a suffix of the whole text. In the suffix trees, each distinct path from the root to a leaf represents a unique suffix. For instance, consider the text fragment: "abadabadaba", which contains the suffixes described in Table 1.

Each suffix found in this example finishes with an implicit special symbol, marking the end of the text. Figure 1 describes the suffix tree for storing all the eleven suffixes of this text fragment. The circles in the trees contain internal nodes and their numbers indicate the position in the text where their children differ from each other. The square nodes are the leaves of the suffix tree and their numbers represent suffix ids (suffixes are usually represented by their position in the text). The letters marking each node in the tree indicate the value found on the positions where the node differ from their siblings nodes. The "eof" represents the end of the text is this example.

Text Indexing Techniques. Table 1. Suffixes found in the text fragment "abadabadaba"

Suffix	Suffix ID
"abadabadaba"	1
"badabadaba"	2
"adabadaba"	3
"dabadaba"	4
"abadaba"	5
"badaba"	6
"adaba"	7
"daba"	8
"aba"	9
"ba"	10
"a"	11



Text Indexing Techniques. Figure 1. Suffix tree for the text fragment "abadabadaba".

For instance, in the root node, the number 1 indicates that the suffixes are different in their first position. At this position, the suffixes may have value 'a', 'b' or 'c'. When searching for a suffix starting with an 'a', then the left most sub-tree should be taken in order to continue the search. In this case, the next comparison position to continue the search is position 2. The search continues until the current search position is longer than the search pattern, which means all the patterns in the sub-tree contain the search key; or until the current position in the search key does not match any child of the current node, which means the search key is not in the text.

Using this structure, it is possible to perform a variety of complex search operations at a relatively low computational cost. One of the drawbacks of using a suffix tree is the space required to store the index. If the space is a restriction, a more compact structure known as suffix array can be adopted. A suffix array is an array of pointers to each suffix indexed in the text. This array is sorted in the alphabetical order of the suffixes it represents and can then be used to perform search tasks. The use of suffix arrays increases the cost of search operations when compared to suffix trees. For instance, a given search pattern can be found in a suffix array at cost $O(log(n))$, where n is the number of suffixes in the text, while the cost for searching a simple pattern in a suffix tree is $O(m)$, where m is the size of the searched pattern, and is not affected by the number of suffix in the text.

A practical problem when using suffix trees or suffix arrays is the cost to build and maintain the indexes. Further, when searching for words inverted indexes are usually faster than suffix trees and suffix arrays. Exceptions may occur when it is necessary to process complex queries, such as regular expression patterns and search for word fragments.

Key Applications

Text indexing techniques have important practical applications, being of great importance in the construction of Web Search Engines, Web Directories and Enterprise Search systems. These techniques are also useful for allowing fast search on DNA or protein databases, which can also be treated as texts. In these cases, the text indexing techniques are adopted to accelerate more complex operations performed over the databases, such as the comparison of DNA fragments allowing small differences between them. Text indexing operations have also played an important role in several algorithms related to data management, such as data integration and data disambiguation.

Knowledge discovery in text (KDT)

Definition

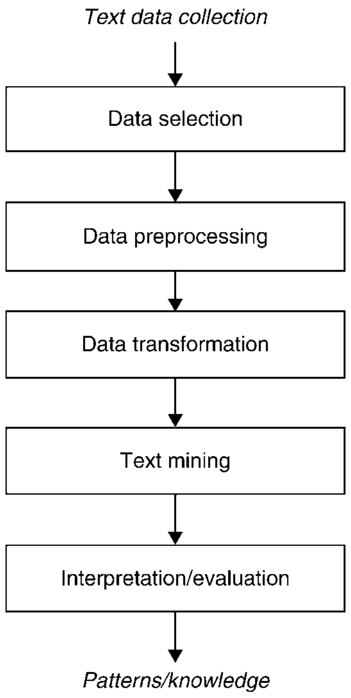
Text mining is the art of data mining from text data collections. The goal is to discover knowledge (or information, patterns) from text data, which are unstructured or semi-structured. It is a subfield of Data Mining (DM), which is also known as Knowledge Discovery in Databases (KDD). KDD is to discover knowledge from various data sources, including text data, relational databases, Web data, user log data, etc. Text Mining is also related to other research fields, including Machine Learning (ML), Information Retrieval (IR), Natural Language Processing (NLP), Information Extraction (IE), Statistics, Pattern Recognition (PR), Artificial Intelligence (AI), etc.

Historical Background

The phrase of *Knowledge Discovery in Databases (KDD)* was first used at 1st KDD workshop in 1989. Marti Hearst [4] first used the term of text data mining (TDM) and differentiated it with other concepts such as information retrieval and natural language processing.

Foundations

Typical steps of knowledge discovery in databases can be found in [7] by Usama Fayyad et al. The process of knowledge discovery in text data collections is similar, as shown in Fig. 1. Given one collection of text data as input, the goal is to extract patterns/knowledge from them. As the first step, data selection is to select proper data that will be processed and analyzed in the following steps. In the data preprocessing step, the task is to filter out noisy information and do some preliminary processes to facilitate the following steps, e.g., extracting name entities from the text data or part-of-speech tagging of the text data. In the data transformation step, the text data are converted to the format that is easy to be processed by mining algorithms, e.g., the format of vectors, sequences or inverted index tables. Text mining is to apply mining algorithms to find candidate patterns. In the interpretation/evaluation step, the candidate patterns produced in the former step are evaluated and the interesting ones are outputted as final knowledge.



Text Mining. Figure 1. Steps of knowledge discovery from text data.

Text preprocessing strongly affects the success of the outcome of text mining. Tokenization, or splitting the input into words, is an important first step that seems easy but is fraught with small decisions: how to deal with apostrophes and hyphens, capitalization, punctuation, numbers, alphanumeric strings, whether the amount of white space is significant, whether to impose a maximum length on tokens, what to do with non-printing characters, and so on [9]. It may be beneficial to perform some rudimentary morphological analysis on the tokens such as removing suffixes or representing them as words separate from the stem. Tokens may be standardized by using a dictionary to map different, but equivalent, variants of a term into a single canonical form. Once the input is tokenized, some level of syntactic processing is usually required. One operation is to remove stop words. Another is to identify common phrases and map them into single features. Tokenizing a document and discarding all sequential information yields the "bag of words." Additional linguistic preprocessing may also be needed [1]. Part-of-speech tagging (POS) determines the part of speech tag for each word, e.g., noun, verb, adjective. Text chunking aims at grouping adjacent words of a sentence. Word Sense Disambiguation (WSD) tries to resolve the ambiguity for individual words or phrases. Parsing produces a full parse tree for a sentence, which can identify the relation of each word in the sentence to all the others, and typically also its function in the sentence, e.g., subject, object.

Various statistical techniques and learning methods have been employed in text mining, including Naive-Bayes methods, support vector machines (SVM), decision trees, hidden Markov models (HMM), neural networks, etc. Major ways in which text is mined [1,9] are discussed in the following subsections.

Text Classification

Text classification is the assignment of text documents to predefined categories according to their contents. The pre-defined categories are symbolic labels with no additional semantics. When classifying a document, no information is used except for the document's content itself. A large number of feature selection and machine learning techniques have been applied to text classification. Typical approaches extract features from each document, and use the feature vectors as input to a scheme that learns how to classify documents. Using words as features and word occurrence frequencies as feature values, a model is built for each category. The documents in that category are positive examples and the remaining documents are negative ones. The model predicts whether or not that category is assigned to a new document based on the words in it, and their occurrence counts. Given a new document, each model is applied to determine which categories to assign. Automatic text classification has many practical applications, including indexing for document retrieval, automatically extracting metadata, word sense disambiguation by detecting the topics a document covers, and organizing and maintaining large catalogues of Web resources.

Text Clustering

Text clustering is unsupervised learning in which there is no predefined category or class, but groups of documents that belong together are sought. Clustering schemes not require training data to be preclassified, and the algorithms themselves are generally far more computation-intensive than supervised schemes. Usually the quality of clustering is considered better if the contents of the documents within one cluster are more similar and between the clusters more dissimilar.

Information Extraction

Information extraction is used to refer to the task of filling templates from natural language input, one of the principal subfields of text mining. A template is a composite structure with slots that are filled by individual pieces of structured information. A commonly-cited domain is that of terrorist events, where the template may include slots for the perpetrator, the victim, type of event, where and when it occurred, etc.

Machine learning has been applied to the information extraction task by seeking pattern-match rules that extract fillers for slots in the template. The rules can be expressed in pattern-action form, and the patterns comprise constraints on words in the surrounding context and the slot-filler itself. These constraints involve the words included, their part-of speech tags, and their semantic classes. An application of information extraction is extracting information from job ads such as those posted on Internet newsgroups.

The extracted information by information extraction can also be used in a subsequent step to learn rules that characterize the content of the text itself.

Document Summarization

A text summarizer strives to produce a condensed representation of its input, intended for human consumption. Useful distinctions can be made between different kinds of summaries: an extract picks certain key sentences scattered throughout the document. In contrast, an abstract contains material that is not present in the input, or at least expresses it in a different way. An indicative summary's main purpose is to suggest the contents of the article without giving away details of the article content. It can serve to entice the user into retrieving the full form [5]. Book jackets, card catalog entries and movie trailers are examples of indicative summaries. An informative summary is meant to represent the original document. Therefore it must contain all the pertinent information necessary to convey the core information and omit ancillary information. Another distinction is between a generic summary, aimed at a broad readership, and a topic-focused one, tailored to the requirements of a particular group of users. Summaries may also be produced from a single document or multiple documents [3]. In single-document summarization, features like word frequency, key phrases, sentence position, sentence length and uppercase words are used. Multi-document summarization extracts a single summary from multiple documents, and is used in the domain of news articles. It departs from single-document summarization since the problem involves multiple sources of information that overlap and supplement each other, being contradictory at occasions. So the key tasks are not only identifying and coping with redundancy across documents, but also recognizing novelty and ensuring that the final summary is both coherent and complete.

Key Phrase Extraction

Keywords and key phrases are attached to documents to give a brief indication of what they are about.

Key phrases are a useful form of metadata because they condense documents into a few pithy phrases that can be interpreted individually and independently of each other. In key phase extraction, all the phrases that occur in the document are listed and information retrieval heuristics are used to select those that seem to characterize it best. Most key phrases are noun phrases, and syntactic techniques may be used to identify these and ensure that the set of candidates contains only noun phrases. The heuristics used for selection range from simple ones such as the position of the phrase's first occurrence in the document to more complex ones such as the occurrence frequency of the phrase in the document versus its occurrence frequency in a corpus of other documents in the subject area.

Topic Detection and Tracking (TDT)

Topic Detection and Tracking (TDT) [8] refers to a variety of automatic techniques for discovering and threading together topically related material in streams of data such as newswire and broadcast news. The TDT research applications keep track of topics or events of interest, in a constantly expanding collection of multimedia stories. There are five research applications defined in the TDT Program. Story Segmentation detects changes between topically cohesive sections. Topic Tracking keeps track of stories similar to a set of example stories. Topic Detection builds clusters of stories that discuss the same topic. First Story Detection detects if a story is the first story of a new, unknown topic. Link Detection detects whether or not two stories are topically linked. Shared resources, such as TDT corpora, language resources and evaluation software, provide the necessary tools to build a TDT application. The TDT corpora consist of broadcast news and newswire texts sampled daily during most of 1998. The Linguistic Data Consortium (LDC) exhaustively annotated the corpora by identifying which stories discuss a predefined set of topics.

Opinion Mining

Opinion mining [8] refers to the research work of mining user opinion data. It is also known as sentiment analysis. Typical research problems include: (i) subjectivity/objectivity classification is to identify if the text data contains user opinion; (ii) sentiment classification is to predict the polarity of user sentiment (e.g., positive or negative); (iii) opinion summarization is to provide a condensed representation for a set of user opinion texts; (iv) opinion anti-spamming is to detect if the opinion data are written by review spammers.

Key Applications

Bioinformatics

Bioinformatics is the study of the information content and information flow in biological systems and processes [6]. Text mining can be applied to bioinformatics literatures for named entity recognition and relationship extraction. Named entity recognition identifies entities such as drugs, receptors, enzymes, toxins, genes and their features (box, chain, sequence, subunit, etc.). Relation extraction detects the relationship between a pair of entities such as the relationship between genes, protein, or other biological entities.

Email Spam Filtering

The explosive growth of unsolicited emails, more commonly known as spam, has been undermining constantly the usability of emails. One solution is provided by spam filters. Some spam filters use black lists and hand-crafted rules, which are not easy to adapt to new types of spam. On the other hand, the success of machine learning methods in text classification provides the possibility to compete with rule-based filters and quickly adapt to new types of spam. Many spam filters based on machine learning are using Naive-Bayes classifiers. A prominent example is Mozilla's email client. Different classifier methods such as SVM are also used.

Business Intelligence

Business intelligence (BI) is a broad category of applications and technologies for gathering, storing, analyzing, and providing access to data to help enterprise users make better business decisions. BI applications include decision support systems, query and reporting, online analytical processing, statistical analysis, forecasting, and data mining. People express their opinions and post reviews of products on the Web. Opinion mining [3] identifies whether users like or dislike a product and products summary from the reviews. Opinion mining can help manufactures to identify problems in their products, and also provides valuable information for placing advertisements in Web pages.

Text Mining of Biological Resources

PADMINI SRINIVASAN
The University of Iowa, Iowa City, IA, USA

Synonyms

Knowledge discovery from biological resources; Hypothesis generation and exploration from biological resources; Literature-based discovery from biological resources

Definition

Text mining is about automatically or semi-automatically exploring hypotheses or new ideas from a set of resources. The mined hypotheses require further tests with methods native to the discipline, in this case with scientific methods in biomedicine. An overall goal in text mining is to support the intellectual activities of biomedical scientists as they explore new ideas using a collection of resources. Text mining is similar to data mining. But instead of mining a collection of well-structured data, text mining operates off semi-structured text collections. Current text mining efforts in biomedicine increasingly involve more structured data sources such as the Entrez Gene database maintained by the National Library of Medicine (NLM).

There is some diversity of opinion on the *kinds* of research that fall within the realm of text mining. As an example, some include text classification, which is about building models to predict one or more topical categories for a text. Still others include information extraction goals such as in research on identifying named entities, definitions and expansions of abbreviations in texts. Some go so far as to include text retrieval, i.e., research on finding documents relevant to a user query. Despite these diverse viewpoints, there is wide agreement that a core focus of text mining is on hypothesis generation and exploration based upon *implicit* connections present in the sources. Consistent with this viewpoint, Blagosklonny and Pardee [1] refer to text mining as conceptual biology, a field that fuels hypothesis-driven biomedical exploration. These hypotheses typically postulate relationships between at least two entities (or more generally concepts). The emphasis is also on novelty at least in the context of the mined sources. Note also that novelty itself eludes definition as it is difficult to pinpoint when and how an idea acquires the status of being *known*.

Historical Background

The motivation underlying biomedical text mining with its focus on hypothesis generation and exploration is that it is difficult for any one scientist or even a group of collaborators to keep abreast with research developments. This difficulty becomes compounded many times given the increasing importance of interdisciplinary perspectives to solve biomedical problems. Another motivation comes from the serendipitous nature of many scientific discoveries. Serendipity may be influenced by several intangibles, such as researcher intuition, prior experience and knowledge, including also the ability to creatively scan and combine the literature of multiple disciplines. With the biomedical literature growing at an astounding pace, there is a definite need for text mining tools to assist bioscientists gauge new ideas against prior research.

Text mining has its origins in the work of Swanson conducted during the mid 1980's. In 1986, Swanson mined the MEDLINE bibliographic database and proposed that fish oils may be used to treat Raynaud's disease [13]. Swanson observed from the literature that Raynauds is exacerbated by platelet aggregability, vasoconstriction, and blood viscosity. He also observed that fish oils reduce these phenomena. Combining these observations he postulated that fish oils may be beneficial for persons with Raynauds which was later corroborated by other scientists. The decade from the mid-1980's to the mid-1990's is marked by a series of papers by Swanson and his collaborator Smalheiser on using text mining to propose a variety of other hypotheses such as connections between estrogen and Alzheimer's disease [10]. These papers created a fertile for text mining research, especially in the context of MEDLINE. Remarkably, it was only in the mid-1990's that other researchers became seriously attracted to biomedical text mining. The first few papers were on automating several of the text mining steps in Swanson and Smalheiser's methodology [5,11]. Since then researchers have proposed other hypotheses such as viruses that may be used as bioweapons [14], possible therapeutic uses for substances such as thalidomide [16] and for turmeric (*Curcumin Longa*) [12], possible functional connections between genes as well as between genes and diseases [9]. Now past the 20 year mark, the text mining field is a fertile ground for research and development. It is mature to the point that several annual workshops affiliated with major conferences have been established. There is also a Journal of Biomedical Discovery and Collaboration that is dedicated to the field and finally there are recent reviews as for example on biomedical text mining tools [15].

Foundations

Resources

A central aspect to text mining in biomedicine is the use of MEDLINE, the bibliographic database produced by the National Library of Medicine. MEDLINE records contain a variety of fixed and variable length fields such as publication date, title, abstract, authors and author affiliations, chemical terms and subject representations in the form of assigned phrases. Phrases assigned to a record are selected from the MeSH (Medical Subject Headings) controlled vocabulary by trained indexers. Text mining systems sometimes differ in the MEDLINE field(s) used. Some methods use the free-text fields such as title and abstract [5] while others are based on controlled vocabulary fields such as MeSH and chemical terms (e.g., [11]). Systems using controlled vocabularies have the advantage of more precise vocabulary. But they take the risk of missing important information that may be present in the free-text alone. Systems using the free-text fields usually involve procedures for information extraction to identify key concepts that occur in the texts such as gene, protein, disease and drug name. In this regard research on natural language processing in the biomedical domain has had a huge influence on text mining. This direction is of increasing importance as other forms of textual collections such as patient records are brought into the fold of text mining.

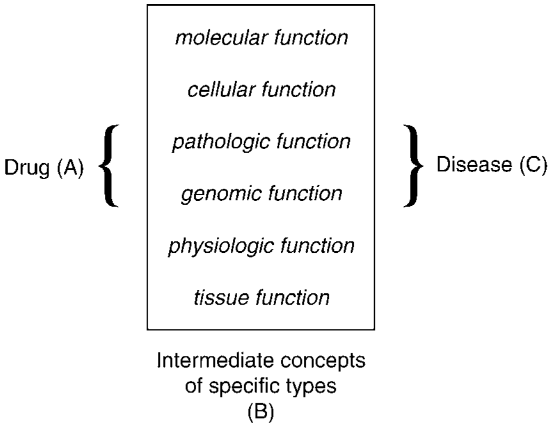
Many text mining approaches also avail of allied vocabulary resources such as the UMLS (Unified Medical Language System) also produced by the NLM. The UMLS offers a rich variety of conceptual and linguistic details and it also offers interconnections between the many general and specialized vocabularies arising from different subfields of biomedicine. Other core resources seen, especially in applications targeting bioinformatics, are Entrez Gene [3] and Gene Ontology [4]. Information about annotation links between GO terms and genes frequently accompanied by the MEDLINE records providing supporting evidence, are utilized in text mining. Beyond these core resources several others have been used for text mining such as DIP, the Database of Interacting Proteins [2].

Methods

There is a growing variety of text mining methods, orientations and applications. In general, methods appear to be selected or designed to fit the problem at hand. And since the space of text mining problems is broad (and growing), there is an almost bewildering array of text mining solutions. While this situation offers almost free rein to researchers and developers, it also makes it challenging to determine what methods (or aspects about methods) are most successful or most appropriate for a given problem or in a specific domain. Seemingly similar problems are sometimes addressed using significantly different approaches while certain approaches exhibit broader appeal.

Two established text mining approaches derive from Swanson and Smalheiser's early research. These are generally referred to as *open* discovery and *closed* discovery. The open discovery process is initiated with a single concept (A) and the goal is to identify one or more concepts (C) that are connected but only indirectly with A, i.e., through other intermediate concepts. In closed discovery, two concepts A and C are provided as input and the idea is to seek out novel connections between them.

Figure 1 displays these strategies. An example of open discovery represented by the figure is where the starting A concept is a specific drug and the user is interested in novel connections with C concepts representing diseases. Moreover, the intermediate (B) concepts could be constrained to concepts of particular types such as functions of different kinds, molecular, tissue etc. Or, they may be constrained to concepts designating genes already known to be associated with the disease. The novelty aspect is satisfied by ensuring that the A drug and the identified C disease have not yet been studied together. A typical approach implemented to satisfy this requirement is that the A-B concept(s) and B concept(s)-C connections should be found in disjoint portions of the literature collection or that the A-C connection is not recorded in an appropriate knowledge source. For closed discovery an example illustrated by the figure is where the user inputs both a specific drug (A) and a disease (C). The algorithm then looks for new connections, i.e., B concepts that tie the two together. Now it may be the case that no connections between the drug and the disease are known thus far or it may be that some connections are known and other novel ones are being sought. In all of these it can be seen that investigator participation is of value not only to specify the inputs but also to specify the kinds of outputs and to constrain the intermediate connection types of interest. Typically when multiple novel C concepts are discovered through open discovery or multiple B concepts discovered with closed these are ranked by some estimate of confidence.



Text Mining of Biological Resources. Figure 1. Open and closed discovery.

Many variations of these two basic strategies have been explored. One type of variation extends the transitive nature of these methods to allow for implicit connections ranging over longer distances, i.e., with longer connecting path lengths. For example in G2D [7] researchers start by connecting a disease to its pathological conditions and then to their co-occurring chemical terms in MEDLINE. These are in turn connected through co-occurrence with terms representing protein function from Gene Ontology (GO). These GO terms are then used to identify RefSeq [8] sequences through annotation links. Homology is then used to connect these with candidate sequences that are then constrained to those mapping to the same chromosomal region where the disease is mapped. Another key distinguishing feature across implementations of these text mining algorithms is that confidence estimates may be made in different ways. There is certainly variability in the particular confidence estimation functions used. But more generally, some utilize weights along the single best path while others utilize some function (such as a mean or median) computed over all the connecting paths. Still others, inspired by association rules, adopt the dual notions of confidence and support while several utilize symmetric measures exploiting concept co-occurrence based statistics.

Besides open and closed discovery, there are other text mining methods that rely on exploring graph properties. A graph may be constructed where the nodes represent biomedical objects and the links represent their interconnections. For example, gene networks have been studied by many researchers. Here links between pairs of genes may be directed to indicate influence of one gene over another and weighted by some estimate of degree of influence. Or, these may be undirected with link weight being a function of co-appearance in MEDLINE records. Such graphs may be studied for their structural properties including to identify core groups of objects (here genes).

Unexpected members of such groups may suggest ideas and lead to specific hypotheses and further research.

A recent trend is to embed text mining functions in systems designed with larger scope. iHOP is an example of such a system [6]. In such systems hypothesis generation becomes one of several sub goals. Wide ranging functions are offered by such systems such as easy connections between records of different databases and knowledge sources, literature retrieval and ranking as well as syntactic analysis of the text sentences to extract entities and relationships.

Key Applications

For pointers to current text mining applications the reader may explore sources such as the *Application Notes* sections of Bioinformatics (*Data and Text Mining* subsection); the *Software* and *Database* sections of BMC Bioinformatics; the *Web Server* issue of Nucleic Acid Research and similar sections of other biomedical journals.

Future Directions

Biomedical text mining is at a highly creative age with its scientific basis still in infancy. The area has been heavily influenced by research and development in several fields such as text retrieval, machine learning and computational linguistics. The rapid growth in terms of research papers is a strong indicator of its perceived potential.

There are several open problems in text mining. Certainly the relative merits of alternative methods, their generalizability and criteria for gauging relevance to specific application contexts are still open. There is also a need to obtain a deeper understanding of what is meant by a *novel* idea or hypothesis, as this is a key motivation for text mining research. Methods for evaluating text mining systems is also an open problem. Evaluations tend to be somewhat subjective and non standardized. A common strategy is to see if the algorithms can discover knowledge that is already recorded in sources such as the Database of Interacting Proteins [2]. Another strategy is to obtain the opinion of domain specialists on the connections found. Both strategies have their limitations. Also important is research on how to successfully integrate text mining systems into the work patterns of bioscientists. This will require a better understanding of research strategies used by bioscientists. Overall it remains to be seen how well text mining will address the needs of the biomedical research community. For the moment, at the very least, it is clear that text mining has significantly extended the frontiers of text based applications in biomedicine.

Text Representation

JUN YAN
Microsoft Research Asia, Haidian, China

Definition

Text representation is one of the fundamental problems in text mining and Information Retrieval (IR). It aims to numerically represent the unstructured text documents to make them mathematically computable. For a given set of text documents $D = \{d_i, i=1, 2,...,n\}$, where each d_i stands for a document, the problem of text representation is to represent each d_i of D as a point s_i in a numerical space S, where the distance/similarity between each pair of points in space S is well defined.

Historical Background

Mining the unstructured text data has attracted much attention of researchers in different areas due to its great industrial and commercial application potentials. A fundamental problem of text mining is how to represent the text documents to make them mathematically computable. Various text representation strategies have been proposed in the past decades for different application purposes such as text categorization, novelty detection and Information Retrieval (IR) [5]. This entry focuses on the text representation strategies specifically for IR applications.

Nowadays, the most commonly used text representation model in the area of Information retrieval is called as the Vector Space Model (VSM) [4,5]. It aims representing each text document by a numerical vector such that the similarity between vectors (documents) can be computed by different kernels. A simple and commonly used kernel is their normalized inner product, which is also known as the Cosine similarity. One of the commonly used VSM is the Bag of Words model (BOW). It uses all words appeared in the given document set D as the index of the document vectors. Under the BOW model, different term weighting schema give different text representation results. The simplest case of BOW is the Boolean model. It utilizes the binary vectors to represent text documents. In other words, if a term appears in a document, there has a "1" in the position, which corresponds to this term, in the document vector. Otherwise, the term weight is "0". As an extension of the Boolean model, Term Frequency Inversed Document Frequency (TFIDF) model was proposed. It uses real values which capture the term distribution among documents to weight terms in each document vector. However, there are many limitations in the traditional BOW text representation model. For example, (i) BOW ignores the within document term correlation such as the order of terms in a given document; (ii) the polysemy and synonymy problems can greatly decrease the IR performance in the TFIDF text representation model; and (iii) the TFIDF model cannot capture the semantics of documents for IR.

To solve the limitations of BOW model, various advanced text representation strategies have been proposed. The N-gram statistical language models [2] were proposed to capture the term correlation within document. However, the exponentially increasing data dimension with the increase of N limits the application of N-gram models. The Latent Semantic Indexing (LSI) [3] was proposed to reduce the polysemy and synonym problems. At the same time, LSI can also represent the semantics of text documents through the linear combination of terms, which is computed by the Singular Value Decomposition (SVD). However, the high complexity of SVD [1] make LSI seldom used in real IR tasks. In addition, some external resources such as the Wordnet and Wikipedia are recently used for solving the polysemy and synonym problems in text representation. Since the effectiveness of these external resources for text representation can only be learned in research papers and there still has no evidence to show their power in real IR applications, this article will not introduce their details. Motivated by the LSI, the Probabilistic Latent Semantic Indexing (PLSI) [6] is also proposed for representing the semantics of text documents. However, it is still limited by the computation complexity due to the increasing scale of Web data. As a summary, though various approaches have been proposed for solving the limitations of BOW, the BOW with TFIDF term weighting schema is still one of the most commonly used text representation strategies in real IR applications.

Beyond VSM, many propose to represent text documents in other formats instead of vectors or represent text documents through their meta-information. For instance, the text documents can be represented through neural network, through graphs and in tensor space model. The text documents in Web pages can be semantically represented by the search queries which have clicked these pages, the social bookmarks which have annotated these pages. However, most of them are used for solving specific text mining problems or used to enhance performance of some special IR tasks. In the next Section of this article, the details for text representation in two parts will be given, which are the traditional BOW text representation model with TFIDF term weighting schema and the semantic text representation through LSI.

Foundations

In the bag of words (BOW) model, a text document is represented as a collection of unordered terms. Given the document collection D={d_i, i=1, 2,...,n}, suppose there are m unique terms appeared in this collection (The stop words removal and stemming will be introduced later). Mathematically, this corpus of documents can be represented by a m by n matrix $S \in R^{m\times n}$. Each text document is denoted by a column vector $s_i, i = 1, 2,\ldots,n$ and each term is denoted by a row vector. The j^{th} entry of s_i is denoted by $s_{ji}, j = 1, 2,\ldots,m$. As an example, suppose the document collection D implies two documents,

d_1: He investigates the text representation approaches.
d_2: What is the meaning of text representation approach for text documents?

There are a list of 13 unique terms, which are,

“He, investigates, the, text, representation, approaches, What, is, meaning, of, approach, for, documents”.

The list of terms roughly represents the two documents by a 13 by 2 matrix. The problem is how to weight each entry of this matrix. Considering the simple Boolean model first. If a term appears in a document, its corresponding weight is 1; otherwise, it is 0. The transform of the matrix for the collection D is,

$$S^T = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 0 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}$$

where the order of term index is the same as the term list given above, i.e., the first term is “He” and the last term is “documents.” There are three obvious problems in this text representation strategy: (i) not all terms have the physical meaning in representing text documents such as “the,” “is” etc; (ii) some terms such as “approach” and “approaches” are actually the same; and (iii) the importance of all the terms is treated as the same in this strategy. Can the difference of the term importance be reflected in text representation? The answers for these three questions correspond to three key steps in text representation, which are *stop words removal*, *stemming* and *TFIDF indexing*.

The stop words (or stopwords) is the name of the terms that should be filtered out before text documents indexing or natural language processing. There has no fixed stop words list for all text processing applications. Generally the stop words list will include the terms like “a,” “the,” “an,” etc. After removing the stop words, a stemming procedure is applied before the TFIDF indexing. The stemming aims at reducing inflected words to their stem. For example, “approaches” is stemmed to “approach,” “investigates” is stemmed to “investigate” and “representation” is stemmed to “represent.” Thus in the above example, the list of terms is reduced to,

“He, investigate, text, represent, approach, what, mean, document.”

Thus the two documents d_1 and d_2: can be represented by an 8 by 2 matrix. The transpose of it is,

$$S^T = \begin{pmatrix} 1 & 1 & 1 & 1 & 1 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 1 & 1 & 1 & 1 \end{pmatrix}$$

Until now, the problems (i) and (ii) have been solved. The last problem is how to tell the importance of different terms in text representation. One of the commonly used approaches is called as the TFIDF indexing. The TFIDF aims to assign a weight to each term according to a document in a collection or corpus. In other words, TFIDF aims to assign different weights for all entries s_{ji} in matrix S. An intuition is that the more times a term appears in a document, the more important is this term to this document. Thus the weight should increase proportionally to the number of times a term appears in the document. On the other hand, if a word appears in many documents in the corpus, the discriminative power of the term will be weak. Thus the weight is offset by the frequency of the word in the corpus. The former step is called the Term Frequency (TF). It can be counted directly from the documents. As an example, the TF of term stext” in d_2 is 2. A normalizing factor is always used for calculating the TF of a term in a document. Since in d_2 there are 7 terms after stop words removal and stemming. Among them, 2 of them are "text." Thus the TF for term "text" in d_2 is 2/7. The latter step is called the Inverse Document Frequency (IDF). It is a log function. The IDF for term t is,

$$\log \frac{n}{\#\text{document involve term } t}$$

Thus the TFIDF weighting schema can be as simple as TF*IDF. There are various variations of TFIDF text indexing. The major differences are how to normalize and smooth the weighting equation.

In the BOW model, the TFIDF indexing gives a way to weight the terms for text documents. However, this kind of term frequency based approaches cannot discover the semantics of the text documents. In the following several paragraphs, the Latent Semantic Indexing (LSI) is briefly introduced, which aims to discover the text semantics through linear combination of term weights. As introduced above, the term by document matrix is a sparse matrix whose rows correspond to terms and columns correspond to documents. LSI aims to transform the matrix S into a reduced matrix which can reflect the relation between the documents and some *concepts*. Thus the terms and documents are indirectly related through the concepts.

Mathematically, LSI aims to find a projection matrix $W \in R^{m \times p}$ such that the linear projection $y_i = W^T s_i \in R^p, i = 1, 2, \ldots, n$ can reflect the p semantic concepts implied by document d_i, where $p << m$. In other words, LSI assumes that the linear combination of terms can reflect the concepts in text documents. $W \in R^{m \times p}$ can give p different linear combinations for term weights vector s_i. Through the linear projection matrix W, the text document d_i which is represented by m terms' weights in vector s_i is represented by p concepts' weights in vector $y_{i.}$ The problem left is how to get the projection matrix W, i.e., how to get the weights for the linear combination of terms, from the matrix S. The calculating of W can be formulated from different perspectives. For example, it can be formulated as optimization problem through the essential relationship between LSI and Principal Component Analysis (PCA). It can also be formulated as the best low rank matrix approximation problem. Intuitively, LSI is computed through the matrix decomposition. Given the term by document matrix S, where s_{ji} stands for the weight of term j in document i. Assume that there exists a decomposition of matrix $S = U \Sigma V^T$, where U and V are orthogonal matrices and S is a diagonal matrix. This matrix decomposition is called as the Singular Value Decomposition (SVD). If preserve only the first p columns of U, it is the projection matrix $W \in R^{m \times p}$ for LSI. For details for LSI please refer to [3].

Key Applications

The text representation is the fundamental work for IR and text mining. Besides IR, it can also be used for text categorization, text clustering, topic detection and novelty detection etc.

Future Directions

The future directions of text representation problem can be roughly classified into two categories. The first is the large scale computation and the second is the semantic text representation. For the former, the goal is to make the text representation strategies which have high cost to be usable in real IR tasks. For example, one can develop the distributed infrastructure for N-gram model which can be used to enrich the BOW model if the computation of N-gram model is efficient enough. One can develop the incremental approximation or distributed computation algorithms for large scale LSI which can discover the semantic of documents in large scale IR systems. For the latter, besides LSI and PLSI, some semantic Web related research works give good information sources about how to discover the semantics of text documents.

Data Sets

For testing the effectiveness of text representation strategies, there are many commonly used text datasets in different scales. As some examples, the Reuters-21578 (http://www.daviddlewis.com/resources/testcollections/reuters21578/), RCV1 (http://jmlr.csail.mit.edu/papers/volume5/lewis04a/lewis04a.pdf), 20 Newsgroup (http://people.csail.mit.edu/jrennie/20Newsgroups/), Open Di rectory Project (ODP) (http://rdf.dmoz.org/) and the TREC text datasets (http://trec.nist.gov/data.html) are all commonly used for text mining or IR research.

Document segmentation

Definition

Text segmentation is a precursor to text retrieval, automatic summarization, information retrieval (IR); language modeling (LM) and natural language processing (NLP). In written texts, text segmentation is the process of identifying the boundaries between words, phrases, or some other linguistic meaningful units, such as sentences or topics. The term separated from such processing is useful to help humans reading texts, and are mainly used to assist computers to do some artificial processes as fundamental units, such as NLP, and IR.

Historical Background

Natural language processing (NLP) is an important research field. Its primary problem is how to segment text correctly. Various segmentation methods have emerged in the past decades for different kinds of language and applications. Text segmentation is language dependent (different language has its own special problems, which would be introduced later), corpus dependent, character-set dependent, and application dependent. Most existing text segmentation systems are language specific and corpus dependent.

This entry mainly focuses on traditional English and some Chinese text segmentation strategies. To do such segmentations, there are two major approaches: (i) Manually analyzing the characters of text to get some heuristic approaches; (ii) Doing annotations for the sample corpus with boundary information, then adopting some machine learning (ML) methods to learn from annotated corpus, and finally doing automatic text segmentation.

The problem of word segmentation (also known as tokenization), which is the process of dividing the sequence of characters into words by locating words boundaries, does not appear to be difficult for written languages that have explicit word boundary markers, such as English in which words are separated by white spaces. When such clues are not consistently retained in written languages, such as Chinese, in which sentences can be considered to be a character string, doing word segmentation should be the most important and essential part of text segmentation. On the contrary, sentence segmentation (which also can be referred to as sentence boundary detection, sentence boundary disambiguation (SBD), or sentence boundary recognition) is more difficult in English text segmentation, which must disambiguate punctuations that might denote sentence boundaries.

Based on previous analysis, for English text segmentation, words can be isolated by white spaces. So, the main problem of this kind of segmentation is how to recognize the boundaries of sentences, which involves resolving the use of ambiguous punctuation, such as periods, commas, and semicolons. Some recognizable tokens contain ambiguous punctuation, such as numbers (e.g., 1,236.78), dates (e.g., 02/05/96), acronyms (e.g., AT&T), and abbreviations (e.g., U.S.). Some example sentences containing ambiguous punctuations follow:

1. *Clairson International Corp. said it expects to report a net loss for its second quarter ended March 26 and doesn't expect to meet analysts' profit estimates of $3.0 to $4 million, or 1,276 cents a share to 1,279 cents a share, for its year ending Sept. 24.* (From the Wall Street Journal (1988))
2. *The contemporary viewer may simply ogle the vast wooded vistas rising up from Saguenay River and Lac St. Jean, standing in for the St. Lawrence River.* (From the Wall Street Journal (1991))
3. *The firm said it plans to sublease its current headquarters at 55 Water St. A spokesman declined to elaborate.* (From the Wall Street Journal (1987))

As can be seen, periods have been used three different ways in the first example - within a decimal *($3.0)*, in abbreviations (*Corp.* and *Sept.*), and at the end of the sentence. A comma is used in a number (*1,276 and 1,279*). Consider the second and third examples in which "*St.*" appears three times. The first two instances of "*St.*" do not denote the boundary of the sentence, whereas the last one delimits the sentence. At the same time, it is also essential to do word segmentation in English text segmentation. It is necessary to recognize whether a period within a number *($3.0)* should be a part of decimal or the end of a sentence – that is, should *$3.0* be parsed as a word "*/$3.0/*" or be parsed as "*/$3/. /0/*". The comma used in the number (*1,276 and 1,279*) also should be recognized as a part of number rather than a break of a sentence – that is, whether "*1,276*" should be broken to "*/1,276/*" rather than "*/1/, /276/*". Taking the third and first example sentences above, the first two "*St.*" should be segmented to "*/St./*". Though the last "*St.*" is also supposed to be segmented to "*/St./*", one must always realize that this period also stands for the end of sentence.

If there were a dictionary containing all kinds of words and including all the acronyms and abbreviations, it would be much easier to recognize words and do tokenization. In actuality, however, acronyms and abbreviations are emerging continuously and will never stop. In order to solve this problem, many approaches have been proposed. There are mainly two approaches: First, manual analysis often uses regular expression grammars and lexicon to solve those problems. The systems based on such methods are always called rule-based systems. In such systems, Lexicon is used to obtain the information of words, such as capitalization, spelling, and suffixes, to determine whether a word followed with a period should be a common word or a boundary signal of a sentence. Regular expressions are established for detecting special kinds of words, such as numbers and dates. Another way of performing sentence boundary disambiguation (SBD) is to use machine learning (ML) techniques, such as decision tree classifier, maximum entropy modeling, and neural network. The most essential information for Machine Learning systems to obtain are good features, such as word spelling, suffix, capitalization, and word classes. The difficulty is how to obtain a well annotated sample corpus with labels of word boundaries and sentence boundaries.

For Chinese text segmentation, sentences are always isolated by non-ambiguous punctuations, but words are character strings without explicit boundary markers. So, the main problem of Chinese text segmentation is how to recognize the boundaries of words. All the same, Word Sense Disambiguation is the primary issue in word segmentation. Three types of ambiguity string are present in Chinese text segmentation: overlapping ambiguity string, combinatorial ambiguity string, and hybrid ambiguity string. To solve those problems, various approaches have been proposed. The most typical solution is using forwards maximum matching (FMM) and backwards maximum matching (BMM) based on a dictionary.

Except for these two typical languages, there are still other types of languages with many different features of written text. Many more difficulties for each language have appeared.

In addition to language-dependent word segmentation and sentence segmentation, there is another segmentation that has emerged: topic segmentation, since a document always contains several topics and even one topic may have different aspects. Topic segmentation is much harder than word and sentence segmentation due to difficulties in detecting semantic units and dividing them into topics. Many approaches have been tried to deal with such problems [1,4]. Applications based on topic segmentation are abundant, such as document summarization, text processing, and NLP.

Foundations

Using regular expression grammars and lexicon to solve ambiguous punctuation is classic and to some extend useful. Different regular expressions have been defined for all kinds of tokens containing ambiguous punctuation. First, lexicon is used to find if a token exists in the dictionary or not. If it does not exist, a regular expression is used.

1. Numbers. Take "123,456.789%" as an example. The regular expression should be ((0–9]+,)*[0–9]+(.(0–9]+)*%? (ab means matching a, and then matching b.
   a + means one or more a would be matched.
   a* means zero or more a would be matched.
   a? means zero or one a would be matched.). Once this expression is used to recognize numbers, periods, commas and percent within a number, those ambiguous punctuations will not be parsed falsely as a boundary of a sentence.
2. Dates, such as "05/11/95". Heuristic regular expression would be [0–9][0–9]/[0–9][0–9]/[0–9][0–9].
3. Acronyms and Abbreviations, typically "U.S., St., Ash., and Corp." Regular Expression [A–Z]+[A–Za-z0–9]*.([A–Za–z0–9].)* will be used to find those acronyms and abbreviations. It should be noted that when an acronym or abbreviation is located at the end of a sentence, after the expression mentioned above has been used to parse such kind of sentences, an error would occur. For example, the sentence "*The firm said it plans to sublease its current headquarters at 55 Water St. A spokesman declined to elaborate.*" would be parsed to one sentence, although it should actually be split into two sentences "*/The firm said it plans to sublease its current headquarters at 55 Water St./*" and "*/A spokesman declined to elaborate./*".

Three typical kinds of tokens have been presented above. There are still many other types of words containing ambiguous punctuations. Many more regular expressions are required to deal with all of them. The set of expressions would be extremely huge. It is important to mention that these typical kinds of tokens are language dependent. This implies that different regular expression sets for each language would need to be established, which is a labor consuming enterprise. Also, the expressions are usually corpus related, which makes those rules unable to be ported across domains.

Because there are so many limitations in using regular expressions to segment words and sentences, as mentioned above, machine learning (ML) techniques have been taken into this field. These techniques can be retrained quickly for a new domain, a new corpus, a new language only if a well-annotated sample corpus has been given. Some systems also use part-of-speech (POS) information to improve performance [3].

In order to discuss how to deal with Chinese text segmentation, first, three kinds of ambiguity string should be introduced. (i) Overlapping Ambiguity String. It is defined as follows: ABC can be segmented into A/BC and AB/C, such as "和/平等" could be segmented into"和/平等" and "和平等" in different situations. In sentence "独立/自主/和/平等/独立/的/原则" and "讨论/战争/与/和平/等/问题", the segmentation of "和平等" is different. (ii) Combinatorial Ambiguity String. It is defined as follows: AB can be segmented into AB and A/B, such as "马上" should be segmented into "马上" in sentence "马上/过来" and should be "马/上" in sentence "他/骑/在/马/上". (iii) Hybrid Ambiguity String. It combines overlapping and combinatorial ambiguity. To figure out the first kind of ambiguity string problem, forwards maximum matching (FMM) and backwards maximum matching (BMM) are used to segment sentence separately. Such as sentence "独立/自主/和/平等/独立/的/原则", with FMM, it should be segmented into "独立/自主/和平/等/独立/的/原则"; with BMM, it should be "独立/自主/和/平等/独立/的/原则". When the result of segmentation with FMM and BMM is different, syntax, semantic, pragmatic information will be added to determine which segmentation should be chosen. To solve the combinatorial ambiguity string problem, FMM and Backwards Minimum Matching are adopted. For example with FMM, the sentence "他骑在马上" should be segmented into "他/骑/在/马上"; with BMM, it should be "他/骑/在/马/上". The following processing is the same as overlapping ambiguity string segmentation.

Key Applications

Text segmentation is an important aspect in developing text processing applications, such as Information Extraction, Document Summarization, Machine Translation (MT), Natural Language Processing, Information Retrieval, Language Modeling, and Speech Recognition.

Future Directions

There are roughly two directions for text segmentation in the future. One is text segmentation based on specific language. Another is its use in other fields, such as the rich transcription field. For the former, there are more than 200 languages in the world. Each has its own difficulties in doing text segmentation, such as word segmentation in Chinese text segmentation. These problems are do not have ideal solutions. For the latter, sentence boundary disambiguation (SBD) has attracted increased attention recently as a way to improve speech recognition output for better readability and downstream natural language processing and some subsequent tasks, such as speech translation and speech summarization.

Data Sets

Two main data sets are typically used for testing, evaluation and development in large amount of text segmentation and text processing tasks: Brown Corpus and the Wall Street Journal (WSJ) corpus – containing the Penn Treebank (Marcus, Marcinkiewicz, and Santorini, 1993). Texts in those corpora are all split into documents, paragraphs, and sentences and are annotated with POS information. The above information is necessary to develop and evaluate text segmentation systems.

Other data sets on Rich Transcription can be used to perform sentence boundary disambiguation, such as the Rich Transcription data sets provided by National Institute of Standards and Technology (NIST).

Text Semantic Representation

JUN YAN, JIAN HU
Microsoft Research Asia, Haidian, China

Definition

The classical text representation strategies aim to numerically represent the unstructured text documents to make them mathematically computable. With the rapid growth of information retrieval and text data mining research, the semantic text representation is attracting more and more attention. The problem is how to represent the text documents by explicit or implicit semantics instead of word occurrence in the document. The goals of semantic text representation are to improve the text clustering, classification, information retrieval and other text mining problems' performance.

Historical Background

In the past decades, semantic text representation has attracted much attention in the area of information retrieval and text data mining research. There have different ways for categorizing various semantic text representation strategies. This entry generally classifies the previous efforts for this problem into two categories: explicit semantic text representation and implicit semantic text representation.

The explicit semantic text representation aims to represent text documents by explicit readable sentences, key phrases or keywords, which can semantically describe the main topic of the given text documents. The related approaches can be further classified into automatic approaches and manual approaches. From the automatic approaches' perspective, the Text Summarization technologies aim at learning one or more sentences to represent a given text document; the Information Extraction technologies aim at extracting one or more key phrases for describing the semantic of a given text document. In addition, many previous works propose to annotate the Web pages, which is a special type of text documents, by search engine click through logs. With the rapid growth of Semantic Web (http://infomesh.net/2001/swintro/#furtherReading) in recent years, the automatic web page annotation and ontology learning, etc can all be utilized for automatically represent Web pages semantically. As some examples, the WordNet and Wikipedia have both been utilized for semantically enhance the text representation for various applications. From the manual approaches' perspective, there are many commercial systems target at semantic text representation by key phrases or key words. Two of the most representative examples of these commercial systems are delicious and flicker. Both of them aim to semantically represent the Web pages through manually assigned social annotation to a large number of Web pages.

To date, the work on integrating semantic background knowledge into text representation is quite few and the results are not good enough. Buenaga Rodriguez et al. and Urena Loez et al. successfully integrated the WordNet resource for a document categorization task. They improved classification results of Rocchio and Widrow-Hoff algorithms on Reuters corpus. In contrast some work utilized WordNet in a supervised scenario without employing WordNet relations such as hypernyms and associative relations. Meanwhile, they built the term vectors manually. Dave et al. has utilized WordNet synsets as features for document representation and subsequent clustering. That work did not perform word sense disambiguation and found that WordNet synsets decreased clustering performance in the experiments. Hotho et al. integrated WordNet knowledge into text clustering, and investigated word sense disambiguation strategies and feature weighting schema through considering the hypernym relations from WordNet. The experimental results on Reuters corpus show improvements compared with the best baseline. However, considering the few word usage contexts provided by WordNet, the word sense disambiguation effect is quite limited. Meanwhile, the enrichment strategy which appends or replaces document terms with their hypernym and synonym is overly simple. To solve the limitations of many previous work, Hu et al. proposed to enhance the text representation by Wikipedia.

On the other side, one of the most classical implicit semantic text representation approaches is known as the Latent Semantic Indexing (LSI) [2]. Nowadays, the most commonly used text representation model is called as the Vector Space Model (VSM) [3]. It aims to represent each text document by a numerical vector such that the similarity between vectors (documents) can be computed by different kernels. Latent Semantic Indexing (LSI) was originally proposed for dealing with the problem of *synonymy* and *polysemy* in the vector space model. In VSM, LSI represents the semantics of text documents through the linear combination of terms, which is computed by the Singular Value Decomposition (SVD) [1]. The reason why LSI is known as the implicit semantic text representation strategy is that the linear combination of keywords, which are semantics of the text documents, cannot be explained intuitively. A variety of tests and applications have been developed to validate its power in text representation. Special interests have been paid to investigate its ability in improving the IR performance. Besides general IR tasks, LSI has also been successfully applied for the cross-language retrieval and distributed information retrieval tasks. However, classical LSI suffers from the high computational cost involved in the Singular Value Decomposition (SVD), especially when applied to large scale text corpus. To avoid the costly computation, it has been proposed to use other strategies such as Semi-Discrete matrix Decomposition (SDD) and Concept Indexing (CI) instead of LSI for implicitly and semantically representing text documents. There are many variances of the classical LSI, the Probabilistic Latent Semantic Indexing (PLSI) [4] and the Supervised LSI are some of the examples.

Foundations

This entry mainly introduces one classical algorithm in each algorithm category. In the explicit semantic text representation category, the Wikipedia for text enrichment is introduced. On the other hand, in the implicit semantic text representation category, the traditional latent semantic indexing is introduced.

Wikipedia is a dynamic and fast growing resource – articles about newsworthy events are often added within few days of their occurrence. Each article in Wikipedia describes a single topic; its title is a succinct, well-formed phrase that resembles a term in a conventional thesaurus. Meanwhile, each article must belong to at least one category of Wikipedia. Hyperlinks between articles keep many of the same semantic relations as defined in international standard for thesauri, such as equivalence relation (synonymy), hierarchical relation (hypernym) and associative relation. However, as an open resource, it inevitable includes much noise. To make it a clean and easy-to-use as a thesaurus, a recent work proposed by Hu et al. first preprocess the Wikipedia data to collect Wikipedia concepts, and then explicitly derive relationships between Wikipedia based on the structural knowledge of Wikipedia.

Each title of a Wikipedia article describes a topic, and they are denoted as a concept. After process the Synonymy, Polysemy and Hypernymy, since each Wikipedia article contains a lot of hyperlinks, which express relatedness between them, The cosine similarity of article pairs in Wikipedia may reflect the relatedness between the two concepts. However the drawback of this measurement is the same as that of *BOW* approach, since it only considers terms appeared in text documents which have no semantic information. Another method to measure the relatedness between a pair of Wikipedia articles is to compare the similarity between outlinked categories of the two articles. It can be observed that if two articles share some out-linked categories, the concepts described in these two articles are most likely related. To get an overall relatedness of two Wikipedia concepts, the above two measures are linearly combined.

As introduced above, to represent text documents semantically, many previous approaches enriched text representation with external resources such as WordNet and ODP. The same to them, for the Wikipedia, first, the algorithm generates new features for each document in the dataset. The features can be synonym or hypernym for document terms or expanded features for terms, sentences and documents. Second, the generated new features replace or append to original document representation and construct new vector representation.

On the other hand, the classical LSI due to its effectiveness in the area of text data mining and information retrieval research. More details about other related approaches please refer to the recommended readings. In the bag of words (BOW) model, a text document is represented as a collection of unordered terms. Given the document collection $D = \{d_i,\ i = 1, 2,...,n\}$, suppose there are m unique terms appeared in this collection. Mathematically, this corpus of documents can be represented by a m by n matrix. $S \in R^{m\times n}$ Each text document is denoted by a column vector $s_i, i = 1, 2,...,n$ and each term is denoted by a row vector. The j^{th} entry of s_i is denoted by $s_{ji}, j = 1, 2,...,m$.

Mathematically, LSI aims to find a projection matrix $W \in R^{m\times p}$ such that the linear projection $y_i = W^T s_i \in R^p, i = 1, 2,...,n$ can reflect the p semantic concepts implied by document d_i, where $p << m$. In other words, LSI assumes that the linear combination of terms can reflect the concepts in text documents. $W \in R^{m\times p}$ can give p different linear combinations for term weights vector s_i. Through the linear projection matrix W, the text document d_i which is represented by m terms?' weights in vector s_i is represented by p concepts?' weights in vector $y_{i.}$ The problem left is how to get the projection matrix W, i.e., how to get the weights for the linear combination of terms, from the matrix S. The calculating of W can be formulated from different perspectives. For example, it can be formulated as optimization problem through the essential relationship between LSI and Principal Component Analysis (PCA). It can also be formulated as the best low rank matrix approximation problem. Intuitively, LSI is computed through the matrix decomposition. Given the term by document matrix S, where s_{ji} stands for the weight of term j in document i. Assume that there exists a decomposition of matrix $S = U\Sigma V^T$, where U and V are orthogonal matrices and Σ is a diagonal matrix. This matrix decomposition is called as the Singular Value Decomposition (SVD). If preserve only the first p columns of U, it is the projection matrix $W \in R^{m\times p}$ for LSI.

Key Applications

The semantic text representation has various different applications. Generally speaking, it is very important for the traditional text clustering, text categorization and information retrieval tasks. As some detailed examples, the LSI is generally used for relevance based information retrieval and text clustering. Documents summarization can be used for search results snippet generation. Key word extraction can be used as a component of the ontology learning of semantic Web. The social annotation is a fundamental work for semantic Web. As a summary, the semantic text representation is a fundamental problem for text mining and analysis.

Future Directions

The future directions of semantic text representation problem can be roughly classified into threefold. The first is how to develop novel semantic text representation approaches by designing novel algorithms and leveraging other meta-information. In more details, the Wordnet was first proposed to enhance the semantic text representation. Simultaneously, the search engine click-through log was proposed to enhance the text representation. Recently, the Wikipedia and social annotation were widely studied as the meta-information of text documents for semantic text representation. The remaining problem is whether other better data sources for text enrichment will be found. The second is the scalability issue for current strategies. For example, the SVD computation for LSI is highly expensive. A big problem is how to design scalable algorithm for LSI to deal with large scale data. The advanced algorithm could be approximated LSI, parallel computation and incremental computation etc. The third direction is how to apply the semantic text representation strategies for pushing the progress of semantic Web and other applications of semantic text representation. For example, one problem is how to enhance the text clustering or classification by semantic text representation.

Data Sets

For testing the effectiveness of semantic text representation strategies, there are many commonly used text datasets in different scales. As some examples, the Reuters-21578 (http://www.daviddlewis.com/resources/testcollections/reuters21578/), RCV1 (http://jmlr.csail.mit.edu/papers/volume5/lewis04a/lewis04a.pdf), 20 Newsgroup (http://people.csail.mit.edu/jrennie/20News, groups/), Open Directory Project (ODP) (http://rdf.dmoz.org/) and the TREC text datasets (http://trec.nist.gov/data.html) are all commonly used for text mining or IR research.

Text Streaming Model

Ning Liu
Microsoft Research Asia, Beijing, China

Definition

Text streaming model (TSM) is one of the fundamental problems in streaming model and text mining. It aims to process a sequence of text data that comes at a rate. In this model, text data does not take the form of arriving in multiple, continuous, rapid, time-varying data streams. Input text streaming D_1, D_2, ... arrives sequentially, one by one, and the aim of TSM is to analysis the streaming text data.

Historical Background

Mining the streaming data has attracted much attention of researchers in different areas due to its great industrial and commercial application potentials. Specifically, text streaming data models are of interest to the machine learning and data mining community. The world wide web has many text data, such as web pages, news-feeds, emails and blogs. And most of them are classical text streaming data. Then, how to model text streaming data is important.

Traditional text data model is Vector Space Model (VSM). One of the commonly used VSM is the Bag of Words model (BOW), which index the document as a set of terms. This set of terms defines a space such that each distinct term represents the entries in that space. Since VSM represents the documents as a set of terms, this space can be viewed as a "document space." A numeric weight can then be assigned to each term in a given document, representing an estimate of the usefulness of the given term as a descriptor of the given documents. The weights assigned to the terms in a given documents can then be interpreted as the coordinates of the document in the documents space. Then, Term Frequency Inversed Document Frequency (TFIDF) model was proposed. It uses real values, which capture the term distribution among documents to weight terms in each document vector. Moreover, the N-gram statistical language model was proposed to model text data with VSM.

However, there are two challenges in the traditional VSM for text streaming data.

1. Update the data automatically
2. Do analyses of updated streaming data in acceptable time

Foundations

In the bag of words (BOW) model, a text document is represented as a collection of unordered terms. Given the document collection $D = \{d_i,\ i = 1,\ 2,...,n\}$, suppose there are m unique terms appeared in this collection (stop words removal and stemming are introduced later). Mathematically, this corpus of documents can be represented by a m by n matrix $S \in R^{m \times n}$. Each text document is denoted by a column vector $s_i, i = 1, 2,...,n$ and each term is denoted by a row vector. The j^{th} entry of s_i is denoted by $s_{ji}, j = 1, 2,...,m$. As an example, suppose the document collection D implies two documents,

– d_1: He investigates the text representation approaches.
– d_2: What is the meaning of text representation approach for text documents?

There is a list of 13 unique terms, which are,

► *"He, investigates, the, text, representation, approaches, What, is, meaning, of, approach, for, documents."*

Thus, one roughly represents the two documents by a 13 by 2 matrix. Consider the simple Boolean model first. In other words, if a term appears in a document, its corresponding weight is 1; otherwise, it is 0. The transform of the matrix for collection D is,

$$S_2^T = \begin{pmatrix} 1\,1\,1\,1\,1\,1\,0\,0\,0\,0\,0\,0\,0 \\ 0\,0\,1\,1\,1\,0\,1\,1\,1\,1\,1\,1\,1 \end{pmatrix}$$

where the order of term index is the same as the term list given above, i.e., the first term is "He" and the last term is "documents."

For text streaming data, a new text is coming,

– d_3: Text mining is important in IR.

Now, the term list of $d_1$and d_2 should be changed. The problem is how the model streaming text data, which is how to update the indexing matrix.

$$S_s^T = \begin{bmatrix} S_2^T & 0 & 0 \\ 0 & s_{3i} & 0 \end{bmatrix}$$

Key Applications

The streaming text model is the fundamental work for IR and text mining. Besides IR, it can also be used for news categorization and RSS clustering etc.

Data Sets

For testing the effectiveness of text representation strategies, there are many commonly used text datasets in different scales. As some examples, the Reuters-21578, RCV1, 20 Newsgroup, Open Directory Project (ODP) and the TREC text datasets are all commonly used for streaming text model.

Text Summarization

DOU SHEN
Microsoft Corporation, Redmond, WA, USA

Synonyms

Document summarization

Definition

Text summarization is the process of distilling the most important information from a text to produce an abridged version for a particular task and user [9].

Historical Background

With more and more digitalized text being available, especially with the development of the Internet, people are being overwhelmed with data. How to help people effectively and efficiently capture the information from the data becomes extremely important. Many techniques have been proposed for this goal and text summarization is one of them.

Text summarization in some form has been in existence since the 1950s [8]. Two main influences have dominated the research in this area, as summarized by Mani in [10]. Work in library science, office automation, and information retrieval has resulted in a focus on methods for producing extracts from scientific papers, including the use of "shallow" linguistic analysis and the use of term statistics. The other influence has been research in artificial intelligence, which has explored "deeper" knowledge-based methods for condensing information. While there are a number of problems remaining to be solved, the field has seen quite a lot of progress, especially in the last decade, on extraction-based methods. This progress has been greatly accelerated by the rather spectacular advances in shallow natural language processing, and the use of machine learning methods which train summarization systems from text corpora consisting of source documents and their summaries. In the following sections, a brief introduction of different kinds of text summarization will be introduced, which is followed by an overview of the existing algorithms.

Foundations

Text summarization can be categorized along two different dimensions: abstract-based and extract-based. An extract-summary consists of sentences extracted from the document while an abstract-summary may employ words and phrases that do not appear in the original document but that are semantically meaningful [9]. The summarization task can also be categorized as either generic or query-oriented. A query-oriented summary presents the information that is most relevant to the given queries, while a generic summary gives an overall sense of the documents content [4]. In addition to single document summarization, which has been first studied in this field for years, researchers have started to work on multi-document summarization whose goal is to generate a summary from multiple documents that cover related information.

Most current text summarizers are extractive, since extraction is widely used, such as the snippets generated by search engines, while it is much easier than abstracting. Therefore, this entry focuses on extraction. For extractive summarizers (either for single-document summarization or multi-document summarization), they usually need to solve three problems: (i) Content selection, that is what should be selected from the text to form the summaries, which are most in the form of sentences or phrases; (ii) Information ordering, that is how to order the extracted sentences or phrases; (iii) Sentence realization, that is what kind of clean up to perform on the extracted sentences or phrases so they form a coherent summary. It is clear that the first problem is the critical one for extractive summarizers. The algorithms for this problem can be categorized as either unsupervised methods, or supervised methods. Unsupervised methods do not need any training data (pairs of a texts and the corresponding summaries). They calculate the importance of a sentence by considering the position of the sentence, the contained terms or phrases, the discourse centrality and so on. Supervised methods rely on a set of training data, which designs some features to capture the importance of sentences and a model can be learned from the training data to predict the importance of sentences. With this model, the most important sentences can be selected to form a summary.

Extractive Summarization Algorithms

Unsupervised Methods The simplest and straightforward way to select sentences is based on the sentences' locations. Generally speaking, certain locations of the text (titles, headings, the first sentence in each paragraph, etc.) tend to contain important information. Therefore, by simply taking sentences in these locations, a summary can be constructed, which forms a strong baseline, even better than other methods [2]. Besides locations of sentences, the importance of a sentence is indicated by cue phrases. For example, once a sentence contains the phrases like "To sum up," "In summary," it is more likely to be extracted as an summary sentence. On the contrary, some other phrases like "specifically," "in details" indicate that the sentence is not "abstract" enough to be a summary sentence. In [15], Teufel and Moens manually built a list of 1,423 cure phrases in a genre of scientific texts and each cue phrase has a (positive or negative) "goodness score," also assigned manually.

There are also some methods calculating the importance of sentences based term importance and the term importance can be estimated by its frequency. The system of Luhn [8] is an typical example of this kind. In Luhn's method, every sentence is assigned with a significance factor, and the sentences with the highest significance factor are selected to form the summary. In order to compute the significance factor of a sentence, it is necessary to build a "significant words pool" which is defined as those words whose frequency is between high-frequency cutoff and low-frequency cutoff that can be tuned to alter the characteristics of the summarization system. After this is done, the significant factor of a sentence can be computed in the following way: (i) set a limit L for the distance at which any two significant words could be considered as being significantly related. (ii) find out a portion in the sentence that is bracketed by significant words not more than L non-significant words apart. (iii) count the number of significant words contained in the portion and divide the square of this number by the total number of words within the portion.

In the above mentioned unsupervised methods, the sentences in a text are treated independently. In the following part, several more unsupervised methods are introduced, which exploit the relationship among sentences to some extent. The first one, as presented in [5], organizes the sentences in a text into a matrix and then apply a technique named Latent Semantic Analysis (LSA) [1] to derive the importance of sentences. A brief overview of LSA can make it easier to understand the LSA-based summarization method. LSA is based on singular value decomposition (SVD), a mathematical matrix decomposition technique that is applicable to text corpora as known by people. Given an m*n matrix $A = [A_1, A_2,...,A_n]$, with each column vector A_i representing the weighted term-frequency vector of sentence i in the document under consideration, the SVD is defined as:

$$A = U\Sigma V^T$$

where $U = [u_{ij}]$ is an m*n column-orthonormal matrix whose columns are called left singular vectors; $\Sigma = diag\ (\sigma_1,\sigma_1,...,\sigma_n)$ is an $n \times n$ diagonal matrix whose diagonal elements are non-negative singular values sorted in descending order. $V = [v_{ij}]$ is an $n \times n$ othonormal matrix whose columns are called right singular vectors.

As noted in [1], LSA is applicable in summarization for two reasons. First, LSA is capable of capturing and modeling interrelationships among terms by semantically clustering terms and sentences. Second, LSA can capture the salient and recurring word combination pattern in a document which describes a certain topic or concept. In LSA, concepts are represented by one of the singular vectors where the magnitude of the corresponding singular value indicates the importance of this pattern within the document. Any sentence containing this word combination pattern will be projected along this singular vector. The sentence that best represents this pattern will have the largest index value with this vector. Therefore, a summary can be constructed by collecting the sentences having largest index values over all concepts.

In [12], Mihalcea explicitly models the relationship among sentences by building a graph. In the graph, each node corresponds to a sentence and the weight of the edge linking two nodes is the similarity between the corresponding sentences. The direction of the edges can be decided by the appearance order of the sentences. After constructing the graph, Mihalcea employed some graph-based ranking algorithms like HITS and PageRank to decide the importance of a vertex (sentence) which can take into account the global information recursively computed from the entire graph. Finally, the sentences with highest ranking scores are selected to form a summary.

The third kind of summarization methods of exploiting sentence relationship is based on coherence relations. One example for the coherence relations is RST (rhetorical structure theory) relations. The RST relations are often expressed in terms of a satellite and a nucleus and nucleus sentences are more likely to be a summary sentence. More details of using RST for summarization can be found in [11].

Supervised Methods In the above mentioned unsupervised methods, each method estimates the importance of sentences based on some evidences from a certain aspect and then generate summaries based on the estimated importance. Therefore, a proper combination of these evidences may improve the generated summaries. Some supervised machine learning methods have been exploited for this goal. Among these methods, most of them treat the summarization task as a two-class classification problem at the sentence level, where the summary sentences are positive samples while the non-summary sentences are negative samples. After representing each sentence by a vector of features, a classification function such as Naive Bayes and Support Vector Machine can be trained [6]. Then for a new text, the trained classification function can be applied on each sentence in the text and decide whether it is a summary sentence. Although such methods are effective in most cases, they assume that the sentences are independent and classify each sentence individually without leveraging the relation among the sentences.

In order to address this shortcoming, some methods based on Hidden Markov Model (HMM) are exploited [3]. In Conroy et al.'s work [3], there are two kinds of states, where one kind corresponds to the summary states and the other corresponds to non-summary states. The observations are sentences that are represented by a vector of three features. Given the training data, the state-transition probabilities and the state-specific observation probabilities can be estimated by the Baum-Welch algorithm or an EM algorithm. Given a new document, the probability that a sentence corresponds to a summary state can be calculated. Finally, the trained model can be used to select the most likely summary sentences.

It is clear that such approaches can handle the positional dependence and feature dependence when the feature space is small by taking some special assumptions. However, the HMM based methods have two open problems. Firstly, when the feature space is large and the features are not independent or are even overlapping in appearance, the training process will become intractable. Therefore this approach cannot fully exploit the potential useful features for the summarization task due to the computational inefficiency. Secondly, the HMM based methods set the HMM parameters to maximize the likelihood of the observation sequence. By doing so, the approach fails to predict the sequence labels given the observation sequences in many situations because they inappropriately use a generative joint-model in order to solve a discriminative conditional problem when observations are given. In [14], the authors use Conditional Random Fields (CRF) to replace HMM for text summarization which avoids these problems.

Evaluation

For extractive summarization methods, there are two popular evaluation measurements. The first one is by Precision, Recall and F_1 which are widely used in Information Retrieval. For each document, the manually extracted sentences are considered as the reference summary (denoted by S_{ref}). This approach compares the candidate summary (denoted by S_{cand}) with the reference summary and computes the precision, recall and F_1 values as shown in the following equation:

$$p = \frac{|S_{ref} \bigcap S_{cand}|}{S_{cand}} \quad r = \frac{|S_{ref} \bigcap S_{cand}|}{S_{ref}} \quad F_1 = \frac{2pr}{p + r}$$

A second evaluation method is by the ROUGE toolkit, which is based on N-gram statistics [7]. This tool is adopted by DUC for automatic summarization evaluation that was found to highly correlate with human evaluations.

Key Applications

Text summarization has been applied in many fields. For example, the snippets generated by search engines such as Google, Live Search are successful examples. Another example is to generate summaries for hand-held devices, whose screens are usually small [10]. Besides these, text summarization has also been used as a preprocessing step for some text mining tasks such as Web-page classification, which is expected to catch the main content of the Web pages while removing the noises [13].

Data Sets

Document Understanding Conferences (2001–2007) provide an open data source for different kinds of summarization tasks: http://duc.nist.gov/. More useful URLs are at http://www.summarization.com/.

Synonyms

Document visualization

Definition

Text visualization is a subarea of information visualization. The definition of information visualization is as follows: The use of computer-supported, interactive, visual representations of abstract data to amplify cognition [2]. Thus, the definition of text visualization is analogous: The use of computer-supported, interactive, visual representations of abstract text to amplify cognition. A more comprehensive and user-friendly definition is similar: The visual representation of text and its relationships.

Historical Background

In the early years, information such as texts and pictures were organized linearly: they were put in order and searched from beginning to end. But this is obviously not the most efficient way to organize information. It is well known that "A picture is worth a thousand words." People like to see news along with pictures, music, and even videos, rather than see purely raw text. Various technologies are also developed to help people graphically and visually represent their ideas, problems, challenges, solutions, and results. Today, information is not only presented one-dimensionally as in previous centuries, but also presented in two and more dimensions to help people understand the underlying idea clearly and thoroughly. Putting the right data in the right location and right format will greatly facilitate people seeking and understanding the information.

The history of text visualization is not very long. It started in the 1980s, when bandwidth and storage was very expensive. At that time, it was a luxury to play with advanced and real-time interactive graphics and visual effects. But with the rapid developments during the past several years, the standard PC platform provides high performance for processing videos and graphics and can present many advanced visual effects to users now. The 3D graphic interface has gradually dominated the gaming area, and 2D and 3D information visualization will become the mainstream of search engine retrieval and many other services.

Today, people are not satisfied with simply interacting with information in one dimension. Instead, they are more willing to search and manipulate their ideas and contents in multiple dimensions. This is becoming the main trend today and is also presenting a great challenge to traditional information organizations, such as libraries and museums. They are required to develop advanced 2D and 3D text visualization technologies to maintain their market share.

Foundations

Text visualization is about representing the underlying structure of a text or a group of texts. Text visualization offers several benefits for users. With text visualization, for example, users could have a view of texts in different levels of abstraction, could have a better view of the relationships between texts, and could have a high-level view of the topics in the text collection.

Generally, the ideas of many text visualization algorithms are borrowed from data analysis research areas while accounting for the specific properties of texts. These properties include the following [6,8]: "(i) High data dimensionality when using typical bag-of-words representation, where each word and each phrase represents on dimension in the data space. (ii) High redundancy, meaning that many dimensions can be easily merged into one dimension without losing much information. This is caused by the two properties of words, namely synonymy (different surface word forms having the same meaning – e.g., singer, vocalist) and hyponymy (one word denotes a subclass of an another – e.g., breakfast, is a subclass of a meal). (iii) Ambiguity between words in the cases where the same surface form of the word has different meanings (homonomy – e.g., the word "bank" can mean "river bank" or "financial institution") or in the cases where the same form has related meaning (polysemy – e.g., "bank" can mean "blood bank" or "financial institution"). (iv) Frequency of words (and phrases) follows power distribution. Appropriate weighting schemas (e.g., most popular being TFIDF) are used to normalize importance of the words to be able to work with the standard data analytic techniques."

Meanwhile, there are many types of texts, such as web documents, emails and news group postings, literature, and legal documents. In developing a text visualization algorithm or a system for a special type of text, the properties of the type of text also needs to be considered. For example, to visualize news articles, [8] have considered the following properties in their approach: (i) shorter documents; (ii) written by professionals; (iii) low number of mistakes; (iv) having good rhetorical structure; (v) rich information about people, companies, or phrase; and (vi) single documents as pieces of larger stories spanning over several documents.

Many text visualization algorithms adopt bag-of-words text representation, where text is viewed as a bin of independent words with term dependencies and with any other positional information of terms ignored. This simplification appears to be reasonable, since in many cases the efficiency of solving relevant problems does not degrade much. In the bag-of-words representation, each word is represented as a separate variable with a numeric weight. This numeric weight is often calculated using the famous TFIDF weighting schema: the weight is the multiply of term frequency and the inverse document frequency. The idea of TFIDF is very intuitive: if the word appears more times in a text, it would be more important; and if the word appears in fewer texts in the text corpus, it would be more important. In the bag-of-words representation, a text is represented as high-dimensional sparse vector, so it cannot be directly visualized. A clustering algorithm needs to be applied to indentify the relationships between texts and then to map them into 2D or 3D space. The cosine similarity measure is widely used to evaluate relationship between texts. There are also some other typical ways of text visualization using graphs or trees to present frequent co-occurrences of words and phrases. Typical visualization algorithms include graph based visualization and tiling based visualization as introduced in [4]:

Graph-based visualization has the following algorithm sketch: (i) First, documents are transformed into the bag-of-words sparse-vectors representation. Words in the vectors are weighted using TFIDF. (ii) Then, K-Means clustering algorithm is used to split the documents into K groups. Each group consists of similar documents and these are compared using cosine similarity. The K groups form a graph with groups corresponding to graph nodes and similar groups linked. Each group is represented by characteristic keywords. (iii) Finally, simulated annealing is used to draw a graph.

Tiling-based visualization has the following algorithm sketch: (i) First, documents are transformed into the bag-of-words sparse-vectors representation. Words in the vectors are weighted using TFIDF. (ii) Then, hierarchical top-down two-wise K-Means clustering algorithm is used to build a hierarchy of clusters. The hierarchy is an artificial equivalent of hierarchical subject index just like Yahoo. (iii) Finally, the leaf nodes of the hierarchy (bottom level) are used to visualize the documents. Each leaf is represented by characteristic keywords and each hierarchical splits the rectangular area into two sub-areas recursively.

Key Applications

WebSom [7] gives self-organizing Maps for Internet Exploration. An ordered map of the information space is provided: similar documents lie near each other on the map. The algorithm automatically organizes the documents onto a two-dimensional grid so that related documents appear close to each other.

ThemeScape [3] graphically displays images based on word similarities and themes in text. Themes within the document spaces appear on the computer screen as a relief map of natural terrain. The mountains indicate where themes are dominant, valleys indicate weak themes. Themes close in content will be close visually based on the many relationships within the text spaces. The algorithm is based on K-means clustering.

ThemeRiver [5] helps users identify time-related patterns, trends, and relationships across a large collection of documents. The themes in the collection are represented by a "river" that flows left to right through time. The theme currents narrow or widen to indicate changes in individual theme strength at any point in time.

The text representation is the fundamental work for IR and text mining. Besides IR, it can also be used for text categorization, text clustering, topic detection and novelty detection etc.

Future Directions

Although there have been many text visualization systems that have achieved much success in the past, there still exists many ways to improve them. One is to use natural language processing tools to do more detailed analysis or to improve the text summarization. Another may be to design more and better interaction tools for users to manipulate the texts. Advanced 2D and 3D graphics techniques may also be used to make the user interfaces friendlier.

Synonyms

Term frequency by inverse document frequency

Definition

A weighting function that depends on the term frequency (TF) in a given document calculated with its relative collection frequency (IDF). This weighting function is calculated as follows [1] Assuming that term *j* occurs in at least one document *d* (*dj* ≠ *0*), the inverse document frequency (idf) would be

$$\mathrm{Log}_2(\mathrm{N}/\mathrm{d}_j) + 1 = \log_2 \mathrm{N} - \log_2 \mathrm{d}_j$$

The ratio dj/N is the fraction of documents in the collection that contain the term. The term frequency-inverse document frequency weight (TF*IDF) of term *j* in document *i* is defined by multiplying the term frequency by the inverse document frequency:

$$\mathrm{W}_{ij} = f_{\mathrm{ij}}{}^*[\log_2 \mathrm{N} - \log_2 \mathrm{d}_j]$$

Where

N: number of documents in the collection

d_j: number of documents containing term *j*

f_{ij}: frequency of term *j* in document *i*

W_{ij}: is the weight of term *j* in document *i*

The use of the logarithm in the formula rather than the actual values of N and D_k moderates the effect of increasing the collection size and the effect of a high term frequency.

Key Points

The significance of a certain term in a given document is determined using the term frequency (TF) of that term in the document. Unfortunately, while term frequency is a good measure for term significance in one document, it is not an adequate measure for its significance in a collection of documents. The use of this factor alone in calculating the term weights in a collection of documents does not guarantee adequate retrieval performance. Some high frequency terms are not concentrated in a few particular documents, they are common in the whole collection which means that all these documents will be retrieved, affecting the performance of the information retrieval system.

The solution for this problem [4] is correlating the term frequency with its relative collection frequency (IDF), making the collection frequency a variable in retrieval. The use of collection frequency places a greater emphasis on the value of a term as a means of distinguishing one document from another than its value as an indication of the content of the document itself. Combining the two factors, TF and IDF enables the information retrieval system to exploit the good features of both. TF emphasizes term significance in a given document, and IDF emphasizes term significance in the collection as a whole; i.e., if the term was common in a document and rare in the collection it would be heavily weighted in both schemes. This way a term can distinguish certain documents from the remainder of the collection.

Even though this weighting function is a good indication of the term importance in a given set of documents it overlooks an important factor which is the document length. This problem may affect the weighting process because in real life documents have different lengths, and longer documents may have higher frequencies for a given term because it is repeated several times in the document. This increases the weight of the term and increases the possibility of retrieving these documents because of the higher weight of terms in them. Long documents also may have more different terms them which may affect the retrieval as well. More terms in a given document increases the possibility of matching between this document and multiple queries [3]. A possible way to overcome this problem is to incorporate a normalization factor for the document length to reduce its effect and make the weighting function more effective. A number of variant formulae for tf*idf weighting are given in [2].

Thematic Map

Hans Hinterberger
ETH Zurich, Zurich, Switzerland

Synonyms

Thematic map; Data map; Chart

Definition

The graphical representation of quantitative data or qualitative data for a given geographic area (e.g., regional unemployment rate or type of crops grown).

The many different methods that cartographers apply to create thematic maps are used to define a thematic map more precisely. The following five are found most often.

1. *Coropleth maps.* In coropleth maps the areas of the map are shaded or patterned in proportion

to the value of the data to be displayed for a particular area.

2. *Dot maps.* These maps use equal sized dots to show the presence of a feature at a particular geographic location and thus display spatial distributions. A dot need not be restricted to a single occurrence; it may indicate any number of entities.
3. *Proportional symbol maps.* When drawing proportional symbol maps, a cartographer selects a symbol (e.g., a circle or a bar), places it at the spot on the map to which the data apply and varies the symbol's size from place to place in proportion to the value of the variable that the symbol represents.
4. *Isarithmic maps.* These maps use contour lines to join points of equal value. Examples are barometric pressure lines in weather maps or elevation above sea level in topographic maps.
5. *Dasymetric maps.* These maps divide a geographic region with contour lines and shade or pattern the resulting regions in proportion to the value that applies to the region bounded by a contour line.

Topographic maps that provide reference to geographic features (political boundaries, roads, lakes, mountains) are generally not categorized as thematic maps.

Key Points

History. Edmund Halley (famous for discovering the comet bearing his name) is recognized as the author of the first thematic map. Drawn in 1686, it shows the direction of trade winds on a world map. Probably the best known example of using thematic maps for data analysis is John Snow's cholera map of 1855, a data display based on principles still applied in today's geographic information systems. These and more historical notes are summarized in [3]).

Usage. Thematic maps display the spatial distribution of data for a specific subject or a specific purpose. They represent information about particular locations in such a way that spatial patterns emerge. Frequently thematic maps are used to compare patterns on two or more maps. Examples are election results, occurrence of particular types of diseases, usage of agricultural land, climatic change over time and so on. Major contributions to thematic mapping come from the French cartographer Jacques Bertin ([1]). A more modern treatment of the topic can be found in [2].

Third Normal Form

Marcelo Arenas
Pontifical Catholic University of Chile, Santiago, Chile

Definition

Let $R(A_1,...,A_n)$ be a relation schema and Σ a set of functional dependencies over $R(A_1,...,A_n)$. An attribute A_i ($i \in \{1,...,n\}$) is a *prime* attribute if A_i is an element of some key of $R(A_1,...,A_n)$. Then specification (R, Σ) is said to be in Third Normal Form (3NF) if for every nontrivial functional dependency $X \rightarrow A$ implied by Σ, it holds that X is a superkey for R or A is a prime attribute [2].

Key Points

In order to avoid update anomalies in database schemas containing functional dependencies, 3NF was introduced by Codd in [2]. This normal form is defined in terms of the notions of prime attribute and key as shown above. For example, given a relation schema $R(A, B, C)$ and a set of functional dependencies $\Sigma = \{AB \rightarrow C, C \rightarrow B\}$, it holds that $(R(A, B, C), \Sigma)$ is in 3NF since AB is a superkey and C is a prime attribute (given that AC is a key for R). On the other hand, $(S(A, B, C), \Gamma)$ is not in 3NF if $\Gamma = \{A \rightarrow B\}$, since A is not a superkey for S and B is not a prime attribute.

For every normal form two problems have to be addressed: how to decide whether a schema is in that normal form, and how to transform a schema into an equivalent one in that normal form. On the positive side, for every relation schema S there exists a database schema S' such that, S' is in 3NF and S' is a lossless and dependency preserving decomposition of S. Furthermore, schema S' can be generated efficiently by using the synthesis approach proposed in [1]. On the negative side, it is expensive to check whether a schema is in 3NF. It was shown by Jou and Fischer that this problem is NP-complete [3].

Three-Dimensional GIS and Geological Applications

Martin Breunig
University of Osnabrueck, Osnabrueck, Germany

Synonyms

Spatial information system; Geoscientific information system

Definition

An information system for the in-/output, modeling, management, processing, analyzing and visualization of geoscientific data including geo-referenced three-dimensional geometric, topological and attribute data. The three-dimensional geometric data may consist of points/vertices (x,y,z-coordinates), curves, surfaces and polyhedra, respectively. The topological data may consist of nodes, edges, faces and solids, respectively. Typical attribute data are descriptions of geological strata, i.e., properties of strata such as "geological age," "soil type," "main components of the stratum" etc.

The implementation of a three-dimensional GIS provides data types, spatial access structures including geometric/topological algorithms and a spatial or visual query language for the modeling, management and analysis of geo-referenced three-dimensional data.

Historical Background

Three-dimensional GIS have two roots in the history of information systems. The first has its origin in the field of 3D modeling and visualization. 3D modeling and visualization systems usually provide a large collection of geometric and topological 3D algorithms. An example is the Discrete Smooth Interpolation (D.S.I.) algorithm of Jean-Laurent Mallet and others [12,13] used for creating and editing triangulated surfaces. Given an arbitrary mesh with an arbitrary set of vertices fixed by the user, D.S.I. assigns coordinates to the other nodes of the mesh, enabling the fixed vertices to be interpolated smoothly [12]. The second root has its origin in the field of *Geographical Information Systems* (GIS). GIS are inherently using both, spatial and attribute data, in their data management. However, standard Geographical Information Systems usually are not prepared to manage and process real 3D data. They only allow the visualization of 2.5D data representation such as digital elevation models. However, in this representation every (x,y)-coordinate may only have one z-coordinate. That is why Geographical Information Systems cannot be used to solve 3D geological problems. In particular, polyhedra and solids cannot be treated in Geographical Information Systems. In today's Geographical Information Systems, the third dimension is only treated as a thematic attribute such as the height value of an isoline map.

Relevant work in the field of three-dimensional GIS has been published by [2,5–7, 13,16,18,–20,22], and by other authors. For example, theoretical work on three-dimensional GIS and topological data models has been worked out by [15]. Literature about *spatial database systems* can be found in [8]. Spatial database systems can be extended for the management of three-dimensional GIS data. For example, an R-Tree can be used to access 3D data.

The term "three-dimensional GIS" (3D GIS) is not yet used in a standardized way. Unfortunately, the term "3D GIS" or "3D city model" is often used for information systems that only deal with surface and face data, but not with polyhedra and solids. Correctly, such information systems should be called "2.5D GIS," because they only allow to represent surfaces with the following property, valid for all of their points P(x, y, z): z = f (x, y). i.e., every point (x, y) of the surface has a different z-value.

First standardization efforts for the exchange of data between 3D GIS have been undertaken by the Open Geospatial Consortium [14] within the *Geography Markup Language* (GML).

Foundations

Spatial planning processes and the study of geoscientific processes often require three-dimensional information. This digital information must be modeled, managed, visualized and analyzed. A three-dimensional GIS is an information system that accomplishes these requirements. To work adequately, it needs 3D data types, 3D spatial access structures, and 3D geometric and topological algorithms to manage and process three-dimensional data of these applications. Furthermore, a user interface with a query language is required. A spatial database system may be embedded into a 3D GIS to support these requirements.

In a 3D GIS, objects of different dimension d ($0 \leq d \leq 3$) have to be processed. The 3D geometry of a geological object can be composed of sets of points, lines, surfaces and volumes, respectively. As a reference model for 3D geometric data types in three-dimensional GIS, *Simplicial Complexes* may be used: points, polylines, triangle nets and tetrahedron nets in three-dimensional space. They are often used in geological applications, because they well approximate 3D solids and surfaces formed by nature.

In a 3D topology model of a 3D GIS, the components of the objects are interpreted as a mesh of nodes, edges, faces, and solids that describes both the interior structure of the geological objects and their mutual neighborhood relationships in 3D space. As a reference model for 3D topological data types in three-dimensional GIS, cellular complexes [4,13] and Generalized Maps [10,11,13] respectively, may be used. They provide a general topological model treating 2D, 2.5D and 3D objects in a uniform way. Furthermore, they are based on the clear mathematical theory of algebraic topology.

To access 3D data, existing spatial access structures such as the R-Tree [9] or R*-Tree [3] may be applied. The spatial access structures can also be used internally within the processing of geometric 3D algorithms as a first filter step to compute on approximated geometries – 3D boxes are used most – to achieve better performance, for example to support the intersection of very large geometries such as sets of tetrahedron nets. For the analysis of 3D data, 3D GIS are using geometric and topological algorithms, e.g., for computing the distance between two objects, the intersection between two polyhedra, or the neighbor objects of a given geological object.

Three-dimensional GIS are subject of current research [1,21]. Concepts and prototypical software considering aspects of three-dimensional GIS such as architectural issues, spatial data modeling with constraints, efficient spatial data access and geological applications have been described in detail by many authors of the GIS and database communities (see Recommended Reading). First 3D GIS prototype systems are already used in some application domains of three-dimensional GIS such as geology, geophysics, archaeology, and early diagnosis of natural disasters. Also database vendors are integrating first simple 3D data types and operations in their products.

Key Applications

One of the most relevant applications of three-dimensional GIS is geology. In geology, the starting point of the examinations is the present condition of the earth's structure. Hence the three-dimensional geometric analysis of recent geological strata and solids is the key for further investigations concerning the interaction of former geological structures and processes [19]. Furthermore, consistent geometric 3D models and the use of GIS are the precondition for the production of digital geological maps. For example, the 3D models can be intersected with digital elevation models to improve maps or to define boundary conditions for 3D models. The computational expense of GIS, however, is high, because the third dimension is included.

Some of the relevant data in geological applications are sections, stratigraphic boundaries, and faults. Sections describe a mostly vertical intersection through the geological structure of an examination area, i.e., an estimation of the geological surfaces and solids including geological faults. A cross section through the series of sediments consists of a set of stratigraphic lines. Their geometry is mostly given by a point set in three-dimensional space.

The geometry of stratigraphic boundaries is based on stratigraphic lines in the sections where the stratum occurs. The stratigraphic surfaces are spread between the cross sections. Triangle nets in three-dimensional space can result from the triangulation of the surfaces between the point sets of the cross sections. Concerning topology, on each cross section the underlying and hanging stratum of each stratigraphic line can be identified.

Faults are modeled as surfaces, along which the tectonic deformation of the sediments took place. Usually the geometry of a fault consists of a triangle net in three-dimensional space. The modeling of strata and faults from cross section to cross section is an interpolation of new geometries from the sections.

Figure 1 shows an example of geological data managed by a three-dimensional GIS. During the modeling process of geologically defined geometries, a large amount of data are accumulated. Thus the handling of three-dimensional data in a spatial database system [8] is recommended for 3D GIS. for example, the efficient spatial access on a large set of geological objects is necessary to compute intersections between single strata and faults with different thematic attributes, respectively. Therefore, the implementation of efficient three-dimensional geometric algorithms has to be provided by the three-dimensional GIS. Checking the consistency of geometric

3D models is essential for the geometric 3D reconstruction of geological structures and geological processes [19].

Three-Phase Commit

Yousef J. Al-Houmaily[1], George Samaras[2]
[1]Institute of Public Administration, Riyadh, Saudi Arabia
[2]University of Cyprus, Nicosia, Cyprus

Definition

Three-phase commit (3PC) is a synchronization protocol that ensures *global atomicity* of distributed transactions while alleviating the *blocking* aspect of 2PC (Two-Phase Commit) in the events of *site* failures. That is, 3PC never requires operational sites to wait (i.e., block) until a failed site has recovered.

Historical Background

3PC was one of the first attempts to resolve the blocking aspects of 2PC [6]. The main purpose of the protocol is to allow operational sites to continue transaction processing and reach agreement about the final status of transactions in spite of the presence of site failures. 3PC can tolerate any number of site failures (except for total sites' failures), assuming a highly reliable network (i.e., a network that never causes operational sites to be partitioned into more than one set of communicating sites, implying a network that never fails).

Foundations

In 2PC, a participant is *blocked* if it fails to communicate with the coordinator of a transaction while in a prepared-to-commit state. Blocking means that the participant cannot determine the final status of the transaction in the presence of a failure, rendering all resources held by the prepared-to-commit transaction at its site unusable by any other transaction until the final status of the transaction is resolved, i.e., the transaction is either committed or aborted. Blocking is inevitable in 2PC and it may occur either because of (i) a communication (link) failure or (ii) a coordinator's system crash. These two types of failures lead to blocking, in 2PC, even under the assumption that all participants remain operational and can communicate collaboratively to resolve the status of the prepared-to-commit transaction. For example, if a coordinator fails after all participating sites in a transaction's execution have entered their prepared-to-commit states; the participants (collectively) can neither commit nor abort the transaction. This is because the operational participants cannot be sure whether the coordinator had received all their votes and made a commit final decision just before it failed or it had received only some votes and did not have the chance to make the final decision before its failure and the transaction will be aborted by the coordinator when it recovers. Thus, the participants are blocked until the coordinator recovers.

The negative impact of blocking on the (i) overall system performance and (ii) availability of critical data on other transactions motivated the design of *non-blocking* atomic commit protocols (ACPs). In 3PC, an *extra (buffering) phase* is inserted between the two phases of 2PC to capture all the participants' intentions to commit, as shown in Fig. 1.

Dynamics of Three-Phase Commit

The basic idea behind the insertion of the buffering phase is to place the two (possible) reachable final states (i.e., the commit and the abort states) for a transaction apart from each other such that they cannot be reached from the *same* state. That is, if a final state can be reached from the current state of a site, then, the reachable final state can be either the commit or the abort state but not both. In 2PC, when a participant is in a prepared-to-commit state, both final states can be reached. Hence, if the coordinator fails, the participant cannot determine the final state for the transaction without any possible conflict in its decision with the coordinator. For this reason, the protocol is blocking. On the contrary and as shown in Fig. 1, the commit final state for a site (whether it is the coordinator or a participant), in 3PC, cannot be reached from the same

state as the abort final state. In the former case, the commit state can be reached from the *pre-commit* state whereas, in the latter case, the abort state can be reached from the *prepared* state.

When a site is in a pre-commit state, it means that each of the other sites is at least in a prepared-to-commit state (Notice that the other sites might lag in their states because of system's delays such as queuing and network delays.). Thus, the pre-commit state is called a *committable state* since it implies that all participants have voted "yes" and the coordinator agreed on the commitment of the transaction. In 3PC, a *non-committable* state, i.e., a state that does not imply that all the participants have voted "yes," is not placed adjacent to a commit state. This is not the case in 2PC as the prepared state, which non-committable, is placed adjacent to a commit state.

The insertion of the buffering state makes the structure of 3PC to satisfy the two necessary and sufficient conditions for the construction of synchronous non-blocking ACPs within one state transaction, i.e., a structure where neither the coordinator nor any participant leads each other by more than one state transition during its execution of the protocol. That is, 3PC is synchronous within one state transaction that (i) does not contain a state that is adjacent to both a commit and an abort state, and (ii) it does not contain a non-committable state that is adjacent to a commit state.

Based on the above, if the coordinator of a transaction fails at any point during the execution of the protocol, the operational participants can collectively and deterministically decide the final status of the transaction. The decision is commit if any of the participants is in *at least* a pre-commit state (because it is not possible for the coordinator to have decided to abort). Otherwise, the decision is abort (because it could be possible for the coordinator to have decided to abort but not to commit). To reach an agreement on the final status of a transaction, there is a need for a termination protocol which is invoked when the coordinator fails.

Recovery in Three-Phase Commit

When a participant times out while waiting for a message from the coordinator, it means that the coordinator must have failed (or it is perceived as a coordinator failure). In this case, the participant initiates an election protocol to determine a *new* coordinator. One way to determine the new coordinator is based on sites' identification numbers such that the participant with the highest (or the lowest) number becomes the new coordinator. Once a new coordinator is elected, the participants exchange status information about the transaction. If the new coordinator finds the transaction in at least a pre-commit state at any participant, it commits (in its local log) the transaction; otherwise, it aborts the transaction. Then, this new coordinator proceeds to complete the 3PC for the transaction in all the other participants. If the new coordinator fails, the election process is repeated again.

When a participant starts recovering from a failure, it needs to determine the status of each prepared or pre-committed transaction as recorded in its log. Notice that a recovering participant cannot commit a transaction even if the participant is in a pre-commit state with respect to the transaction. This is because the operational sites might have decided to abort the transaction after the participant had failed if none of them was in a pre-commit state. In this case, the participant must ask the other sites about the final status of the transaction.

A final note on 3PC is about total sites' failure where there is a need to determine the last participant to have failed. This is because such participant is the only one which can decide the status of the transaction for the other participants. Determining the last participant that has failed could be implemented by maintaining an "UP" list at each participating site. This list contains the identities of operational participants as seen by the participant that is maintaining the list and is stored (in a non-forced or asynchronous manner) onto the stable log of the participant. Thus, the "UP" lists allow a set of participants to determine, upon their recovery from the total failure, whether they contain among themselves the last participant to have failed, reducing the number of participants that needs to recover before the transaction status can be resolved. Alternatively, all participants should recover and become operational again before the status of the transaction can be resolved.

Non-Blocking Commit Protocol Variants

As discussed above, blocking occurs in 2PC when the coordinator of a transaction crashes while the transaction is in its *prepared-to-commit* state at a participating site. In such a case, the participant is blocked until the coordinator of the transaction recovers. In general, all ACPs are susceptible to blocking. They just differ in the size of the window during which a site might be blocked and the type of failures that cause their blocking. Several ACPs have been designed to eliminate some of the blocking aspects of 2PC, besides 3PC, by adding extra coordination messages and forced log writes. These protocols can be classified into whether they preserve the prepared-to-commit state, such as cooperative 2PC, or allow *unilateral or heuristic* decisions in the presence of unbearable delays, such as IBM's presumed nothing (IBM-PrN).

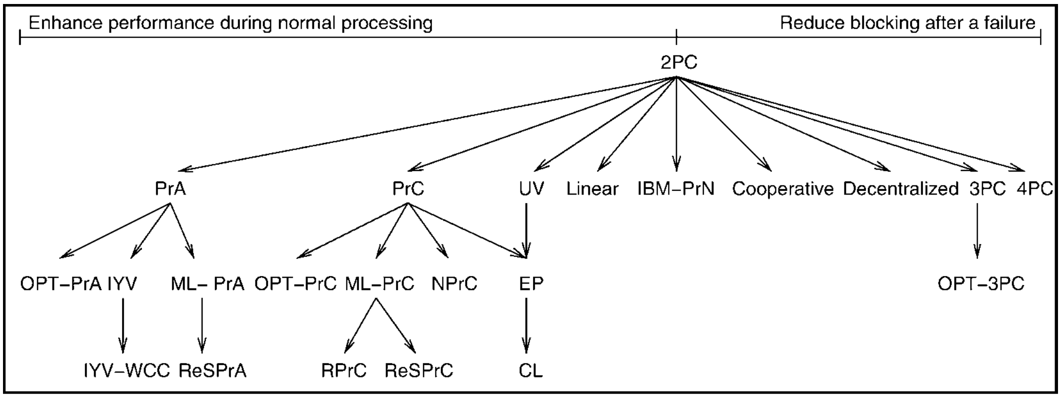
The *cooperative* 2PC (1981) reduces the *likelihood* of blocking in case of a coordinator's failure. In the cooperative 2PC, the identities of all participants are included in the prepare-to-commit message so that each participant becomes aware of the other participants. In the case of a coordinator's or a communication's failure, a participant does not block waiting until it reestablishes communication with the coordinator. Instead, it inquires the other operational participants in the transaction's execution about the final decision and if any of them has already received the final decision prior to the failure, it informs the inquiring participant accordingly.

The IBM-PrN (1990) is a 2PC variant that allows blocked participants to unilaterally commit or abort a transaction and detects atomicity violations due to conflicting heuristic decisions. In the event of atomicity violations, it reports any damage on transactions and data, simplifying the task of identifying problems that must be fixed. *Generalized presumed abort* (1994) is another IBM protocol that behaves like IBM-PrN when complete confidence in the final outcome and recognition of heuristic decisions is required and behaves like PrA during normal processing. Recent efforts to enhance commit protocols with heuristic decision processing resulted in the *allow-heuristics presumed nothing* (1996) commit protocol.

Other Atomic Commit Protocol Variants and Optimizations

Figure 2 shows some of the significant steps in the evolution of ACPs including the two most notable 2PC variants which are *presumed abort* (PrA) and *presumed commit* (PrC) [2]. The *new PrC* (NPrC) (1993) and *rooted PrC* (RPrC) (1997) protocols were proposed to reduce the log complexity of PrC further at the cost of slower recovery in the presence of failures. NPrC eliminates the initiation log record at the coordinator's site whereas RPrC eliminates the initiation log record at each cascaded coordinator when the *tree-of-processes* (or *multi-level transaction execution*) model is used.

In contrast to PrA and PrC variants, other 2PC variants have been proposed for specific environments. The common characteristic of these protocols is that they exploit the semantics of the communication networks, the database management systems and/or the transactions to enhance the performance of 2PC. For example, the *linear* 2PC (L2PC) reduces message complexity at the expense of time complexity compared to 2PC by assuming token-ring like networks. In L2PC, the participants are linearly ordered with the coordinator being the first in the linear order. The coordinator initiates the voting and each participant sends its "yes" vote to its successor in the linear order. The last participant in the order makes the decision and sends it to its predecessor and so on. In this way, L2PC maintains the same log complexity as 2PC, reduces



Three-Phase Commit. Figure 2. Some significant steps in the evolution of ACPs.

the message complexity of 2PC from "3" to "2n" while increasing the time complexity of 2PC from "3" to "2n" rounds, where n is the number of participants. In contrast to L2PC, *decentralized* 2PC (D2PC) reduces time complexity at the expense of message complexity which is $n^2 + n$ messages. In D2PC, the interconnecting communication network is assumed to be fully connected and efficiently supports the broadcasting of messages. In D2PC, two rounds of messages are required for each individual participant to make a final decision. During the first round, the coordinator broadcasts its vote (implicitly initiating commit processing) whereas, during the second one, all the participants broadcast their votes. Thus, each participant receives the votes of all the other participants, as well as the coordinator, and thereby, is able to independently conclude the final decision. By reducing the time complexity to two rounds, it becomes less likely for a participant, in D2PL, to be blocked during commit processing in the case of a coordinator's failure.

There are four transaction type specific 2PC protocols, all of which, when applicable, improve both the message and time complexities of 2PC by eliminating the explicit voting phase of 2PC. The *unsolicited-vote* protocol (UV) (1979) shortens the voting phase of 2PC assuming that each participant knows when it has executed the last operation for a transaction. In this way, a participant sends its vote on its own initiative once it recognizes that it has executed the last operation for the transaction. When the coordinator receives the votes of the participants, it proceeds with the decision phase. The *early prepare* protocol (EP) (1990) combines UV with PrC without assuming that a participant can recognize the last operation of a transaction. Every operation is, therefore, treated as if it is the last operation executing at the participant and its acknowledgment is interpreted as a "yes" vote. This means that a participant has to force write its log each time it executes an operation so that it can preserve the global atomicity of the transaction after a system crash. In contrast to EP which reduces time and message complexities at the expense of log complexity, the *coordinator log* (CL) and *implicit yes-vote* (IYV) protocols do not require force writing the log records, at the participants' sites, after the execution of each operation. Instead, they replicate the participants' logs at the coordinators' site. Hence, reducing log complexity compared to EP at the expense, however, of slower recovery. In CL, a participant does not maintain a local stable log and, therefore, it has to contact all coordinators in the system in order to recover after a failure. Moreover, a participant may need to contact the coordinator of a transaction during normal processing to maintain *write-ahead logging* (WAL) or to undo the effects of an aborting transaction. This is because the log of a participant is scattered across the coordinators' sites. In contrast, the log of a participant in IYV is partially replicated across the coordinators' sites. That is, only the *redo* records are replicated at the coordinators' sites while the *undo* records are stored locally. Thus, a participant, in IYV, never communicates with any coordinator to maintain WAL or to undo the effects of aborting transactions. Thus, in IYV, the replicated records are used only to recover a participant after a system's crash. Furthermore, IYV is based on PrA while CL is derived from PrC.

Existing 2PC variants are incompatible with each other and need to be made to interoperate in order to be integrated in (heterogeneous) multidatabase systems and the Internet. Thus, the continued research for more efficient ACPs has expanded to include the investigation of integrated ACPs. Efforts in this direction include the Harmony prototype system that integrates *centralized* participants that use centralized (asymmetric) ACPs with *centralized* participants that use decentralized (symmetric) ACPs (1991), the integration of *distributed* participants that use symmetric ACPs with *distributed* participants that use asymmetric ACPs (1994), and the *presumed any* protocol (1996) that integrates participants that use 2PC, PrA, or PrC. Besides that, recent efforts are targeted towards understanding the sources of incompatibilities [1] and the integration of ACPs in an adaptive manner to achieve higher system performance [8].

Several optimizations have been proposed that can reduce the costs associated with ACPs [5,2]. These include the *read-only, last agent, group commit, sharing the log, flattening the transaction tree* and *optimistic* optimizations. The read-only optimizations can be considered as the most significant ones, given that read-only transactions are the majority in any general database system. In fact, the performance gains allowed by the *traditional read-only* optimization provided the argument in favor of PrA to become the current choice of ACPs in the ISO OSI-TP (1998) and X/Open DTP (1996) distributed transaction processing standards, and commercial systems. The basic idea behind the read-only optimizations is that a read-only participant, a participant that has not performed any updates on behalf of a transaction, can be excluded from the decision phase of the transaction. This is because it does not matter whether the transaction is finally committed or aborted at a read-only participant to ensure the transaction's atomicity. In the traditional read-only optimization [4], a read-only participant votes "read-only" instead of a "yes" and immediately releases all the resources held by the transaction without writing any log records. A "read-only" vote allows a coordinator to recognize and discard the read-only participant from the rest of the protocol. The *unsolicited update-vote* (1997) is another read-only optimization that further reduces the costs associated with read-only participants. Not only that, but it incurs the same costs when used with both PrA and PrC, supporting the arguments for PrC to be also included in the standards.

The *last agent* optimization has been implemented by a number of commercial systems to reduce the cost of commit processing in the presence of a *single remote* participant. In this optimization, a coordinator first prepares itself and the nearby participants for commitment (fast first phase), and then delegates the responsibility of making the final decision to the remote participant. This eliminates the voting phase involving the remote participant. This same idea of delegating part of commitment (i.e., transferring the commit responsibilities) from one site to another has been also used to reduce blocking, for example, in open commit protocols (1990) and IYV with a commit coordinator (1996).

The *group commit* optimization has been also implemented by a number of commercial products to reduce log complexity. In the context of centralized database systems, a commit record pertaining to a transaction is not forced on an individual basis. Instead, a single force write to the log is performed when a number of transactions are to be committed or when a timer has expired. In the context of distributed database systems, this technique is used at the participants' sites *only* for the commit records of transactions during commit processing. The *lazy commit* optimization is a generalization of the *group commit* in which not only the commit records at the participants are forced in a group fashion, but *all* log records are lazily forced written onto stable storage during commit processing. Thus, the cost of a single access to the stable log is amortized among several transactions. The s*haring of log* between the transaction manager and data managers [5] at a site is another optimization that takes advantage of the sequential nature of the log to eliminate the need of force writing the log by the data managers.

The *flattening of the transaction tree* optimization is targeted for the tree-of-processes transaction model and is a big performance winner in distributed transactions that contain deep trees. It can reduce both the message and log complexities of an ACP by transforming the transaction execution tree of *any* depth into a two-level commit tree at commit initiation time. In this way, the root coordinator sends coordination messages directly to, and receives messages directly from, any participant. Thus, avoiding propagation delays and sequential forcing of log records. *Restructuring-the-commit-tree-around-update-participants* (RCT-UP) is an enhancement to the flattening technique that flattens only update participants (participants that have executed update operations on behave of the transaction), thereby, connecting them directly to the coordinator while leaving read-only participants connected in a multi-level manner. This is to reduce the effects of the communication delays on the overall system performance in systems that do not support simultaneous message multicasting to all participants.

Another optimization is *optimistic* (OPT) (1997) which can enhance the overall system performance by reducing blocking arising out of locks held by prepared transactions. OPT shares the same assumption as PrC, that is, transactions tend to commit when they reach their commit points. Under this assumption, OPT allows a transaction to *borrow* data that have been modified by another transaction that has entered a prepared-to-commit state and has not committed. A borrower is aborted if the lending transaction is finally aborted.

Key Applications

3PC has never been implemented in any commercial database system due to its cost, during normal transaction processing, compared to the other ACPs. This is besides its implementation complexity and, especially, the complexity of its termination protocol. Even with the added implementation complexity and cost, 3PC does not *completely* eliminate blocking since it is still susceptible to blocking in case of network partitioning. In fact there is no ACP that is non-blocking in the case of site as well as communication failures. This is an inherent characteristic of the *Byzantine Generals Problem*, the more general problem of atomic commitment. However, the protocol remains an instrumental theoretical result for understanding the behavior of ACPs and the limitations in solving the atomic commitment problem.

Tight Coupling

Serguei Mankovskii
CA Labs, CA Inc., Thornhill, ON, Canada

Synonyms

Strong coupling

Definition

Tight coupling indicates strong dependency between software components. The dependency is strong in the sense that two or more components have multiple and complex dependencies between internal states, data and functions of the components.

Key Points

Tight coupling often achieves high performance characteristics at the expense of flexibility and ease of maintenance. It is often justified for systems that are going to be used as a black box, with no expectation of ongoing maintenance or upgrade. The smaller a systems is, the more congruent its function is, the more likely it would justify tight coupling as a design principle. This is why one can find tight coupling in the components of larger systems. In this situation a number of tightly coupled components might be interacting using loosely coupled approach. This type of systems leads to robust designs where maintainability and flexibility is achieved by simply replacing one or more components. At the same time, each component performs in the best possible way because of tight coupling inside of it. This is the idea behind Service Oriented Architectures (SOA). This way SOA achieves balance between performance and flexibility. However it is not of the case for other architectures and because of that it is often beneficial to evaluate tradeoffs of both approaches during system design.

Time Aggregated Graphs

Betsy George, Shashi Shekhar
University of Minnesota, Minnesota, Minneapolis, MN, USA

Synonyms

Spatio-temporal graphs; Time-dependent graphs; Time-dependent networks

Definition

A time aggregated graph [1,2] is a model that can be used to represent a spatio-temporal network. The topology and the attributes in a spatio-temporal network are typically time-dependent. Time aggregated graphs aggregate the time-dependent attributes over edges and nodes. This model facilitates the computation of path queries on a network accounting for the time-dependence of network parameters.

Key Points

Graphs have been extensively used to model spatial networks; weights assigned to nodes and edges are used to encode additional information. For example, the travel time between two intersections in a road network can be represented by the weight of the edge connecting the nodes that represent the intersections. In a real world scenario, it is not uncommon for these network parameters to be time-dependent. A time aggregated graph is a model that can capture the time-dependence of network parameters. In addition, the model captures the possibility of edges and nodes being absent during certain instants of time.

The model represents the time-variance of attributes by modeling them as time series.

Spatio-temporal networks have critical applications in domains such as transportation science. Developing storage efficient models for such networks that support the design of efficient query processing algorithms is important. Time aggregated graphs provide a means to model spatio-temporal networks and formulate algorithms that honor the time dependence of spatial networks.

Temporal information retrieval

Definition

Traditional information retrieval (IR) is concerned with models, algorithms, and architectures for the retrieval and ranking of documents from a document collection based on their relevance to search queries. In temporal information retrieval, expressions (words or phrases) that relate to instants in time, events, time periods, or other temporal descriptions are extracted from documents and handled in a special way to rank (and optionally group) the documents returned for a search query. Thus, in temporal information retrieval, temporal expressions extracted from documents play a special role in the overall relevance and in the organization and exploration of search results along timelines.

Historical Background

Research on using time information for retrieval and browsing activities is fairly recent. From a search perspective, there is previous work on placing search results in a timeline to facilitate the exploration of information [2,3,10]. A general overview of the basic idea of search result clustering using temporal document annotations obtained through a named-entity extraction approach has been outlined by Alonso and Gertz [4].

Research on temporal annotations has gained a lot of attention lately, and it is covered in great depth in the book edited by Mani et al. [8]. The work also includes discussions about tense and structural analysis and temporal reasoning techniques. The special issue on temporal information processing shows a wide range of current research directions and applications like question-answering and summarization [9].

News in particular have been the preferred information source for most of the related work in temporal information retrieval. Swan and Allan combine news topic detection and tracking with timelines as a browsing interface [14]. Automatic assignment of document event-time periods and automatic tagging of news messages using entity extraction is presented by Schilder and Habel in [11]. Their work also presents a temporal tagger along with its evaluation. There is very interesting work on adding time to applications like news for presenting temporal summaries as introduced by Allan et al. [1]. The work by Shaparenko et al. [12] concentrates on analyzing the development of a document collection over time and identifying temporal pattern. The work by Koen and Bender in Time Frames is one approach to augment news articles by extracting time information [7]. Recently, new research has emerged for future retrieval proposed by Baeza-Yates [5] where the idea of exploiting temporal information is developed for searching the future.

Foundations

Overview and Motivation

Time is an important dimension of any information space and can be very useful in information retrieval. Time and time measurements can help in outlining a particular historical period or establishing the context of a document. As an alternative to document ranking techniques like those based on popularity, time can be valuable for placing search results in a timeline for document exploration purposes. Current information retrieval systems and applications, however, do not take advantage of all the time information available within documents to provide better search results and thus to improve the user experience.

A quick look at any of the current search engines and information retrieval systems shows that the temporal viewpoint is restricted to sorting the search result represented in a hit list by date only. The date attribute is mainly the creation or last modified date of a Web page or document. In some cases it can be misleading, because the timestamp provided by a Web server or any other document management system may not be accurate. Other search applications provide a range date search as part of the advanced search options. Still, the search results are filtered based on the date attribute. For search purposes, the time axis is mainly constructed using that type of document metadata.

Even simple queries against Web search engines show that oftentimes organizing the documents in a hit list along some timeline can be helpful. For example, a query for "soccer world cup" against search engines now returns mostly pointers to documents that cover the recent event in Germany. But every soccer fan knows that this event happens every four years. Another example is "Iraq war;" here, results are primarily related to the latest events with little from the 1990's war. Clearly, it would be useful if a tool on top of a traditional retrieval system is more aware of the temporal information embedded in the documents and allows the user to have search results presented in different ways based on the temporal information. For this, it is essential to extract temporal information from documents and associate documents with points in time along well-defined timelines.

Time and Timelines

As the basis for associating points in time with documents, it is customary to assume a discrete representation of time based on the Gregorian Calendar, with a single day being an atomic time interval called a *chronon*. A base timeline, denoted T_d, is an interval of consecutive day chronons. For example, the sequence "March 12, 2002; March 13, 2002; March 14, 2002" is a contiguous subsequence of chronons in T_d. Contiguous sequences of chronons can be grouped into larger units called *granules*, such as weeks, months, years, or decades. A grouping based on a granule results in a more coarse-grained timeline, such as T_w based on weeks, T_m based on months, or T_y based on years. Examples of week chronons in T_w are "3rd week of 2005" or "last week of 2006." Depending on the type of underlying calendar, base timeline, and grouping of chronons, timelines of different time granularity can be constructed. Chronons from two timelines then can also be compared. For example, "March 18, 2002" (chronon in T_d) lies before "December 2006" (chronon in T_m). Timelines constructed in this way then serve as the basis to have temporal expressions in documents refer to chronons in one or more timelines.

Temporal Expressions

There is quite a lot of temporal information in any corpus of documents. For example, financial news tend to be rich in describing near future events; resume documents contain several references to the past in a very precise way; and project documentation involves phase milestones that are captured in time. However, what types of temporal information (besides a simple document timestamp) are there and how do they relate to timelines?

In general, with the textual content of a document, a set of *temporal entities* can be associated. A temporal entity describes a point in time, event, or time period at a conceptual level. The identification of such entities involves a linguistic analysis of the document, where approaches based on named-entity extraction determine so-called *temporal expressions*. A temporal expression is basically a sequence of tokens that represent an instance of a temporal entity. Contrary to other entities such as names and places, temporal entities can be represented as temporal expressions that are sequences of not necessarily contiguous tokens or words. Expressions can be mapped to temporal entities that are defined in some time ontology. Similar to the approach by Schilder and Habel [11], this discussion distinguishes between explicit, implicit, and relative temporal expressions. *Explicit temporal expressions* directly describe entries in some timeline, such as an exact date or year. For example, the token sequences "December 2004" or "September 12, 2005" in a document are explicit temporal expressions and can be mapped directly to chronons in a timeline (here T_m and T_d, respectively).

Depending on the underlying time ontology and capabilities of the named-entity extraction approach, even apparently imprecise temporal information, such as names of holidays or events can be anchored in a timeline. For example, the token sequence "Columbus Day 2006" in the text of a document can be mapped to the expression "October 12, 2006," or the sequence "Labor Day 2008" can be mapped to "September 1, 2008." Such types of temporal expressions whose mapping to entities relies on the capability of the underlying time ontology are called *implicit temporal expressions*.

Relative temporal expressions represent temporal entities that can only be anchored in a timeline in reference to another explicit or implicit, already anchored temporal expression (which, in the worst case, is the document timestamp). For example, the expression "today" alone cannot be anchored in any timeline. However, it can be anchored if the document is known to have a creation date. This date therefore can be used as a reference for that expression, which then can be mapped to a chronon. There are many instances of relative temporal expressions, such as the names of weekdays (e.g., "on Thursday") or months (e.g., "in July") or references to such points in time like "next week" or "last Friday."

Given a document collection $\mathcal{D}$, the temporal expressions that have been determined for each document $d \in \mathcal{D}$ can be represented in the form of a *temporal document profile*. For example, a profile then records for each type of expression the token sequence, position of the sequence in the document d, and the chronon to which the expression has been mapped. With a document, several expressions of different types and corresponding chronons (in different timelines) can be associated. The same expression and chronon can even appear several times in the same document, but then at different positions in the document. Each document at least has one explicit temporal expression, which is assumed to be the document timestamp. Next, an extraction approach for temporal expressions using existing tools is outlined.

Temporal Processing Pipeline

Given a document collection $\mathcal{D}$, the identification of the temporal expressions in each document $d \in \mathcal{D}$ is realized through a *document processing pipeline*, which includes a sequence of operations as follows. The first step is to extract the timestamp from the document. This can be the creation or last modified date for a file. In case of a Web page, one can rely on the information provided by the Web server. The second step is to run a part of speech tagger (POS tagger) on every document. A POS tagger returns the document with parts of speech assigned to each word/token like noun, verb etc. The tagger also tags sentence delimiters that later are needed for extracting the temporal expressions. The third step is to run a temporal expression tagger on the POS-tagged version of the document, which recognizes the extents and normalized values of temporal expressions [6]. This step extracts temporal expressions based on the TimeML standard and produces an XML document. The TimeML specification for temporal annotations seems to be a suitable approach here, because it has emerged as the standard markup language for events and temporal expressions in natural language [15]. The resulting XML document is the original document annotated by various information about the temporal expressions that have been determined for the original document. This information then can be used to construct the temporal document profile for the document, which, in turn, can be used for different time-centric document information retrieval and exploration approaches.

Document Retrieval

A fundamental property of any information retrieval system is the ability to help users find documents that satisfy their information needs. At a first glance, this looks pretty obvious but it is not, because users are not very expressive in describing what information they want. Furthermore, the information needs they specify can be ambiguous, making the retrieval task even harder. A user will judge whether or not a query result satisfies her information needs based on whether she considers the result to the search query relevant. The central idea underlying a temporal information retrieval approach is to utilize the temporal expressions that have been determined for each document in a given document collection $\mathcal{D}$ in order to group and/or rank search results based on the temporal information embedded in the documents. By using this approach, time plays a central role in the overall quality of the search results. Assume a standard information retrieval or search application that returns a hit list of n documents $L_q = \langle d_1,...,d_n \rangle$ for a search query q. The search application retrieves the result based on the relevance of the documents with respect to q using traditional metrics based on tf/idf and the distance of the query terms to the first token of temporal expressions in the documents. After all, *tense* happens at the sentence level so it is important to detect these "boundaries" with respect to the query q. There are several ways in which the temporal expressions in the documents in L_q can be used to group the documents using temporal aspects. In the following, only the general idea of these approaches is illustrated. For example, the following algorithm outlines how the usage of temporal expressions can help to group search results based on the temporal expressions determined from the documents in L_q.

1. Determine the document hit list $L_q = \langle d_1,...,d_n \rangle$ that satisfies the search query q, sorted by relevance of the documents.
2. Determine the temporal expressions $T = \{te_1,...,te_m\}$ for all the n documents in the hit list. Note that a document $d_i \in L_q$ can have several temporal expressions, represented in d_i's temporal document profile.
3. Choose a type of time granule g (e.g., year or month). Sort the temporal expressions in T using that granule as key. For example, the expression "September 1, 2007" then comes before the expression "August 2007," assuming a descending order.
4. For each granule of type g (e.g., a particular year or month), take all those documents from L_q that contain a temporal expression covered by that granule. Rank these documents using the distance between the query terms in q to the temporal expressions.
5. Display document groups using the granule type g as label in a timeline fashion in descending order. For example, if the granule type year has been chosen, for each year, there is a group of documents that contain a temporal expression related to that year (perhaps at a finer level of granularity). Note that instances of the granule type are based on a timeline.

If a document $d \in L_q$ contains several temporal expressions, this document can end up in different groups and at a different rank in each group. In general, the above approach organizes documents from a hit list along a timeline based on a time granule type. A group of documents related to a particular instant of a granule then can be organized further, i.e., based on a more fine-grained time granule.

Key Applications

Recently, exploratory search system have emerged as a specialization of information exploration to support serendipity, learning, and investigation, and, more generally, to allow users to browse available information. For such systems, taking advantage of temporal expressions embedded in the documents leads to a much richer framework for exploration. This is an important ingredient for the information forager who is trying to see the profit in terms of the interaction cost required to gain useful information from an information source. Users tend to prefer sources, in this case search engines, that are richer in good results. These good results involve adding important nuggets such as temporal information and relationships. The news domain is another area where search, presentation, and filtering can be greatly improved by using more temporal information. As an example, financial news about a company's Q4 earnings has a very precise meaning in a time-related context. Exploring and analyzing news by these types of temporal expressions can be very useful for particular application domains, for example, in the area of financial analysis.

Timeline-Based Exploration

Current interfaces to search engines typically present search results sorted by the relevance of documents from a document collection to a search query. For this, the freshness of the information is considered an important part of the quality of the result. Temporal attributes in Web pages or documents such as date, however, are just viewed as some structured criteria to sort the result in descending order of relevance. At the time of this writing there is a new experimental feature for timelines as part of Google (`view:timeline`).

Another exploratory search prototype outlined in the following is a Web-based application that uses the SIMILE timeline toolkit for visualization and exploration purposes [13], here with respect to a document collection of journal articles from DBLP (http://www.informatik.uni-trier.de/~ley/db/). The interface is organized as follows. The main section takes half of the screen and contains the search box and the timeline. The timeline consists of two bands that represent different time scales (types of granules): decade and year. Both bands are synchronized such that panning one band also scrolls the other. The lower band (decade) is much smaller since the goal is to show the activity in a decade. The upper band shows all articles in a given year. Figure 1 shows the exploratory search interface in action for the query "compiler" against the collection. The system retrieves all journal articles that contain the term "compiler" in the title and returns a hit list clustered by year (in which the article appeared). Search results are anchored in the timeline, that is, documents (or rather the embedded temporal expressions) are linked to instants in time. If more than one article falls within a year, the order of the documents in such a group is based on each document's relevance to the query. Obviously, such an information exploration and visualization approach and tool on top of a more traditional search application can be extremely valuable in the context of temporal information retrieval.

Future Directions

Evaluations of the impact of temporal attributes for search and retrieval are needed to asses the importance of these techniques. This, of course, can only be

Temporal domain; Temporal structure

Definition

In its full generality, a time domain can be defined as a set of *temporal individuals* connected by a set of *temporal relations*. Different choices for the temporal individuals and/or the temporal relations give rise to different temporal ontologies.

In the database context, the most common temporal ontology takes *time instants* (equivalently, points or moments) as the temporal individuals and a *linear order* over them as the (unique) temporal relation [5]. In addition, one may distinguish between discrete and dense, possibly continuous, time domains and between bounded and unbounded time domains. In the discrete case, one may further consider whether the time domain is finite or infinite and, in the case of unbounded domains, one can differentiate between left-bounded, right-bounded, and totally unbounded domains. Moreover, besides linear time, one may consider *branching time*, where the linear order is replaced with a partial one (a tree or even a directed acyclic graph), or circular time, which can be used to represent temporal periodicity.

As for temporal individuals, time instants can be replaced with *time intervals* (equivalently, periods or anchored stretches of time) connected by (a subset of) Allen's relations `before`, `meets`, `overlaps`, `starts`, `during`, `equal`, and `finishes`, and their inverses or suitable combinations [7]. As in the case of instant-based domains, one may distinguish between discrete and dense domains, bounded and unbounded domains, linear, branching, and circular domains, and so on.

Finally, as most temporal database applications deal with both qualitative and quantitative temporal aspects, instant-based time domains are usually assumed to be isomorphic to specific numerical structures, such as those of natural, integer, rational, and real numbers, or to fragments of them, while interval-based ones are obtained as suitable intervallic constructions over them. In such a way, time domains are endowed with *metrical features*.

Historical Background

The nature of time and the choice between time instants and time intervals as the primary objects of a temporal ontology have been a subject of active philosophical debate since the times of Zeno and Aristotle. In the twentieth century, major contributions to the investigation of time came from a number of disciplines. A prominent role was played by Prior who extensively studied various aspects of time, including axiomatic systems of tense logic based on different time domains.

Nowadays, besides physics, philosophy, and linguistics, there is a considerable interest in temporal structures in mathematics (theories of linear and branching orders), artificial intelligence (theories of action and change, representation of and reasoning with temporal constraints, planning), and theoretical computer science (specification and verification of concurrent and distributed systems, formal analysis of hybrid temporal systems that feature both discrete and continuous components). A comprehensive study and logical analysis of instant-based and interval-based temporal ontologies, languages, and logical systems can be found in [2].

As for *temporal databases*, the choice of the time domain over which temporal components take their value is at the core of any application. In most cases, a discrete, finite, and linearly ordered (instant-based) time domain is assumed. This is the case, for instance, with SQL standards [9]. However, there is no single way to represent time in a database, as witnessed by the literature in the field. To model when something happened, time instants are commonly used; validity of a fact over time is naturally represented by the (convex) set of time instants at which the fact holds, the time *period of validity* in the temporal database terminology; finally, to capture processes as well as some kinds of temporal aggregation, time intervals are needed.

Foundations

Basics

The choice between time instants and time intervals as the basic time constituents is a fundamental decision step that all temporal systems have in common. In mathematics, the choice of *time instants*, that is, points in time without duration, is prevalent. Although quite abstract, such an solution turned out extremely fruitful and relatively easy to deal with in practice. In computer science, additional motivations for this choice come from the natural description of computations as possibly infinite sequences of instantaneous steps.

The alternative option of taking *time intervals*, that is, anchored stretches of time with duration, as temporal individuals seems to better adhere to the concrete experience of people. Physical phenomena as well as natural language expressions involving time can be more easily described in terms of time intervals instead of time instants. Nevertheless, the complexity of any systematic treatment of time intervals prevents many systems from the adoption of an interval-based ontology.

The instant and the interval ontologies are systematically investigated and compared in [2]. The author identifies the conditions an instant-based (resp., interval-based) structure must satisfy to be considered as an adequate model of time. Then, through an axiomatic encoding of such conditions in an appropriate language, he provides a number of (first-order and higher order) logical theories of both instant-based and interval-based discrete, dense, and continuous structures. Finally, he illustrates the strong connections that link the two time ontologies. In particular, he shows how interval-based temporal structures can be obtained from instant-based ones through the standard process of interval formation and how instant-based temporal structures can be derived from interval-based ones by a (non-trivial) limiting construction.

A metric of time is often introduced to allow one to deal with time distance and/or duration. In particular, a time metric is needed to define calendar times, such as those based on the commonly used Gregorian calendar.

Temporal Models and Query Languages

The choice of the time domain has an impact on various components of temporal databases. In particular, it influences temporal data models and temporal query languages.

As for *temporal data models*, almost all of them adopt an instant-based time ontology. Moreover, most of them assume the domain to be linear, discrete and finite. However, many variants of this basic structure have been taken into consideration [8]. Right-unbounded domains have been used to record information about the future. Dense and continuous domains have been considered in the context of temporal constraint databases, that allow one to represent large, or even infinite, sets of values, including time values, in a compact way. Branching time has been exploited in applications where several alternatives have to be considered in the future and/or past evolution of temporal data.

Many data models distinguish between absolute (anchored) and relative (unanchored) time values. Absolute time values denote specific temporal individuals. In general, they are associated with a time metric, such as that of calendar times. As an example, the 14th of September 2007 is an absolute time value that denotes a specific element of the domain of days in the Gregorian calendar. Relative time values specify the distances between pairs of time instants or the durations of time intervals. Absolute and relative time values can also be used in combination. As an example, the expression 7 days after the 14th of September 2007 denotes the 21st of September 2007.

As for *temporal query languages*, they typically assume that time is isomorphic to natural numbers. This is in agreement with the most common, *linear-time* dialect of temporal logic. In temporal constraint databases, however, the use of classical query languages like relational calculus or algebra accommodates a variety of time domains, including dense and continuous ones.

Time Domain and Granularity

Despite its apparent simplicity, the addition of the notion of time domain to temporal databases presents various subtleties. The main ones concern the nature of the elements of the domain. As soon as calendar times come into play, indeed, the abstract notion of instant-based time domain must be contextualized with respect to a specific *granularity* [3,4]. Any given granularity can be viewed as a suitable abstraction of the real time line that partitions it into a denumerable sequence of homogeneous stretches of time. The elements of the partition, granules in the temporal database terminology, become the individuals (non-decomposable time units) of a discrete time domain. With respect to the considered granularity, these temporal individuals can be assimilated to time instants. Obviously, if a shift to a finer granularity takes place, e.g., if one moves from the domain of months to the domain of days, a single granule must be replaced with a set of granules. In such a way, being instantaneous is not more an intrinsic property of a temporal individual, but it depends on the time granularity one refers to. A detailed analysis of the limitations of the temporal database management of instant-based time domains can be found in [9].

The Association of Time with Data

The association of the elements of the time domain with data is done by *timestamping*. A timestamp is a time value associated with a data object. In the relational setting, one distinguishes between attribute-timestamped data models, where timestamps are associated with attribute values, and tuple-timestamped data models, where timestamps are associated with tuples of values. As a third possibility, a timestamp can be associated with an entire relation/database.

Timestamps can be single elements as well as sets of elements of the time domain. Time instants are usually associated with relevant events, e.g., they can be used to record the day of the hiring or of the dismissal of an employee. (Convex) sets of time instants are associated with facts that hold over time. As an example, if a person E works for a company C from the 1st of February 2007 to the 31st of May 2007, one keeps track of the fact that every day in between the 1st of February 2007 and the 31st of May 2007, endpoints included, E is an employee of C.

Time intervals are needed to deal with situations where validity over an interval cannot be reduced to validity over its subintervals (including point subintervals) [10]. This is the case with processes that relate to an interval as a whole, meaning that if a process consumes a certain interval it cannot possibly transpire during any proper subinterval thereof. Examples are the processes of baking a cake or of flying from Venice to Montreal. This is also the case when validity of a fact at/over consecutive instants/intervals does not imply its validity over the whole interval. As an example, two consecutive phone calls with the same values are different from a single phone call over the whole period. The same happens for some kinds of temporal aggregation [4]. Finally, the use of time intervals is common in several areas of AI, including knowledge representation and qualitative reasoning, e.g., [1].

It is important to avoid any confusion between this latter use of intervals as timestamps and their use as compact representations of sets of time points (time periods in the temporal database literature). Time intervals are indeed often used to obtain succinct representations of (convex) sets of time instants. In such a case, validity over a time period is interpreted as validity at every time instant belonging to it. As an example, the fact that a person E worked for a company C from the 1st of February 2007 to the 31st of May 2007 can be represented by the tuple (E, C, [2007/02/01, 2007/05/31]) meaning that E worked for C every day in the closed interval [2007/02/01, 2007/05/31].

Key Applications

As already pointed out, the time domain is an essential component of any temporal data model, and thus its addition to SQL standards does not come as a surprise.

In SQL, time domains are encoded via *temporal data types* (they have been introduced in SQL-92 and preserved in SQL:1999). In SQL-92, five (anchored) time instant data types, three basic forms and two variations, are supported (DATE, TIME, TIMESTAMP, TIME WITH TIME ZONE, TIMESTAMP WITH TIME ZONE). In addition, SQL-92 features two (unanchored) data types that allow one to model positive (a shift from an instant to a future one) and negative (a shift from an instant to a past one) distances between instants. One can be used to specify distances in terms of years and months (the YEAR-MONTH INTERVAL type), the other to specify distances in terms of days, hours, minutes, seconds, and fractions of a second (the DAY-TIME INTERVAL type). As a matter of fact, the choice of using the word interval to designate a time distance instead of a temporal individual – in contrast with the standard use of this word in computer science – is unfortunate, because it confuses a derived element of the time domain (the interval) with a property of it (its duration). An additional (unanchored) temporal data type, called PERIOD, was included in the SQL/Temporal proposal for the SQL3 standard, which was eventually withdrawn. A period is a convex sets of time instants that can be succinctly represented as a pair of time instants, namely, the first and the last instants with respect to the given order.

SQL also provides *predicates*, *constructors*, and *functions* for the management of time values. General predicates, such as the equal-to and less-than predicates, can be used to compare pairs of comparable values of any given temporal type; moreover, the specific overlap predicate can be used to check whether two time periods overlap. Temporal constructors are expressions that return a temporal value of a suitable type. It is possible to distinguish datetime constructors, that return a time instant of one of the given data types, and interval constructors, that return a value of YEAR-MONTH INTERVAL or DAY-TIME INTERVAL types. As for functions, they include the datetime value functions, such as the CURRENT_DATE function, that return an instant of the appropriate type, the CAST functions, that convert a value belonging to a given (temporal or non temporal) source data type into a value of the target temporal data type, and the extraction functions, that can be used to access specific fields of instant or interval time values.

Future Directions

Despite the strong prevalence of instant-based data models in current temporal databases, a number of interesting problems, such as, for instance, that of temporal aggregation, motivate a systematic study and development of *interval-based data models*. Moreover, in both instant-based and interval-based data models intervals are defined as suitable sets of elements of an instant-based time domain. The possibility of assuming time intervals as the primitive temporal constituents of the temporal domain is still largely unexplored. Such an alternative deserves a serious investigation.

Time in Philosophical Logic

Peter Øhrstrøm, Per F. V. Hasle
Aalborg University, Aalborg, Denmark

Synonyms

Temporal logic; Logic of time

Definition

The aim of the study of time in philosophical logic is to provide a conceptual framework for an interdisciplinary study of the nature of time and to formalize and study various conceptions and systems of time. In addition, the introduction of time into logic has led to the development of formal systems, which are particularly well suited to represent and study temporal phenomena such as program execution, temporal databases, and argumentation in natural language.

Historical Background

The philosophy of time is based on a long tradition, going back to ancient thought. It is an accepted wisdom within the field that no attempt to clarify the concept of time can be more than an accentuation of some aspects of time at the expense of others. Plato's statement that time is the "moving image of eternity" and Aristotle's suggestion that "time is the number of motion with respect to earlier and later" are no exceptions (see [17]). According to St. Augustine (354–430) time cannot be satisfactorily described using just one single definition or explanation: "What, then, is time? If no one asks me, I know: if I wish to explain it to one that asketh, I know not." [5, p. 40] Time is not definable in terms of other concepts. On the other hand, according to the Augustinian insight, all human beings have a tacit knowledge of what time is. In a sense, the endeavor of the logic of time is to study important manifestations and structures of this tacit knowledge.

There were many interesting contributions to the study of time in Scholastic philosophy, e.g., the analysis of the notions of beginning and ending, the duration of the present, temporal ampliation, the logic of "while," future contingency, and the logic of tenses. Anselm of Canterbury (ca. 1033–1109), William of Sherwood (ca. 1200–1270), William of Ockham (ca. 1285–1349), John Buridan (ca. 1295–1358), and Paul of Venice (ca. 1369–1429) all contributed significantly to the development of the philosophical and logical analysis of time. With the Renaissance, however, the logical approach to the study of time fell into disrepute, although it never disappeared completely from philosophy.

However, the twentieth century has seen a very important revival of the philosophical study of time. The most important contribution to the modern philosophy of time was made in the 1950s and 1960s by A. N. Prior (1914–1969). In his endeavors, A. N. Prior took great inspiration from ancient and medieval thinkers and especially their work on time and logic.

The Aristotelian idea of time as the number of motion with respect to earlier and later actually unites two different pictures of time, the dynamic and the static view. On the one hand, time is linked to motion, i.e., changes in the world (the flow of time), and on the other hand time can be conceived as a stationary order of events represented by numbers. In his works, A. N. Prior logically analyzed the tension between the dynamic and the static approach to time, and developed four possible positions in regard to this tension. In particular, A. N. Prior used the idea of branching time to demonstrate that there is a model of time which is logically consistent with his ideas of free choice and indeterminism. (See [8, 189 ff.].)

After A. N. Prior's development of formalised temporal logic, a number of important concepts have been studied within this framework. In relation to temporal databases the studies of the topology of time and discussions regarding time in narratives are particularly interesting.

Foundations

In the present context, the following four questions regarding time in philosophical logic seem to be especially important:

1. What is the relation between dynamic and static time?
2. What does it mean to treat time as "branching"?
3. What is the relation between punctual and durational time (i.e., instants and durations)?
4. What is the role of time in storytelling (narratives)?

In the following, a brief introduction to each of these issues will be given.

Dynamical and Static Time: A-Theory vs. B-Theory

The basic set of concepts for the *dynamic* understanding of time are past, present, and future. In his very influential analysis of time the philosopher John Ellis McTaggart (1866–1925) suggested to call these concepts (i.e., the tenses) the A-concepts. The tenses are well suited for describing the flow of time, since the future will become present, and the present will become past, i.e., flow into past. The basic set of concepts for the *static* understanding of time are before/after and "simultaneous with." Following McTaggart, these are called the B-concepts, and they seem especially apt for describing the permanent and temporal order of events. The two kinds of temporal notions can give rise to two different approaches to time. First, there is the dynamic approach (the A-theory) according to which the essential notions are past, present and future. In this view, time is seen "from the inside." Secondly, there is the static view of time (the B-theory) according to which time is understood as a set of instants (or durations) ordered by the before-after relation. Here time is seen "from the outside." It may be said to be a God's eye-perspective on time.

There is also an ontological difference between the two theories. According to the A-theory the tenses are real whereas the B-theorists consider them to be secondary and unreal. According to the A-theory the Now is real and objective, whereas the B-theories consider the Now to be purely subjective.

The debate between proponents of the two theories received a fresh impetus with A. N. Prior's formal analysis of the problem. (See [9, 216 ff.]). According to the B-theory, time is considered to be a partially ordered set of instants, and propositions are said to be true or false at the instants belonging to the set. According to the A-theory, time is conceived in terms of the operators *P* (Past) and *F* (Future), which are understood as being relative to a "Now." A. N. Prior suggested a distinction between four possible grades of tenselogical involvement corresponding to four different views of how to relate the A-notions (past, present and future) to the B-notions ("earlier than"/"later than," "simultaneous with"):

1. The B-notions are more fundamental than the A-notions. Therefore, in principle, the A-notions have to be defined in terms of the B-notions.
2. The B-notions are just as fundamental as the A-notions. The A-notions cannot be defined in terms of the B-notions or vice versa. The two sets of notions have to be treated on a par.
3. The A-notions are more fundamental than the B-notions. All B-notions can be defined in terms

of the A-notions and a primitive notion of temporal possibility.

4. The A-notions are more fundamental than the B-notions. Therefore, in principle the B-notions have to be defined in terms of the A-notions. Even the notion of temporal possibility can be defined on terms of the A-notions.

A. N. Prior's four grades of tense-logical involvement represent four different views of time and also four different foundations of temporal logic. In fact, theory 1 is the proper B-theory and theory 3 and 4 are versions of the proper A-theory. Theory 2 is a kind of intermediate theory.

In theory 1, the tense operators, P (past) and F (future), can be introduced in the following way:

$$T(t, Fq) \equiv_{def} \exists t_1 : t < t_1 \wedge T(t_1, q)$$

$$T(t, Pq) \equiv_{def} \exists t_1 : t_1 < t \wedge T(t_1, q)$$

where $T(t, q)$ is read "q is true at t," and $t < t_1$ is read "t is before t_1."

In theory 3 and 4, A. N. Prior has shown how instants can be introduced as maximally consistent sets of tense-logical propositions and how the before-after relation can be consistently defined in terms of tense-logical concepts (i.e., A-notions).

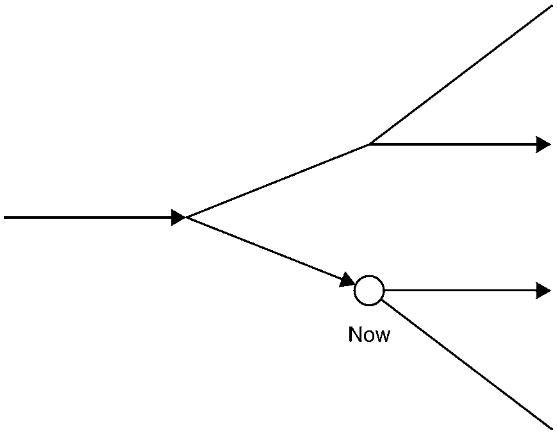
From a B-theoretical viewpoint, at any instant, an infinite number of propositions, including tensed ones, will be true about that instant. But from the A-theoretical point of view, precisely the infinite conjunction of the propositions in this set is a construction which, when called an "instant," makes the B-theoretical notion of "instant" secondary and derivable.

It should be noted, that whereas the A-theorist (theory 3 or 4) can translate any B-statement into his language, many A-statements cannot be translated into the B-language. For instance, there is no way to translate the A-statement "it is raining now in Aalborg" into the B-language. The "now" cannot be explained in terms of the B-language consisting of an ordered set of instants and the notion of a proposition being true at an instant. This asymmetry seems to be a rather strong argument in favor of the A-theory (i.e., A. N. Prior's theory 3 or 4).

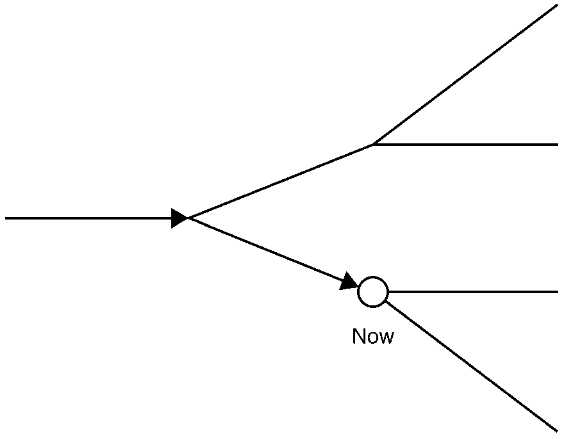
Linear vs. Branching Time

The idea of formalised branching time was first brought forward by Saul Kripke in a letter to A. N. Prior in 1958 [8, pp. 189–90]. Kripke's later development of the semantics for modal logics is well-known within computer science. But it has in fact been shown by Jack Copeland [3] that the kernel of the ideas published by Kripke were in fact present already in the work of Meredith and A. N. Prior in 1956.

The difference between A. N. Prior's theory 3 and 4 is important if time is considered to be branching. In theory 3, the notion of possibility is primitive. In theory 4, this notion can be derived from the tenses. But then it turns out to be very difficult to distinguish between the possible future, the necessary future and the "plain" future — e.g., between "possibly tomorrow," and "necessarily tomorrow" and just "tomorrow." In all obvious models constructed in accordance with A. N. Prior's theory 4, "tomorrow" is conflated either with "possibly tomorrow" or with "necessarily tomorrow." On the basis of theory 3, there is no difficulty in maintaining a difference between the three kinds of notions discussed. In a theory 3 model, one can refer not only to what happens in some possible future, $\Diamond Fq$, and to what happens in all possible futures, $\Box Fq$, but one can also refer to what is going to happen in the future, Fq, as something different from the possible as well as the necessary future. A branching time model with this property is said to be Ockhamistic, whereas a branching time model in which Fq is identified with $\Box Fq$ is said to be Peircean. Graphically, the two kinds of branching time models can be presented as in Figs. 1 and 2 respectively.



Time in Philosophical Logic. Figure 1. An Ockhamistic model of branching time. At every branching point there will be one possible future which is the true future.



Time in Philosophical Logic. Figure 2. A Peircean model of branching time. There is no difference between the status of the possible futures at any branching point.

Punctual vs. Durational Time

The notion of a "duration" is important within the study of time. Several logicians have tried to formulate a logic of durations. The medieval logician John Buridan (ca. 1295–1358) regarded the present as a duration and not as a point in time. One example which he considered was the sentence: "If a thing is moving, then it was moving." In his analysis Buridan suggested that the logic of tenses can be established in two different ways based on the durational structure of time. Either the tenses can be taken absolutely, in the sense that no part of the present time is said to be past or future. Or the tenses can be taken in the relative sense, according to which "the earlier part of the present time is called past with respect to the later, and the later part is called future with respect to the earlier." Buridan pointed out that if a thing is moving now, then there is a part of the present during which it is moving, and hence, it is moving in some part of the present, which is earlier than some other part of the present. Therefore, if the thing is moving, then it was moving (if the past is taken in the relative sense), i.e., $\text{moving}(x) \Rightarrow P(\text{moving}(x))$. For this reason, the above sentence must be accepted if the past is understood relatively, whereas it has to be rejected if the past tense is understood absolutely. The reason is that one could in principle imagine a beginning of a process of motion. (Details can be found in [8, 43 ff.].)

The first modern logician to formulate a kind of durational calculus was Walker [15]. Walker suggested a model according to which time is considered as a structure $(S, <)$, where S is a non-empty set of periods (also called "durations" or "intervals"). The "$a < b$"-relation is to be considered as "strict" in the sense that no overlap between a and b is permitted, and the ordering is assumed to be irreflexive, asymmetrical, and transitive. In addition, he considered the notion of overlap, which can be defined as:

$$a|b \equiv_{def} \neg(a < b \vee b < a)$$

Walker formulated an axiomatic system using the following two axioms:

Definition

(W1)$a|a$

(W2)$(a < b \wedge b|c \wedge c < d) \Rightarrow a < d$

Using a set-theoretic method, Walker demonstrated that it is possible to define instants in terms of durations, thus making it possible to view a temporal instant as a "secondary" construct from the logic of durations.

In 1972 Charles Hamblin [6] independently also put forth a theory of the logic of durations. He achieved his results using a different technique involving the relation:

$$a \text{ meets } b \equiv_{def} a < b \wedge \neg(\exists c : a < c \wedge c < b)$$

A decade later, James Allen [1], in part together with Patrick Hayes [2], showed that two arbitrary durations (in linear time) can be related in exactly 13 ways. It has been shown that all these durational theories are equivalent when seen from an ontological point of view. They all show that just as durations (temporal intervals) can be set-theoretically constructed from an instant-logic, it is also possible to construct instants mathematically from durations. In fact, all the durational theories put forth so far appear to give rise to the same ontological model.

The theories formulated by Walker, Hamblin, and Allen can all be said to be B-theoretical. But Buridan's studies already suggested that it is possible to take an A-theoretical approach to durational logic. In modern durational logic an idea similar to Buridan's absolute/relative distinction was introduced in 1980 by Peter Röper [13] and others (see [8, 312 ff]).

Time and Narratives

A narrative is a text which presupposes a kind of event structure, i.e., a story. The temporal order of the story is often called “told time.” In many cases the story can be represented as a linear sequence of events. However, even if the event structure of the system is linear, the discourse structure can be rather complicated, since the reader (user) can in principle be given access to the events in any order. The order in which the events are presented is often referred to as “telling time.” Keisuke Ohtsura and William F. Brewer [10] have studied some interesting aspects regarding the relation between the event structure (told time) and the discourse structure (telling time) of a narrative text.

Key Applications

The philosophy of time has typically been carried out for its own sake. In many cases philosophers and logicians have seen the study of time as intimately related to essential aspects of human existence as such. For this reason, the study of time within philosophical logic has been motivated by a fundamental interest in the concepts dealing with time themselves and not by the search for a possible application. Nevertheless, such fundamental studies of time have turned out to give rise to theories and models which are useful in many ways. For instance, A. N. Prior’s analysis of the systematic relation between the dynamic and the static approach to time led him to the invention of what is now called hybrid logic (http://hylo.loria.fr). In general, temporal logic has turned out to be very useful in artificial intelligence and in other parts of computer science.

A. N. Prior’s tense logic seems especially relevant for a proper description of the use of interactive systems. A description of such systems from a B-logical point of view alone cannot be satisfactory, since that would ignore the user’s “nowness” which is essential in relation to the user’s choices and thus to the very concept of interactivity. On the other hand, if a conceptual start is made from A. N. Prior’s tense logic (i.e., the A-logical point of view), all B-logical notions can be defined in terms of the A-language.

The need for an A-logical description becomes even clearer when turning to a temporal analysis of systems which are non-linear even from a B-logical perspective, for instance a game-like multimedia system. In her studies of narratives and possible-world semantics, Marie-Laure Ryan [14] has made it clear that such a system is not to be viewed as a static representation of a specific state of affairs. Rather, it contains many different narrative lines which thread together many different states of affairs. Thus it is the choices of the user which will send the history in case on its specific trajectory.

Time Instant

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Event; Moment; Time point

Definition

A time *instant* is a single, atomic time point in the time domain.

Key Points

Various models of time have been proposed in the philosophical and logical literature of time. These view time, among other things, as discrete, dense, or continuous.

Instants in the dense model of time are isomorphic to the rational numbers: between any two instants there is always another. Continuous models of time are isomorphic to the real numbers, i.e., they are dense and also, unlike the rational numbers, without "gaps."

A discrete time domain is isomorphic to (a possibly bounded subset of) the natural numbers, and a specific instant of such a domain then corresponds to some natural number.

The elements of a discrete time domain are often associated with some fixed duration. For example, a time domain can be used where the time elements are specific seconds. Such time elements are often called *chronons*. In this way, a discrete time domain can approximate a dense or continuous time domain.

A time domain may be constructed from another time domain by mapping its elements to granules. In this case, multiple instants belong to the same granule, and the same granule may therefore represent different instants. For example, given a time domain of seconds, a time domain of day-long granules can be constructed.

Concerning the synonyms, the term "event" is already used widely within temporal databases, but is often given a different meaning, while the term "moment" may be confused with the distinct terms "chronon" or "granule."

Time Interval

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Duration; Span; Time distance; Time period

Definition

Definition 1:

A *time interval* is a convex subset of the time domain. A time interval may be open or closed (at either end) and can be defined unambiguously by its two delimiting time instants. In a system that models the time domain using granules, an interval may be represented by a set of contiguous granules.

Definition 2:

An *interval* is a directed duration of time. A duration is an amount of time with known length, but no specific starting or ending instants. For example, the duration "1 week" is known to have a length of 7 days, but can refer to any block of seven consecutive days. An interval is either positive, denoting forward motion of time, or negative, denoting backwards motion in time.

Key Points

Unfortunately, the term "time interval" is being used in the literature with two distinct meanings: as the time between two instants, in the general database research literature and beyond, and as a directed duration of time, in the SQL database language. The term "time period" is associated with the first definition above.

Definition 1 is recommended for non-SQL-related scientific work. Definition 2 is recommended for SQL-related work.

Concerning the synonyms, the unambiguous term "span" has been used previously in the research literature, but its use seems to be less widespread than "interval." While precise, the term "time distance" is also less commonly used. A "duration" is generally considered to be non-directional, i.e., always positive.

Time Period

Nikos A. Lorentzos
Agricultural University of Athens, Athens, Greece

Synonyms

Time interval

Definition

If the *time domain* is a totally ordered set T = {t_1, t_2, t_3...} then *a time period* over T is defined as a convex subset of elements from T.

Example: If T = {d_1, d_2, d_3,...}, where d_i are consecutive dates, then [d_{10}, d_{20}] and [d_{30}, d_{80}] represent two time periods over T.

Key Points

In the area of *temporal databases*, a time period over T is usually defined as a distinct data type. Some researchers define a time period data type of the form [t_p, t_q]. Some others define such a data type of the form [t_p, t_q), i.e., its right end is closed.

Note that, initially, the term *time interval* was used instead of *time period*. This was later abandoned in order to avoid confusion, given that *interval* is a reserved word in SQL. Instead, time interval in today used with a different meaning (see *time interval*).

Time sequence query; Time series search; Time sequence search

Definition

A time series query refers to one that finds, from a set of time series, the time series or subseries that satisfy a given search criteria. *Time series* are sequences of data points spaced at strictly increasing times. The search criteria are domain specific rules defined with time series statistics or models, temporal dependencies, similarity between time series or patterns, etc. In particular, similarity queries are of great importance for many real world applications like stock analysis, weather forecasting, network traffic monitoring, etc., which often involve high volumes of time series data and may use different similarity measures or pattern descriptions. In many cases, query processing consists of evaluating these queries in real-time or quasi-real time by using time series approximation techniques, indexing methods, incremental computation, and specialized searching strategies.

Historical Background

Time series queries play a key role in temporal data mining applications such as time series analysis and forecasting. It was in the recent years that these applications with massive time series data became possible due to the rapidly emerging query processing techniques, especially those for similarity queries. In 1993, Rakesh Agrawal et al. [1] proposed an indexing method for processing similarity queries in sequence databases. The key was to map time series to a lower dimensionality space by only using the first few Fourier coefficients of the time series, and building R*-trees to index the time series. This work laid out a general approach of using indexes to answer similarity queries with time series. In 1994, Christos Faloutsos et al. [6] extended this work to subsequence matching and proposed the GEMINI framework for indexing time series. In 1997, Davood Rafiei and Alberto Mendelzon [12] proposed a set of linear transformations on the Fourier series representation of a time series that can be used as the basis for similarity queries. Subsequent works have focused on new dimensionality reduction techniques [2,9,10], new similarity measures [4,5,14], and queries over streaming time series [3,7,15].

Foundations

Basic Concepts

A *time series* x is a sequence of data points spaced at strictly increasing times. The number of elements in the sequence is called the *length* of the time series. The data points are often real numbers, and therefore x can often be represented as a vector of real numbers, $x(n) = \langle x_{t_1},\ldots,x_{t_n}\rangle$, where n is the length of x, and each t_i is the timestamp associated with the data point with $t_i < t_{i+1}$ for $i = 1,\ldots,n-1$. The time intervals between successive data points are usually, but not always, assumed uniform, and hence $t_{i+1} - t_i$ is often assumed a constant for $i = 1,\ldots,n - 1$. When the specific t_i values are irrelevant but only signify the temporal order, x is also represented as $x(n) = \langle x_1,\ldots, x_n\rangle$. A subsequence of x that consists of consecutive elements is called a *subseries* or *segment* of *x*. Time series normally refer to those finite sequences of *static* elements. If the sequence has new elements continuously appended over time, they are specially called *streaming* time series [7].

Raw time series often need pre-processing to fit the application needs. It is possible to perform the following pre-processing to remove irregularities of time series. *Time regulation* is to convert a non-uniform time series to a uniform one with interpolation functions to obtain the elements at uniform time intervals. *Normalization* is to make the distance between two time series invariant to offset shifting and/or amplitude scaling. For example, given time series *x*, its mean $\bar{x}$ and standard deviation σ_x, the normalization function can be either $\tilde{x} = (x - \bar{x})$ or $\tilde{x} = (x - \bar{x})/\sigma_x$. *Linear trend reduction* is to remove the seasonal trend impact on time series, e.g., $\tilde{x}_{t_i} = x_{t_i} - (a{*}t_i + b)$ for all *i*. To reduce data noise, *smoothing techniques* such as moving average can also be applied.

Similarity is the degree of resemblance between two time series, and the choice of similarity measure is highly domain dependent. For applications without value scaling and time shifting concerns, a simple L_p-norm Distance, of which L_1 and L_2 are the well known Manhattan and Euclidean Distances, respectively, is sufficient. For other applications, more robust similarity measures may be needed, such as scale invariant distances (such as correlation), warping distances that allow an elastic time shifting (such as DTW or Dynamic Time Warping, Longest Common Subsequence and Spatial Assembling Distances [3]), Edit Distance With Real Penalty (ERP) [4], and model based and histogram based distances. Since most similarity measures are defined non-negative, and the smaller the values, the closer the time series, the notions of similarity and distance are often used interchangeably.

Example 1 (L_p-`norm Distances, a.k.a. Minkowski Distance`): Given time series $x(n)$ and $y(n)$, and positive integer *p*, let

$$L_p(x, y) = \sqrt[p]{\sum\nolimits_{i=1}^{n} |x_i - y_i|^p}\ .$$

A special case is given as $L_\infty(x, y) = \max\{|x_i - y_i|, i = 1,...,n\}$. Note when $p \to \infty$, $L_p(x, y) = L_\infty(x, y)$.

Example 2 (`DTW Distance`): Given time series $x(m)$ and $y(n)$, then recursively, for all $1 \le i \le m$ and $1 \le j \le n$

$$\begin{aligned} DTW(x(i), y(j)) = d(x_i, y_j) + \min\{&DTW(x(i-1),\\ &y(j-1)), DTW(x(i-1), y(j)),\\ &DTW(x(i), y(j-1))\}, \end{aligned}$$

where $d()$ is a distance function defined on two elements x_i and y_j, and $x(i)$ and $y(j)$ denote the prefixes of the time series $x(m)$ and $y(n)$ of lengths *i* and *j*, respectively. The base case of the above is when $i = j = 1$ in which case $DTW(x(1),y(1)) = d(x_1, y_1)$. When both *i* and *j* are 0, $DTW(x(0),y(0))$ is defined as 0. Otherwise, when either *i* or *j* is out of range, $DTW(x(i),y(j))$ is defined as $+\infty$. DTW is usually accompanied with one of the following global constraints, in regard to the two prefix lengths *i* and *j*.

`Sakoe-Chiba Band`: The allowed range of *i* and *j* in the definition above satisfies $|j - i| \le r$ for some $r \ge 0$.

`Itakura Parallelogram`: Use the constraint $g(i) \le j - i \le f(i)$ for *i* and *j*, where *f* and *g* are functions of *i* such that the allowed region for $j–i$ given by the constraint shows a parallelogram shape with two opposing corners at (0,0) and (m,n), respectively.

Example 3 (`Edit Distance With Real Penalty` [4]): Given time series $x(m)$ and $y(n)$, recursively for all $i \le m$ and $j \le n$, let

$$ERP(x(i), y(j)) = \min\begin{cases} ERP(x(i-1), y(j-1)) + d(x_i, y_j)\\ ERP(x(i-1), y(j)) + d(x_i, g)\\ ERP(x(i), y(j-1)) + d(g, y_j) \end{cases}$$

In the above, *g* is a constant value (and can be 0), $x(i) = y(j) = \langle g \rangle$ (i.e., a time series of length 1) is assumed for all $i \le 0$ and $j \le 0$, and $d(a, b) = |a - b|$. The base case of the above is when both argument time series are of length 1 in which case $ERP(x, y) = d(x_1, y_1)$. Intuitively, the constant *g* is used to fill a *gap* referring to an added element.

Time Series Query

Many forms of time series queries have been proposed over the years. Among them, one of the mostly used is *similarity search*, defined as follows: Given a set of candidate time series *X*, a similarity measure *D*, and a query series *y*, (i) find all the series in *X* whose distances to *y* are within a given threshold (near neighbor query), and (ii) find *k* series in *X* that are closest to

y (k-nearest neighbor query). Other queries are also possible, e.g., all pairs query that finds, in X, all pairs of series with distance below a given threshold. Besides similarity search, other types of queries include detecting elastic burst over streaming time series, retrieving values at any arbitrary time [13], etc. In the following, time series query refers to similarity search.

The time series query can be either *whole series matching* or *subseries matching*. The former refers to the query that concerns the whole time series, both for the query series y and each candidate series x in X. The latter concerns the subseries of all x in X. For example, given time series $y(l)$, for each $x(n) \in X$, the latter query may need to consider $x(i+1,i+l) = \langle x_{i+1},\ldots,x_{i+l}\rangle$ for all $0 \leq i \leq n-l$.

In the above definition, if the query object is a set of *patterns*, the query is called *pattern matching*. A pattern is an abstract data model of time series, often seen as a short sequence, representing a class of time series that have the same properties. For pattern matching, all the involved time series may be mapped to the space in which the patterns and the similarity measure are defined.

Like the notion of time series, time series queries by default refer to those with static time series. In case of streaming time series, the queries are often monitoring the subseries within a sliding widows, and need to be evaluated periodically or continually to identify the similar series or those with the given patterns [7,15].

Query Processing: Index-based Methods for Similarity Search

Due to large volumes of data and the complexity of similarity measures, directly evaluating time series queries is both I/O and CPU intensive. There are many approaches to process these queries efficiently. Among them, one is to convert time series to other data types (e.g., strings and DNA sequences), so that the corresponding search techniques (e.g., string matching and DNA sequence matching) can be applied. Another approach is to index time series based on their approximations (or *features*), which is detailed in the following.

Time series x of length n can be viewed as a point in an n-dimensional space. However, spatial access methods such as *kd*-tree and *R*-tree cannot be used to index the time series directly. The problem is due to the *dimensionality curse* – the performance of spatial access methods degrades rapidly once the dimensionality is above 16, while n is normally much larger than this number.

The general solution is to map time series to points in a lower N-dimensional space ($N << n$) and then construct the indexes in this space. The mapped points are called the time series *approximation*. Each dimension of the N-dimensional space represents one characteristic of the time series, such as mean, variance, slope, peak values, or a Fourier coefficient, at some coarse levels of time granularity and possibly within a shifted time window. Further, the domain of the N-dimensional space can be nominal so the time series approximation can be represented as a symbolic sequence [11].

Example 4 (Piecewise Aggregate/Constant Approximation [14,8]): Time series x of length mN can be mapped to a point in the N-dimensional space: $\bar{x} = (\bar{x}_1,\ldots,\bar{x}_N)$ where the value in the *ith* dimension is the mean over the *ith* segment of x, $\bar{x}_i = \frac{1}{m}\sum_{j=m(i-1)+1}^{mi} x_j$.

Example 5 (Line Fitting Approximation [11]): Given an alphabet A{"*up*", "*down*", "*flat*"}, define a mapping function $s(z) \in \mathcal{A}$ where z is a time-series of length m. Time series x of length mN can be mapped to a length-N symbolic sequence, $\langle s(x_1,\ldots,x_m), s(x_{m+1},\ldots,x_{2m}),\ldots, s(x_{(N-1)m+1},\ldots,x_{mN})\rangle$, e.g., ⟨"*up*", "*up*", ...,"*down*"⟩. Function s can be line fitting and, based on the slope of the fitting line, decides if the value is "*up*" or "*down*" etc.

A multi-step algorithm can be used to process a query. Take the k-nearest neighbor search as an example. First step: find k-nearest neighbors in the lower-dimensional index structure. Find the actual distance between the query series and the *kth* nearest neighbor. Second step: use this actual distance as a range query to find (in the lower-dimensional index) all the database points. Third step: calculate the actual distances found in step 2 and obtain the actual k-nearest neighbors. An improvement to this algorithm is to incrementally obtain nearest neighbors in the lower-dimensional approximation, and each time an actual distance is obtained, it is used to remove some database points that are returned by the range query (second step above).

The index-based methods need to guarantee soundness (no false alarms) and completeness (no false dismissals) in the query result. Soundness can be guaranteed by checking the original data as in step 3. The completeness can be guaranteed only if the chosen approximation method has the *lower-bounding property* [6]. That is, given a similarity measure D, for any candidate time series x and query time series y, let $\bar{x}$ and $\bar{y}$ be their lower-dimensional approximations and $D^{'}$ be the distance defined on $\bar{x}$ and $\bar{y}$, then $D^{'}(\bar{y}, \bar{x}) \leq D(y, x)$ must hold for any x and y.

Example 6 (Lower Bounding Approximation for Euclidian Distance): Method (1): apply an orthonormal transform (Fourier transform, Wavelet transform, and SVD) to both query and candidate time series and ignore many "insignificant" axes after the transform. The distance defined on the remaining axes gives the lower bounding approximation for Euclidian Distance [1]. Method (2): apply segmented mean approximation to both query and candidate time series. It is easy to see $\sqrt[p]{m}L_p(\bar{x}, \bar{y}) \leq L_p(x, y)$ for all p, while m is the factor of dimensionality reduction, i.e., x's length divided by $\bar{x}$'s. Since this lower-bounding approximation works for all p, one index tree can be used for all L_p-norm distances [8,14].

Example 7 (Lower Bounding Approximation for DTW Distance [9]): To derive a lower bounding approximation for DTW, approximate the candidate time series x using segmented mean approximation, and approximate the query time series y as follows. Let $y = \langle y_1,\ldots,y_{mN}\rangle$. Define $U = \langle U_1,\ldots,U_{mN}\rangle$ and $L = \langle L_1,\ldots,L_{mN}\rangle$ where $U_i = \max(y_{i-r},\ldots,y_{i+r})$ and $L_i = \min(y_{i-r},\ldots,y_{i+r})$ (r is the allowed range for $m - n$ in Sakoe-Chiba Band or Itakura Parallelogram). Sequences U and L form a bounding envelope that encloses y from above and below. Then reduce U and L to a lower dimension N, define $\hat{U} = \langle \hat{U}_1,\ldots,\hat{U}_N\rangle$ and $\hat{L} = \langle \hat{L}_1,\ldots,\hat{L}_N\rangle$, where $\hat{U}_i = \max(U_{(i-1)m+1},\ldots,U_{im})$ and $\hat{L}_i = \min(L_{(i-1)m},\ldots,L_{im})$, that is, $\hat{U}$ and $\hat{L}$ are piecewise constant functions that bound U and L, respectively. Let

$$LB\_PAA(y, \bar{x}) = \sqrt{m\sum_{i=1}^{N}\begin{cases}(\bar{x}_i - \hat{U}_i)^2 & \text{if } \bar{x}_i > \hat{U}_i;\\ (\bar{x}_i - \hat{L}_i)^2 & \text{if } \bar{x}_i < \hat{L}_i;\\ 0 & \text{otherwise.}\end{cases}},$$

then $LB\_PAA(y, \bar{x}) \leq DTW(y, x)$.

Query Processing: Similarity Search over Streaming Time Series

These queries are different from those with static time series, in that (i) having a sliding window or windows of multiple lengths at the same time; (ii) continuous monitoring; and (iii) incremental evaluation. In the following, consider the two problems: Euclidean distance or correlation monitoring among pairs of streams, and Euclidean distance or correlation monitoring between a stream time series and a time series database.

The first query problem is, given many streaming time series, how to find pairs of time series that have strong (positive or negative) correlations in the last sliding window [15].

The idea is to use the notion of "basic windows," similar to segmented mean application. Instead of mean, the coefficients of the Fourier transform of each segment is used to approximate the time series. Given $x = \langle x_1,\ldots,x_b\rangle$ and $y = \langle y_1,\ldots,y_b\rangle$, where b is the size of the basic window. If $x_i = \sum_{m=0}^{N-1} C_m^x f_m(i)$ and $y_i = \sum_{m=0}^{N-1} C_m^y f_m(i)$ is a family of orthogonal functions, then the inner product of x and y,

$$\begin{aligned} x{*}y &= \sum_{i=1}^{b} x_i y_i \\ &= \sum_{i=1}^{b}(\sum_{m=0}^{N-1} C_m^x f_m(i) \sum_{p=0}^{N-1} C_p^y f_p(i)) \\ &= \sum_{m=0}^{N-1}\sum_{p=0}^{N-1} C_m^x C_p^y (\sum_{i=1}^{b} f_m(i) f_p(i)). \end{aligned}$$

Note $\sum_{i=1}^{b} f_m(i)f_p(i)$ does not depend on x and y and can be pre-computed. From this, the inner product of two time series can be computed for each sliding window aligned with the basic windows (i.e., a sliding window must be the union of some basic windows). Fourier bases can be used as the f functions, and discrete Fourier transform (DFT) can compute the coefficients efficiently in an incremental way.

By only taking a few Fourier coefficients (small N), the approximate inner products and hence the Euclidean distance can be evaluated efficiently. To compute correlations, the normalized series of $\hat{x}_i = (x_i - \bar{x})/\sigma_x$ need only be considered, where $\bar{x}$ and σ_x are the mean and standard deviation of x over the sliding window.

A step further: since two series are highly correlated if their DFT coefficients are similar, an indexing structure can help to store the coefficients and look for series with high correlation only in series with similar coefficients.

The second query problem is, given a database of pattern time series, a streaming time series, and window size N, how to find the nearest neighbor of the streaming time series (using the last N values) in the database, at each time position [7].

The idea is a batch processing that uses fast Fourier transform (FFT) and its inverse to calculate the cross correlation of streaming time series and patterns at many time positions. Given $x = \langle x_1,\ldots,x_N \rangle$ and $y = \langle y_1,\ldots,y_N \rangle$, the circular cross correlation sequence is defined as

$$CirCCorr_d^{x,y} = \sum_{i=1}^{N} x_{(d+i-1)\ mod\, \mathrm{N}} y_i, \quad d = 1, 2, \ldots, N,$$

where d is the time lag. Let $\dot{x}$ and $\dot{y}$ be the DFT transforms of x and y respectively, then sequence $\langle \dot{x}_1 \dot{y}^*{}_1,\ldots, \dot{x}_N\, \dot{y}_N^* \rangle$ is the result of DFT transform of $CirCCorr^{x,y}$. Here $\dot{y}^*{}_i$ is the conjugate of $\dot{y}_i$.

With the CirCCorr, calculation of the Euclidean distances of a number of time positions can be done in a batch mode. This is faster than calculating the individual distances, as the batch process has time complexity $O(N\lg N)$, as compared to the direct computing of $O(Nl)$, where l ($l < N$) is the number of time positions covered by one batch processing. So it is profitable to wait for a few time steps and then find the nearest neighbors for these time steps all together. The longer the wait is, the more computation time saved. However, this causes a lengthening of the response time, i.e., a loss of the chance of finding the answer as early as possible. To overcome this, one may use a certain model to roughly predict the future values of the time series and apply the batch processing to compute all the Euclidean distance (or correlations) of many future time positions. When the actual values come, triangular inequality can filter out a lot of time series in the database that are not the nearest neighbor [7].

Key Applications

Market data analysis and trend predication, network traffic control, intrusion detection, temporal data mining.

Time Series Search

▶ Time Series Query

Time Span

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tuscon, AZ, USA

Synonyms

Time interval; Time distance

Definition

A span is a directed duration of time. A duration is an amount of time with known length, but no specific starting or ending instants. For example, the duration "1 week" is known to have a length of 7 days, but can refer to any block of seven consecutive days. A span is either positive, denoting forward motion of time, or negative, denoting backwards motion in time.

Key Points

Concerning the synonyms, the terms "time interval" is generally understood to denote an anchored span in the general community of computer science. Only in the SQL language does "time interval" denote a span. The term "span," which has only one definition, is thus recommended over "time interval" for works not related to the SQL language. This use is unambiguous.

A "duration" is generally considered to be non-directional, i.e., always positive. The term "time distance" is precise, but is longer.

Time-Line Clock

Curtis Dyreson
Utah State University, Logan, UT, USA

Synonyms

Clock; Base-line clock; Time-segment clock

Definition

In the discrete model of time, a *time-line clock* is defined as a set of *physical clocks* coupled with some specification of when each physical clock is authoritative. Each *chronon* in a time-line clock is a chronon (or a regular division of a chronon) in an identified, underlying physical clock. The time-line clock switches from one physical clock to the next at a *synchronization point.* A synchronization point correlates two, distinct physical clock measurements.

Key Points

A time-line clock is the clock for (concrete) times stored in a temporal database. A time-line clock glues together a sequence of physical clocks to provide a consistent, clear semantics for a time-line. Since the range of most physical clocks is limited, a time-line clock is usually composed of many physical clocks. For instance, a tree-ring clock can only be used to date past events, and the atomic clock can only be used to date events since the 1950s. Though several physical clocks might be needed to build a time-line, in some cases a single physical clock suffices. For instance SQL2 uses the mean solar day clock – the basis of the *Gregorian calendar* – as its time-line clock.

Timeslice Operator

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Rollback operator; State query

Definition

The *valid-timeslice operator* may be applied to any temporal relation that captures valid time. Given also a valid-time element as a parameter, it returns the argument relation reduced in the valid-time dimension to just those time(s) specified by the valid-time element. The *transaction timeslice operator* is defined similarly, with the exception that the argument relation must capture transaction time.

Key Points

Several types of timeslice operators are possible. Some may restrict the time parameter to intervals or instants. Some operators may, given an instant parameter, return a conventional relation or a transaction-time relation when applied to a valid-time or a bitemporal relation, respectively; other operators may always return a result relation of the same type as the argument relation.

Oracle supports timeslicing through its flashback queries. Such queries can retrieve all the versions of a row between two transaction times (a key-transaction-time-range query) and allows tables and databases to be rolled back to a previous transaction time, discarding all changes after that time.

Concerning the synonyms, "rollback operator" is an early term that has since been abandoned. This term indicates that the result of a timeslice is a relation obtained by moving backwards in time, presumably from the current transaction time. This kind of result is less general than those that may be obtained using a timeslice operator. Specifically, this kind of result assumes a time parameter that extends from the beginning of the time domain to some past time (with respect to the current time). Similarly, “state query” suggests a less general functionality than what is actually offered by timeslice operators.

Topic Detection and Tracking

Ning Liu
Microsoft Research Asia, Haidian, China

Definition

According to the definition at http://projects.ldc.upenn.edu/TDT/, Topic Detection and Tracking (TDT) is a multi-site research project to develop core technologies for a news understanding systems. Specifically, TDT systems discover the topical structure in unsegmented streams of news reporting as it appears across multiple media and in different languages. Some terms are defined below before the TDT problem is fully understood (The definitions are borrowed from Omid Dadgar’s work).

1. Event – An event is something that happens at some specific time and place, and the unavoidable consequences. Specific elections, accidents, crimes and natural disasters are examples of events.
2. Activity – An activity is a connected set of actions that have a common focus or purpose. Specific campaigns, investigations, and disaster relief efforts are examples of activities.
3. Story – A story is a newswire article or a segment of a news broadcast with a coherent news focus. They must contain at least two independent, declarative clauses.
4. Topic – The topic is defined as a seminal event or activity, along with all directly related events and activities.

With the definition of topic, the Topic Detection and Tracking can be known as to investigate the state of the art in finding and following new events in a stream of broadcast news stories. According to the Pilot-study, the original TDT problem consists of three major tasks: (i) segmenting a stream of data, especially recognized speech, into distinct stories; (ii) identifying those news stories that are the first to discuss a new event occurring in the news; and (iii) given a small number of sample news stories about an event, finding all following stories in the data stream.

Historical Background

The TDT study starts from 1996 through a Pilot-study [2] which aims to explore the approaches and performance baselines. After that, it quickly attracted much attention. Followed by the TDT2, TDT3 etc, increasing number of research works are focusing on the TDT problem. TDT2 in 1998 was the first major step in TDT after the pilot study since it established the foundation for the following works. It addresses the same three problems, which are segmentation, detection, and tracking with the original Pilot study. The evaluation procedures were modified and the volume and variety of data and the number of target topics were expanded. TDT2 attacked the problems introduced by imperfect, machine-generated transcripts of audio data. The TDT3 was used for the year 1999, 2000 and 2001 test. The TDT4 and TDT5 are used for the year 2002, 2003 and 2004 test respectively.

From the algorithms' perspective, start from the Pilot-study, many algorithms and applications about TDT have been proposed [1]. As some examples, in the Pilot-study, the Dragon approach, UMass approach and CMU approach were introduced for text segmentation. The same three approaches are used for new event detection. They are finally utilized for event tracking. As some recent progresses, Masaki et al. proposed the Topic Detection and Tracking for News Web Pages by cluster and SuffixTree [4]. He et al. proposed to conduct the topic detection and Tracking by topic sensitive language model [5]. Makkonen et al. proposed to utilizing the temporal information for topic detection and tracking. In the next section, the TDT problems is considered as several sub-problems. Some algorithms are summarized to address the sub-problems of TDT.

Foundations

According to the Pilot study [1], the TDT problem has the following several sub-problems (the major contents of this section is borrowed from the Pilot study).

The Segmentation Task

The segmentation task is defined to be the task of segmenting a continuous stream of text (including transcribed speech) into its constituent stories. To support this task the story texts from the study corpus will be concatenated and used as input to a segmenter. This concatenated text stream will include only the actual story texts and will exclude external and internal tag information. The segmentation task is to correctly locate the boundaries between adjacent stories, for all stories in the corpus.

The Detection Task

The detection task is characterized by the lack of knowledge of the event to be detected. In such a case, one may wish to retrospectively process a corpus of stories to identify the events discussed therein, or one may wish to identify new events as they occur, based on an on-line stream of stories. Both of these alternatives are supported under the detection task.

Retrospective Event Detection

The retrospective detection task is defined to be the task of identifying all of the events in a corpus of stories. Events are defined by their association with stories, and therefore the task is to group the stories in the study corpus into clusters, where each cluster represents an event and where the stories in the cluster discuss the event. It will be assumed that each story discusses at most one event. Therefore each story may be included in at most one cluster.

Online New Event Detection

The on-line new event detection task is defined to be the task of identifying new events in a stream of stories. Each story is processed in sequence, and a decision is made whether or not a new event is discussed in the story, after processing the story but before processing any subsequent stories). A decision is made after each story is processed. The first story to discuss an event should be flagged YES. If the story doesn't discuss any new events, then it should be flagged NO.

The Tracking Task

The tracking task is defined to be the task of associating incoming stories with events known to the system. An event is defined ("known") by its association with stories that discuss the event. Thus each target event is defined by a list of stories that discuss it.

To solve these sub-problems, various algorithms have been proposed. For the segmentation, as addressed by the Pilot study, there is a relatively small but varied body of previous work that has addressed the problem of text segmentation. This work includes methods based on semantic word networks, vector space techniques from information retrieval and decision tree induction algorithms. As for some classical algorithms, the Dragon's approach to segmentation is to treat a story as an instance of some underlying topic, and to model an unbroken text stream as an unlabeled sequence of these topics. In this model, finding story boundaries is equivalent to finding topic transitions. Given a text stream, a probability can be attached to any particular hypothesis about the sequence and segmentation of topics in the following way:

1. Transition from the start state to the first topic, accumulating a transition probability.
2. Stay in topic for a certain number of words or sentences, and, given the current topic, accumulate a selfloop probability and a language model probability for each.
3. Transition to a new topic, accumulating the transition probability. Go back to step 2.

A search for the best hypothesis and corresponding segmentation can be done using standard HMM techniques and standard speech recognition tricks.

After the segmentation work, Event *detection* is the problem of identifying stories in several continuous news streams that pertain to new or previously unidentified events. Using the same Dragon approach as example, Dragon's online and retrospective detection systems are applications of the clustering technology used to train background models for the segmenter. This technology is an implementation of a k-means clustering algorithm. The next step after event detection is the event tracking.

The TDT event tracking task is fundamentally similar to the standard routing and filtering tasks of Information Retrieval (IR). Given a few sample instances of stories describing an event (i.e., stories that provide a description of the event), the task is to identify any and all subsequent stories describing the same event. Event tracking is different from those IR tasks in that events rather than queries are tracked, and in that events have a temporal locality that more general queries lack. These differences shift the nature of the problem slightly but at the same time shift the possible solutions significantly. The narrowing of the scope of information filtering encourages modifications to existing approaches and invites entirely new approaches that were not feasible in a more general query centric setting.

Dragon's event tracker is an adaptation of its segmenter. As discussed there, the segmentation algorithm does segmentation and topic assignment simultaneously. In general, the topic labels assigned by the segmenter are not useful for classification, as they are few in number and do not necessarily correspond to categories a person would find interesting. However, by supplementing the background topic models with a language model for a specific event of interest, and allowing the segmenter to score segments against this model, it becomes possible for the segmenter to output a notification of an occurrence of that event in the news stream whenever it assigns that event model's label to a story. In this implementation, the topic models have the role of determining the background against which the event model must score sufficiently well to be identified.

Key Applications

TDT techniques have wide range of applications especially on the Web documents. As for the key applications, the major goal of TDT is to finding and following new events in a stream of broadcast news stories.

Future Directions

The future directions of TDT are in several fold. The first is to propose more effective algorithms for some classical problems such as monitoring streams of news in multiple languages (e.g., Mandarin) and media – newswire, radio, television, web sites or some future combination. On the other hand, due to the rapid growth of World Wide Web, the scale of the data for topic detection and tracking is getting larger and larger, thus more scalable algorithms are highly desired. Another direction for exploring is to find new online applications of the TDT problem.

Data Sets

The most commonly used corpus for TDT study start from the Pilot-study. And then the TDT2, TDT3, TDT2000, TDT2001, TDT4 and TDT5 were released. The details about the datasets, tasks and evaluation metrics can be found at http://projects.ldc.upenn.edu/TDT/. LDC is the provider of the corpus for the second phase of TDT and is currently developing the phase three corpus. As an example, some details about TDT2 are introduced.

Topic Hierarchies

► Lightweight Ontologies

Topic Maps

James Caverlee
Texas A&M University, College Station, TX, USA

Definition

Topic Maps provide a standardized way to represent and interchange knowledge through the modeling of abstract concepts (called *topics*), the relationships among topics (called *associations*), and the connection between abstract concepts and real-world resources (called *occurrences*). By distinguishing the high-level topic space from real-world resources, Topic Maps may be used both as a semantic map among related concepts (in the topic space) and as a way to describe real-world resources (through occurrence mapping from the topic space into the resource space). Topic Maps have been formally standardized by the international standards body ISO.

Historical Background

The pre-cursors of what are now known as Topic Maps began in the early 1990s with an effort to merge independently created and maintained indexes for information sharing. This early work motivated the need for a more general and more useful knowledge description meta framework. By 1999, the original ISO standard for Topic Maps was published as ISO/IEC 13250 based primarily on SGML and the hypermedia linking language HyTime.

Foundations

Topic Maps support the modeling and exchange of knowledge based on a standardized framework centered around topics, occurrences, and associations [1,3,4]. These constructions serve as n-ary connections between items that express overarching semantics.

Using Topic Maps

According to the ISO standard, Topic Maps [2] are designed to facilitate knowledge representation and interchange by:

- Providing an abstract layer of topic-centered metadata over information resources for supporting navigational tools like indexes, glossaries, and citation systems.
- Linking topics in a clearly defined fashion so that users can navigate between them. Such linking can support thesaurus-like interfaces to disparate information stores.
- Supporting different "views" over a set of information resources by filtering information resources based on the metadata described in Topic Maps.
- Adding a structured layer over unstructured information resources in the form of a markup that is completely external to the original resources.

The Basics of Topic Maps

To represent and interchange knowledge in a standardized way, Topic Maps rely on three key concepts: (i) topics, which represent abstract concepts; (ii) associations, which model relationships among topics; and (iii) occurrences, which connect topics to real-world resources.

The most basic element in a topic map is a *topic*. In general, a *topic* is an abstract concept or subject of concern within the framework of Topic Maps. A topic can be used to represent people, places, events, organizations, Web pages, documents, or any other reasonable unit of interest. In an example universe of discourse, it may be appropriate to represent the author Jane Austen as a topic, as well as the concepts of author, person, novel, and so on. A topic may be associated with one or more names; in the running example, Jane Austen the topic may be referred to by multiple names, including Austen, Jane Austen, and jane-austen.

Using XTM, the topic for novel and the topic for Jane Austen (as an instance of a Writer) can be expressed as:

```
<topic id="novel">
   <baseName>
      <baseNameString>Novel
      </baseNameString>
   </baseName>
</topic>
```

```
<topic id="jane-austen">
   <instanceOf><topicRef xlink:href=
   "#writer"/></instanceOf>
   <subjectIdentity>
      <subjectIndicatorRef xlink:href=
      "{http://en.wikipedia.org/wiki/
      Jane_Austen}"/>
   <subjectIdentity>
   <baseName>
      <baseNameString>Austen, Jane 1775-
      1817</baseNameString>
   </baseName>
</topic>
```

Note that the Jane Austen topic includes a special *subject indicator* syntax that refers to the Wikipedia entry for Jane Austen. A subject indicator is a guideline for a human consumer of the topic map that, although Jane Austen the writer cannot be directly addressed by a URL, the Wikipedia article uniquely identifies her. In this way, the *subject indicator* serves as a *subject identifier* for the topic Jane Austen. By construction, two topics that have the same subject identifier must refer to the same abstract concept.

The second key component of Topic Maps is an *association*. An *association* is a relationship between topics in a topic map. For example, a topic for the author Jane Austen and a topic for the novel *Pride and Prejudice* (which was written by Jane Austen) could be linked by the association "written-by" which links an instance of an Author with an instance of a Novel. These instances serve as roles in the association. Since associations imply no directionality, the "written-by" association implicitly has a dual association "wrote." There are no limits on the number and nature of associations in a Topic Map, so the Topic Maps paradigm may be used to model complex and sophisticated domains, as well as simpler domains as in the Jane Austen example.

```
<association>
   <instanceOf><topicRef xlink:href="#
   written-by"/></instanceOf>
   <member>
      <roleSpec><topicRef xlink:
      href="#author"/> </roleSpec>
      <topicRef xlink:href="#jane_
      austen"/>
   </member>
   <member>
      <roleSpec><topicRef xlink:
      href="#novel"/> </roleSpec>
      <topicRef xlink:href="#pride_and_
   prejudice"/>
   </member>
</association>
```

Finally, an *occurrence* is a real representations of a topic. For example, a Web-accessible file of the book *Pride and Prejudice* is an occurrence of the topic of the same name. Similarly, the *Pride and Prejudice* topic may also occur in a scholarly article discussing the role of women in British literature that happens to mention *Pride and Prejudice*. In an XTM topic map, an occurrence must be a resource that is addressable using a Uniform Resource Identifier (URI) or may be placed inline as character data. Hence, an occurrence of Jane Austen could be an external resource like a Web page or an image, or a brief in-line description of the author.

In the following example, two of Jane Austen's works are referenced as occurrences:

```
<topic id="pride_and_prejudice">
   <instanceOf><topicRef xlink:href="#
   novel"/> </instanceOf>
      <baseName><baseNameString>Pride
      and Prejudice</baseNameString>
      </baseName>
```

```
  <occurrence>
    <instanceOf><topicRef  xlink:href=
    "#pdf-format"/></instanceOf>
    <resourceRef xlink:href="http://
    www.gutenberg.org/dirs/etext98/
    pandp12p2.pdf"/>
  </occurrence>
</topic>

<topic id="sense_and_sensibility">
  <instanceOf><topicRef xlink:href="
  #novel"/> </instanceOf>
  <baseName><baseNameString>Sense and
  Sensibility</baseNameString>
  </baseName>
  <occurrence>
    <instanceOf><topicRef xlink:href=
    "#pdf-format"/></instanceOf>
    <resourceRef xlink:href="http://
    www.gutenberg.org/dirs/etext94/
    sense11p.pdf"/>
  </occurrence>
</topic>
```

Extending the Basic Model

Topic Maps can be further refined through the use of *types* and *scope*.

A *type* is fundamentally a special kind of association between topics, used to indicate that one topic is an "instance-of" another topic. For example, since *Pride and Prejudice* is a book, there may also exist in the topic map an "instance-of" association between the topic *Pride and Prejudice* and a topic representing the concept of a book. A topic may have multiple types.

A *scope* provides additional contextual information about the elements of a Topic Map. Scope allows for the same topic map to exist at different levels of specification. Users of the topic maps can then decide if they are interested in things from any scope or only from one particular scope or subset of scopes. For example, scope can be used to provide localized names for topics – one name for English, one for Spanish, and one for French.

Merging Topic Maps

Since Topic Maps may be developed in a distributed or independent environment, one of the key features of Topic Maps is the notion of *merging*. Merging means that two topic maps with identical topics can have their associations and occurrences combined together to build a richer semantic model. In particular, two topics can be combined (or "merged") into a single topic containing the union of the types, the names, and the occurrences of the original two topics. This merged topic replaces the original two topics wherever they participate as a role in an association or serve as a topic type.

Using Topic Maps

The Topic Maps standard provides a reference point for the appropriate syntax and functionality of topic maps, leaving the implementation details of a topic maps processing engine to commercial and non-commercial applications and tools. Currently, there are topic map processing libraries in most popular languages like Java, C, Perl, and Python. In an effort to provide a uniform programmatic interface to topic maps, regardless of the particular language and platform, the Common Topic Map Application Programming Interface (TMAPI) has been recently developed. The TMAPI specification provides a base set of core interfaces for accessing and manipulating topic maps.

Key Applications

Web, Semantic Web, digital libraries, business-to-business exchange.

Topic-based Publish/Subscribe

Hans-Arno Jacobsen
University of Toronto, Toronto, ON, Canada

Synonyms

Subject-based publish/subscribe

Definition

Topic-based publish/subscribe is a communication abstraction that supports selective message dissemination among many sources and many sinks. Messages are associated with topics and are selectively routed to destinations with matching topic interests. Data sinks specify interest in receiving messages of a given topic and data sources publish messages on different topics. Topic-based publish/subscribe is an instance of the more general publish/subscribe concept.

Key Points

Topic-based publish/subscribe is an instance of the more general publish/subscribe concept. In the topic-based publish/subscribe model, a data source submits publication messages associated with a topic to the publish/subscribe system, while a data sink subscribes its interest in receiving messages of certain topics by submitting subscription expressions on available topics to the system. The kind of topics to publish or subscribe that exist is either out of band information and must be know to clients, or is dynamically discoverable by clients based on additional support provided by the system. For example, by subscribing to control channel topics, where the creation of new topics is announced. Topics are an integral part of the messages disseminated through the publish/subscribe system. The publish/subscribe system only knows how to interpret the topics, but not the rest of the publication message, which remains opaque to the system.

A publication message published to the topic-based publish/subscribe system is delivered to all subscribers with matching subscriptions. A subscription matches a publication if the topic associated with the publication message matches the subscription expression. In very simple realizations of this model, a topic is simply a string that represents a name, a subject, or a topic according to which messages are classified. In more sophisticated realizations, topics draw from a hierarchical topic space. The topic space is used to categorize messages. For example, in a market data dissemination scenario, messages may be classified according to the stock exchange, the traded commodity, and the kind of information disseminated. A message could for instance be associated with the following topic: `/NASDAQ/ABC-Inc/AskingPrice`. A subscriber can express interest in receiving messages of a specific topic, such as by subscribing to `/NASDAQ/ABC-Inc/AskingPrice`, or by defining a set of messages it is interested in, such as `/NASDAQ/ABC-Inc/*`, which indicates that the subscriber would like to receive any message published with topic `NASDAQ` and `ABC-Inc`.

As in the other publish/subscribe models, the topic-based publish/subscribe model decouples the interaction among publishing data sources and subscribing data sinks. The same decoupling characteristics as discussed under the general publish/subscribe concept apply here as well. Specific realizations of this model found in practice vary in the exact decoupling offered. To properly qualify as publish/subscribe, at least the anonymous communication style must exist. That is publishing clients must not be aware of who the subscribing clients are and how many subscribing clients exist, and vice versa. Thus, topic-based publish/subscribe enables the decoupled interaction of n sources with m sinks for $n, m \geq 1$.

In topic-based publish/subscribe, the publication data model is defined by the topics that can be associated with messages. Simplistic models allow the application developer to categorize messages by defining a flat topic space, simply a collection of topics. More sophisticated approaches allow the application developer to select topics from a hierarchical topic space. Whether flat or hierarchical, topics are often strings, possibly structured with separators for the hierarchical case. Some approaches additionally type the various levels of a hierarchical topic space allowing the application developer to use various operators supported by the type for expressing subscriptions. For example, in he above example, `AskingPrice` could be defined as `Integer`, to allow the subscriber to express a relational condition on the messages returned. This approach is close in expressiveness to the capabilities of content-based or type-based publish/subscribe, as the matching mechanism now also inspects the message content, i.e., the value associated with `AskingPrice`.

The subscription language model depends on the publication data model. A subscription expression defines the subscriber's interest in receiving messages.

Given a flat publication data model, subscribers can express interest in receiving messages of a given topic by specifying the exact topic or by specifying a regular expression that defines interest in a set of possible topics. For a hierarchical publication data model, any part of the hierarchy can be specified as interest by a subscriber in using a wildcard notation to select all messages published by the specified topics.

The publish/subscribe matching problem has the standard interpretation and is defined as determining the set of subscribers based on their subscription expression for a given publication message. This problem is solved over the topic space, which is much simpler than its content-based counter part.

Topic-based publish/subscribe systems are distinguished by the qualities of service the system offers to its clients, such as various degrees of reliability, topic persistence, message ordering constraints, message delivery guarantees, and message delivery latencies constraints. Topic-based publish/subscribe relates to channel-based publish/subscribe in that publishing a message to a channel is similar to associating a message with a topic, which could be the name or identity of the channel. However, in topic-based publish/subscribe this association is reflected in the message itself, while in channel-based publish/subscribe the association is indirect, reflected by selecting a channel, which must not be represented in the message. Topic-based publish/subscribe has more limited filtering capabilities than content-based publish/subscribe, as the message is opaque to the system, while in content-based publish/subscribe the message structure and content is used for determining the set of recipients of a message.

Examples that follow the topic-based publish/subscribe model are the information bus [3], TIBCO's RendezVous product [5], and the series of Web services standards: WS Topics, WS Base Notifications, WS Brokered Notifications [1]. Elements of channel-based publish/subscribe can also be found in the Java Messaging Service [2], the OMG Data Dissemination Service [4], and other messaging middleware. However, these systems are not directly following the topic-based model as described above; rather these approaches are enriched with elements of message queuing, channel-based publish/subscribe, and content-based publish/subscribe.

Topic-based publish/subscribe is intended to support applications that need to selectively disseminate messages from one or more data source to several data sinks, where the mapping of sources to sinks changes dynamically. That is not all sources always communicate with the same sinks. The mapping of which source communicates with which sink is represented through associating topics with messages and subscribing to topics. Most existing systems allow the application to dynamically change subscriptions to topics. Also, applications of topic-based publish/subscribe exist that use the topic as a message log. For these applications the filtering capabilities of the topic-based model is not so important, but message order guarantees, reliability of the queues underlying each topic, and low message delivery latencies are crucial. There are many applications that follow these characteristics. Examples include system integration, selective information dissemination, system management, and database replication.

The term topic-based publish/subscribe is not used uniformly. Abstractions that exhibit the above described functionality are also often referred to as subject-based publish/subscribe systems that offer subject-based addressing to the applications using the system. Subject-based addressing means that interacting applications address each other by publishing messages associated with subjects and by subscribing to subjects of interest. The term subject and topic are used synonymously. Based on the subscriptions registered with the system, the system determines the set of recipients for a given message, without needing explicit address information that identifies that a given message is to be sent to a given destinations. Also, many messaging systems exhibit part of the above described functionality and are simply referred to as messaging systems, message-oriented middleware, or message queuing systems.

Top-K Selection Queries on Multimedia Datasets

Amélie Marian
Rutgers University, Piscataway, NJ, USA

Synonyms

Ranked multimedia retrieval; Aggregation algorithms for middleware systems; Evaluation of fuzzy queries over multimedia systems

Definition

Traditionally, queries over structured (e.g., relational) data identify the exact matches for the queries. This exact-match query model is not appropriate for a multimedia dataset scenario where queries are inherently fuzzy – often expressing user preferences and not hard Boolean constraints – and are best answered with a ranked, or "top-*k*," list of the best matching objects. Efficient top-*k* query algorithms for such applications must take into account the specific challenges in accessing multimedia data. In particular, the query model should consider the access interfaces available to retrieve object attribute information, as well as the cost of retrieving this attribute information.

Historical Background

Content management in multimedia repositories is an important problem as more and more multimedia applications are developed. For example, digitization of photo and art collections is increasingly popular, multimedia mail and groupware applications are becoming widely available, and satellite images are being used for weather predictions. To access such large repositories efficiently, multimedia objects need to be queried via their attribute values, such as the date the multimedia object was authored, a free-text description of the object, and features like color histograms.

There are at least three major ways in which accesses to a multimedia repository differ from that of a structured database (e.g., a relational database). First, the data are inherently fuzzy: rarely does a user expect an exact match with the features of a multimedia object (e.g., color histogram). Rather, an object does not either satisfy or fail a condition, but has instead an associated grade of match [3,5]. Thus, an atomic query condition will not be a filter testing for an equality between two values (e.g., between a given color *c* and the color *O.c* of an object *O*) as is usually the case in an exact query model scenario, but instead will assign a score representing the grade of match between the two values (e.g., *GradeColor*(*c*,*O.c*)). Next, every condition on an attribute of a multimedia object may only be separately evaluated through calls to a system or index that handles that particular attribute. This is in contrast to a traditional database where, after accessing a tuple, all selection predicates can be evaluated on the tuple. Finally, the process of querying and browsing over a multimedia repository is likely to be interactive, and users will tend to ask for only a few best matches according to a ranking criterion.

Foundations

Existing query processing techniques for relational data cannot efficiently be applied to multimedia scenarios as object attribute information is often kept separate, possibly in different subsystems, and is typically expensive to retrieve. In addition, the fuzzy nature of the queries means that users are only interested in the best matches, making it unnecessary to evaluate every object.

Query Model

Consider a collection *C* of objects with attributes $A_1,\ldots,A_n$. A top-*k* query over collection C simply specifies target values for each attribute A_i. Therefore, a top-*k* query *q* is an assignment of values $\{A_1 = q_1,\ldots,A_n = q_n\}$ to the attributes of interest. The answer to the top-*k* query $q = \{A_1 = q_1,\ldots,A_n = q_n\}$ over a collection of objects C and for a scoring function is a list of the *k* objects in the collection with the highest score for the query. The final score that each object t in C receives for q is generally a function of a score for each individual attribute A_i of t. Typically, the scoring function that is associated with each attribute A_i is application-dependent. Top-k algorithms presented in the literature can be applied to a variety of aggregate scoring functions as long as they satisfy some monotonicity requirements [1,4,5,8].

Typically, multimedia attribute values (or scores) can only be accessed through specific interfaces. Two types of access to data, along with their associated costs, can be distinguished. The first type of access is sorted (or sequential) access, which allows retrieving objects through a list sorted by the objects' attribute scores (for instance, all images stored by degree of redness). The second type of access is random access, which allows to directly access the attribute score of a given object. A sorted access is usually cheaper than a random access as it can make use of sequential access to precomputed index structures. However, sorted access does require to access every object in the attribute's score order. The multimedia system may allow either sorted- or random-access, or both, for each attribute score, depending on the underlying subsystems.

Top-*k* Query Evaluation Algorithms

A naive brute-force top-k query processing strategy would consist of computing the score for the query for every object to identify and return k objects with the best scores. For large collections of objects, it is easy to see that this brute-force evaluation could be prohibitively expensive. Fortunately, the top-k query model provides the opportunity for efficient query processing, as only the best k objects need to be returned. Objects that are not part of the top-k answer, therefore, might not need to be processed. The challenge faced by top-k query processing techniques is then to identify the top-k objects efficiently, to limit the amount of processing done on non-top-k objects. To this end, various top-k query processing strategies have been presented.

The Threshold Algorithm

To process queries involving multiple multimedia attributes, Fagin et al. proposed a family of algorithms [3,4,5], developed as part of IBM Almaden's Garlic project. These algorithms can evaluate top-k queries that involve several independent multimedia "subsystems," each producing scores that are combined using arbitrary monotonic aggregation functions. The initial *FA* algorithm [3] was followed by "instance optimal" query processing algorithms over sources that allow for sorted accesses and possibly random accesses (*TA* algorithm) or only for sorted accesses (*NRA* algorithm) [4]. In later work, Fagin et al. [5] introduced the TA_z algorithm, a variation of *TA* that also handles sources that only provide random-access interfaces. These algorithms rely on making dynamic choices for scheduling index lookups during query execution in order to prune low-scoring candidate items as early as possible. *TA* does not need an unbounded buffer, and dynamically considers object grades to decide when to stop retrieving new objects. Specifically, *TA* stops retrieving new objects when it finds a threshold grade G such that (1) at least k objects with grade G or higher have been identified and (2) no unretrieved object can have a grade greater than G.

Nepal and Ramakrishna [10] and Güntzer et al. [6] presented variations of Fagin et al.'s *TA* algorithm [4] for processing queries over multimedia databases. In particular, Güntzer et al. [6] reduce the number of random accesses through the introduction of more stop-condition tests and by exploiting the data distribution.

While these algorithms are proved "instance optimal," i.e, the consider the minimum number of objects needed to correctly identify the top-k answer, they completely evaluate each object they consider.

Algorithms based on Expensive Predicates Evaluation

Some works have built upon the *TA* family of algorithms to further improve query processing efficiency by reducing the number of expensive random accesses.

Marian et al.'s *Upper* algorithm [8] picks the most *promising* object-attribute pair to process at any given time based on the result of previous accesses. The *Upper* algorithm requires keeping track of partially evaluated object score bounds. By interleaving the processing of objects, and discarding objects that are not fully evaluated, *Upper* results in significant savings in random access costs. Marian et al. also proposed *TA-EP*, an optimization of *TA* that exploits existing techniques for processing selections with expensive predicates. In addition, Marian et al. [8] proposes extending the *Upper* algorithm to efficient parallel evaluation.

Chang and Hwang [1] presented *MPro*, an algorithm that relies on identifying *necessary* probes to optimize the execution of *expensive predicates* for top-k queries. Unlike *Upper*, *MPro* always evaluate attributes in the same order for every object. Chang and Hwang also briefly discussed parallelization techniques for *MPro* and proposed the *Probe-Parallel-MPro* algorithm.

Filter/Restart Method

Algorithms based on Fagin et al.'s *TA* dynamically refine a threshold value *G* based on the status of evaluated objects. As a result, these algorithms can be processed continuously, until a solution is reached. In contrast, some techniques have focused on translating top-k queries into standard selection queries. While this approach allows using existing query evaluation and optimization implementations, it may require to "restart" a query, if the translation does not return at least k results.

In particular, Chaudhuri et al. built on Fagin's original *FA* algorithm and proposed a cost-based approach for optimizing the execution of top-k queries over multimedia repositories [2]. Their strategy translates a given top-k query into a selection (filter) query that returns a (hopefully tight) superset of the actual top-k tuples using data distribution information to estimate the value G that is expected to be the score of the k^{th} object. Ultimately, the evaluation strategy consists of retrieving the top-k' tuples from as few sources as possible, for some $k' \geq k$, and then probing the remaining sources by invoking existing strategies for processing selections with expensive predicates.

Using Pre-computed Views

Another approach to top-k query evaluation is to use precomputed top-k query indexes. Various top-k queries, with different scoring functions, are evaluated to create indexes, which are used whenever a new top-k query is entered. A challenge of such an approach is to correctly identify the most efficient index for the new query. The *PREFER* system [7] uses pre-materialized views to efficiently answer ranked preference queries over commercial DBMSs. *PREFER* precomputes a set of materialized views that provide guaranteed query performance and, for any new top-k query, selects a near optimal set of views under space constraints.

Handling Joins

Top-k query evaluation algorithms over arbitrary joins have been presented for multimedia applications [1,9]. They use a ranking function that combines individual tuple scores. These algorithm handle the possible explosion in the number of results resulting from the join operation.

Key Applications

Multimedia Search

Typical search queries in multimedia systems require for fuzzy matches on predicates that are expensive to evaluate as the corresponding information is not stored in indexes (e.g., similarity to a user-specified image). Top-k algorithms are designed to minimize the number of accesses to the data, only focusing on those that are needed to identify the best query answers.

Information Integration

In scenarios where many sources may be accessed to answer a query (e.g., web databases, legacy systems), using algorithms that are designed to minimize the number of these expensive remote accesses is an important aspect of query processing efficiency.

Future Directions

Research on top-k query processing in multimedia scenarios has so far focused mostly on efficiency. Relatively little attention has been devoted to evaluating the quality and usefulness of the resulting top-k answers. In contrast, the design of good scoring functions for (relatively unstructured) text documents has been the main focus of the IR community for the last few decades. Many lessons and techniques from IR can be applied to a more structured multimedia scenario.

Synonyms

Topology; Topological fabric; Topological data structure

Definition

Topology is defined as a mathematical model used to define the location of and relationships between geographical phenomena. These topological relationships are independent of distance or direction. Topology may depict connectivity of one entity to another; for example, an edge will have topological relationships to it's from and to nodes.

Topology is useful with spatial data because many spatial modeling or geoprocessing operations do not require geometric coordinate values. For example, to find the shortest path between two nodes requires a list of which edges connect to each other and the cost of traversing along each edge. Geometric coordinates are only necessary to draw the shortest path after it is calculated.

More generally, topology, in the context of spatial data, can have several other meanings:

- A mathematical model of features in space (e.g., nodes, edges, and faces).
- A physical data model for efficient representation of feature data.
- A mechanism that can be used to ensure data quality (e.g., no gaps or overlaps between polygons).
- A mechanism that allows the management of shared geometry.
- A mechanism that facilitates navigation between features using topological relationships (e.g., equal, disjoint, intersects, touches, crosses, within, contains, overlaps, and relate – the nine topological relationships in the dimensionally extended nine-intersection model [5]).

A topological data model is used to represent collections of features that are assembled into a topology (or topological fabric). Topological data models come in many different variants (as described in the following), but the central theme for each of the models is the storage and representation of spatial data that forms a topological fabric.

Historical Background

Topological data structures have been used to represent geographic information for over 40 years [3,14]. The topological model has been the basis of a number of operational systems (see, for example DIME [3], GIRAS [11], ODYSSEY [13], ARC/INFO [1], TIGRIS [7], and TIGER [9]). Many of these systems have been based on binary file and in-memory data structures and supported a single-writer editing model on geographic libraries organized as a set of individual map sheets or tiles.

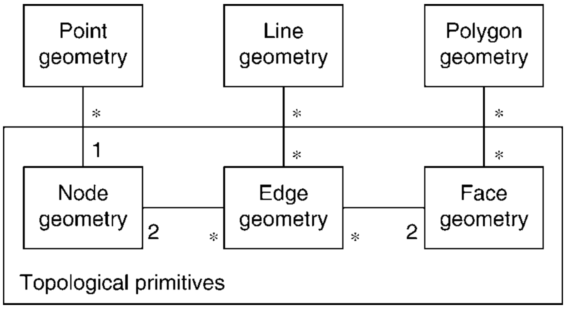
Topology has historically been viewed as a spatial data structure used primarily to ensure that the associated data forms a consistent and clean topological fabric. Topology is used most fundamentally to ensure data quality (e.g., no gaps or overlaps between polygons representing land parcels) and allow a GIS to more realistically represent geographic features. Topology allows one to control the geometric relationships between features and maintain their geometric integrity.

Foundations

Topological data structures for representing geographic information are a standard topic in geographic information science (see [6], for example, for an excellent definition of the mathematical theory underlying this information model). In general, the topological data model represents spatial objects (point, line, and area features) using an underlying set of topological primitives. These primitives, together with their relationships to one another and to the features, are defined by embedding the feature geometries in a single planar graph. Such datasets are said to be "topologically integrated."

The model associates one or more topological primitives (i.e., nodes, edges, and faces; or 0-cells, 1-cells, and 2-cells in the TIGER parlance) with spatial objects of varying geometry type (i.e., points, lines, and polygons respectively). More specifically, a feature with point geometry is associated with a single node element, a feature with line geometry is associated with one or more edge elements, and a feature with polygon geometry is associated with one or more face elements. This is depicted in Fig. 1 as the generic topology model.

There are additional relationships between the topological elements themselves as is also shown in Fig. 1. A node element may or may not be associated with a collection of edge elements. A face element may be associated with one or more edge elements. Finally, an edge element is associated with two node elements and two face elements. The relationships between nodes and faces may either be implicit or explicit.



Topological Data Models. Figure 1. Generic topology model.

The common representation of a topology is as a collection of topological primitives – i.e., nodes, arcs, and faces, with explicit relationships between the primitives themselves. For example, an arc would have a relationship to the face on the left, and the face on the right. With advances in GIS development, an alternative view of topology has evolved. Topology can be modeled as a collection of rules and relationships that, coupled with a set of editing tools and techniques, enables a GIS to more accurately model geometric relationships found in the world.

Topology, implemented as feature behavior and user specified rules, allows a more flexible set of geometric relationships to be modeled than topology implemented as a data structure. For example, older data structure based topology models enforce a fixed collection of rules that define topological integrity within a collection of data. The alternative approach (feature behavior and rules) allows topological relationships to exist between more discrete types of features within a feature dataset. In this alternative view, topology may still be employed to ensure that the data forms a clean and consistent topological fabric, but also more broadly, it is used to ensure that the features obey the key geometric rules defined for their role in the database.

Topological data structures, beginning with DIME in 1967 [3] have been used to represent features assembled into a topological fabric in a number of different ways over the past 40 years. In the following, the seven or so significant variants that have emerged during this period are described.

DIME Files

The US Census Bureau, as part of the New Haven Census Use Study of 1967, undertook the development of an explicit topological data model for their geographic data [3]. This system was called DIME (for Dual Independent Map Encoding) and was intended to facilitate the automation of detecting topological errors in the base geographic data. DIME files were based upon planar line segments defined by two endpoints. The line segments correspond to the Street Segment records as shown in Fig. 1. Each street segment was associated with a start and end node identifier (endpoint), left and right side block and tract identifiers, as well as an address range. Drawbacks of the DIME model include the need to perform searches in order to assemble polygons from the street segment records, or to determine all the segments sharing a given node.

In Fig. 2, Main Street is represented as a collection of four records in the Street Segment Records. Each (line) segment is defined by two end points (there are no midspan shape points for the segment). The segment is associated with the start and end node, identifiers for the blocks and tracts on the left and right sides of the segment, as well as the low and high address ranges for each side of the segment. In addition, it is assumed that the segments are planar – segments may not cross each other.

The "dual independent" portion of the DIME model reflects the redundant nature of how the topology is represented. Topological fabrics can be represented using the collection of relationships between edges and nodes, or nodes and faces, or faces and edges. With DIME, the topological correctness may be verified using either block chaining or node chaining. Block chaining involves finding all the segment records that have a given block on the left or right side. By rearranging the from/to orientations of each segment (and the associated left/right oriented attributes) such that the block is on the right side of each segment, it is possible to chain the nodes. This involves walking from the "to node" of one segment to the "from node" of another segment, continuing until all segments are visited. If there is a topological problem, it will not be possible to chain the blocks in this manner [2].

Due to the dual nature of DIME, it is also possible to chain the nodes in order to find topological -problems. Specifically, for a given node, select all segments that have it as a "to" or "from" node. Then, after rearranging the from/to orientations of each segment such that the node is always in the "to node" position, one may chain all the blocks surrounding the node (moving from the "block right" record in one segment to the "block left" record in another segment). Thus, because of the dual independent encoding of DIME, one may use two independent mechanisms to detect topological problems.

POLYVRT

The Harvard Laboratory for Computer Graphics and Analysis developed a topological data structure, termed POLYVRT, that was intended to serve as a data structure to facilitate interchange between various other data models [14]. POLYVRT extended the representational capabilities of DIME to allow planar segment chains to exist between nodes. This allowed line detail to be efficiently handled. In addition, POLYVRT enables the user to readily flip between segment chains and polygons.

Topological Data Models. Figure 3. Example of the POLYVRT approach to storing topology.

Figure 3 contains an analogous example as shown in Fig. 2 but using the POLYVRT representation as well as adding shape points to various segments (e.g., segments 344, 399, and 433). A POLYVRT chain record contains a unique identifier, a pointer to the shape points (termed Points), identifiers of the from and to nodes, and identifiers of the polygons on the left and right sides. Records in the nodes table contain a unique identifier and an (x, y) coordinate value. Entries in the Polygons table have a unique identifier and a pointer to a list of all associated chains that compose the boundary of the polygon (e.g., for polygon 4, the list contains chains 344, 222, 399, 433, and 446).

GIRAS

GIRAS (Geographical Information Retrieval and Analysis System) was developed by the US Geological Survey the mid 1970s [11]. The GIRAS topological data structure was motivated by the need to represent polygonal data. In addition, it was determined that it was more efficient to store certain types of data rather than recompute it. As a consequence, a large amount of ancillary data such as polygon perimeter and area was explicitly stored in the data structure. The data structure was based upon arcs and was considered a direct descendent of DIME and POLYVRT due to its topological similarities.

Figure 4 contains the same example dataset as shown in Figs. 2 and 3 except using the GIRAS topology model. The GIRAS model differs from DIME and POLYVRT as various attributes unrelated to storing the topology are maintained. This includes the length as well as bounding rectangle information for the Arc records (Length, MinXY, and MaxXY). In addition, the Arc records store the attribute codes of the left and right polygons (this is not represented in the figure). The Polygon records similarly store the area and perimeter of the polygon, the bounding rectangle information, as well as the attribute code and the island count (number of islands found within the polygon). Note depicted in the figure is the identifier of the enclosing polygon if the polygon serves as an island to another polygon. Finally, there are structures for representing the vertex coordinates of the arcs (e.g., LastCoord in the Arc Records table), as well as another structure that maps arcs to polygons (the FAP file in GIRAS).

TIGER

TIGER (Topologically Integrated Geographic Encoding and Referencing) was developed by the US Census Bureau during the 1980s as an evolution of the earlier DIME-file model [9]. New features and capabilities were added (e.g., curve points for linear features) to the model in order to create a comprehensive system that could support all of the various censuses. TIGER was first used for the 1990 Census of Population and Housing.

Topological Data Models. Figure 4. Example of the GIRAS approach to storing topology.

The topology model within TIGER was based upon the two dimensional network model of Corbett [6]. This model used three topological primitives termed 0, 1, and 2-cells (analogous to nodes, edges, and faces in other topological data models).

Figure 5 contains the same example dataset as shown in Figs. 2–4 except using the TIGER topology model (note – some liberty has been taken as in reality, the entries in the list tables are all consecutively numbered – this is not necessarily shown here; e.g., the file position in the C1RALS table). Within TIGER, 0 and 2-cells may be accessed via a directory mechanism. In the figure, the directory for 0-cells is shown (termed C0DIR). This directory contains a record for each 0-cell in the 0-cell List table (C0RALS). The directory entries are sorted by a simple Peano key (an alternating bit merging of longitude and latitude values for the associated point); this enables nearest point queries, etc. Each record in the directory table references a 0-cell in the 0-cell List table. The 0-cell List table is not geographically sorted. The 0-cell entries contain the x, y coordinate value of the point, and a pointer to the 1-cell List table (C1RALS) for the lowest value 1-cell (according to the file position) that is associated with the 0-cell at an endpoint. The entries in the 1-cell List table contain back-pointers to the from and to 0-cells, as well as threading pointer to other 1-cell records that enable a counter-clockwise traversal of all 1-cells associated with a given 0-cell (note that the last record in the thread contains a terminator – "EOT" in the figure). The 1-cell records also contain references to the 2-cells (faces) on the left and right sides as well as threading pointers to other 1-cells that enable the traversal of all 1-cells associated with a 2-cell. Finally, the 2-cell List (or C2RALS) table contains an entry for each 2-cell. Each entry contains a reference to the first 1-cell found in the C1RALS table that is associated with the 2-cell.

ARC/INFO Coverages

The motivating requirements behind the development of the ARC/INFO Coverage model were a model that had a strong theoretical basis (topology), as well as simplicity and efficiency (e.g., ability to support efficient geoprocessing functions such as polygon overlays and dissolves) [12].

The Coverage topological data model uses a collection of tables. End users are responsible for populating the ARC and LAB files. The entries in the ARC file correspond to line segments with optional attributes. In Fig. 6, the shaded portions of the ARC file correspond to system generated fields. Thus, the user specifies the user id field along with the shape (geometry) as well as any attributes. End users are also responsible for populating entries in the LAB (for label) file. Each label is used to specify the attributes

that will be associated with a polygon in the topology. Following the population of the ARC and LAB files, the user will perform a topological integration and structuring of the data. The result of this is the population of the Arc Attribute Table (AAT) and the Polygon Attribute Table (or PAT). In addition, other fields in the ARC file are populated (i.e., the FNODE, TNODE, LPOLY, and RPOLY). There are other tables that form the Coverage data model that are not depicted in Fig. 6 (e.g., the Polygon Arc List, or PAL file) that provide additional explicit topological relationships.

Relational

Many topological data models stored in relational databases utilize a storage representation that relies upon a fixed length record. The winged-edge data structure [1], a fixed-length storage representation for representing the relationships between nodes, edges, and faces, simplified the task of representing

Topological Data Models. Figure 7. Example of an edge and its four wings in the winged-edge data structure of Baumgart.

explicit topological data models within a relational database system. The edge record is the primal structure in this representation. For each edge, the identifiers of the start and end nodes (termed *node*$_{prev}$ and *node*$_{next}$ in Fig. 7), and the two faces, one in the clockwise traversal orientation (*face*$_{cw}$), and the other in the counterclockwise orientation (*face*$_{ccw}$) are represented. Finally, identifiers of four connected edges, two at each node, are stored. The four edges correspond to the previous and next edges found when traversing the two adjacent polygons in the clockwise (*edge*$_{pcw}$ and *edge*$_{ncw}$) and counterclockwise (*edge*$_{pccw}$ and *edge*$_{nccw}$) orientations.

A topological data model can be stored in a relational database. The topology model is represented using three tables – an edge table, a node table, and a face table. The edge table is essentially encoding the winged-edge data structure in addition to the geometry of the portion of the feature associated with the edge. The edge table utilizes negative identifiers to encode the orientation of the four edges found at the start or end nodes.

ArcGIS Geodatabase

The ArcGIS Geodatabase approach to modeling topology represents it as a collection of rules and relationships, coupled with a set of editing tools and techniques [8]. With the standard models (e.g., TIGER, Relational, etc.), it is possible to obtain topological primitives from feature geometry; similarly, it is possible to obtain feature geometry from topological primitives. Effectively, the geometry found in features is a dual representation of the geometry that would be found on the topological primitives. This topology model simplifies the generic explicit topology model and does not need to make both representations persistent. The process of topological integration (validation) results in vertex equality where features share underlying topological primitives. Given vertex equality, reconstruction of topological primitives is straightforward. Vertices on feature geometries in this scheme play the same role as that assigned to embedded foreign keys in data structures that explicitly model topological primitives.

Topological primitives and relationships are only instantiated during the process of topological validation or when required by the client application (this is similar to Intergraph's MGE where topology is selectively built but the topological primitives are not persisted in the RDBMS). The primary reason for this alternative approach is that it is easier (faster, more scalable) to recreate an index (e.g., the topological primitives) than to do all the bookkeeping necessary to make the topological primitives persistent and retrieve the primitives from the database while preserving the database transaction model. Additionally, it is frequently the case that the portion of the topological primitives necessary for an operation is small relative to the entire topology (e.g., editing a few block groups in a localized area within TIGER).

In order for this approach to be viable from a performance standpoint, it is critical that there exists a high performance topology engine that validates the portion of the topology in question as well as instantiate the topological primitives for the given collection of features within the topology [15].

At a high level, this topology model consists of a collection of feature classes (homogeneous collections of features), topology rules, and other metadata used to support the validation model. This metadata includes dirty areas (areas that have not been validated following updates or edits), topology errors, and the cluster tolerance (i.e., the distance range in which vertices and boundaries are considered identical or coincident). Topological integrity is defined with respect to a collection of topology rules. Topology rules are used to define constraints on the permissible topological relationships between features in one or more feature classes that participate in the topology. The collection of topology rules that are associated with the topology are selected on the basis of which topological relationships are important for the user's model.

The validation process is a fundamental operation on a topology performed by a topology engine. The validation process on a topology is responsible for ensuring that the first three of Milenkovic's five normalization rules [10] on all spatial objects participating in the topology are respected:

1. No two vertices are closer than ε.
2. No vertex is closer than ε to an edge of which it is not an endpoint.
3. No two edges intersect except at their endpoints.

In addition, the validation process is responsible for checking all specified topology rules and generating topology errors at locations where rules are violated.

Topology rules are checked when the topology is validated. When a topology rule is violated, a topology error object is generated. This topology error may be represented as a special type of feature that may itself be persisted. At a later point following the validation, the user may then review the topology error objects, and the error conditions may be corrected. Topology rule violations do not prevent the validation operation from completing successfully. Examples of topological rules that may be applied to polygon features include:

- The interiors of polygons in a feature class must not overlap (they may however share edges or vertices).
- Polygons must not have voids within themselves or between adjacent polygons (they may share edges, vertices, or interior areas).
- Polygons of one feature class must share all their area with polygons in another feature class (i.e., they must cover each other).

Key Applications

Cadastral databases, land use information systems, overlay processing, geoprocessing, topological analysis, dataset quality assurance/quality control (QA/QC).

Topological Relationships

Paolino Di Felice, Eliseo Clementini
University of L'Aguila, L'Aguila, Italy

Definition

Topological relationships describe qualitative properties that characterize the relative position of spatial objects. *disjoint, meet, overlap*, and *inside* are few examples (Fig. 1).

Topology is considered the most primitive kind of spatial information, since a change in topology implies a change in other geometric aspects, while the opposite is not true. Generally speaking, topological properties are those that do not change after transformations like rotation, translation, scaling, and rubber sheeting.

Historical Background

Topological relationships have been studied extensively in a number of diverse disciplines since the beginning of the 1990s, achieving theoretical results which have constituted the basis for the definition of most of the topological operators today being part of the SQL dialects supported by commercial DBMSs (e.g., IBM-DB2, Oracle, PostGIS/PostgreSQL, ...). The implementations are all based on the OpenGIS Consortium specifications [8] and ISO/TC 211 standard.

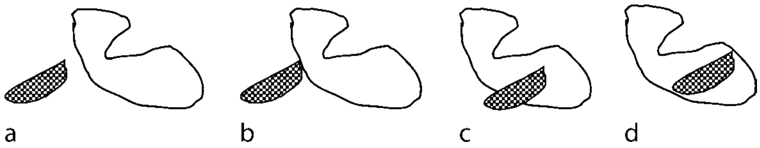
Foundations

The mathematical background behind the published contributions about topological relationships is constituted either by the *point set topology* or *spatial logic*. The study of topological relationships also depends on the embedding space, prevalently assumed to be the two-dimensional Euclidean space.

The major results that appeared in the literature can be clustered in the *three* main groups briefly discussed below.

Topological Relationships for Simple Objects

At the conceptual level, spatial objects can be modeled as *points*, *lines*, and *areas*. *Simple lines* are one-dimensional, continuous features embedded in the plane with two end points; *simple areas* are two-dimensional point sets topologically equivalent to a closed disc (Fig. 2).



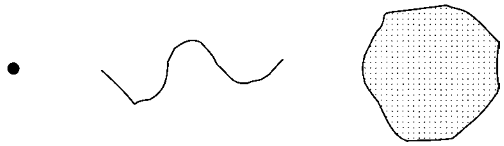
Topological Relationships. Figure 1. Examples of binary topological relationships between objects A and B (the biggest): (a) <A, *disjoint*, B>, (b) <A, *meet*, B>, (c) <A, *overlap*, B>, and (d) <A, *inside*, B>.

The two conceptual approaches, upon which almost all publications in this field have been based, are the *9-Intersection model* [5] and the *RCC model* [3]. Despite rather different foundations (the former relies on point set topology [6], the latter on spatial logic), both methods come to very similar results. Further relevant contributions belonging to this group are: [1,2,4].

The model proposed, in 1991, by Egenhofer and Franzosa, [4], for classifying topological relationships between pairs of 2D area features represents the starting point of the research in the field and the basis for the efficient implementation of the theory on top of commercial query languages [10]. Their classification is based on the cross intersection of the boundaries and interiors of the two features. The four values are collected into a two-by-two matrix, called the 4-intersection; while the approach is called the *4-IntersectionMethod* (4IM).

Topological Relationships for Complex Objects

An important advancement of the results about topological relationships, with respect to those based on the assumption of simple objects, was achieved by extending the definitions of point, line, and area, in order to take into account finite sets of isolated points as a single complex point feature, lines having separations, more than two end-points, and possibly self-intersections, and, finally, complex areas having both separations and holes (Fig. 3). In the reality, complex features are far more common than simple ones: [1,11].



Topological Relationships. Figure 2. Examples of a simple point, a simple line, and a simple area.

Topological Relationships for Objects with Vague Boundary

The models belonging to the previous two groups are applicable only to features whose geometry is exactly known (often called *crisp* spatial objects). Examples of crisp objects are mainly man-made artifacts like land parcels, buildings, and roads. But the reality reveals that the boundaries and extent of most spatial objects cannot be precisely determined. Examples of non-crisp features are: population density, vegetation, oceans, clouds, soil type, Spanish speaking areas, etc.

Three main alternatives have been proposed to model non-crisp spatial objects:

1. Models based on *fuzzy sets*. They allow a fine-grained modeling of vague spatial objects but are computationally rather expensive with respect to data structures and algorithms.
2. Models based on *rough sets*. They work with lower and upper approximations of spatial objects.
3. Models based on *crisp spatial objects*. They extend data models, type systems, and concepts for crisp spatial objects to vague spatial objects.

A discussion of the differences of these approaches can be found in [9], together with links to pertinent references.

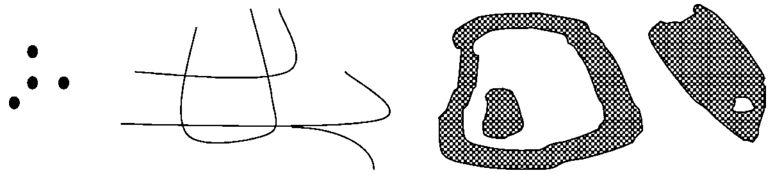
Table 1 summarizes the different subfields in the study of topological relationships discussed above.

Key Applications

The following applications are some examples among the many that benefit from dealing with topological relationships.

Geographic Information Systems (GISs)

Topological queries are relevant when dealing with spatial data. Today's GIS applications use a huge amount of spatial data. Formal models and efficient algorithms are of primary importance to reach optimal solutions.



Topological Relationships. Figure 3. Examples of a complex point, a complex line, and a complex area.

Topological Relationships. Table 1. The different subfields behind the study of topological relationships

Geometry	Boundary
Simple	Crisp
	Vague
Complex	Crisp
	Vague

Qualitative Spatial Reasoning (QSR)

Topological relations capture the everyday commonsense knowledge of space. QSR makes this knowledge explicit, so that, given appropriate reasoning techniques, a computer can make predictions about spatial relations in a qualitative manner, without recourse to an intractable or unavailable quantitative model [3].

Geospatial Semantic Web (GSW)

The Geospatial Semantic Web has become one of the most prominent research themes in geographic information science. In fact, the wide availability of geo-referenced data on the web would make it possible to index and query information based on the spatial attributes. This approach would be facilitated by using qualitative spatial relations, such as topological relations, since people are much more inclined to query web pages through natural language, instead of metric measurements.

Future Directions

Despite of the huge amount of theoretical studies about topological relationships done so far, there is still a lot of work to be done.

For example, the mapping of the topological relationships into operators to be included in future releases of spatial query languages, as well as the development of processing strategies for their efficient evaluation are still open issues. A notable contribution in this direction is constituted by a very recent paper by Praing and Schneider, [10].

Furthermore, major attention needs to be paid with respect to complex objects characterized by uncertainty in order to: a) identify suitable spatial data types for their modeling, b) design a minimal set of operations and predicates defined on top of them, and c) proceed to their integration into the query language of existing DBMSs.

Experimental Results

The IBM DB2 UDB system supports the modelling and the management of spatial data through the so-called *Spatial Extender* (briefly, SE) subsystem [7] which is fully conformant with the OGC Simple Features Specification for SQL [8], starting with version 8.2.

DB2 SE supports four different spatial data formats: a) Well-known text (WKT) representation, b) Well-known binary (WKB) representation, c) Shape representation, and d) Geography Markup Language (GML) representation.

Table below provides two examples according to the WKT text representation (the numerical values represent X-Y coordinates).

Geometry type	WKT representation	Comment
Point	`point(10,20)`	A 2D point
Polygon	`polygon((0 0,0 40,40 40,40 0,0 0))`	A 2D polygon

`{ST_Geometry, ST_Point, ST_LineString, ST_Polygon, ST_GeometryCollection, ST_MultiLineString,ST_MultiPolygon ST_MultiPoint}` is the set of geometric data types being part of the SQL/DDL language running under DB2 SE.

DB2 SE implements a long list of spatial functions conceptually grouped into five macro-categories: a) *data exchange format functions, b) comparison functions, c) functions that return information about properties of geometries, d) functions that derive new geometries from existing ones, and e) miscellaneous functions.* The *comparison functions* implement the topological operators.

In order to give the flavour of how they look like and how easily they can be called as part of SQL statements, a spatial database storing descriptive and spatial data about sites of interest and counties is taken into account.

The SQL/DDL scripts below provide the definition of the corresponding tables according to the DB2 SE syntax:

```
CREATE TABLE sitesOf_interest (id SMALLINT, geometry ST_POINT);
CREATE TABLE counties (id SMALLINT, geometry ST_POLYGON);
```

The SQL/DML scripts below insert 1 and 2 tuples into the previous tables, respectively:

```
   INSERT INTO sitesOf_interest (id,
geometry)
   VALUES (1, ST_Point(10,20,1)), (2,
ST_Point(41,41,1));
   INSERT INTO counties (id, geometry)
   VALUES (100, ST_Polygon('polygon ((0 0,0
40,40 40,40 0,0 0))', 1));
   INSERT INTO counties (id, geometry)
   VALUES (200, ST_Polygon('polygon ((1 1,1
40,40 40,40 1,1 1))', 1));
```

Notice that 1 identifies the *spatial reference system* for the resulting geometry.

The (incomplete) list of available *topological operators are:*

```
   ST_Disjoint, ST_Touches, ST_Equals,
ST_Contains, ST_Overlaps, ST_Crosses, etc.
```

An example of SQL usage of ST_Contains follows: Syntax:

```
   ST_Contains(geometry1,geometry2)
```

Meaning:

`ST_Contains` returns `1 if geometry1` contains `geometry2, 0` otherwise.

The query: *Determine the counties where the points of interest are located in.*

```
   SELECT poly.id AS polygon_id, pts.id AS
   point_id
   FROM sitesOf_interest pts, counties poly
   WHERE ST_Contains (poly.geometry, pts.
   geometry)
```

In summary, RDBMSs with spatial extensions like those featured by the IBM DB2 SE are:

- Reach of data types and functions to deal with geometry. This extends significantly the expressiveness of the relational data model and of SQL. It follows that writing ad hoc applications in high level programming languages, to make spatial analysis, is much easier than before
- Not problematic to be used for people accustomed to use SQL

Traditional Concurrency Control for Replicated Databases

Bettina Kemme
McGill University, Montreal, QC, Canada

Synonyms

Traditional replica and concurrency control strategies; Traditional data replication

Definition

Since the beginnings of distributed computing, the database community has developed strategies for replicated data management. The basic idea is that each "logical" data item has one or more physical data copies, also called replicas, that are distributed across the database servers in the system. Early work on data replication provided a framework to describe transactions in a replicated environment and developed concurrency control mechanisms to control their execution. The formalism and the techniques developed in this early work have been the foundations for much of the further research on database replication. It considered strong consistency requirements where the replicated system behaves similar to a non-replicated system. *Replica control* was introduced as the task of translating the read and write operations of transactions on logical data items into operations on the physical data copies. One-copy-serializability was developed as a first – and very strong – correctness criterion defining when the concurrent execution of transactions in a replicated system is equivalent to a serial execution of these transactions over a single logical copy of the database. Replica control was combined with *concurrency control mechanisms* in order to provide one-copy-serializable transaction execution.

Historical Background

Replication became a hot topic in the early 1980s. In their book "Concurrency Control and Recovery in Database Systems" [2], Bernstein et al. presented a thorough formalism to reason about the correctness of transaction execution and concurrency control mechanisms in central, distributed and replicated database systems. Their definitions of serializability and one-copy-serializability (1SR) are still used to reason about the correctness of transactional systems. Early work on replication took as baseline concurrency control strategies used in non-replicated or distributed databases, extended them and combined them with replica control in order to provide one-copy-serializability [2,3]. Furthermore, the correctness of execution despite site or communication failures has been analyzed thoroughly [1,4]. Work done in this early phase is very visible in textbooks on database systems and distributed systems [6], and builds part of the foundations of academic education in this area. In 1996, Gray et al. [5] indicated that these traditional approaches provide poor performance and do not scale as they commit transactions only if they have executed all their operations on all (available) physical data copies. Many advanced replication schemes have been developed since then. Nevertheless, they reuse many of the base techniques developed in the traditional replication algorithms.

Foundations

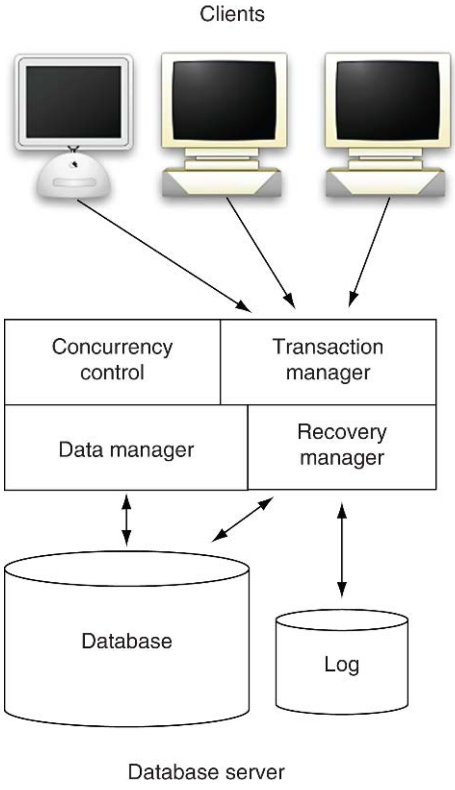
Transactions in a Non-Replicated System

The formalism that describes transactions and their execution in a replicated database is derived from the transaction model in a non-replicated system. In a non-replicated system, a database consists of a set of data items x,y,... . A transaction T_i is a sequence of read operations $r_i(x)$ and write operations $w_i(x)$ on data items that build a logical unit. The database system should provide the transactional properties atomicity, consistency, isolation and durability (see the entry *ACID properties*). Among them, atomicity and isolation require actions in a replicated system that go beyond the tasks in a non-replicated system.

Atomicity means that a transaction T_i either terminates with a commit operation (indicated as c_i) and all its write operations remain effective in the database, or with an abort operation (indicated as a_i), in which case all already executed write operations are undone before the transaction terminates.

Isolation requires that even if transactions execute concurrently in the system, each transaction should have the impression it executes isolated on the data. In particular, when two operations conflict, i.e., they are from different transactions, want to access the same data item and at least one is a write, the execution order matters. Given a set of transactions, a history describes the order in which the database server executes the operations of these transactions. The traditional correctness criterion in a non-replicated system is *serializability.* It requires a history to be equivalent to a serial history where the same transactions are executed serially one after the other. Equivalence typically refers to executing all conflicting operations in the same order.

The execution of transactions is controlled by several components of the database system (see Fig 1). The client starts a transaction and then submits the individual operations of the transaction (including a final commit or abort request). These requests are intercepted by the transaction manager which keeps track of active transactions. The individual read and write operations are forwarded to the concurrency control module that controls when operations are executed by the data manager in order to provide serializability. The recovery manager makes changes persistent at commit time or triggers undo operations in case of abort. In real database systems, clients submit SQL statements that can access and manipulate many records of different tables. However, the abstraction into simple read and write operations on data items allows for a clear and powerful reasoning framework.



Traditional Concurrency Control for Replicated Databases. Figure 1. Transaction components in non-replicated database systems.

Transaction Execution in a Replicated System

In a replicated database, there is a set of database servers *A*, *B*,..., also referred to as sites, and each logical data item *x* has a set of physical copies x^A, x^B, ... where the index refers to the server on which the copy resides. In full replication, each data item has a copy on each server, while using partial replication, it has only copies on a subset of the servers.

Execution Model As replication should be transparent to clients they continue to submit operations on the logical data items. Replica control has to map an operation $o_i(x)$, $o_i \in \{r,w\}$, of transaction T_i into operations on the physical copies of *x*, e.g., $o_i(x^A), o_i(x^B), \ldots$. Given the mapping for a set of transactions, when executing these transactions in the replicated system each database server *A* produces a local history showing the execution order of all the operations performed on the copies maintained by *A*.

The most common execution model for transactions in a replicated environment is to perform a read operation on one data copy while write operations update all copies. This is referred to as ROWA (or read-one-write-all). As most database applications typically have more read than write operations is makes sense to provide fast read access and only penalize write operations.

A problem of ROWA is that if one copy is not accessible, write operations cannot be performed anymore on the data item. In order to be able to continue even if failures occur, ROWAA (read-one-write-all-available) needs to be used. It does not require to perform updates on copies that are currently not available. An alternative are quorum protocols that require both read and write operations to access a quorum of copies.

Isolation One-copy-serializability was the first correctness criterion for replicated histories. The execution of a set of transactions in a replicated environment is one-copy-serializable if it is equivalent to a serial execution over a single, non-replicated (logical) database. Defining equivalence is not straightforward since the replicated system executes on physical copies while the non-replicated on the logical data items. The handling of failures further complicates the issue.

Atomicity Guaranteeing atomicity in a replicated system requires that all sites that have performed operations on behalf of a transaction agree on the outcome (commit or abort) of a transaction. Traditional replication solutions typically achieve atomicity by running a commit protocol at the end of a transaction. Commit protocols, such as the Two-Phase-Commit Protocol, are a special form of agreement protocol in a distributed system. The challenge here is to define a protocol that works correctly in the presence of crash and network failures.

This entry does not further look at failures but focuses on providing isolation in a ROWA system.

Replica and Concurrency Control in a Replicated System

There are many ways to distribute concurrency and replica control tasks across the system. Figure 2a shows a centralized architecture. Each individual server is only responsible for data and recovery management. Additionally, there is one central transaction manager, one concurrency control module and one replica control module in the system. Together, they control the execution of all operations in the system. They could be all located in one of the data servers, or, as shown in the figure, in a special middleware. Figure 2b shows a distributed architecture where each site has its own transaction manager, concurrency and replica control modules. Decisions on where and when to execute operations are made locally at each site. A hybrid approach is shown in Fig 2c. Each database server has its traditional transaction and concurrency control modules. A middleware layer controls transactions globally and performs replica control. It relies partially on the concurrency control modules of the individual servers. As this might not be enough for a globally correct execution, the middleware performs some additional scheduling. Other combinations of distribution are also possible.

Given a concurrency control mechanism developed for a non-replicated system, there exist many ways to extend it to a replicated system. The following depicts a few examples.

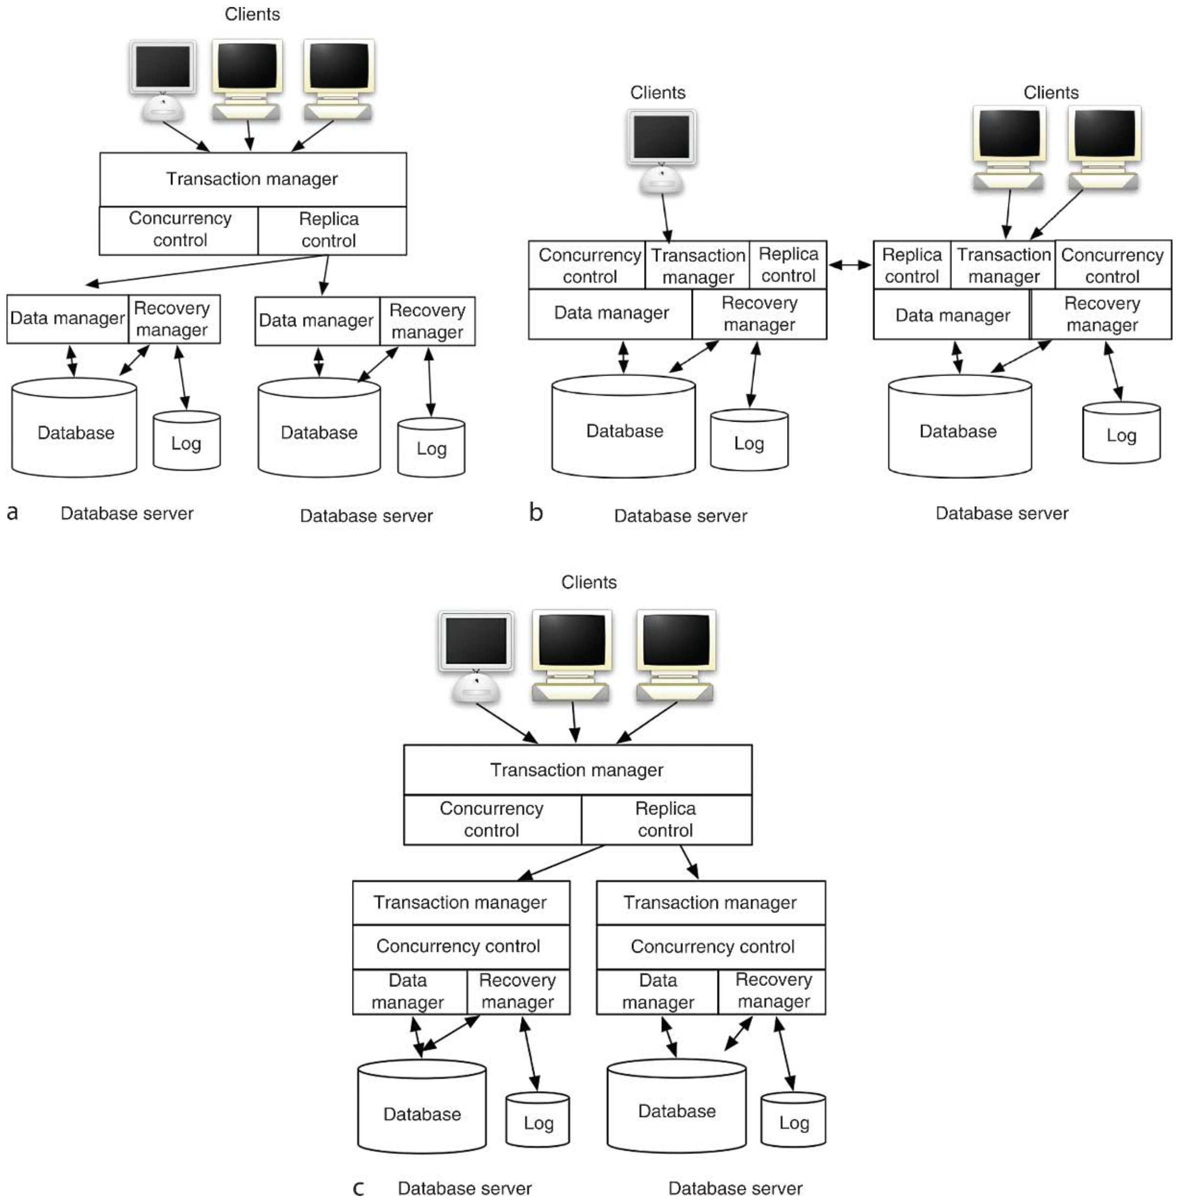
Strict Two-Phase Locking (S2PL) is probably the best known concurrency control mechanism. In this case, the concurrency control module implements a lock manager. Using S2PL, a transaction has to acquire a shared lock on data item x before performing a read on x, and an exclusive lock on x before writing x. An exclusive lock on x conflicts with other shared and exclusive locks on x. If a transaction requests a lock and another transaction holds a conflicting lock, the requesting transaction has to wait. Only when a transaction terminates it releases all its locks, which then can be granted to waiting transactions. S2PL guarantees serializability because the order in which locks are granted for the first pair of conflicting operations between two transactions determines the serialization order. Deadlocks can occur. A deadlock involving two transactions can happen if the transactions have two pairs of conflicting operations and execute them in different order.

Applying S2PL in a replicated system with a centralized architecture (Fig 2a), clients submit theiroperations to the global transaction manager. The transaction manager gets the appropriate lock via the lock manager and then the replica control module transfers each read operation to one database server with a copy of the data item, and write operations to all servers with copies. In the distributed architecture (Fig 2b), a client connects to any site. The execution of individual operations is illustrated in Fig 3a. The figure shows the message exchange between a client and two sites. When the client submits a read operation on logical data item x to the local server A, a local shared lock is acquired on the local physical copy ($sl(x^A)$) and the read operation executes locally. If it is a write operation, an exclusive lock (xl (x^A)) is acquired locally and the operation executes locally. At the same time, the operation is forwarded to the server B. B, upon receiving the request, acquires a lock on the local copy, performs the operation, and sends a confirmation back to A. When A has received all confirmations, it sends the confirmation back to the client.

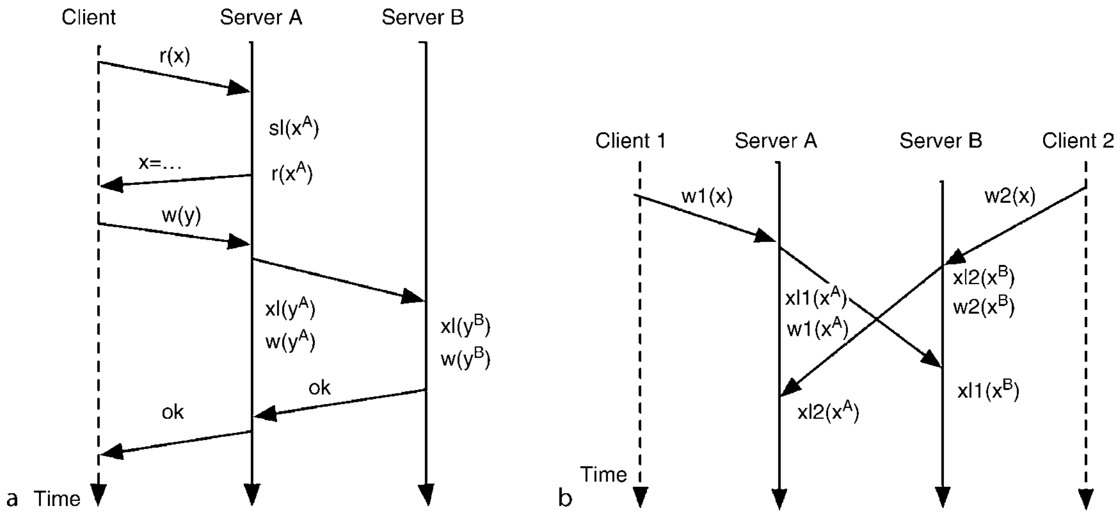
Architectural Comparison Comparing how well S2PL maps to the two architectures reflects well the principle trade-offs between a centralized and a decentralized architecture.

In favor of a centralized architecture. In principle, a central component makes the design of coordination algorithms often simpler. It directs the flow of execution, and has the *global knowledge* of where copies are located. One central concurrency control module serializes all operations. In the distributed architecture, the flow of execution is more complex as no single component has the full view of what is happening in the system.

While the centralized architecture acquires one lock per each operation on a logical data item, the distributed architecture acquires locks per data copies. Thus, a write operation involves many exclusive locks, adding to the complexity. The distributed architecture has the additional disadvantage of potential *distributed deadlocks*: there is no deadlock at any site locally but globally, a deadlock has occurred. Figure 3b depicts an example execution where a distributed deadlock occurs although the transactions both only access a single data item (something not even possible with the centralized architecture). *T*1 first acquires the lock on server *A* which forwards the request to server *B*. Concurrently,



Traditional Concurrency Control for Replicated Databases. Figure 2. Concurrency Control and Replica Control Architecture.



Traditional Concurrency Control for Replicated Databases. Figure 3. Distributed Transaction Execution.

*T*2 acquires the lock first on *B* and then requests it on *A*. At *A*, *T*2 has to wait for *T*1 to release the lock, on *B*, *T*1 waits for *T*2. The deadlock is distributed since no single server observes a deadlock. Such deadlocks need to be resolved via timeout or a deadlock detection mechanism, which in turn, could be implemented centrally or distributed.

In favor of a decentralized architecture. A central middleware is a potential bottleneck and a single point of failure. In contrast, in the distributed architecture, if ROWAA is used, the system can continue executing despite the failure of individual sites.

Furthermore, the middleware approach has an extra level of indirection. In the above example algorithm, this leads to four messages per read operation (a pair of messages between clients and middleware, and a pair between middleware and one database server). In contrast, the distributed architecture has two messages (between the client and one database server).

A further disadvantage is that the global controller does not have access to the data manager modules of the database servers. For example, assume clients submit SQL statements. The middleware cannot know what records will actually be accessed by simply looking at the SQL statement. Such information is only available during the execution. Thus, the central lock manager might need to set locks on the entire relation. In contrast, the distributed architecture can execute an SQL statement first locally, lock only the tuples that are updated, and then forward the update requests on the specific records to the other servers, allowing for a finer-grained concurrency control. Generally, a tighter coupling often allows for a better optimization.

Optimistic Concurrency Control A last example looks at optimistic concurrency control (OCC) [7]. In a non-replicated system, a write operation on *x* generates a local copy of *x*. A read on *x* either reads the local copy (if the transaction has previously written *x*) or the last committed version of *x*. At commit time of a transaction T_i, validation is performed. If validation succeeds, a write phase turns T_i's local copies into committed versions and T_i commits. Otherwise, T_i aborts. In the simplest form of OCC, validation and write phase are executed in a critical section. The validation order determines the serialization order. Therefore, validation of T_i fails if there is a committed transaction T_j that is concurrent to T_i (committed after T_i started), and T_j's writeset (data items written by T_j) overlaps with T_i's readset (data items read by T_i). As T_i validates after T_j it should be serialized after T_j, and thus, read what T_j has written. In the concurrent execution, however, it might have read an earlier version. Therefore, it needs to be aborted. Optimistic execution assumes conflicts are rare, and thus, it is sufficient to detect them at the end of transaction.

One possible implementation of OCC in a system using full replication uses the hybrid architecture of

Fig 2c. Upon the first operation of a transaction, the middleware starts a transaction and then executes all operations at one of the database servers. The local OCC of the server retrieves the latest committed versions and keeps track of local copies. At commit time the middleware retrieves the read- and writesets from the server at which the transaction executed, and performs validation. For that, it has to keep track of the writesets of previously committed transactions and use some timestamping mechanism to determine concurrent transactions. If validation succeeds, the write phase is triggered at all database servers with copies. Concurrency control is distributed: the middleware performs validation and ensures execution within a critical section while the local concurrency control is needed for the generation of local copies.

A distributed OCC strategy is proposed in [3]. It integrates validation into the commit protocol performed for atomicity. Therefore, a transaction can first execute completely locally at one database server and only at commit time communication takes place. This reduces the message overhead considerably.

Key Applications

Although the exact algorithms developed in this early phase of research are barely found in any system, the fundamental techniques behind the coordinated execution are used widely. For example, although few commercial solutions actually provide one-copy-serializability, the concept of ordering conflicting operations to some degree is common. Locking, timestamping, multi-version management, OCC, and distributed and centralized solutions are common place in the management of replicated data.

Experimental Results

Gray et al. [5] show that traditional approaches do not scale well. They analyzed the distributed locking approach and determined that the potential of deadlock increases quickly with the number of replicas in the system, the message overhead becomes too high, and transaction response times become too long. The goal of more recent research into replica and concurrency control has aimed at reducing the overhead by either providing lower levels of correctness or by developing more efficient ways to control the flow of execution in the system.

Trajectory

Ralf Hartmut Güting
University of Hagen, Hagen, Germany

Synonyms

Trajectory; Moving point

Definition

Representation of a time dependent position observed over some period of time. Usually represented as a polyline in a 3D (2D + time) space for an object moving in the 2D plane.

Key Points

Trajectories describe complete histories of movement; they are stored in *moving objects databases*, sometimes called *trajectory databases* in the literature.

When operations are included, a trajectory corresponds to a value of a *moving point* data type. Queries on databases containing trajectories can be formulated using *moving object languages*. When uncertainty about an object's precise position is taken into account, an uncertain trajectory [3] results which can be viewed as a kind of cylindrical volume in the 2D + time space. There exists a lot of work on indexing trajectories [2]. Querying for trajectories similar to a given one is also an important research area [1].

Transaction

Gottfried Vossen
University of Münster, Münster, Germany

Synonyms

Transaction; ACID transaction

Definition

A transaction is a tool for application programmers to delegate the responsibility for preventing damage to data from threats such as concurrent execution, partial execution, or system crashes to the database system software; at the same time, application programmers retain the obligation to think about the impact on data consistency of the code they are writing, when executed alone and without failures. From a programmer's perspective, the power of the transaction paradigm hence lies in the fact that it reduces the task of concurrent failure-aware programming of the entire system to that of correct sequential programming of each application program separately. The transaction concept offers the ACID properties (short for *atomicity, consistency preservation, isolation*, and *durability*) and materializes through concurrency control and recovery. It is nowadays used beyond database systems.

Key Points

Database *transactions* go back to the work of Gray et al. [3,4] in the mid-1970s. Their development has been driven by applications where programs run against data stored in a single database system or a collection of such systems. There are many threats to the overall dependability of a system formed as a combination of databases and application programs; database transactions deal with the threats from concurrent execution, from incomplete execution (e.g., due to crashes or cancelations), and from system crashes that lose information from volatile buffers that has not yet been saved. The problem itself has not only been recognized in the context of database applications [1], yet has finally been solved by the notion of a transaction.

The key point of a transaction is that it comes with system-guaranteed properties collectively known as the *ACID properties* which considerably simplify the development of OLTP applications in that application programs can safely ignore a major portion of the system complexity. In particular, application programs are completely freed up from taking care of the issues of *concurrency*, i.e., effects that may result from concurrent or even parallel program executions and especially data accesses, and of *failures*, i.e., effects that would result from program executions being interrupted at random points due to process or computer failures.

In order to make this work, database systems offer the transaction concept as well as *transaction management*, commonly broken down into *concurrency control* for the synchronization of concurrent access to common data objects from multiple transactions, as well as into *recovery* for being able to restore a consistent state of the database after a crash. From a conceptual point of view, transactions can be modeled in various ways, which essentially boil down to the *page model* as well as the *object model* [5], and they have evolved from an abstraction concept into a system mechanism nowadays offered beyond database systems [2]. The page model considers transactions and transaction management at the syntactic level of disk pages that can either be read or written, while the object model considers them at a level where the semantics of operations on database objects can be taken into account.

Transactions are executed in interleavings called *schedules* or *histories*, which need to satisfy a correctness criterion that commonly comes in a form of *serializability*. Serializability is based on the perception that serial executions are correct and hence tries to make a non-serial execution "look" as if it was run serially. Similar approaches can be applied to both page-model as well as object-model transactions.

Transaction Chopping

DENNIS SHASHA
New York University, New York, NY, USA

Definition

Transaction chopping is a technique for improving the concurrent performance of a database system by reducing the time locks are held. The idea is to break up each transaction into smaller "pieces," such that each piece executes as a transaction, but the effect is as if the original transactions executed serializably.

Key Points

Imagine an application that locks the entire database and then accesses a few rows in a table that does not fit into memory. If one looked at the resource statistics, one would find low CPU consumption and low disk utilization, yet the throughput would be very bad. For example, if ten pages were accessed even at 1 ms per page, then throughput would be only 100 transactions per second. The point is that it is possible to slow down performance greatly just because of a poor locking strategy, even if there are plenty of resources.

One might consider a less extreme case: a transaction that processes an order. The transaction might check whether there is sufficient cash available, then add the appropriate quantities to inventory, subtract the value from cash, and commit the transaction. Because any application that invokes this transaction will access the "cash" data item, that data item may become a bottleneck. Transaction chopping is a technique for circumventing such bottlenecks by dividing transactions into smaller transactional pieces that will hold locks for only a short time, yet still preserve the serializability of the original transactions.

Assumptions

Transaction chopping makes the following main assumptions: (i) One can characterize all the transactions that will run in some time interval. The characterization may be parameterized. For example, one may know that some transactions update account balances and branch balances, whereas others check account balances. However, one need not know exactly which accounts or branches will be updated. (ii) The goal is to achieve the guarantees of serializability, while obtaining as much concurrency as possible. That is, one would like either to use degree 2 isolation, snapshot isolation, or to chop transactions into smaller pieces. The guarantee should be that the resulting execution be equivalent to one in which each original transaction executes serializably. (iii) If a transaction makes one or more calls to rollback, one knows when these occur and can arrange the transaction to move them towards the beginning.

Basic Definitions

A *chopping* partitions each T_i into *pieces* $c_{i_1}, c_{i_2}, \ldots c_{i_k}$. Every database access performed by T_i is in exactly one piece. A chopping of a transaction T is said to be *rollback-safe* if either T has no rollback statements or all the rollback statements of T are in its first piece. The first piece must have the property that all its statements execute before any other statements of T. This will prevent a transaction from half-committing and then rolling back. All transactions should be *rollback-safe*. Each piece will act like a transaction in the sense that each piece will acquire locks according to some standard method that guarantees the serializability of the piece.

For example, suppose T updates an account balance and then updates a branch balance. Each update might become a separate piece, acting as a separate transaction.

Correct Choppings

One may characterize the correctness of a chopping with the aid of an undirected graph having two kinds of edges. (i) *C edges*: C stands for *conflict*. Two pieces p and p' from different original transactions conflict if there is some data item x that both access and at least one modifies. In that case, one draws an edge between p and p' and label the edge C. (ii) *S edges*: S stands for *sibling*. Two pieces p and p' are siblings if they come from the same transaction T. In this case, draw an edge between p and p' and label the edge S.

The resulting graph is called the *chopping graph*. (Note that no edge can have both an S and a C label.) A chopping graph has an *SC-cycle* if it contains a simple cycle that includes at least one S edge and at least one C edge. A chopping of $T_1, T_2, \ldots, T_n$ is *correct* if any execution of the chopping is equivalent to some serial execution of the original transactions. "Equivalent" is in the sense of the serializability entry.

Theorem 1: *A chopping is correct if it is rollback-safe and its chopping graph contains no SC-cycle.*

Theorem 1 shows that the goal of any chopping of a set of transactions should be to obtain a rollback-safe chopping without an SC-cycle.

Conclusion

Transaction chopping is a method to enhance concurrency by shortening the time a bottleneck resource is held locked. It works well in practice and the theory extends naturally to snapshot isolation as well as read committed isolation levels.

Transaction Management

Gottfried Vossen
University of Münster, Münster, Germany

Synonyms

Concurrency control and recovery; Transaction scheduling; Transaction processing

Definition

Transaction management [2,6] refers to the tasks of processing multiple transactions issued by various clients of a database server in such a way that the ACID contract can be fulfilled, that is, the properties of *atomicity, consistency preservation, isolation,* and *durability* of each individual transaction can be guaranteed. Transaction management is generally understood as requiring serializability-based concurrency control as well as recovery from failures. Concurrency control is the task of scheduling transactions such that their serializability can be guaranteed, while recovery has to restore a consistent database state after a system or media failure. Assuming that the database server is in charge of the "C," the former guarantees the "I" in ACID, the latter the "A" and "D" properties. Transaction management has to be highly efficient, as modern transaction servers need to accommodate thousands of transactions per minute. This is achieved by a comprehensive combination and interplay of theoretical research and practical developments.

Historical Background

Transaction management emerged in the 1970s in early database management systems [5], and has become an indispensable part of a database server [1,3]. Its goal is to devise efficient algorithms for handling transactions, the essential "contract" between an application program and transactional server that combines a number of requests to the server into a logical unit. Over the years, transaction management has received theoretical underpinnings as well as system implementations in various ways, the former of which have allowed it to extend beyond simple database objects (pages) [7]. Indeed, transaction management can essentially be "positioned" at any level of abstraction within the functional layers of a data server, where the price to pay for expressiveness typically is efficiency. Nevertheless, transaction management has also been extended into areas beyond database management, among them operating systems and, more recently, programming languages.

Foundations

To recognize the essence of what transaction management is about, consider the operation of a bank that uses a relational database to keep track of its account business. The database may contain a table *Accounts* which describes bank accounts in terms of their account id, associated customer name, identification of the respective bank branch, balance, and possibly other data. Transactions in the bank are either *withdrawals* or *deposits* (debit/credit transactions) applied to *Accounts*, and these operations are often combined into *funds transfers*, i.e., withdrawals from one account and immediate deposit into another. With a huge number of clients potentially issuing simultaneous requests to the bank's database server, a *concurrent* execution of multiple debit/credit transactions is mandatory in order to exploit the server's hardware resources and to achieve processing speeds acceptable to clients. Concurrently executing transactions are typically modifying the underlying database of the banking application (table *Accounts*) frequently. In order to be able to ignore the potential fallacies of this concurrency, each transaction would ideally be executed as if there were no other transactions, but that would mean no concurrency. This tradeoff between concurrency for the sake of performance on the one hand, and potential sequential execution for the sake of correctness on the other, is one aspect of transaction processing, formally captured through notions of *serializability* and reconciled by the *concurrency control techniques* of a transactional server.

Figure 1 illustrates that concurrency may indeed be tricky, since it may have a disastrous impact on the consistency of the underlying data. Consider two debit/credit transactions t_1 and t_2 that are concurrently executed and that are both operating on the same account x (which could be the account id). To distinguish the two different instances of the local variable "balance" that temporarily holds the value of the account balance, they can be referred to as "balance1" for transaction t_1 and "balance2" for t_2. The first transaction then intends to withdraw $30, the second transaction intends to deposit $20, and it is assumed that the initial account balance is $100. The table in Fig. 1 shows those

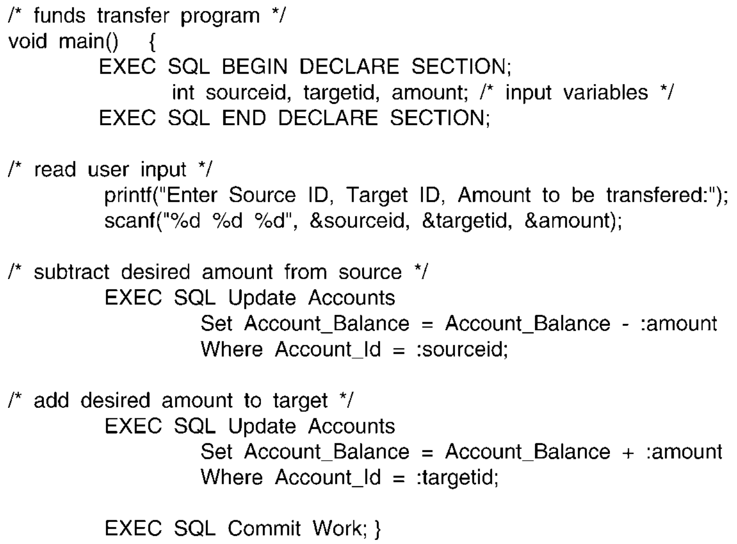
Transaction t_1	Time	Transaction t_2
/* balance1 = 0, x.Account_balance = 100, balance2 = 0 */		
Select account_balance Int:balance1 from account Where account_Id = x	1	
/* balance1 = 100, x.Account_balance = 100, balance2 = 0 */		
	2	Select account_balance Int:balance2 from account Where account_Id = x
/* balance1 = 100, x.Account_balance = 100, balance2 = 100 */		
balance1 = balance1 - 30	3	
/* balance1 = 70, x.Account_balance = 100, balance2 = 100 */		
	4	balance2 = balance2 + 20
/* balance1 = 70, x.Account_balance = 100, balance2 = 120 */		
Update account Set account_balance = :balance Where account_Id = x	5	
/* balance1 = 70, x.Account_balance = 70, balance2 = 120 */		
	6	Update account Set account_balance = :balance2 Where account_Id = x
/* balance1 = 70, x.Account_balance = 120, balance2 = 120 */		

Transaction Management. Figure 1. Concurrent transactions requiring concurrency control.

parts of the two transactions that read and modify the account record. Upon completion of the execution, the balance of account *x*, as recorded in the persistent database, will be $120, although it should be $90 after execution of the two transactions. Thus, the recorded data are incorrect, a kind of "anomaly" must be prevented, and concurrent executions must be treated with care. Similar anomalies can arise from transaction failures.

A second fundamentally important point is that the various accesses a transaction has to perform need to occur *in conjunction*: Once a transaction has begun execution, its data accesses should look to the outside world as an atomic operation which is either executed completely or not at all. This property of atomicity should be guaranteed even in a failure-prone environment where individual transactions or the entire database server may fail at an arbitrary point in time. To this end, a transactional server needs to provide *recovery techniques* to cope with failures. In addition to ensuring transaction atomicity, these techniques also serve to ensure the *durability* of a transaction's effects once the transaction is completed. The scenario shown in Fig. 2 illustrates this. It shows a program which transfers a given amount of money between two accounts, by first withdrawing it from a source account and then depositing it in a target account. The program is described in terms of SQL statements embedded into a C program. It is assumed that the funds transfer program has started executing and has already performed the withdraw operation (i.e., the first SQL `Update`). If there is a hardware or software failure that interrupts the program's execution at this point, the remaining second update operation will not be performed. Thus, the target account will not receive the money.

A recovery procedure, to be invoked after the system is restarted, will try to find out which updates were already made by ongoing transaction program executions and which ones were not yet done, and will try to fix the situation. However, implementing recovery procedures on a per-application case basis is a difficult task that is itself error prone because of its sheer complexity, especially because multiple transactions issued by different programs may have accessed the data at the time of the failure. So rather than programming recovery in an ad hoc manner for each application separately, a systematic approach is needed, as described, for example, in [9,2]. System-provided recovery ensures the atomicity of transactions and simplifies the understanding of the post-failure state of the data and the overall failure handling on the application side. In the sample scenario of Fig. 2, rather than being left with the inconsistent state in the middle



```
/* funds transfer program */
void main()    {
          EXEC SQL BEGIN DECLARE SECTION;
                  int sourceid, targetid, amount; /* input variables */
          EXEC SQL END DECLARE SECTION;

/* read user input */
           printf("Enter Source ID, Target ID, Amount to be transfered:");
           scanf("%d %d %d", &sourceid, &targetid, &amount);

/* subtract desired amount from source */
           EXEC SQL Update Accounts
                      Set Account_Balance = Account_Balance - :amount
                      Where Account_Id = :sourceid;

/* add desired amount to target */
           EXEC SQL Update Accounts
                      Set Account_Balance = Account_Balance + :amount
                      Where Account_Id = :targetid;

           EXEC SQL Commit Work; }
```

Transaction Management. Figure 2. Sample funds transfer that needs atomicity.

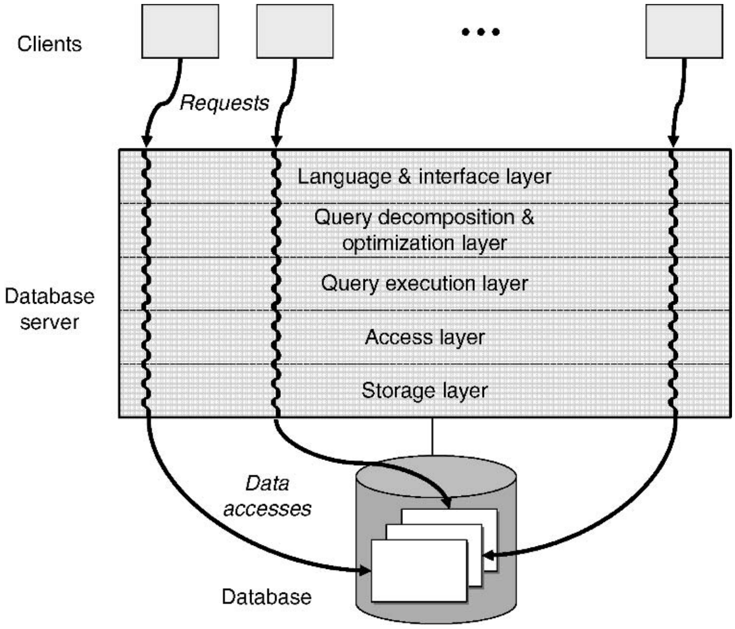
of the transaction, the system recovery will restore the state as of before the transaction began. On the other hand, if the transaction had already issued its "commit transaction" call, then the system would guarantee the durability of the transaction's complete funds transfer.

Guaranteeing the ACID properties of a transaction, which allow application developers to disregard concurrency and failures, are the major goal of transaction management; the means to accomplish this are concurrency control and recovery. These cornerstones for building highly dependable information systems can also be successfully applied outside the scope of *online transaction processing* (OLTP) applications.

Key Applications

Figure 3 shows the layered architecture shared by essentially all database servers in one form or another. When a client request arrives at the server, the server executes code that transforms the request into one or more operations at each of the underlying layers, ultimately arriving at a sequence of disk accesses (unless caching avoids the disk access). The *language and interface layer* makes various kinds of interfaces available to the application developer, usually in the form of APIs (e.g., SQL and ODBC). The *query decomposition and optimization layer* works on an internal, tree based representation of a request and is concerned with the further decomposition of the request into smaller units that can be directly executed; this is the level where also optimizations are carried out. The execution plan chosen is often represented as an operator tree where each operator can be directly mapped to a piece of server code. This code is provided by the *query execution layer*. Next, index structures and also the capabilities for accessing and manipulating data records are provided by the *access layer*. Finally, the *storage layer* is responsible for managing the pages of a database, including disk I/O and caching.

The layered architecture in Fig. 3 does not explicitly mention transaction management, for the simple reason that the functionality of transactional concurrency control and recovery can be tied to any of the five layers shown. For many applications that run simple transactions, each of which accesses a small portion of the data only, transaction management is commonly integrated into the access and storage layers. Applications in this category include classical OLTP scenarios such as banking (see above) or reservation systems, where high availability, high throughput, and high reliability are of utmost importance. However, transactions in electronic commerce applications, where client requests may span multiple databases as well as other information sources across enterprise boundaries, or transactions arising from an execution of business processes which typically take some form of semantic information (stemming from higher-level, for example SQL-type operations) into account can also benefit



Transaction Management. Figure 3. Functional database system layers.

from transaction concepts. Through appropriate transaction models and an appropriate adaptation of the relevant concurrency control and recovery algorithms to these models, transaction management can be applied in almost any area that needs to handle concurrent requests to shared resources in such a way that the ACID properties can be guaranteed [9].

Future Directions

With constant changes in network-centric computing, including the proliferation of Web services, long-running processes across organizational boundaries, large scale peer-to-peer publish-subscribe and collaboration platforms, and ambient-intelligence environments with large numbers of mobile and embedded devices, support for handling or even masking concurrency and component failures is critical in many modern application areas, but can no longer use traditional atomicity concepts alone. In open systems applications are constructed from pre-existing components, and these components and their configurations are not known in advance and they can change on the fly. Thus, it is crucial that atomicity properties of components become composable and allow for reasoning about the behavior of the resulting system. Transaction management will thus continue to require research for the foreseeable future.

Experimental Results

Since transaction management typically has to meet high efficiency requirements, experimental evaluation and comparison of algorithmic approaches to concurrency control and recovery has always been crucial, as is tuning of the transaction management component of a database server for the system administrator. Prominent references including implementation recipes as well as experimental evaluations are [4,8].

Transaction Management in Distributed Database Systems

► Distributed Transaction Management

Transaction Manager

Andreas Reuter[1,2]
[1]EML Research gGmbH, Villa Bosch, Heidelberg, Germany
[2]Technical University Kaiserslautern, Kaiserslautern, Germany

Definition

The transaction manager (TxM) is a special resource manager that implements the resource type "transaction." It handles all the state transitions that a transaction can perform. For simple ACID transactions these are: begin, savepoint, rollback, abort, prepare commit; for more refined transaction models there will be additional states. The resource managers register with the TxM when they get employed by a transaction for the first time. Thus, the TxM keeps a record for each transaction of which resource managers have been involved with it. In the same vein, it stores which sessions each transaction has used in case it has performed operations on other nodes in a distributed system. The TxM closely interacts with the concurrency control manager who can make transaction wait for other transactions in case of access conflicts. It also interacts with the logging and recovery subsystem and the communications manager.

Key Points

The TxM keeps track of all active transactions. When a transaction starts, it is assigned a transaction ID that is unique across any distributed system and will never repeat. For each transaction the TxM stores which resource managers and which sessions are associated with it; for sessions the polarity (outgoing/incoming) is also important. For each state transition of a transaction, the TxM will orchestrate the proper protocol. The most important of these protocols is the two-phase commit (2PC) protocol. Depending on the structure of a transaction, the TxM will act as a coordinator or a participant – or both. Using the information about the participating resource managers and communication sessions, the TxM calls them at their proper callback entries to perform all the necessary actions to go, for example, into the prepared state. TxMs are often implemented as interpreters of the formal description of a state machine, so they can dynamically switch between different (optimizations of) commit protocols.

Upon recovery, the TxM is the first resource manager that is reconstructed by the recovery manager. When the recovery manager has completed its initial backward scan of the online log, the table of active transactions is completely recovered. If there are any in-doubt transactions left, the TxM starts handling that particular part of the 2PC in order to resolve those transactions.

Transaction Model

► Transaction Models – The Read/Write Approach

Transaction Models – the Read/Write Approach

Gottfried Vossen
University of Münster, Münster, Germany

Synonyms

Transaction model; Page model; Read/write model

Definition

The transaction concept essentially establishes an "ACID contract" in data-processing situations, and a transaction model is an abstraction concept that makes this concept amenable to realizations. Two fundamental models are the *page model* as well as the *object model*, where the former is an execution model and the latter is more a conceptual model. The page model is based on the perception that database operations ultimately are read or write operations on pages that need to be transferred between secondary storage and main memory or the database buffer. The model allows making all relevant notions (in particular interleavings of multiple transactions and schedule correctness) precise in a syntactic manner, and it forms the basis for verifying a variety of concurrency control algorithms that can be used in database management as well as other systems.

Historical Background

The read/write or page model of transactions goes back to the work of Jim Gray [5,6] and Kapali Eswaran et al. [4]. Related notions of atomic actions have been discussed by others around the same time, the mid- to late-1970s, including [8,9]. The page-model transaction concept became the subject of intensive theoretical studies, in particular in the work of Christos Papadimitriou and, independently, Phil Bernstein et al. around 1980 [2,3,10,11]. It is essentially valid in its original form until today, yet has received a number of extensions and variations over the years [13].

Foundations

The read/write model of database transactions is motivated by the observation that all operations on data (i.e., queries as well as updates) are eventually mapped into indivisible read and write operations on disk pages or on a page cache in main memory. Thus, to study the effects of concurrent executions, it essentially suffices to inspect the interleavings of the resulting page operations. The abstraction from higher-level data operations, such as SQL commands or method invocations on business objects, down to the view that a resulting transaction consists of reads and writes *only* is a strong one, yet suffices for many practical purposes. In fact, a comprehensive theory of concurrency control and of recovery can be built on it, which is directly applicable to real-world systems, albeit with some performance limitations.

Definition of a Transaction

To define the model of read/write transactions formally, a database is assumed to contain a (finite) set $D = \{x,y, z,...\}$ of (indivisible and disjoint) items (*pages*) with indivisible read and write operations. Data items are often denoted by small letters from the end of the alphabet, where indices are used if necessary (e.g., x_1,y_4). A transaction can then be defined as a total or a partial order of steps; for total orders, a formal definition is as follows: A *transactiont* is a (finite) sequence of steps (actions) of the form $r(x)$ or $w(x)$, written $t = p_1...p_n$, where $n < \infty$, $p_i \in \{r(x), w(x)\}$ for $1 \leq i \leq n$, and $x \in D$ for a given database D. Here, r stands for "read" and w for "write." Thus, a transaction abstracts from the details of a program execution and instead focuses on the sequence of read and write operations that results from that execution.

Each step occurring in a transaction can be uniquely identified so that two distinct transactions do not have steps in common. Let p_j denote the *j*th step of a given transaction, and let p_{ij} denote the *j*th step of transaction i in the presence of multiple transactions. Then the following terminology is common: If $p_j = r(x)$, the interpretation is that step j reads data item x; if $p_j = w(x)$, the interpretation is that step j writes data item x. A transaction is hence a purely syntactic entity whose semantics or interpretation is unknown. In the absence of information on the semantics of the program that launches a transaction, however, the best that can be done is to devise a *Herbrand semantics*, i.e., a "syntactic" interpretation of the steps of a transaction that is as general as possible: (i) In case $p_j = r(x)$, the current value of x is assigned to a local variable v_j. (ii) In case $p_j = w(x)$, a possibly new value, computed by the respective program, is written into x. Each value written by a transaction t potentially depends on the values of *all* data items that t has previously read; if t writes x,

x is the return value of an arbitrary but unknown function f_j applied to all values read before the respective write step. The Herbrand semantics of a read/write transaction thus is a technical vehicle, only useful for making various correctness notion for transaction interleavings precise.

The *total ordering* requirement to the steps of a transaction can be relaxed into a *partial ordering*; thus, a *transaction t* becomes a partial order of steps (actions) of the form $r(x)$ or $w(x)$, where $x \in D$ and reads and writes as well as multiple writes applied to the same data item are ordered. More formally, a *transaction* is a pair $t = (\mathrm{op}, <)$, where op is a finite set of steps of the form $r(x)$ or $w(x)$, $x \in D$, and $< \subseteq \mathrm{op} \times \mathrm{op}$ is a partial order on set op for which the following holds: If $\{p, q\} \subseteq \mathrm{op}$ s.t. p and q both access the same data item and at least one of them is a write step, then $p < q \vee q < p$. In other words, in the partial ordering of a transaction's steps, a read and write operation on the same data item or two write operations on the same data item need to be ordered. With "conflicting" steps inside a transaction being ordered, the "semantics" outlined above for totally ordered transactions carries over to partially ordered ones. For simplicity, however, most discussions of correctness criteria in the literature stick to total orders. Although read/write transactions are considered syntactic entities only, it is an advantage of this model that its theory can be developed in the absence of semantic information and hence can be used for *every possible interpretation* of the transactions. In other words, the read/write page model is fairly general despite its simple structure.

The model as described above allows a transaction to read or write the same data item more than once, as it is the case in the example $t = r(x)w(x)r(y)r(x)w(x)$. Here t reads and writes x twice, although it is reasonable to assume that the value of x remains available, after having been read the first time, in the local variables of the underlying program for as long as it is needed by t, and that only the last write step determines the final value of x produced by this transaction. To exclude "redundancies" of this kind, it is common to assume that (i) in each transaction each data item is read or written at most once, and (ii) no data item is read (again) after it has been written. The latter condition does not exclude the possibility of "blind writes," which is a write step on a data item that is not preceded by a read of that data item.

Schedules and Histories

The distinction between partial and total orderings is also appropriate for interleavings of transactions, i.e., for schedules and histories: Let $T = \{t_1,\ldots,t_n\}$ be a (finite) set of transactions, where each $t_i \in T$ has the form $t_i = (\mathrm{op}_i, <_i)$, with op_i denoting the set of operations of t_i and $<_i$ denoting their ordering, $1 \leq i \leq n$. A *history* for T is a pair $s = (\mathrm{op}(s), <_s)$ s.t. (i) $\mathrm{op}(s) \subseteq \mathrm{U}_{i=1}^{n}\ \mathrm{op}_i \cup \mathrm{U}_{i=1}^{n}\ \{a_i, c_i\}$ and $\mathrm{U}_{i=1}^{n}\ op_i \subseteq op(s)$, i.e., s consists of the union of the operations from the given transactions plus a termination operation, which is either a c_i (commit) or an a_i (abort), for each $t_i \in T$, (ii) $(\forall i, 1 \leq i \leq n)\ c_i \in \mathrm{op}(s) \Leftrightarrow a_i \notin \mathrm{op}(s)$, i.e., for each transaction, there is either a commit or an abort in s, but not both, (iii) $\mathrm{U}_{i=1}^{n} <_i \subseteq <_s$, i.e., all transaction orders are contained in the partial order given by s, (iv) $(\forall i, 1 \leq i \leq n)(\forall p \in \mathrm{op}_i) p <_s a_i$ or $p <_s c_i$, i.e., the commit or abort operation always appears as the last step of a transaction, and (v) any pair of operations $p,q \in \mathrm{op}(s)$ from distinct transactions accessing the same data item s.t. at least one is a write operation is ordered in s in such a way that either $p <_s q$ or $q <_s p$. A *schedule* is a prefix of a history. A history s is *serial* if for any two transactions t_i and t_j in it, where $i \neq j$, all operations from t_i are ordered in s before all operations from t_j or vice versa. Thus, a history (for partially ordered transactions) has to contain all operations from all transactions (i), needs a distinct termination operation for every transaction (ii), preserves all orders within the transactions (iii), has the termination steps as final steps in each transaction (iv), and orders "conflicting" operations (v). The view that two operations which access the same data item and of which at least one is a write operation are in conflict is identical to the notion of conflict that will shortly be used as the basis for a notion of serializability. The notions "schedule" and "history" are not always used in the sense defined here in the literature, but are often used as synonyms.

Schedule Correctness

For transaction executions, it is important to not only have a model of interleavings and their constituents, but also to fix a notion of schedule or history *correctness.* To this end, *conflict serializability* (CSR) is the notion which is most important for the practice of transactional information systems, in particular for designing scheduling algorithms and for building schedulers. CSR is computationally easy to test, and it has a number of interesting theoretical properties which can justify an exploitation of this concept in practice in a variety of ways. Finally, it can be generalized to other transaction models and different data settings. Conflict serializability is based on a simple notion of conflict which was mentioned already in connection with partially ordered histories, and which is appropriate for the syntactical nature of read/write transactions. Two data operations from distinct transactions are *in conflict* in a schedule if they access the same data item and at least one of them is a write. The notion of conflict gives rise to a notion of serializability: A history is *conflict serializable* if there exists a serial history with the same conflicts.

Commutativity of Operations

Conflict serializability can be characterized via acyclic conflict graphs, which gives rise to efficient testability. It is can also be characterized via *commutativity rules* for page model data operations. In these rules "$\sim$" means that the ordered pair of actions on the left-hand side can be replaced by the right-hand side, and vice versa: (C1) $r_i(x)r_j(y) \sim r_j(y)r_i(x)$ if $i \neq j$, i.e., two read steps $r_i(x)$ and $r_j(y)$, $i \neq j$, which occur in a schedule in this order and are adjacent (with no other operation in between), may be commuted. (C2) $r_i(x)w_j(y) \sim w_j(y)r_i(x)$ if $i \neq j$, $x \neq y$, i.e., a read and write step can be exchanged if they are from distinct transactions and access different data items. (C3) $w_i(x)$ $w_j(y) \sim w_j(y)w_i(x)$ if $i \neq j$, $x \neq y$, i.e., two write steps can be commuted if they refer to different data items. These commutativity rules can be applied to a given schedule or history in a stepwise fashion, for example to transform $s = w_1(x)r_2(x)w_1(y)w_1(z)r_3(z)w_2(y)w_3(y)$ $w_3(z)$ into $w_1(x)w_1(y)w_1(z)r_2(x)w_2(y)r_3(z)w_3(y)w_3(z)$, thereby proving it equivalent to the serial history $t_1t_2t_3$. The above transformations have implicitly assumed that operations in a schedule are totally ordered. With partial orders, one may need an additional transformation rule which simply states that two unordered operations can be arbitrarily ordered if they are non-conflicting.

The commutativity rules can be used for introducing another relation on schedules: Let s and s' be two schedules s.t. op(s) = op(s'). Define $s \sim s'$ if s' can be obtained from s by a single application of the commutativity rules to the steps of the schedule. Let "$^*\sim$" denote the reflexive and transitive closure of "$\sim$," i.e., $s *\sim s'$ if s' can be obtained from s by a finite number of applications of the rules. It turns out that "$\overset{*}{\sim}$" is an equivalence relation on the set of all schedules for a given set of transactions, and that finitely many applications of the rules may transform a given history into a serial one, as in the example above. More formally, a history s is *commutativity based reducible* if there is a serial history s' s.t. $s \overset{*}{\sim} s'$, i.e., s can be transformed into s' through a finite number of allowed transformation steps according to the commutativity rules. Therefore, a history s is commutativity based reducible iff s is CSR. An important application of this alternative characterization of schedule correctness is that it can immediately be generalized. Indeed, it is irrelevant to know of a schedule whether a step reads or writes or which data item it accesses, as long as it is known which steps of the schedule are in conflict. The latter suffices for deciding about the correctness of the schedules, even without any knowledge about the meaning of the operations [11]. Thus, the steps of a schedule or history to which a commutativity argument is applied may be of a completely different type, such as *increment* and *decrement* on a counter object, *push* and *pop* on a stack object, or *enqueue* and *dequeue* on a queue object. This observation can be exploited in the context of extended transaction models, where notions of serializability can be established that are based on semantic information.

The page model of transactions can also be extended to accommodate transaction recovery. Indeed, when a transaction aborts, the intuitive reaction of the underlying system is to "undo" the effects of that transaction, which can adequately be captured by inverse write operations. To execute an abort operation, the system would have to execute inverse writes in reverse order of their occurrence [1].

Key Applications

Key applications for transactions started out from debit/credit scenarios in banks and financial institutions, where multiple customer activities against shared accounts need to be synchronized, yet executed at a high throughput rate. In a debit/credit transaction, the activities are either *withdrawals* or *deposits*, and these are often combined into *funds transfers*. The typical structure of a debit/credit program is shown below, using SQL commands embedded into a C program. Note the distinction between local variables of the invoked program and the data in the underlying database that is shared by all programs.

```
/* debit/credit program */
void main()
{EXEC SQL BEGIN DECLARE SECTION;
 int accountid, amount;
  /* input variables */
 int balance; /* intermediate variable */
 EXEC SQL END DECLARE SECTION;
/* read user input */
 printf("Enter Account ID, Amount for
 deposit (positive) or withdrawal (nega-
 tive): ");
 scanf("%d %d", &accountid, &amount);
/* determine current balance of the ac-
count, reading it into a local variable
of the program */
 EXEC SQL
 Select Account_Balance Into :balance
 From Accounts
 Where Account_Id = :accountid;
/* add amount (negative for withdrawal) */
balance = balance + amount;
/* update account balance in the database */
 EXEC SQL Update Accounts
  Set Account_Balance = balance
  Where Account_Id = :accountid;
EXEC SQL Commit Work; }
```

The crucial situation is that, say, two transactions access the same account, where one makes a withdrawal and the other a deposit, i.e., both transactions write new values of the account balance. If unsynchronized, these transaction could overwrite each other's results, thereby leaving the account in an inconsistent state. Another crucial situation is that a transaction makes a withdrawal from one account and a deposit into another (i.e., a transfer); if this transaction crashes in the middle, i.e., after the withdrawal but before the deposit, money would be lost if the system is not capable of restoring the state prior to the withdrawal. The read/write model allows for a straightforward formalization of these situations, and efficient concurrency control as well as recovery procedures can be devised to handle them.

For scenarios like the one just sketched (in particular transfers that need to appear atomic to the outside world), there are numerous applications in today's information systems landscape of electronic business over the Internet, where client requests are rarely restricted to single data servers, but often span multiple databases and other information sources across enterprise boundaries, yet the mutual consistency of all this data is crucial and thus important to maintain. Then, the resulting transactions operate in a distributed system that consists of multiple servers, often with heterogeneous software. To go one step further, a *business process* is a set of *activities* (or steps) that belong together in order to achieve a certain business goal. Business processes are also at the heart of advanced, business-to-consumer (B2C) or business-to-business (B2B) services on the Internet, for example, electronic auctions (B2C) or supply chains (B2B). Typical examples would be the processing of a credit request or an insurance claim in a bank or insurance company, respectively, the administrative procedures for real estate purchase, or the "routing" of a patient in a hospital.

Future Directions

Transactions have originally been developed in the database system community, but their usage and potential benefits are by no means limited to database management. Not surprisingly, the transaction concept is also being explored in the operating systems and programming languages communities. Recent trends include, for example, enhancing the Java language with a notion of atomic blocks that can be defined for methods of arbitrary classes. This could largely simplify the management of concurrent threads with shared objects, and potentially also the handling of failures and other exceptions. The run-time environment could be based on an extended form of *software transactional memory*. Another important direction in ongoing research is to design and reason about guarantees that resemble transactions but are weaker than the ACID properties, especially with regard to the notion of isolation. A model that is widely deployed in industrial data management systems is *snapshot isolation* (based on keeping a versioned history of data items).

Experimental Results

The read/write model of transactions has in part been so successful since it allows for highly efficient implementations of concurrency control and recovery methods, and it allows for tuning a system on the fly. Surveys are provided by [7] and in particular [12].

Transaction Time

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Registration time; Extrinsic time; Physical time; Transaction commit time; Belief time

Definition

A database fact is stored in a database at some point in time, and after it is stored, it remains current, or part of the current database state, until it is logically deleted. The *transaction time* of a database fact is the time when the fact is current in the database. As a consequence, the transaction time of a fact is generally not a time instant, but rather has duration.

The transaction time of a fact cannot extend into the future. Also, as it is impossible to change the past, meaning that (past) transaction times cannot be changed.

In the context of a database management system that supports user transactions, the transaction times of facts are consistent with the serialization order of the transactions that inserted or logically deleted them. Transaction times may be implemented using transaction commit times, and are system-generated and -supplied.

Key Points

A database is normally understood to contain statements that can be assigned a truth value, also called facts, that are about the reality modeled by the database and that hold true during some non-empty part of the time domain. Transaction times, like valid times, may be associated with such facts. It may also be noted that it is possible for a database to contain the following different, albeit related, facts: a non-timestamped fact and that fact timestamped with a valid time. The first would belong to a snapshot relation, and the second would belong to a valid-time relation. Both of these facts may be assigned a transaction timestamp. The resulting facts would then be stored in relations that also support transaction time.

A transaction time database is append-only and thus ever-growing. To remove data from such a database, *temporal vacuuming* may be applied.

The term "transaction time" has the advantage of being almost universally accepted and it has no conflicts with the other important temporal aspect of data, valid time.

The Oracle DBMS explicitly supports transaction time. Applications can access prior transaction-time states of their database, by means of transaction time-slice queries. Database modifications and conventional queries are temporally upward compatible.

Concerning the alternatives, the term "registration time" seems to be straightforward. However, this term may leave the impression that the transaction time is only the time instant when a fact is inserted into the database. "Extrinsic time" is rarely used. "Physical time" is also used infrequently and seems vague. "Transaction commit time" is lengthy, but more importantly, the term appears to indicate that the transaction time associated with a fact must be identical to the time when that fact is committed to the database, which is an unnecessary restriction. The term is also misleading because the transaction time of a fact is not a single time instant as implied. The term "belief time" stems from the view that the current database state represents the current belief about the aspects of reality being captured by the database. This term is used infrequently.

Transactional Middleware

Gustavo Alonso

Synonyms

TP monitor; Object monitor; Application server; Transaction manager; Transaction service

Definition

Transactional Middleware is a generic term used to refer to the IT infrastructure that supports the execution of electronic transactions in a distributed setting. The best known form of transactional middleware is Transaction Processing Monitors (TP Monitors or TPM), which have been around for more than 3 decades (e.g., CICS of IBM). Today, TP Monitors are at the heart of most application servers and are a key component of any enterprise computing architecture. The main role of these systems is to run transactions, i.e., to support the illusion that certain distributed operations are executed atomically. This makes the design of complex systems easier for the programmer, who does not need to implement this functionality but can rely on the transactional middleware to ensure that groups of operations are executed in their entirety or not all, with the transactional middleware taking care of all the work necessary to do so. Historically, transactional middleware has often provided much more functionality than just transactions and, in many ways, they were some of the earliest forms of middleware. They were already used in early mainframes to connect different applications.

Historical Background

The background for transactional middleware is TP Monitors. TP Monitors originated with the first commercial applications running on mainframes and the need to provide additional functionality not provided by the operating system. As the needs of applications and developers flourished, so did the capabilities and features of TP Monitors. This is how TP Monitors became a general term to refer to complex infrastructure and collection of tools that provide not only transactional support but also specialized networking capabilities, batch jobs, job control languages, multithreading, transactional extensions to programming languages, load-balancing capabilities, transactional message queues, etc. When enterprise applications broke away from the mainframe and started running on mixed environments (e.g., a large database in the mainframe, workstations for processing, and PCs for the clients), TP Monitors proved to be the ideal platform to develop and operate such distributed systems. During the 1990s, TP Monitors dominated the middleware arena and were not only the most prominent but also the clearly dominant form of middleware in the market.

The conventional TP Monitors with extensive functionality were called TP-Heavy. These were standalone products were intended for the development of distributed, transactional applications with high performance requirements. A simpler form of TP Monitor was the so called TP-Light systems. Typically, these were extensions to database engines to support interactions with the database through RPC calls and the addition of some basic data processing capabilities to the database engine without having to resort to a full middleware layer such as that required by TP-Heavy approaches. The dominance and importance of TP-Monitors is illustrated by the struggles of CORBA systems to implement the Object Transactional Services described in the CORBA specification. Object Transactional Services are exactly the transactional functionality provided by a TP-Monitor and in many commercial systems it was implemented by using an already existing TP Monitor. Such combined systems enjoyed a short period of popularity under the name of Object Monitors or Object Transaction Monitors.

TP Monitors today are still widely used although the name TP Monitor has been replaced by others, more all-encompassing terms. For instance, applications servers have a TP Monitor as one of the central components. Platforms like .NET o J2EE also rely heavily on TP Monitor functionality. Hence, today these systems are collectively referred to as transactional middleware.

Foundations

To understand transactional middleware, one needs to understand that it is not just about transactions (or, at least, historically it was not just about transactions). Nevertheless, the core functionality of transactional middleware is to run distributed transactions in an efficient manner. Thus, the discussion starts by covering this aspect of transactional middleware and postpone the system issues till later.

Transactions are an abstraction used in database engines to implement the so called ACID properties (Atomicity, Consistency, Isolation, and Durability). Unlike what is commonly found in many textbooks, the vast majority of transactional middleware systems are not there to support the four ACID properties but only one: atomicity in distributed transactions and in the interaction between applications and databases. To the extent that records of the transaction executed are kept, transactional middleware can also provide durability but in a different sense than database durability and not as one of its main operational features. Some systems also supported isolation (e.g., Encina), but such systems run into the same difficulties that all other solutions for concurrent programming have faced and are still facing today.

Atomicity in the context of transactional middleware translates into running a 2 Phase Commit protocol among all the entities involved in executing parts of a transaction. The interactions and interfaces required to do so were standardized in the early 1990s as part of the X/Open models for transactions and distributed transactions, which also defined the XA interface. The XA interface describes how a transaction manager (the transactional middleware) interacts with a resource manager (e.g., a database) to run a 2 Phase Commit protocol. Once standardized, the XA interface allowed TP Monitors to execute transactions across heterogeneous systems, greatly simplifying the task of writing code integrating several systems.

The standard and generic procedure for running a transaction in a transactional middleware platform involves invoking some primitive that tells the middleware that a transaction needs to be started. This primitive typically hides a call to a transaction manager that records the transaction and return and identifier and a context for the transaction. The application then proceeds to make calls as part of this transaction. Each call is augmented with the transaction identifier and context, which allows the recipient of the call to realize that its execution has become part of a transaction and tells it of which one. The recipient of the call uses the transactional context it has received to register with the transactional manager. Part of this registration procedure also involves telling the transaction manager where the actual transaction will be executed (typically the part of the system that supports the XA interface). After registration, the transaction manager knows who is involved in running parts of the transaction, information that maintains in a transaction record that contains all participants in that transaction. When the original application invokes a commit on the transaction, the transaction manager uses the transaction record to start a 2 Phase Commit protocol between all the participants that have registered for this transaction. At the end of the protocol, the transaction manager informs the original application of the success or failure of the commit. If the commit was successful, the original application has the guarantee that the transaction has been executed and completed at all sites where it was invoked. If the commit fails, the original application has the guarantee that all side effects and changes made by the transaction have been rolled back. Of course, these guarantees hold only if the code that is being invoked does not cause any side effects or persistent changes outside the transaction (e.g., on a sub-system that does not support the XA interface) as those changes will not be rolled back for obvious reasons.

The system side of transactional middleware involves all the machinery necessary to run transactions plus a great deal of additional functionality to cope with distribution. Historically, transactional middleware also had to provide a wide range of functionality to compensate for the lack of support at the operating system level. A good example is support for multi-threading, which is necessary to allow the system to cope with concurrent requests to the same service. Other examples include name and directory services, load balancing, life cycle management for services, logging, domain definition, and authentication. For performance reasons, many commercial products also supported specialized network interfaces (e.g., to communicate with a mainframe) and provided additional sub-systems such as message queuing or transactional file systems. Providing such a wealth of functionality made transactional middleware, especially TP Monitors, very generic tools where sometimes the support for transaction management was not the primary reason to use the system. To a large extent, especially during the 1980s and the first half of the 1990s, transactional middleware was the most efficient way to build a distributed system and TP Monitors became not only middleware but also development platforms for distributed applications. A good example of this was Encina (the commercial version of Camelot [2]), which provided its own versions or C or C++ (Transactional C and Transactional C++).

Key Applications

High performance transaction processing (financial, on line trading, banking).

Application servers (web shops, multi tier systems).

Future Directions

TP Monitors are and will remain a key component of any enterprise computing solution. As the key functionality of TP Monitors (the ability to efficiently process large volumes of transactions) is embedded deeper and deeper within larger systems, some of the additional functionality that conventional TP Monitors always provided has migrated to other platforms (e.g., application servers) or become independent systems on their own (e.g., message brokers). Hence the generic name of transactional middleware when referring to such systems. A challenge in the future will be providing similar transactional semantics on Service Oriented Architectures where the interactions might be based on asynchronous messages instead of through blocking calls (RPC/RMI). What the proper transactional semantics are for an asynchronous enterprise bus or an event based architecture is a topic that is still open and needs attention.

Transactional Processes

Heiko Schuldt
University of Basel, Basel, Switzerland

Synonyms

Transactional workflows; Transactional business processes

Definition

A *Transactional Process* is a partially ordered sequence of activities which is executed in a way that guarantees transactional consistency for all activities or a subset of them. Activities can be either transactional (e.g., they are again transactional processes or conventional database transactions) or non-transactional (e.g., invocations of application services). Activities are ordered by means of control flow and data flow dependencies.

Key Points

In most cases, transactional consistency for processes focuses on notions of atomicity which go beyond the "all-or-nothing" semantics of ACID database transactions. This is done by supporting a process designer in explicitly specifying how consistency has to be achieved. Models for transactional processes include support for failure handling which can either be integrated into control flow dependencies (i.e., distinguishing between regular execution and alternative executions in case of failures) or, in a rather programmatic style, as exception handlers. Failure handling also needs to take into account that certain activities can neither be compensated after having been successfully executed (i.e., to semantically undo their effects) nor be deferred until the end of a process, due to control flow dependencies. For this, backward recovery (partial compensation in case of failures) and forward recovery (alternative executions) need to be combined. Forward recovery also requires to make the state of a process persistent during execution so that it can be resumed in case of system failures. For applications in which also concurrent executions of transactional processes need to be controlled, isolation and atomicity can be jointly considered.

Commercial tools for transactional processes distinguish between microflows (short running processes where all activities are transactional) and macroflows (long-running processes). The former can actually be considered conventional database transactions and are executed using protocols such as two phase commit (2PC) while the latter have to be treated as transactional processes. Several Web services standards define protocols that allow to execute Web services in a transactional context and thus facilitate their integration into transactional processes.

Transaction-time access methods

Definition

A transaction-time index is a temporal index that enables fast access to transaction-time datasets. In a traditional database, an index is used for selection queries. When accessing transaction-time databases, selection queries also involve the transaction-time dimension. The characteristics of the transaction-time axis imply various properties that such temporal index should have to be efficient. As with traditional indices, the performance is described by three costs: (i) storage cost (i.e., the number of pages the index occupies on the disk), (ii) update cost (the number of pages accessed to perform an update on the index; for example when adding, deleting or updating a record), and (iii) query cost (the number of pages accessed for the index to answer a query).

Historical Background

Most of the early work on temporal indexing has concentrated on providing solutions for transaction-time databases. A basic property of transaction-time is that it always *increases*. This is consistent with the serialization order of transactions in a database system. Each newly recorded piece of data are time-stamped with a new, larger, transaction time. The immediate implication of this property is that previous transaction times *cannot* be changed (since every new change must be stamped with a new, larger, transaction time). This is useful for applications where every action must be registered and maintained unchanged after registration, as in auditing, billing, etc. Note that a transaction-time database records the history of a database activity rather than "real" world history. As such it can "rollback" to, or answer queries for, any of its previous states.

Consider, for example, a query on a temporal relation as it was at a given transaction time. There are two obvious but inefficient approaches to support this query, namely the "copy" and "log" approaches. In the "copy" approach, the whole relation is "flushed" (copied) to disk for every transaction for which a new record is added or modified. Answering the above rollback query is simple: the system has to then query the copy that has the largest transaction-time less or equal to the requested time. Nevertheless, this approach is inefficient for its storage and update costs (the storage can easily become quadratic to the number of records in the temporal database and the update is linear, since the whole temporal relation needs to be flushed to disk for a single record update). In contrast, the "log" solution simply maintains a log of the updates to the temporal database. Clearly, this approach uses minimal space (linear to the number of updates) and minimal update cost (simply add an update record at the end of the log), but the query time is prohibitively large since the whole log may need to be traversed for reconstructing a past state of the temporal database. Various early works on transaction-time indexing behave asymptotically like the "log" or the "copy" approaches. For a worst-case comparison of these methods see [7]. Later on, two methodologies were proposed to construct more efficient transaction-time indices, namely the (i) *overlapping* [3,10] and (ii) (partially) *persistent* approaches [1,6,9,]. These methodologies attempt to combine the benefits of the fast query time from the "copy" approach with the low space and update costs of the "log" approach.

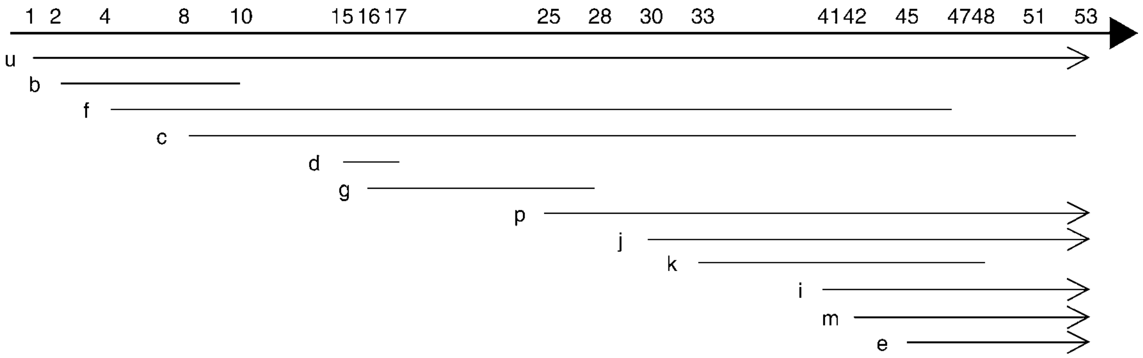
Foundations

The distinct properties of the transaction-time dimension and their implications to the index design are discussed through an example; this discussion has been influenced by [8]. Consider an initially empty collection of objects. This collection evolves over time as changes are applied. Time is assumed discrete and always increasing. A change is the addition or deletion of an object, or the value change of an object's attribute. A real life example would be the evolution of the employees in a company. Each employee has a surrogate (*ssn*) and a salary attribute. The changes include additions of new employees (as they are hired or re-hired), salary changes or employee deletions (as they retire or leave the company). Each change is time-stamped with the time it occurs (if more than one change happen at a given time, all of them get the same timestamp). Note that an object attribute value change can be simply "seen" as the artificial deletion of the object followed by the simultaneous rebirth (at the same time instant) of this object having the modified attribute value. Hence, the following discussion concentrates only on object additions or deletions.

In this example, an object is called "alive" from the time that it is added in the collection until (if ever) it is deleted from it. The set *s(t)*, consisting of all alive objects at time *t*, forms the state of the evolving collection at *t*. Figure 1 illustrates a representative evolution shown as of time *t* = 53. Lines ending to ">" correspond to objects that have not yet been deleted at *t* = 53. For simplicity, at most one change per time instant is assumed. For example, at time *t* = 10 the state is *s*(10) = *{u, f, c}*. The interval created by the consecutive time instants an object is alive is the "lifetime" interval for this object. Note that the term "interval" is used here to mean a "convex subset of the time domain" (and not a "directed duration"). This concept has also been named a "period" in this discussion however, only the term "interval" is used. In Fig. 1, the lifetime interval for object *b* is [2,10). An object can have many non-overlapping lifetime intervals.

Note that in the above evolving set example, changes are always applied to the current state *s(t)*, i.e., past states *cannot* be changed. That is, at time *t* = 7, the deletion of object *d* is applied to *s*(16) = *{u, f, c, d, g}* to create *s*(17) = *{u, f, c, g}*. This implies that, at time *t* = 54, no object can be retroactively added to state *s*(5), neither the interval of object *d* can be changed to become [15,25]. All such changes are not allowed as they would affect previous states and not the most current state *s*(53).

Assume that all the states *s(t)* of the above evolution need to be stored in a database. Since time is always increasing and the past is unchanged, a transaction time database can be utilized with the implicit updating assumption that when an object is added or deleted from the evolving set at time *t*, a transaction updates the database system about this change at the same time, i.e., this transaction has commit timestamp *t*. When a new object is added in the collection at time *t*, a record representing this object is stored in the database accompanied by a transaction-time interval of the form *[t, UC)*. In this setting, *UC* (Until Changed) is a variable representing the fact that at the time the object is added in the collection, it is not yet known when (if ever) it will be deleted from it. If this object is later deleted at time *t*', the transaction-time interval



Transaction-Time Indexing. Figure 1. An example of a transaction-time evolution.

of the corresponding record is updated to *[t, t')*. A real-world object deletion is thus represented in the database as a "logical" deletion: the record of the deleted object is still retained in the database, accompanied by an appropriate transaction-time interval. Since the past is kept, a transaction-time database conceptually stores, and can thus answer queries about, any past state *s(t)*.

Based on the above discussion, an index for a transaction-time database should have the following properties: (i) store past logical states, (ii) support addition/deletion/modification changes on the objects of the current logical state, and (iii) efficiently access and query any database state.

Since a fact can be entered in the database at a different time than when it happened in reality, the transaction-time interval associated with a record is actually related to the process of updating the database (the database activity) and may not accurately represent the times the corresponding object was valid in reality. Note that a valid-time database has a different abstraction, which can be visualized as a dynamic collection of "interval-objects." The term interval-object is used to emphasize that the object carries a valid-time interval to represent the temporal validity of some object property. Reality is more accurately represented if both time dimensions are supported. A bitemporal database has the characteristics of both approaches. Its abstraction maintains the evolution (through the support of transaction-time) of a dynamic collection of (valid-time) interval-objects.

Traditional indices like the B^+-tree or the R-tree are not efficient for transaction-time databases because they do not take advantage of the special characteristics of transaction time (i.e., that transaction time is always increasing and that changes are always applied on the latest database state). There are various index proposals that are based on the (partially) *persistent* data-structure approach; examples are the Time-Split B-tree (TSB) [6], the Multiversion B-tree (MVBT) [1], the Multiversion Access Structure [11], the Snapshot Index [9], etc. It should be noted that all the above approaches facilitate "time-splits": when a page gets full, current records from this page are copied to a new page (this operation is explained in detail below). Time-splits were first introduced in the Write-Once B-tree (WOBT), a B-tree index proposed for write-once disks [5]. Later, the Time-Split B-tree used time-splits for read-write media and also introduced other splitting policies (e.g., splitting by other than the current time, key splits etc.) Both the WOBT and TSB use deletion markers when records are deleted and do not consolidate pages with few current records. The MVBT uses the time splitting approach of the WOBT, drops the deletion markers and consolidated pages with few current records. It thus achieves the best asymptotic behavior and it is discussed in detail below. Among the index solutions based on the *overlapping* data-structure approach [2], the Overlapping B-tree [10] is used as a representative and discussed further.

For the purposes of this discussion, the so-called *range-timeslice* query is considered, which provides a key range and a specific time instant selection. For example: "find all objects with keys in range $[K_1, K_2]$ whose lifetimes contain time instant *t*." This corresponds to a query "find the employees with ids in range [100,..,500] whose entries were in the database on July 1, 2007." Let *n* be the total number of updates in a transaction-time database; note that *n* corresponds to the minimal information needed for storing the whole evolution. [7] presents a lower bound for answering a range-timeslice query. In particular, any method that uses linear space (i.e, $O(n/B)$ pages, where *B* is the number of object records that fit in a page) would need $O(\log_B n + s/B)$ I/O's to answer such a query (where an I/O transfers one page, and *s* corresponds to the size of the answer, i.e., the number of objects that satisfy the query).

*The Multiversion B-tree (MVBT)***:** The MVBT approach transforms a timeslice query to a partial persistence problem. In particular, a data structure is called *persistent* [4] if an update creates a new version of the data structure while the previous version is still retained and can be accessed. Otherwise, if old versions of the structure are discarded, the structure is termed *ephemeral*. *Partial* persistence implies that only the newest version of the structure can be modified to create a new version.

The key observation is that partial persistence "suits" nicely transaction-time evolution since these changes are always applied on the latest state $s(t)$ of the evolving set (Fig. 1). To support key range queries on a given $s(t)$, one could use an ordinary B^+-tree to index the objects in $s(t)$ (that is, the keys of the objects in $s(t)$ appear in the data pages of the B^+-tree). As $s(t)$ evolves over time through object changes, so does its corresponding B^+-tree. Storing copies of all the states that the B^+-tree took during the evolution of $s(t)$

is clearly inefficient. Instead, one should "see" the evolution of the B$^+$-tree as a partial persistence problem, i.e., as a set of updates that create subsequent versions of the B$^+$-tree.

Conceptually, the MVBT stores all the states assumed by the B$^+$-tree through its transaction-time evolution. Its structure is a directed acyclic graph of pages. This graph embeds many B$^+$-trees and has a number of root pages. Each root is responsible for providing access to a subsequent part of the B$^+$-tree's evolution. Data records in the MVBT leaf pages maintain the transaction-time evolution of the corresponding B$^+$-tree data records (that is, of the objects in $s(t)$). Each record is thus extended to include an interval [*insertion-time*, *deletion-time*), representing the transaction-times that the corresponding object was inserted/deleted from $s(t)$. During this interval the data-record is termed *alive*. Hence, the MVBT directly represents object deletions. Index records in the non-leaf pages of the MVBT maintain the evolution of the corresponding index records of the B$^+$-tree and are also augmented with insertion-time and deletion-time fields.

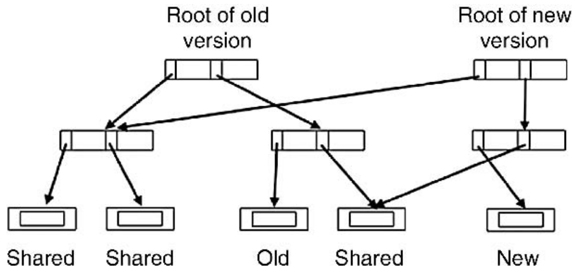
Assume that each page in the MVBT has a capacity of holding B records. A page is called *alive* if it has not been *time-split* (see below). With the exception of root pages, for all transaction-times t that a page is alive, it must have at least q records that are alive at t ($q < B$). This requirement enables clustering of the alive objects at a given time in a small number of pages, which in turn will minimize the query I/O. Conceptually, a data page forms a rectangle in the time-key space; for any time in this rectangle the page should contain at least q alive records. As a result, if the search algorithm accesses this page for any time during its rectangle, it is guaranteed to find at least q alive records. That is, when a page is accessed, it contributes enough records for the query answer.

The first step of an update (insertion or deletion) at the transaction time t locates the target leaf page in a way similar to the corresponding operations in an ordinary B$^+$-tree. Note that, only the latest state of the B$^+$-tree is traversed in this step. An update leads to a *structural change* if at least one new page is created. *Non-structural* are those updates which are handled within an existing page.

After locating the target leaf page, an insert operation at the current transaction time t adds a data record with a transaction interval of [t, UC) to the target leaf page. This may trigger a structural change in the MVBT, if the target leaf page already has B records. Similarly, a delete operation at transaction time t finds the target data record and changes the record's interval to [insertion-time, t). This may trigger a structural change if the resulting page ends up having less than q alive records at the current transaction time. The former structural change is called a *page overflow*, and the latter is a *weak version underflow* [1]. Page overflow and weak version underflow need special handling: a *time-split* is performed on the target leaf-page. The time-split on a page x at time t is performed by copying to a new page y the records alive in page x at t. Page x is considered *dead* after time t. Then the resulting new page has to be incorporated in the structure [1].

Since updates can propagate to ancestors, a root page may become full and time-split. This creates a new root page, which in turn may be split at a later transaction time to create another root and so on. By construction, each root of the MVBT is alive for a subsequent, non-intersecting transaction-time interval. Efficient access to the root that was alive at time t is possible by keeping an index on the roots, indexed by their time-split times. Since time-split times are in order, this root index is easily kept (this index is called the root* in [1]). In general, not many splits propagate to the top, so the number of root splits is small and the root* structure can be kept in main memory. If this is not the case, a small index can be created on top of the root* structure.

Answering a range-timeslice query on transaction time t has two parts. First, using the root index, the root alive at t is found. This part is conceptually equivalent to accessing $s(t)$ or, more explicitly, accessing the B$^+$-tree indexing the objects of $s(t)$. Second, the answer is found by searching this tree in a top-down fashion as in a B$^+$-tree. This search considers the record transaction interval. The transaction interval of every record returned or traversed should include the transaction time t, while its key attribute should satisfy the key query predicate. A range-timeslice query takes $O(\log_B n + s/B)$ I/O's while the space is linear to n (i.e., $O(n/B)$). Hence, the MVBT optimally solves the range-timeslice query. The update processing is $O(\log_B m)$ per change, where m is the size of $s(t)$ when the change took place. This is because a change that occurred at time t traverses what is logically a B$^+$-tree on the m elements of $s(t)$.



Transaction-Time Indexing. Figure 2. The Overlapping B-tree.

The Overlapping B-tree: Similar to the MVBT approach, the evolving set $s(t)$ is indexed by a B^+-tree. The intuition behind the Overlapping B-tree [2,10] is that the B^+-trees of subsequent versions (states) of $s(t)$ will not differ much. A similar approach was taken in the EXODUS DBMS [3]. The Overlapping B-tree is thus a graph structure that superimposes many ordinary B^+-trees (Fig. 2). An update at some time t creates a new version of $s(t)$ and a new root in the structure. If a subtree does not change between subsequent versions, it will be shared by the new root. Sharing common subtrees among subsequent B^+-trees is done through index nodes of the new B^+-tree that point to nodes of previous B^+-tree(s). An update will create a new copy of the data page it refers to. This implies that a new path is also created leading to the new page; this path is indexed under the new root.

To address a range-timeslice query for a given transaction time t, the latest root that was created before or at t must be found. Hence, roots are timestamped with the transaction time of their creation. These timestamps can be easily indexed on a separate B^+-tree. This is similar to the MVBT root* structure; however, the Overlapping B-tree creates a new root per version. After the appropriate root is found, the search continues traversing the tree under this root, as if an ordinary B^+-tree was present for state $s(t)$.

Updating the Overlapping B-tree involves traversing the structure from the current root version and locating the data page that needs to be updated. Then a copy of the page is created as well as a new path to this page. This implies $O(\log_B m)$ I/O's per update, where m is the current size of the evolving set. An advantage of the Overlapping structure is in the simplicity of its implementation. Note that except the roots, the other nodes do not involve any time-stamping. Such time-stamping is not needed because pages do not have to share records from various versions. Even if a single record changes in a page, the page cannot be shared by different versions; rather a new copy of the page is created. This, however, comes at the expense of the space performance. The Overlapping B-tree occupies $O(n \log_B n)$ pages since, in the worst case, every version creates an extra tree path. Further performance results on this access method can be found in [10].

Key Applications

The characteristics of transaction-time make such databases ideal for applications that need to maintain their past; examples are: billing, accounting, tax-related etc.

Index Sequential Access Method (ISAM); B+-tree; R-tree

Definition

Consider a relation R with some numeric attribute A taking values over an (ordered) domain D. A *range query* retrieves all tuples in R whose attribute A has values in the interval $[low, high]$. That is, $low \leq R.A \leq high$. To enable fast processing of range selection queries, an access method that maintains order is needed. Such an index has the form of a tree, where each node corresponds to a page. Leaf nodes contain (or index) the actual values of A, while index nodes provide ordered access to the nodes underneath. Examples of tree-based indexing are the B+-tree and the R-tree (for single- and multi-dimensional ranges, respectively).

Key Points

A major performance goal of a database management system is to minimize the number of I/O's (i.e., blocks or pages transferred) between the disk and main memory. One way to achieve this goal is to minimize the number of I/O's when answering a query. Consider for example relation *Employee* (*ssn, name, salary, dept, address*); the query: "Find the employees who reside in Santa Monica" references only a fraction of *Employee* records. It would be very inefficient to have the database system sequentially read all the pages of the *Employee* file and check the *address* field of each employee record for the value "Santa Monica." Instead the system should be able to locate the pages with "Santa Monica" employee records directly.

To allow such fast access additional data structures called access methods (or indices) are designed per database file. The term *search-key* is used to identify the attribute(s) on which the access method is built. There are two fundamental access methods, namely tree-based and hash-based indexing. They differ on the kind of queries that they can efficiently address. Tree-based indexing maintains the order of the search-key values. It is thus applicable to attributes that are *numeric* and hence it can be used to address *range* queries (and also *equality* queries, when the range query interval is reduced to one value). Hash-based indexing on the other hand does not assume any ordering; rather it is based on mapping the search-key values on a collection of buckets. Therefore it can only address *equality* (or *membership*) queries. Since a tree-based index maintains the order of the indexed values in its leaf pages, a (one-dimensional) range query is implemented as a search for the leaf page with the lower value of the range interval, followed by the accessing of sibling pages until a page that contains the higher value of the range interval is reached.

Tree-based indices are further categorized by whether their search-key ordering is the same with the file's logical order (if any). Note that a file may or may not be ordered according to the value of an (a sequence of) attribute(s). A file stored without any logical order is called an unordered file or heap. If the search-key of a tree-based index is the same as the ordering attribute of a (ordered) file then the index is called *primary*. Since such an index also clusters the values of the file, the term *clustering* index has also been used. The search-key of a primary index is usually the file's primary key, however this is not necessary. An index built on any non-ordering attribute of a file is called *secondary*. A relation can have several indices, on different search-keys; among them, at most one is primary (clustering) index and the rest are secondary ones (obviously, a file can have at most a single logical order since it is physically stored once).

Historically, the first tree-based index used in relational databases was the ISAM file (a static tree). Currently, the most widely used tree-based index is the B+-tree which is a dynamic structure (i.e., its size increases or decreases as the size of the indexed file changes by record insertions/deletions). As with any data structure, the performance of an access method is characterized by three costs, namely: query time, update time and space. Query time corresponds to the number of page accesses (I/O's) needed to answer a query. Update time counts the number of I/O's needed for updating the method when a record is updated, inserted or deleted. Space measures the number of pages occupied by the method's data structures. The B + -tree uses logarithmic update and query costs while its space requirements are linear to the size of the indexed file.

Treemaps

Jean-Daniel Fekete
INRIA, LRI University Paris Sud, Orsay Cedex, France

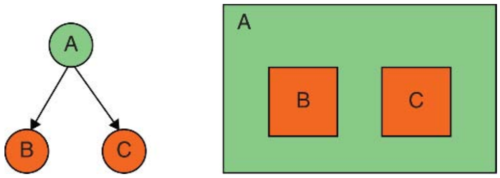
Definition

Treemaps [5] have been designed to visualize rooted trees using containment to express the hierarchy (Fig. 1 right). It is a space-filling technique and uses all the available space to render the tree. One important feature of Treemaps is their use of surface to represent an attribute value that adds up with the hierarchy. The number of leaves under a node is the simplest of these attributes. This number is one for a leaf and, for an interior node, it is the sum of the number of leaves of all its children.

This additive property is frequent on real trees. In an organizational chart, the salary of employees adds up, in an administrative geographical decomposition such as the one used by the census, population adds up, as well as income.

The traditional visual representation of rooted trees is called a *node-link diagram* (Fig. 1 left). Treemaps are not as good as standard node-link diagrams to represent the hierarchy depth on the tree; if an important task on the tree is to compare the depth of two nodes, node-link diagrams are more appropriate.

However, Treemaps can be applied on trees ranging from tens to hundred-thousands of nodes, much more



Treemaps. Figure 1. Rendition of a rooted tree as a node-link diagram on the left and as a Treemap on the right.

than standard node-link diagrams. Computing the layout of Treemaps is fast and their reading is easy with some training.

Historical Background

Treemaps were introduced by Shneiderman in 1992 [5]. They are restrictions of Euler diagrams to represent inclusion. Furthermore, when Euler diagrams are usually drawn with circles, ellipses, or curved shapes, Treemaps are drawn with rectangles to better use the screen real-estate.

The original Treemap algorithm is called "Slice and Dice" because at each level in the hierarchy, the children of a node cut the node's rectangle in slices horizontally or vertically, flipping direction at each level. Further refinements of Treemaps have tried to improve two main features: the aspect ratio of the rectangles and their order.

With the original "Slice and Dice" algorithm, the ratio between width and height of nodes can vary widely in the same Treemap. Some slices can become very thin while others can be almost square. Comparing visually the surface of rectangles with different aspect ratio is difficult for the human vision so one important improvement was to try to create nodes as square as possible. The most popular algorithm for achieving this property is due to van Wijk and is called "Squarified Treemap" [3].

Neither the "slice and Dice," nor the squarified algorithm maintains the order of children visually. When the leaf order is important, Bederson et al. have compared several algorithms and found that a simple variant of the squarified algorithm called "Ordered Treemaps" provided a good tradeoff between complexity and performance [2].

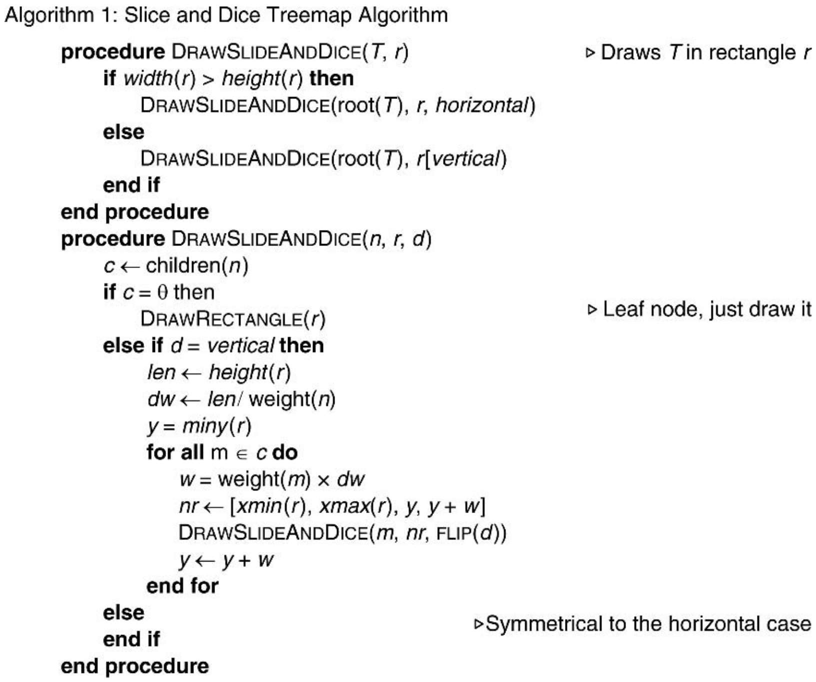
Further research have been conducted to study the limits of Treemaps in term of tree size and density [4] or to enhance their readability. Variant layouts have also been proposed, such as circular Treemaps (not space efficient) and Voronoï Treemaps [1] that are space efficient but costly to compute.

Foundations

As in all the visualization techniques, Treemaps visualizations consist in computing a *layout* for the tree – here a rectangle associated with each node – and drawing these rectangles using adequate visual attributes.

A rooted tree T is defined as a set of nodes $n \in T$ and three functions *root* , *parent* and *children* . It is convenient to define the element NIL to represent an undefined node. A rooted tree verifies the following axioms:

$$\text{parent}(T, n) \in \ T \cup \{\text{NIL}\}$$
$$\text{parent}(T, n) = \text{NIL} \Leftrightarrow n = \mathit{root}(T)$$
$$\text{children}(T, n) = \{c_1, c_2, \ldots c_k\} \in T^k$$
$$\text{parent}(T, n) = p \Leftrightarrow n \in \text{children}(T, p)$$



Algorithm 1: Slice and Dice Treemap Algorithm

```
procedure DrawSlideAndDice($T$, $r$)                         ▷ Draws $T$ in rectangle $r$
    if $width(r) > height(r)$ then
        DrawSlideAndDice(root($T$), $r$, $horizontal$)
    else
        DrawSlideAndDice(root($T$), $r[vertical]$)
    end if
end procedure
procedure DrawSlideAndDice($n$, $r$, $d$)
    $c \leftarrow$ children($n$)
    if $c = \theta$ then                                       ▷ Leaf node, just draw it
        DrawRectangle($r$)
    else if $d = vertical$ then
        $len \leftarrow height(r)$
        $dw \leftarrow len/$ weight($n$)
        $y = miny(r)$
        for all m $\in c$ do
            $w =$ weight($m$) $\times dw$
            $nr \leftarrow [xmin(r), xmax(r), y, y + w]$
            DrawSlideAndDice($m$, $nr$, flip($d$))
            $y \leftarrow y + w$
        end for
    else                                            ▷Symmetrical to the horizontal case
    end if
end procedure
```

Algorithm 2: Squarified Treemap Algorithm

```
procedure DRAWSQUARIFIED($n$, $r$)
    if is Leaf ($n$) then                                   ▷ Leaf node, just draw it
        DRAWRECTANGLE($r$)
        return
    end if
    $scale \leftarrow width(r) * height(r)$ / weight($n$)
    $sorted$ = SORTBYDECREASINGWEIGHT(children($n$))
    while $sorted \neq nil$ do
        if $width(d) > height(`)$ then                       ▷ Create vertical strips
            $y = miny(r)$
            $len = height(r)$
            ($strip$, $sorted$) = SQUARIFY($sorted$, $len$, $scale$)
            $width \leftarrow \sum_{c \in strip}$ weight($c$) $\times$ $scale/ len$
            for all $child \in strip$ do
                $h$ = weight(child) $\times$ scale / width
                $nr \leftarrow [xmin(r), xmax(r), y, y + h]$
                DRAWSQUARIFIED($child$, $nr$)
                $y \leftarrow y + h$
            end for
            $r \leftarrow [xmin(r) + width, xmax(r), ymin(r), ymax(r)]$
        else
                                                    ▷ Symmetrical for the horizontal case
        endif
    endwhile
end procedure
function SQUARIFY($children$, $w$, $scale$)                  ▷ $w$ is the strip width
  $strip \leftarrow [pop(children)]$                          ▷ Strip starts with one node
  while children $\neq \emptyset$ do
    $c \leftarrow head(children)$
    if WORST($strip$, $w$, $scale$) $\leq$ WORST($strip + c$, $w$, $scale$) then
        $strip \leftarrow strip + c$
        $pop(children)$
        $c \leftarrow head(children)$
    else
        break
    end if
  end while
  return ($strip$, $children$)
end function
```

For convenience, define the degree of a node deg(T,n) to be the number of nodes in its children set and the *is Leaf*(T, m) predicate is deg(T, n) = 0.

Drawing a Treemap requires a positive function weight on the tree such that:

$$\begin{aligned} \text{weight}(T, n) = \sum_{c \in \text{children}(T,n)} \text{weight}(T, c) \wedge \\ \text{weight}(T, n) > 0 \end{aligned} \tag{1}$$

A rectangular portion of the screen is used to display the whole tree. The layout algorithm is recursive and uses the *weight* function to allocate space. The algorithm for "Slice and Dice" is simple (Algorithm 1). The "flip" function and the accessor function for the rectangle type should be self explanatory.

The squarified algorithm is more complex. It tries to assign a rectangle to each node with the ratio w/h close to 1. Computing the optimal configuration is equivalent to bin-packing and is known to be NP-complete so it uses a simple heuristics. It sorts the children by decreasing weights and fills the parent rectangle with strips of children. Each node rectangle is added to the strip until adding the next rectangle decreases the quality of the rectangles already in the strip. Then a new strip is created (see Algorithm 2). The quality is usually the worst aspect ratio of the rectangles in the strip. It is computed as follows: given R a list of areas and s their total sum:

$$worst(R, w) = \max_{r \in R}(\max(w^2 r/s^2, s^2/(w^2 r))$$

In the algorithm 2, a scale argument is passed to the function *worst* to transform the weights in surfaces since in the definition (equation 1), the weights are in arbitrary units. The computation of strips can be done incrementally as described in [3].

Sorted Treemaps only change two lines to the Algorithm 2: line 7 is removed so the nodes are in their natural order and line 9 is removed so the strips are always horizontal.

Key Applications

Treemaps have been used on any kinds of trees. They became visible to a large audience when the company SmartMoney used Treemaps to visualize a "map of the market" (still visible at www.smartmoney.com/mapofthemarket. Other applications include browsers for file systems where one can visualize the whole hierarchy and navigate on it by file sizes and using sophisticated color rendition for the rectangles, such as "cushion" (Fig. 2) or "smooth shading" (Fig. 3).

They are also very useful to visualize data tables using a flexible hierarchy. A set of column is chosen and ordered. The first level of the tree consists in creating a node for each values of the first column (partitioning according to the first column). The second level is built by sub-partitioning by values of the second column etc. This method is well suited to OLAP databases where the partitioning is already available. By interactively changing the column order, different Treemap views of the table can be explored.

Triangular Norms

Vilém Novák
University of Ostrava, Ostrava, Czech Republic

Synonyms

t-Norm

Definition

Triangular norms (briefly t-norms) are special binary operations $\mathbf{T} : [0,1]^2 \to [0,1]$. They are interesting for fuzzy logic because they preserve the fundamental properties of the logical conjunction "and" (to hold at the same time), namely commutativity, monotonicity, associativity, and boundedness and thus, they serve as a natural generalization of the classical conjunction in many-valued logical systems.

A concept associated with the t-norm is the triangular conorm (t-conorm) $\mathbf{S} : [0,1]^2 \to [0,1]$. This corresponds to the behaviour of truth values when joined by the logical connective "or."

Key Points

A t-norm is a binary operation $\mathbf{T} : [0,1]^2 \to [0,1]$ such that the following axioms are satisfied for all $a, b, c \in [0,1]$:

$$\begin{array}{ll}\text{(commutativity)} & a\ \mathbf{T}\ b = b\ \mathbf{T}\ a, \\ \text{(associativity)} & a\ \mathbf{T}(b\ \mathbf{T}\ c) = (a\ \mathbf{T}\ b)\mathbf{T}\ c, \\ \text{(monotonicity)} & a \leq b \quad \text{implies} \quad a\ \mathbf{T}\ c \leq b\ \mathbf{T}\ c, \\ \text{(boundary condition)} & 1\ \mathbf{T}\ a = a.\end{array}$$

The most important t-norms are *minimum*, *product* and *Łukasiewicz conjunction* defined by

$$a\ \mathbf{T}_{\mathrm{L}} b = \max\{0, a + b - 1\}.$$

A t-conorm is a binary operation $\mathbf{S} : [0,1]^2 \to [0,1]$, which is commutative, associative, monotone, and for all $a \in [0,1]$ it fulfils the following boundary condition:

$$0\ \mathbf{S}\ a = a.$$

The most important t-conorms are *maximum*, *probabilistic sum*

$$a\ \mathbf{S}_P\ b = a + b - ab$$

and *Łukasiewicz disjunction*

$$a\ \mathbf{S}_{\mathrm{L}} b = \min\{1, a + b\}.$$

A t-conorm is dual to the given t-norm **T** if $a\ \mathbf{S}\ b = 1 - (1-a)\ \mathbf{T}\ (1-b)$ holds for all $a, b \in [0,1]$. There are many classes of t-norms and their structure is extremely complicated.

Triangulated Irregular Network

Leila De Floriani, Paola Magillo
University of Genova, Genova, Italy

Synonyms

Triangulated terrains; TIN

Definition

A Triangulated Irregular Network (TIN) is a special case of a Digital Elevation Model (DEM).

A terrain can be mathematically modeled as a function $z = f(x, y)$ mapping a point (x, y) in a domain D in the plane to its elevation value $f(x, y)$. In practice, the value of function f is known at a finite set S of points within D. A DEM provides an estimated value for function f at any point (x, y) of the domain, based on the values at the points of S. A DEM consists of a subdivision of the domain into cells and of a piece-wise interpolating function defined on such cells.

A TIN is a DEM in which the domain subdivision is a triangle mesh, i.e., a set T of triangles such that: (i) the set of vertices of T is S, (ii) the interiors of any two triangles of T do not intersect, (iii) if the boundaries of two triangles intersect, then the intersection is either a common vertex, or a common edge.

Usually, a linear interpolating function is defined on the triangles of T, thus providing a continuous terrain approximation. Given a triangle $t = P_1P_2P_3$ and a point $P = (x,y)$ inside triangle t, the following function estimates the elevation value z at P. Let $P_1 = (x_1,y_1,z_1)$ $P_2 = (x_2,y_2,z_2)$ and $P_3 = (x_3,y_3,z_3)$ be the coordinates of the three vertices of t. Then,

$$z = z_1 - (a(x - x_1) + b(y - y_1))/c,$$

where (a,b,c) are the components of the normal vector to the triangle $P_1P_2P_3$ in 3D space:

$$a = (y_1 - y_2)(z_1 - z_3) - (z_1 - z_2)(y_1 - y_3)$$
$$b = (z_1 - z_2)(x_1 - x_3) - (x_1 - x_2)(z_1 - z_3)$$
$$c = (x_1 - x_2)(y_1 - y_3) - (y_1 - y_2)(x_1 - x_3)$$

Key Points

TINs have been extensively studied in Geographic Information Systems (GISs), in Computational Geometry, and in Computer Graphics. Several data structures and algorithms for representing, constructing and manipulating triangle meshes have been proposed.

The quality of the terrain approximation provided by a TIN depends on the underlying triangle mesh. Note that a point set S does not define a unique triangle mesh. The most widely used triangle mesh is the *Delaunay* one, in which the circumcircle of each triangle does not contain any data point in its interior. This means that the triangles of a Delaunay mesh are as much equiangular as possible. It has also been proven that the use of a Delaunay mesh as the basis of a TIN improves the quality of the terrain approximation and enhances numerical stability in computations. Other triangulation criteria have been proposed which consider the triangles of the mesh in 3D space.

Often, not only points, but also lines need to be included in a TIN. Such lines may represent morphological terrain features (coast lines, rivers, ridges), man-made structures (roads, railways, gas lines), political or administrative boundaries, or contour lines. The Delaunay criterion has been modified to deal with lines in two different ways: (i) in the *constrained Delaunay triangulation*, the lines appear as triangle edges (but it may present sliver triangles); (ii) in the *conforming Delaunay triangulation*, each line is discretized by adding points on it (but a large number of points may need to be added).

TINs are used in multiresolution terrain modeling.

Prefix tree

Definition

A trie is a rooted tree used for storing associative arrays where keys are usually strings. Edges are often labeled by individual symbols. Then common prefixes are factorized. Each node of the trie is associated with a prefix of a string of the set of strings: concatenation of the labels of the path from the root to the node. The root is associated with the empty string. Strings of the set are stored in terminal nodes (leaves) but not in internal nodes. A trie can be seen as a Deterministic Finite Automaton.

Tries can be compacted. To get a compact trie from a trie, internal nodes with exactly one successor are removed. Then labels of edges between remaining nodes are concatenated. Thus:

- Edges are labeled by strings.
- Internal nodes have at least two children.
- Edges outgoing an internal node are labeled by strings starting with different symbols.

Historical Background

Tries were first recommended by de la Briandais [1]. The word "trie" comes from information re*trie*val and was suggested by Fredkin [3]. Tries enable to store and retrieve information that consists of key-element pairs. Fredkin suggested, in 1960, that it is an alternative way of storage to unordered lists, ordered lists or pigeonholes. The reader can refer to [6] for further details on tries.

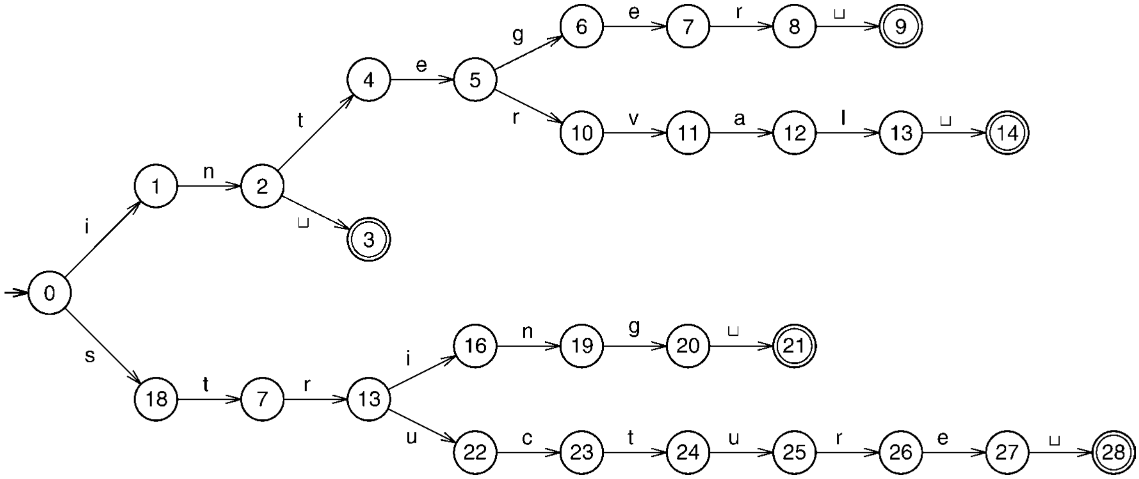
Foundations

In binary search trees, keys are stored in all the nodes of the tree and the search method is based on comparison between keys. In tries, keys are stored in the leaves and the search method involves left-to-right comparison of prefixes of the keys.

The trie of the set of strings $X = \{$`in`, `integer`, `interval`, `string`, `structure`$\}$ is presented Fig. 1. Note that the space sign ␣ has been added at the end of each of the strings of X so that no string of X is a prefix of another string of X. Then each string of X is associated with a leaf of the trie (not with an internal node). The trie for the set X can be implemented in linear space with respect to the total length of the strings in X. The compact trie for the set X can be implemented in linear space with respect to the total number of the strings in X, which dramatically reduces the size of the structure.

Consider that the strings are build over an alphabet of size σ.

Flajolet and Sedgewick [8] provide an average case analysis of tries.



Trie. Figure 1. Trie of X = {`in`, `integer`, `interval`, `string`, `structure`}.

Construction

The algorithm Trie(X) shown in Fig. 2, builds the trie containing all the strings in the set X. It uses a function target(p, a) that gives the successor of a node p for a symbol a or the value special nil if such a node does not exist. It works by inserting all the strings of X successively in the trie starting with the tree consisting with a single node (the root). Then for each string $x \in X$ it spells the longest prefix of x corresponding to an existing path from the root of the trie. When this longest prefix is found, it creates the nodes and the edges of the remaining suffix of x.

The sum of the lengths of all the strings of X is denoted by M. Then, the algorithm Trie(X) run in time $O(M)$ when the branching time from a node with a given symbol is constant or $O(M \times \log \sigma)$ when the branching time depends on the alphabet size (see Implementation below).

Searching

The algorithm IsInTrie(*root*, x), see Fig. 3, tests if the string x is present in the trie and consequently if the string x is a prefix of strings represented by the trie. It works, similarly to the creation of the trie, by spelling, from the root of the trie, the longest prefix of x corresponding to a branch in the trie. If this longest prefix is x itself, then the algorithm returns true and the string x belongs to the trie, otherwise the algorithm returns false and the string is not a prefix of any string in the set. The algorithm IsInTrie(*root*, x) works in time $O(|x|)$ or $O(|x| \times log\ \sigma)$ depending on the branching time.

```
Trie($X$)
  $root \leftarrow$ new node
  for each string $x \in X$ do
    $p \leftarrow root$
    for $i \leftarrow 0$ to $|x| - 1$ do
      $q \leftarrow$ Target $(p, x[i])$
      if $q =$ NIL then
        $q \leftarrow$ new node
        $Succ[p] \leftarrow Succ[p] \cup \{(X[i], q)\}$
      $p \leftarrow q$
    $info[p] \leftarrow x$
  return $root$
```

Trie. Figure 2. Algorithm that builds the trie containing of the string of a set X.

```
IsInTrie($p, x$)
  if $x$ is empty then
    return TRUE
  else $q \leftarrow$ Target$(p, x[0])$
    if $q =$ NIL then
      return FALSE
  else return IsInTrie$(q, x[1..|x| - 1])$
```

Trie. Figure 3. Algorithm that enables to test if a string x belongs to a trie.

Sorting

A trie can be used to sort a set of strings by doing the following: insert all the strings in the trie and output them in lexicographically increasing order by applying a pre-order traversal of the trie (respectively lexicographically decreasing order by applying a post-order traversal of the trie).

Implementation

There exist different possible representations of a trie, each with different branching times. It is possible to use a transition table whose size is the product of the number of nodes times the size of the alphabet. A trie can then be implemented in linear space with respect to the total length of all the strings it represents. The branching time, for finding the successor of a given node with a given symbol, is then constant.

The use of adjacency lists has the advantage to minimize the required space but the branching time depends on the alphabet size. It can be as low as $\log(\sigma)$ if the alphabet is ordered and outgoing edges are stored in a balanced search tree. A representation by binary tree is achieved by using a "first child – right sibling" representation of the trie.

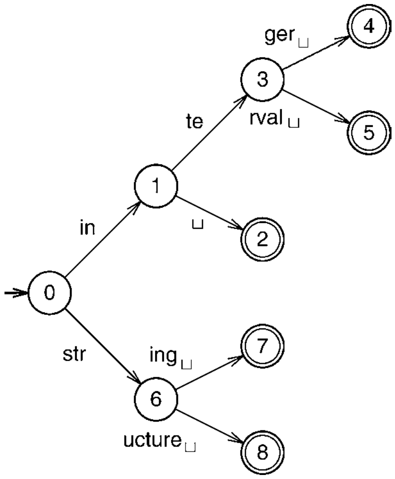
Hashing techniques can be used as a good trade-off between transition tables and adjacency lists. The branching time is then constant on average.

A mixed technique known as the "deep shallow" technique consists of representing the nodes up to a certain level k with a transition table and to use adjacency lists for the nodes with level greater than k. Most of the times nodes with small level have many successors while nodes with large level have only one successor.

However when storage space is an issue and tries do not entirely fit into the central memory, it is possible to use compact tries as described below. Accesses to individual edges are only a bit more involved than in non-compact tries.

Compact Tries

The compact trie of the set of strings X = {in, integer, interval, string, structure} is presented Fig. 4. It is obtained from the trie of Fig. 1 by removing internal nodes with exactly one successor. Then labels of edges between remaining nodes are concatenated.



Trie. Figure 4. Compact trie of X = {in⊔, integer⊔, interval⊔, string⊔, structure⊔}.

Patricia Trees

Morrison [7] designed specific compact tries known as PATRICIA trees. PATRICIA trees are efficient especially for extremely long variable-length strings. The PATRICIA tree of the set of strings X = {in⊔, integer⊔, interval⊔, string⊔, structure⊔} is presented Fig. 5. PATRICIA trees are binary trees that consider the binary encoding of the strings. In Fig. 5 nodes 0, 1 and 3 actually point to in⊔, nodes 4 and 7 point to integer⊔, node 8 points to interval⊔, nodes 2 and 5 point to string⊔ and node 6 points to structure⊔. Small numbers close to the nodes are skip numbers, they indicate on which bit the branching has to be decided. The skip number of node 0 is 1: it corresponds to bit at position 1 (bolded in columns 1, 18, 26, and 34 on Fig. 5), which is the leftmost difference in the bit strings representing the strings of X. The three strings in⊔, integer⊔ and interval⊔ possess a 0 so they are on the left and string⊔ and structure⊔ possess a 1 so they are on the right. The skip number of node 1 is 18: it corresponds to bit at position 18 (bolded on Fig. 5), where is the leftmost difference in the bit strings representing the three strings in⊔, integer⊔ and interval⊔. The string in⊔ has a 0 so it is on the left and integer⊔ and interval⊔ possess a 1 so they are on the right. The skip number of node 2 is 26: it corresponds to bit at position 26, (bolded on Fig. 5), where is the leftmost difference in the bit strings representing the two strings string⊔ and structure⊔. The string string⊔ has a 0 so it is on the left and structure⊔ possesses a 1 so it is on the right. The skip number of node 4 is 34: it corresponds to bit at position 34 (bolded on Fig. 5), where is the leftmost difference in the bit strings representing the two strings integer⊔ and interval⊔. The string interval⊔ has a 0 so it is on the left and integer⊔ possesses a 1 so it is on the right.

The skip number of a node (different from the root) in a PATRICIA tree is never larger than its parent skip number.

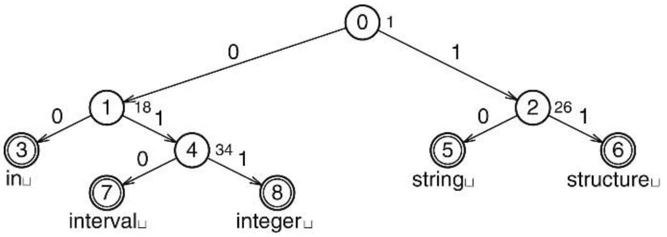
PATRICIA tree of *X*



Trie. Figure 5. PATRICIA tree of *X* = {in␣, integer␣, interval␣, string␣, structure␣}.

The reader can refer to [4] for further details on PATRICA trees.

Key Applications

Tries are used for dictionary representation including spell checking systems or predictive text for mobile phones (T9 system for instance). They are used for text compression (Ziv and Lempel compression schemes), multiple string matching (or multi key search). They are at the basis of the Burstsort for sorting large sets of strings. Also, it should be mentioned that when *X* is the set of suffixes of a string, the structures that are then called Suffix Trie or Suffix Tree are intensively used for Pattern Matching [2,5].

Trust and Reputation in Peer-to-Peer Systems

Zoran Despotovic
NTT DoCoMo Communications Laboratories Europe,
Munich, Germany

Synonyms

Feedback systems; Word of mouth

Definition

Trust means reliance on something or someone's action. As such, it involves risks on the side of the subject of trust, i.e., trustor. Reducing these risks is the main goal of a trust management system. A possible way to do this is through reputation management, i.e., reputation systems.

In a typical large scale online setting, be it on the Web or in P2P networks, it is necessary to learn more about prospective transaction partners prior to engaging in a transaction with them. The size of such systems makes it highly improbable to meet the same partner repeatedly, so own experience is of little use. The types of the performed transactions are often such that well-established forms of quality assurance (e.g., contracts) are highly inefficient. Under such circumstances, reputation systems ("word of mouth" [3]) turn out to be the only viable mechanism to encourage trustworthy behavior and guide people to decide whom to trust and to what degree. They do this through collecting, distributing, and aggregating feedback about the participants past behavior," as Resnick et al. [8] explain. The key presumptions of a reputation system are that the participants of the considered online community engage in repeated interactions and that the information about their past doings is informative of their future performance and as such will influence it. Thus, collecting, processing, and disseminating the feedback about the participants' past behavior is expected to boost their trustworthiness.

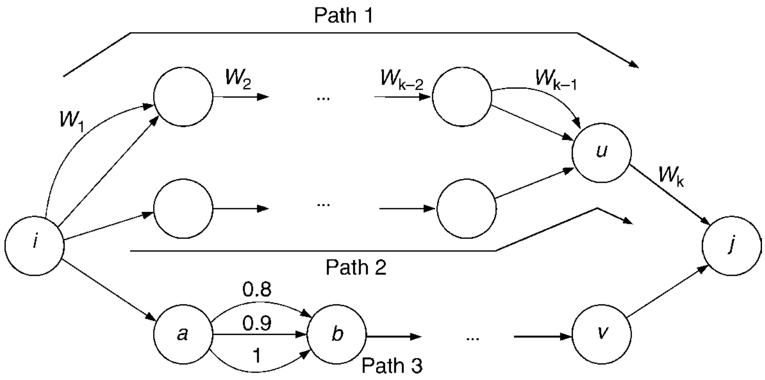
Historical Background

The concept of reputation is almost as old as human society. It was present in ancient times as a key enabler of trade and a broad range of other activities [3]. In the millennia to come, a new form of interaction between interested parties emerged, involving contractual agreements. When necessary, they are enforced by third parties, be it a local feudal sovereign in the medieval time or state, as nowadays. But the need for reputation did not disappear. Quite often, it is not possible to foresee what can go wrong, so that it can be specified in a contract. More important, binding contracts incur transaction costs which sometimes offset the prospective benefits from the interaction. In such cases, people resort to streamlining their interactions in informal ways, one of them being the use of reputation.

Reputation has long been a subject of study in economics. Economists find it vital. Many markets would not exist or they would be highly inefficient without reputation. Consider a market in which sellers sell goods of different qualities. Buyers cannot observe the quality of any good. Thus, they tend to undervalue high quality goods, as they may end up purchasing low quality. But then high quality sellers cannot achieve good prices and may withdraw from the market. So only low quality goods will be traded. This is what George Akerlof calls the "market for lemons" [1]. Information asymmetry between sellers and buyers is critical here. A mechanism to break it is needed. Reputation systems may be such a mechanism.

Today's perception of the P2P systems are old about eight years as of this writing. But that is quite enough for a turbulent history, which demonstrated the need for reputation management, among others. There were numerous reports of viruses spreading through well known P2P file sharing applications such as Gnutella or Kazaa. A quick inspection in Google reveals millions of entries returned to the query `(Gnutella OR Kazaa) AND virus`. As an example, Wired reports as of September 2004 that "forty-five percent of the executable files downloaded through Kazaa, the most popular file-sharing program, contain malicious code like viruses and Trojan horses, according to a new study."

Although these examples illustrate the point, they are benign in the sense that one can select different ways to download content, e.g., through well known web sites. But the P2P paradigm does not coincide with simple file swapping. It aims at making a more serious impact on the online world through offering a range of useful applications. No matter what these applications are, they will need reputation management. The reason is that P2P applications must be implemented through cooperation of their users, which can be unskilled or dishonest.



Trust and Reputation in Peer-to-Peer Systems. Figure 1. A trust graph.

Foundations

The core of any P2P reputation system is how it solves the following problem: how can a peer use the information on experiences between the peers to evaluate the trustworthiness of any other peer? A possible strategy might be as follows. The peer (call it also trustor) can ask its friends to report on their experiences with the unknown peer (trustee). However, the friends might not have any experience with the peer in question. This happens quite frequently in large scale systems, in which virtually every interaction is with a new peer, not seen before. As a result, the peer may search for some other unknown peers which happened to interact with the trustee. Their opinion might help. However, they might lie for whatever reason. So the problem is now how to assess the credibility of their reports. A possible solution is to continue with the search, this time looking for peers who interacted with the feedback providers and so on until enough peers are found with whom the trustor had enough experiences so that it knows their credibility. The whole process is depicted in Figure 1. The figure shows a set of peers, which are shown as vertices in the graph. The arcs represent the interactions among them, i.e., services they provide to each other. For example, peer *b* provided three services to peer *a*. The weights next to the arcs represent the level of satisfaction of the service consumer with the provided service. The structure that is formed in this way is called a trust graph.

There are two classes of reputation systems: *signaling and sanctioning reputation systems* [3]. They make different assumptions on the underlying behavior and also use different amounts of available reputation data, i.e., different fractions of the trust graph. In a signaling reputation system, the interacting entities are presented with signals of what can go wrong in the interactions if they behave in specific ways. Having appropriate signals, the entities should decide what behavior is most appropriate for them. An important assumption of the signaling reputation systems is that the involved entities do not change their behavior in response to a change of their reputation. As an example, the system may just provide a prospective buyer with indications of the probability that the seller will fail to deliver a purchased item. This probability is the main property of the seller. It can change with time, but independently of the seller's reputation.

The other possibility is *sanctioning reputation systems.* The main assumption they make is that the involved entities are aware of the effect the reputation has on their benefits and thus adjust their behavior dynamically as their reputation changes. The main task of a reputation system in this case is to *sanction* misbehavior through providing correlation between the feedback the agent receives and the long-run profit made. The distinction between signaling and sanctioning reputation systems is made explicit in the following discussion.

A typical signaling approach involves the following three-step procedure: (i) enumerating all paths from the trustor to the trustee, (ii) aggregating the feedback along the paths and (iii) merging the obtained values. There is a nice theory developed on this subject. It is due to Richardson et al. [9]. Consider a trust graph and assume that there is only one directed arc from *i* to *j*, for any pair of vertices *i* and *j*. Multiple arcs have been merged somehow. It is not important how exactly this merging is done. Consider the matrix $M \equiv [M_{ij}]_{i,j=1}^{N}$ (N is the number of the peers) corresponding to the trust graph and assume that it has been normalized so that for any $1 \leq i, j \leq N$: $0 \leq M_{ij} \leq 1$ and $\sum_{k=1}^{N} M_{ik} = 1$.

Define two binary operators: trust concatenation, the symbol $\circ$ will be used to denote it, and trust aggregation, denoted by $\diamond$. The former is applied on two consecutive edges in a chain of trust, while the latter applies to two chains. Simple multiplication and addition are good examples of these operators. Define now a matrix "multiplication" operation $\bullet$ as $C = A \bullet B$ such that $C_{ij} = \diamond(\forall k : A_{ik} \circ B_{kj})$. If $A = B \equiv M$, where M is the matrix representation of a given trust graph, then the interpretation of C_{ij} is aggregated trust that i puts on j over all chains of length 2. Again, if $\circ$ and $\diamond$ are ordinary multiplication and addition then $\bullet$ becomes the ordinary matrix multiplication. This is what [6] proposes.

Now, the most interesting result is that if $\diamond$ is commutative and associative and $\circ$ is associative and distributes over $\diamond$ then the aggregated value of all paths (of any length) between any pair of users can be obtained by the following simple algorithm:

$$Q^{(0)} = M, Q^{(k)} = M \bullet Q^{(k-1)} \text{ until } Q^{(k)} = Q^{(k-1)}. \tag{1}$$

The computation will converge after a finite number of steps if the matrix M (or the trust graph) is irreducible and aperiodic. It is important to see that the computation can be performed locally, after each iteration k all the peers can retrieve from their neighbors the currently computed opinions of those neighbors about all other peers and then do the computation of the step $k + 1$. It turns out that this algorithm requires at most $O(N^3)$ computations per peer.

In a similar vein, Xiong and Liu [10] compute the trustworthiness of a given peer as the average feedback about it weighted by the trustworthiness of the feedback originators themselves. This can be expressed by the formula:

$$t_j = \sum_{e \in incoming(j)} w_e \cdot \frac{t_{source(e)}}{\sum_{f \in incoming(j)} t_{source(f)}},$$

where $incoming(j)$ is the set of all edges ending at node j, w_e is the feedback belonging to the edge e and $t_{source(e)}$ the trustworthiness of the originator of this feedback. The formula can be computed by using an iterative computation, similar to (1).

[4] makes explicit the assumption about the peer behavior. The gain is a more efficient algorithm. There is a loss as well; the mechanism is not as robust as [10]. Assume that a peer can perform trustworthy or untrustworthy (1 or 0) in its interactions with others. More precisely, each peer's behavior is modeled as two Bernoulli random variable, i.e., each peer has innate probabilities of performing trustworthy when serving other peers (denote this probability θ_k for peer p_k) and reporting truthfully its experiences with other peers (let l_k be the probability for peer p_k). The distributions of these variables are independent across peers. Consider a peer p_j that interacted with peers $p_1,\ldots,p_n$ and its performances in these interactions were $x_1,\ldots,x_n$, where $x_i \in \{0,1\}$. When asked to report on peer p_j's performances witnesses p_1, $p_2,\ldots,p_n$ may misreport. This happens with their associated misreporting probabilities. The probability of observing report y_k from peer p_k can be calculated as:

$$\begin{aligned} P[Y_k = y_k] &= [l_k(1-\theta_j) \\ &+ (1-l_k)\theta_j]^{y_k}[l_k\theta_j + (1-l_k)(1-\theta_j)]^{1-y_k}. \end{aligned} \tag{2}$$

Given a sample of independent reports $y_1, y_2,\ldots,y_n$, the likelihood function of the sample is computed:

$$L(\theta_j) = P[Y_1 = y_1] \cdot P[Y_2 = y_2] \cdots P[Y_n = y_n]. \tag{3}$$

The final step is finding θ_j that maximizes this expression, i.e., the maximum likelihood estimate of the unknown probability. To do this, one needs to know l_k's in (1.3). [4] proposes a simple method to approximate them. Peer p_i deduce them from its own performances, by comparing own performances with the reports about them. If peer p_i has sufficiently many experiences with peers p_1, $p_2,\ldots,p_n$ as reporters of its performances then it can use them to estimate the misreporting probabilities of those peers. If not, then it can opt to estimate the misreporting probability at the level of the entire network. In this case, all l_k's have the same approximate value, denote it by l, and the maximum likelihood estimate of θ_j becomes $\frac{\bar{y}-l}{1-2l}$, where $\bar{y} = \frac{y_1+\cdots y_n}{n}$.

[10] and [6] on the one hand and [4], on the other, represent different tradeoffs between the computation efficiency and robustness.

So far, an important assumption was that the peer behavior is static. The peers were characterized by probability distributions whose parameters never change. This is an unrealistic assumption. It is dropped in sanctioning reputation systems. As a special case of these systems, game theoretic models of reputation go to the other extreme with respect to the peer behavior. They assume that the involved agents maximize their utilities across their entire lifetime. This means that, at any time instant, the agents condition their actions by the histories of previous play, both theirs and their opponents. The concept of repeated games deals with such long term interactions. However, the game-theoretic models of reputation need one more ingredient. Players are associated with different types (normally, every type assumes a different utility function of a player). Every player knows his type but the others are uncertain about which types of their opponents they face. The game-theoretic tool for modeling such uncertainties is that of games with incomplete information (Bayesian games). Fudenberg and Tirole [5] offer an extensive introduction to the subject.

There are a number of problems with a potential application of game-theoretic reputation models to P2P systems. One deals with human behavior. There are evidences that humans do not behave as utility maximizers (or if they do, it is hard to grasp their utilities within simple economic models). The other one is related to the complexity of game-theoretic models. The problem is that feedback has to be processed by the peers themselves. This leads to enlarged strategy spaces of the peers and complicates the task substantially.

Reputation models of evolutionary game theory present another area of active research. Their assumptions are as follows. A game, most often the celebrated Prisoner's dilemma, is played repeatedly among the players. The play is divided into epochs. In each epoch the players make a choice of (repeated game) strategies. When going to the next epoch, the choice of the players' strategies is biased by their scores in the previous epoch. Hence the name "evolutionary models." Axelrod [2] performed experiments in which he found that one strategy performs particularly well for the Prisoner's dilemma game. He called it "tit-for-tat" -a- it plays at any round whatever the opponent played in the previous round (and starts with cooperation). The setting for his experiments was that in each epoch the same two players played against each other. The question is how much his result extends to setting where the opponents are matched randomly, i.e., their interactions within an epoch are one-shot rather than long-term. Ohtsuki and Ywasa [7] offer an answer in which reputation data plays a critical role. They assume that a public label is associated with each player. All players can read the label, and all players except the owner of the label are allowed to change it. When a pair of players interacts, their labels are modified according to their actions. The behavior of a player can be described with two functions: the *action function* and the *assessment function*. The action function takes the label of self and the opponent and produces the decision to either cooperate or defect. The assessment function is executed after the actions of both agents have taken place. The assessment function takes the label of self, the label of the opponent and the action of the opponent and produces the new value for the opponent's label. There are 16 possible action functions and 256 possible assessment functions. This gives 4096 possible behaviors. [7] performed a systematic experimental study of these behaviors and found 8 of them (termed "the leading eight") evolutionary stable, see Table 1.

A population of agents using one of these strategies is able to sustain cooperation and drive out of existence any small population of defectors and/or reputation liars (i.e., players that set the labels to "bad" value even though their opponent cooperated).

Interestingly, there is a remarkable similarity between tit-for-tat and the leading eight strategies. The leading eight strategies exhibit all the properties of tit-for-tat, found to be important in Axelrod's experiments.

One cannot apply the above reasoning to P2P systems directly. There is a serious problem to solve.

assessment function:

	GG	BG	GB	BB
C	G	*	G	*
D	B	G	B	*

action function:

GG	GB	BG	BB
C	D	C	*

Trust and Reputation in Peer-to-Peer Systems. Table 1. The "leading eight" in the evolutionary indirect reciprocity game. G and B stand for good and bad reputation labels respectively. C and D stand for cooperation and defection. The GG, GB, BG, BB encode four possible states of the labels (of the two players). The three asterisks in the assessment function can take any value, hence eight possible assessment functions are possible (The value at the asterisk in the action function is uniquely determined given the choice of one of the eight assessment functions.)

How to maintain the reputation data when there is no trusted third party to do that, i.e., how to enforce the specific reputation aggregation strategy in a decentralized system? Problems like this constitute an active research area.

Key Applications

P2P applications are provided by participating peers collaboratively. For example, in a file sharing applications, any peer may provide a file that others can download. In a publish-subscribe application, anyone can act as supplier of information that the other peers can use. At the same time, peers are not well established and reputable institutions whose trustworthiness is not questionable. Most often, they are unknown individuals hidden behind meaningless identifiers. This means that reputation management is a natural need in P2P systems. Different P2P applications have varying degrees of need for reputation management, but literally all of them need it.

Interestingly, the operation of core P2P protocols can also benefit from reputation management. When routing messages, peers can take reputation of their neighbors into account and select only those which do not drop messages. This way, reputation management improves routing performance.

Trust in Blogosphere

Nitin Agarwal, Huan Liu
Arizona State University, Tempe, AZ, USA

Synonyms

Reputation; Relationship of reliance

Definition

Trust can be defined as the relationship of reliance between two parties or individuals. *Alice* trusts *Bob* implies *Alice*’s reliance on the actions of *Bob*, based on what they know about each other. Trust is basically prediction of an otherwise unknown decision made by a party or an individual based on the actions of another party or individual. Trust is always directional and asymmetric. *Alice* trusts *Bob* does not imply *Bob* also trusts *Alice*.

From a sociological perspective, trust is the measure of belief of one party in another’s honesty, benevolence, and competence. Absence of any of these properties causes failure of trust. From a psychological perspective, trust can be defined as the ability of a party or an individual to influence the other. The more trusting someone is the more easily (s)he can be influenced.

The past several years witnessed significant changes in the interactions between the individuals and groups. Individuals flock on the Internet and engage in complex social relationships, termed as social networks. Social networking has changed the paradigm of interactions and content generation. Former information consumers are now producers (or, Prosumers). Social networking has given a humongous thrust to online communities, like Blogosphere. Blogosphere is the universe of all the blog sites which contains blog posts in reverse chronological order. Each blog post is a discourse of an individual's opinions, ideas, thoughts on some subject matter. These could be journals of personal experiences. Nonetheless, blog posts could be easily considered as a collection of semi-structured text. This opens up many research opportunities for existing text mining techniques to be adapted for this domain. Trust is highly important in a virtual world because of its low barriers to credibility. Profiles and identities could be easily faked and trust could be compromised, leading to severely critical losses, physical and/or mental.

Historical Background

Many existing works have identified the need for handling the trust aspect in social networks. Social networks can be further divided into friendship networks and the blogosphere. In social friendship networks it is important not only to detect the influential members or experts in case of knowledge sharing communities but also to assess to what extent some of the members are recognized as experts by their colleagues in the community. This leads to the estimation of trust and reputation of these experts. Some social friendship networks like Orkut allow users to assign trust ratings as a more explicit notion of trust. Whereas some websites have an implicit notion of trust where creating a link to a person on a webpage implies some amount of business trust for the person. In other cases, Trust and reputation of experts could be typically assessed as a function of the quality of their response to other members' knowledge solicitations. Pujol et al. [5] proposed a *NodeMatching* algorithm to compute the authority or reputation of a node based on its location in the social friendship network. A node's authority depends upon the authority of the nodes that relate to this node and also on other nodes that this node relates to. The basic idea is to propagate the reputation of nodes in the social friendship network. This is very similar to the *PageRank* and *HITS* algorithm in the traditional web search. However, authors point out the differences between their algorithm and *Pagerank* and *HITS*. For *PageRank* and *HITS* the transition probability matrix and variance-covariance matrix respectively have to be known previously, unlike *NodeMatching* algorithm. This becomes infeasible for very large graphs. Moreover, *PageRank* assumes a fixed graph topology by stratifying the range of transition probability which is different in *NodeMatching* which can automatically adapt to the topology since it depends upon the authority of the related nodes.

While Pujol et al. [5] proposed an approach to establish reputation based on the position of each member in the social friendship network [8], developed a model for reputation management based on the Dampster-Shafer theory of evidence in the wake of spurious testimonies provided by malicious members of the social friendship network. Each member of a social friendship network is called an agent. Each agent has a set of acquaintances a subset of which forms its neighbors. Each agent builds a model for its acquaintances to quantify their expertise and sociability. These models are dynamic and change based on the agent's direct interactions with the given acquaintance, interactions with agents referred to by the acquaintance, and on the ratings this acquaintance received from other agents. The authors point out a significant problem with this approach which arises if some acquaintances or other agents generate spurious ratings or exaggerate positive or negative ratings, or offer testimonies that are outright false. Yu and Singh [8] study the problem of deception using the Dampster-Shafer belief functions so as to capture uncertainty in the rankings caused by malicious agents. A variant of majority weighted function is applied to belief functions and simple deception models were studied to detect deception in the ratings.

Sabater and Sierra [6] propose a combination of reputation scores on three different dimensions. They combined reputation scores not only through social relations governed by a social friendship network, termed as social dimension but also past experiences based on individual interactions, termed as individual dimension and reputation scores based on other dimensions, termed as ontological dimension. For large social friendship networks it is not always possible to get reputation scores based on just the individual dimension, so they can use the social dimension and ontological dimension would enhance the reputation estimation by considering different contexts. The ontological dimension is very similar to the work proposed in [7], where the authors recommend collaboration in social friendship networks based on several factors. They explain the importance of context in recommending a member of social friendship network for collaboration.

In [2], authors consider those social friendship networking sites where users explicitly provide trust ratings to other members. However, for large social friendship networks it is infeasible to assign trust ratings to each and every member so they propose an inferring mechanism which would assign binary trust ratings (trustworthy/non-trustworthy) to those who have not been assigned one. They demonstrate the use of these trust values in email filtering application domain and report encouraging results. Authors also assume three crucial properties of trust for their approach to work: transitivity, asymmetry, and personalization. These trust scores are often transitive, meaning, if Alice trusts Bob and Bob trusts Charles then Alice can trust Charles. Asymmetry says that for two people involved in a relationship, trust is not necessarily identical in both directions. This is contrary to what was proposed in [8]. They assume symmetric trust values in the social friendship network between two members. Personalization of trust means that a member could have different trust values with respect to different members. Trust of a member is absolutely a personal opinion. Consolidating the trust scores for a member might not give a reasonable estimation, so authors propose trust propagation mechanism. Authors define source as the node which is seeking trust value of another node called sink. If there is a direct edge between source and sink then the value is directly transferred, otherwise the trust value is inferred based on the source's neighbors. Source polls each of its neighbors whom it has given a positive trust rating. The neighbors also use this procedure to compute the trust rating of the sink. Hence gradually sink's trust scores propagate to the source. They demonstrate the trust rating in filtering emails with the help of a prototype TrustMail and using Enron email dataset. (http://www.cs.cmu.edu/∼enron/). Guha et al. [3] proposed another trust propagation scheme in social friendship networks based on a series of matrix operations but they included the element of distrust along with the trust scores.

The works discussed above rely on one or the other form of network centrality measures (like degree centrality, closeness centrality, betweenness centrality, eigenvector centrality) to evaluate trustworthy nodes and how trust propagates in the network. Nonetheless, blog networks have very sparse trust information between different pairs of nodes. Using trust propagation approaches for such a sparse network would be highly inaccurate and unreliable. Although not much research has been published that exploits text mining to evaluate trust in Blogosphere, authors in [4] have proposed to use sentiment analysis of the text around the links to other blogs in the network. They study the link polarity and label the sentiment as "positive," "negative," or "neutral." This information mined from the blogs is coupled with Guha et al.'s [3] trust and distrust propagation approach to derive trust values between node pairs in the blog network. They further use this model to identify trustworthy nodes in the blog network and also identify clusters of like-minded blogs.

Foundations

Quantifying and computing trust in social networks is hard because concepts like trust are fuzzy, and is being expressed in a social way. The definitions and properties are not mathematical formalisms but social ones. The two main components of defining trust are belief and commitment. The extent to which someone trusts another is illustrated by the belief and trusted individuals maintain that with their commitment. Note that trust is highly subjective, nevertheless some characteristic properties are pointed:

Transitivity: Trust can propagate through different nodes following transitive property. However, the degree of trust does not remain same. It may decrease as the path length through which trust propagates increases.
Asymmetry: Trust is asymmetric, in the sense that if A trusts B then it is not necessary that B also trusts A. Some existing works relax this assumption and consider trust as symmetric.
Personalization: Trust is a personalized concept. Everyone has a different conception of trust with respect to some other individual. Assigning a global trust value to an individual is highly unrealistic. Trustworthiness of an individual is always evaluated with respect to some other individual.

Trust can be considered as binary-valued with 1 indicating trust and 0 indicating "not-trusted." Trust can also be evaluated as continuous-valued. Moreover, binary-valued trust is little more complicated than meets the eye. A value of 0 could be a little vague as it could represent both "no-opinion" or "distrust." To qualify this notion, often researchers use − 1 to represent distrust and 0 as missing value or "no-opinion." Researchers model the propagation of distrust the same way as the propagation of trust. Propagation of trust (T) and distrust (D) could be governed by the set of rules illustrated in Table 1. Here *A*, *B*, and *C* are

Trust in Blogosphere. Table 1. Rules for trust and distrust propagation

Propagation Scheme	Outcome	Comments
$A \overset{T}{\rightarrow} B \overset{T}{\rightarrow} C$	$A \overset{T}{\rightarrow} C$	*Transitivity*
$A \overset{T}{\rightarrow} B \overset{D}{\rightarrow} C$	$A \overset{D}{\rightarrow} C$	Don't trust someone who is distrusted by a person you trust.
$A \overset{D}{\rightarrow} B \overset{T}{\rightarrow} C$	$A \overset{D}{\rightarrow} C$	Don't trust someone who is trusted by a person you don't trust.
$A \overset{D}{\rightarrow} B \overset{D}{\rightarrow} C$	(1) $A \overset{T}{\rightarrow} C$	Enemy of yopur enemy is your friend.
	(2) $A \overset{D}{\rightarrow} C$	Don't trust someone who is not trusted by a person you don't trust.

different individuals and trust or distrust relationship between *A–B* and *B–C* is known. These rules help in inferring trust or distrust between *A–B*. Propagation of distrust is a little intricate. As shown in the Table 1, if *A* distrusts *B* and *B* distrusts *C* then *A* has reasons for either trusting *C* (enemy of enemy is a friend) or distrusting *C* (do not trust someone who is not trusted by someone else that is not trusted).

In case the link between *A* and *C*, like *B* is missing, which can be used to infer the trust between *A–C*, a different strategy could be used. Trust only if someone is trusted by *k* people, i.e., if *C* is trusted by a *k* number of people then *A* could trust *C*. Do not trust anyone who is distrusted by k' people, i.e., if *C* is distrusted by k' number of people then *A* could distrust *C*. Note that the thresholds *k* and k' could be learned from the data.

Key Applications

Trust in social networks has several applications. Trust and reputation based spam email filters have become popular after naïve spam email filters. The social network information of senders and recipients could be exploited to study trust among them and filter emails based on these values. Trust acts as lubricant that improves information flow and promotes frankness and honesty. Trust can also be helpful in online discussion forums where users look for informative and trustworthy answers to their questions. Giving trustworthy recommendations could also improve the customer retention policies.

Future Directions

Trust is a promising area of research in social networks, especially the blogosphere, where most of the assumptions from friendship networks are absent.

1. Social friendship networks assume initial trust values are assigned to the nodes of the network. Unless some social networking websites allow their members to explicitly provide trust ratings for other members, it is a topic of research and exploration to compute initial trust scores for the members. Moreover, in Blogosphere it is even harder to implicitly compute initial trust scores.
2. Social friendship networks assume an explicit relationship between members of the network. However, in Blogosphere there is no concept of explicit relationship between bloggers. Many times, these relationships have to be anticipated using link structure in the blogs or blogging characteristics of the bloggers.
3. Existing works of trust propagation algorithms assume an initial starting point. In Blogosphere, where both network structure and initial ratings are not explicitly defined, it is challenging to tackle the trust aspect. A potential approach could be to use influential members [1] of a blog community as the seeds for trustworthy nodes.
4. Since text mining has not been sufficiently exploited in Blogosphere domain, several promising research opportunities can be explored.

Data Sets

The following datasets are widely used by many researchers in this area:

A website (http://www.epinions.com/) that maintains trust values for all the available products/services provided by the customers.

Epinions: Movie Recommendation: Netflix (http://www.netflixprize.com/) provides movie recommendation dataset and what recommendations were followed by the customers. Research works have engineered this dataset to evaluate trust among customers.

Enron Email Dataset: A collection of emails that contains both genuine and spam emails. Researchers constructed social network between senders and recipients of the email and studied trust aspect.

Trusted Hardware

Radu Sion
Stony Brook University, Stony Brook, NY, USA

Synonyms

Tamper-proof hardware; Secure hardware

Definition

Trusted Hardware is a broad term used to denote any hardware that has been certified to perform according to a certain set of requirements. Most often however, "trusted hardware" is discussed in adversarial contexts. The term has thus been somewhat hijacked to mean "tamper-proof" hardware, i.e., hardware designed to resist direct physical access adversaries. Often trusted hardware encompasses some cryptographic abilities, i.e., performing encryption and data authentication.

Key Points

Certification. The National Institute of Standards has established a set of standards for security requirements of cryptographic modules and specifically for physical properties and tamper-resistance thereof [2]. The FIPS 140–2 Level 4 certification is at present the highest-attainable hardware security in sensitive, non-classified domains. While a plethora of devices have undergone FIPS certification, the most common types of trusted hardware in use today are TPM micro-controllers and secure CPUs: ***TPM.*** The Trusted Platform Module (TPM) specifications of the Trusted Computing Group [3] define a micro-controller that stores keys, passwords and digital certificates. In actual instances TPMs are connected to the main circuitry of computing devices (such as PC motherboards) and ensure that the stored data are secure from external software attacks. It is important to note however, that a TPM "can only act as a 'lave' to higher level services and applications by storing and reporting pre-runtime configuration information. [...]. At no time can the TCG building blocks 'control' the system or report the status of applications that are running." This passive nature limits the TPM's utility in security paradigms that require active processing.

SCPUs. Secure CPUs (SCPUs) are a term used to denote general-purpose CPUs deployed in a certified tamper-proof enclosure. Instances include the IBM 4758 PCI and the newer IBM 4764 PCI-X cryptographic coprocessors [1]. The IBM 4764 is a PowerPC-based board and runs embedded Linux. The 4758 is based on a Intel 486 architecture and is preloaded with a compact runtime environment that allows the loading of arbitrary external certified code. The CPUs can be custom programmed. Moreover, they (4758 models 2 and 23 and 4764 model 1) are compatible with the IBM Common Cryptographic Architecture (CCA) API. The CCA implements common cryptographic services such as random number generation, key management, digital signatures, and encryption (DES/3DES, RSA). If physically attacked, the devices destroy their internal state (in a process powered by internal long-term batteries) and shut down in accordance with their FIPS 140-2 certification. It is important to note that SCPUs are generally one order of magnitude slower than main processors mainly due to heat dissipation constraints limiting the maximum allowable gate-density within the tamper-proof enclosure.

TSQL2

Richard T. Snodgrass
University of Arizona, Tucson, AZ, USA

Definition

TSQL2 (*Temporal Structured Query Language*) is a temporal extension of SQL-92 designed in 1993–1994 by a committee comprised of Richard T. Snodgrass, Ilsoo Ahn, Gad Ariav, Don Batory, James Clifford, Curtis E. Dyreson, Ramez Elmasri, Fabio Grandi, Christian S. Jensen, Wolfgang Käfer, Nick Kline, Krishna Kulkarni, T. Y. Cliff Leung, Nikos Lorentzos, John F. Roddick, Arie Segev, Michael D. Soo and Suryanarayana M. Sripada. The goal of this language design committee was to consolidate past research on temporal query languages, by the committee members as well as many others, by developing a specification for a consensus language that could form a common core for research.

Historical Background

Temporal databases have been an active research topic since 1980. By the early 1990's, several dozen temporal query languages had been proposed, and many temporal database researchers felt that the time had come to consolidate approaches to temporal data models and calculus-based query languages to achieve a consensus query language and associated data model upon which future research could be based.

In April 1992, Richard Snodgrass circulated a white paper that proposed that a temporal extension to SQL be produced by the research community. Shortly thereafter, the temporal database community organized the ARPA/NSF International Workshop on an Infrastructure for Temporal Databases, held in Arlington Texas in June 1993 [3]. Discussions at that workshop indicated that there was substantial interest in a temporal extension to the conventional relational query language SQL-92 [2]. A general invitation was sent to the community, and about a dozen people volunteered to develop a language specification. Several people later joined the committee. The goal of this language design committee was to develop a specification for a consensus extension to SQL-92, termed the *Temporal Structured Query Language*, or TSQL2.

The group corresponded via electronic mail from early July 1993, submitting, debating, and refining proposals for the various aspects and elements of the language. In September 1993, the first draft specification, accompanied by 13 commentaries, was distributed to the committee. In December 1993, a much enlarged draft, accompanied by some 24 commentaries, was distributed to the committee. A preliminary language specification was made public in March 1994 [6], and a tutorial of the language appeared in September 1994 [7]. The final language specification and 28 commentaries were also made available via anonymous FTP in early October 2004. The final specification and commentaries appeared in a book [4] that was distributed at a temporal database workshop in summer of 1995, less than 2 years after the committee had been founded. TSQL2 is remarkable, and perhaps unique, in that it was designed entirely via electronic mail, by a committee that never met physically (in fact, no one on the committee has met every other committee member).

Work then commenced to incorporate elements and underlying insights of TSQL2 into SQL3. The first step was to propose a new part to SQL3, termed SQL/Temporal. This new part was accepted at the Ottawa meeting in January, 1995 as Part 7 of the

SQL3 specification [11]. A modification of TSQL2's PERIOD data type is included in that part.

The focus at that point changed to adding valid-time and transaction-time support to SQL/Temporal. Two change proposals, one on valid-time support and one on transaction-time support, were unanimously accepted by ANSI and forwarded to ISO [8,9]; a summary appeared shortly thereafter [10]. A comprehensive set of case studies [5] showed that while SQL-92 required 1,848 lines, only 520 lines of SQL/Temporal were required to achieve exactly the same functionality. These case studies showed that, over a wide range of data definition, query, and modification fragments, the SQL-92 version is *three* times longer in numbers of lines than the SQL/Temporal version, and many times more complex. In fact, very few SQL/Temporal statements were more than ten lines long; some statements in SQL-92 comprised literally dozens of lines of highly complex code. Due to disagreements within the ISO committee as to where temporal support in SQL should go, the project responsible for temporal support was canceled near the end of 2001. Nevertheless, concepts and constructs from SQL/Temporal have been implemented in the Oracle database management system, and other products have also included temporal support.

Oracle 9i includes support for transaction time. Its flashback queries allow an application to access prior transaction-time states of its database; they are transaction timeslice queries. Database modifications and conventional queries are temporally upward compatible. Oracle 10g extends flashback queries to retrieve all the versions of a row between two transaction times (a key-transaction-time-range query) and allows tables and databases to be rolled back to a previous transaction time, discarding all changes after that time. The Oracle 10g Workspace Manager includes the period data type, valid-time support, transaction-time support, support for bitemporal tables, and support for sequenced primary keys, sequenced uniqueness, sequenced referential integrity, and sequenced selection and projection, in a manner quite similar to that proposed in SQL/Temporal.

Foundations

The goals that underpinned the process that led to the TSQL2 language design are first considered, then the language concepts underlying TSQL2 are reviewed.

Design Goal for TSQL2

TSQL2 is a temporal query language, designed to query and manipulate time-varying data stored in a relational database. It is an upward-compatible extension of the international standard relational query language SQL-92.

The TSQL2 language design committee started their work by establishing a number of ground rules with the objective of achieving a coherent design.

- TSQL2 will be a *language* design.
- TSQL2 is to be a *relational* query language, not an object-oriented query language.
- TSQL2 should be consistent with existing standards, not another standard.
- TSQL2 should be comprehensive and should reflect areas of convergence.
- The language will have an associated algebra.

The committee enumerated the desired features of TSQL2; these guided the design of the language. The first batch concerned the data model itself.

- TSQL2 should not distinguish between snapshot equivalent instances, i.e., snapshot equivalence and identity should be synonymous.
- TSQL2 should support only one valid-time dimension.
- For simplicity, tuple timestamping should be employed.
- TSQL2 should be based on homogeneous tuples.
- Valid-time support should include support for both the past and the future.
- Timestamp values should not be limited in range or precision.

The next concerned the language proper.

- TSQL2 should be a consistent, fully upwardly compatible extension of SQL-92.
- TSQL2 should allow the restructuring of tables on any set of attributes.
- TSQL2 should allow for flexible temporal projection, but TSQL2 syntax should reveal clearly when non-standard temporal projections are being done.
- Operations in TSQL2 should not accord any explicit attributes special semantics. For example, operations should not rely on the notion of a key.

- Temporal support should be optional, on a per-table basis. Tables not specified as temporal should be considered as snapshot tables. It is important to be an extension of SQL-92's data model when possible, not a replacement. Hence, the schema definition language should allow the definition of snapshot tables. Similarly, it should be possible to derive a snapshot table from a temporal table.
- User-defined time support should include instants, periods, and intervals.
- Existing aggregates should have temporal analogues in TSQL2.
- Multiple calendar and multiple language support should be present in timestamp input and output, and timestamp operations. SQL-92 supports only one calendar, a particular variant of the Gregorian calendar, and one time format. The many uses of temporal databases demand much more flexibility.
- It should be possible to derive temporal and non-temporal tables from underlying temporal and non-temporal tables.

Finally, the committee agreed upon three features aimed at ease of implementation.

- TSQL2 tables should be implementable in terms of conventional first normal form tables. In particular, the language should be implementable via a data model that employs period-timestamped tuples. This is the most straightforward representation, in terms of extending current relational technology.
- TSQL2 must have an efficiently implementable algebra that allows for optimization and that is an extension of the conventional relational algebra, on which current DBMS implementations are based. The temporal algebra used with the TSQL2 temporal data model should contain temporal operators that are extensions of the operations in the relational algebra. Snapshot reducibility is also highly desired, so that, for example, optimization strategies will continue to work in the new data model.
- The language data model should *accept* implementation using other models, such as models that timestamp attribute values. The language data model should allow multiple representational data models. In particular, it would be best if the data model accommodated the major temporal data models proposed to date, including attribute timestamped models.

Language Concepts in TSQL2

The following is a brief outline of the major concepts behind TSQL2.

Time Ontology The TSQL2 model of time is bounded on both ends. The model refrains from deciding whether time is ultimately continuous, dense, or discrete. Specifically, TSQL2 does not allow the user to ask a question that will differentiate the alternatives. Instead, the model accommodates all three alternatives by assuming that an instant on a time-line is much smaller than a chronon, which is the smallest entity that a timestamp can represent exactly (the size of a chronon is implementation-dependent). Thus, an instant can only be approximately represented. A discrete image of the represented times emerges at run-time as timestamps are scaled to user-specified (or default) granularities and as operations on those timestamps are performed to the given scale.

An instant is modeled by a timestamp coupled with an associated scale (e.g., day, year, month). A period is modeled by a pair of two instants in the same scale, with the constraint that the instant timestamp that starts the period equals or precedes (in the given scale) the instant timestamp that terminates the period.

Base Line Clock A semantics must be given to each time that is stored in the database. SQL-92 specifies that times are given in UTC seconds, which are, however, not defined before 1958, and in any case cannot be used to date prehistoric time, as UTC is based in part on solar time. TSQL2 includes the concept of a *baseline clock*, which provides the semantics of timestamps. The baseline clock relates each second to physical phenomena and partitions the time line into a set of contiguous *periods*. Each period runs on a different clock. *Synchronization points* delimit period boundaries. The baseline clock and its representation are independent of any calendar.

Data Types SQL-92's datetime and interval data types are augmented with a *period* datetime, of specifiable range and precision. The range and precision can be expressed as an integer (e.g., a precision of 3 fractional digits) or as an interval (e.g., a precision of a week). Operators are available to compare timestamps and to compute new timestamps, with a user-specified precision. Temporal values can be input and output in user-specifiable formats, in a variety of natural languages. *Calendars* and *calendric systems* permit the application-dependent semantics of time to be incorporated.

A surrogate data are introduced in TSQL2. Surrogates are unique identifiers that can be compared for equality, but the values of which cannot be seen by the users. In this sense, a surrogate is "pure" identity and does not describe a property (i.e., it has no observable value). Surrogates are useful in tying together representations of multiple temporal states of the same object; they are not a replacement for keys.

Time-Lines Three time-lines are supported in TSQL2: user-defined time, valid time, and transaction time. Hence values from disparate time-lines can be compared, at an appropriate precision. Transaction-time is bounded by `initiation`, the time when the database was created, and until changed. In addition, user-defined and valid time have two special values, beginning and forever, which are the least and greatest values in the ordering. Transaction time has the special value until changed.

Valid and user-defined times can be indeterminate. In *temporal indeterminacy*, it is known that an event stored in a temporal database did in fact occur, but it is not known exactly *when* that event occurred. An instant (interval, period) can be specified as determinate or indeterminate; if the latter then the possible mass functions, as well as the generality of the indeterminacy to be represented, can be specified. The quality of the underlying data (termed its *credibility*) and the *plausibility* of the ordering predicates expressed in the query can be controlled on a per-query or global basis.

Finally, instant timestamps can be *now-relative*. A now-relative time of "*now* – 1 day," interpreted when the query was executed on June 12, 1993, would have the *bound* value of "June 11, 1993." The users can specify whether values to be stored in the database are to be bound (i.e., not now-relative) or unbound.

Aggregates The conventional SQL-92 aggregates are extended to take into account change across time. They are extended to return time-varying values and to permit grouping via a partitioning of the underlying time line, termed *temporal grouping*. Values can be *weighted* by their duration during the computation of an aggregate. Finally, a new temporal aggregate, `RISING`, is added. A taxonomy of temporal aggregates [4, Chap. 21] identifies 14 possible kinds of aggregates; there are instances of all of these kinds in TSQL2.

Valid-Time Tables The snapshot tables supported by SQL-92 continue to be available in TSQL2, which, in addition, supports *state* tables, where each tuple is timestamped with a *temporal element* that is a union of periods. As an example, the Employee table with attributes Name, Salary, and Manager could contain the tuple (Tony, 10,000, LeeAnn). The temporal element timestamp would record the maximal (non-contiguous) periods in which Tony made $10,000 and had LeeAnn as his manager. Information about other values of Tony's salary or other managers would be stored in other tuples. The timestamp is implicitly associated with each tuple; it is not another column in the table. The range, precision, and indeterminacy of a temporal element can be specified.

Temporal elements are closed under union, difference, and intersection. Timestamping tuples with temporal elements is conceptually appealing and can support multiple representational data models. Dependency theory can be extended to apply in full to this temporal data model.

TSQL2 also supports *event* tables, in which each tuple is timestamped with an *instant set*. As an example, a Hired table with attributes Name and Position could contain the tuple (LeeAnn, Manager). The instant set timestamp would record the instant(s) when LeeAnn was hired as a Manager. (Other information about her positions would be stored in separate tables.) As for state tables, the timestamps are associated implicitly with tuples.

Transaction-Time and Bitemporal Tables Orthogonally to valid time, transaction time can be associated with tables. The transaction time of a tuple, which is a temporal element, specifies when that tuple was considered to be part of the current database state. If the tuple (Tony, 10,000, LeeAnn) was stored in the database on March 15, 1992 (say, with an `APPEND` statement) and removed from the database on June 1, 1992 (say, with a `DELETE` statement), then the transaction time of that tuple would be the period from March 15, 1992 to June 1, 1992.

Transaction timestamps have an implementation-dependent range and precision, and they are determinate.

In summary, there are six kinds of tables: snapshot (no temporal support beyond user-defined time), valid-time state tables (timestamped with valid-time elements), valid-time event tables (timestamped with valid-time instant sets), transaction-time tables (timestamped with transaction-time elements), bitemporal state tables (timestamped with bitemporal elements), and bitemporal event tables (timestamped with bitemporal instant sets).

Schema Specification The CREATE TABLE and ALTER statements allow specification of the valid- and transaction-time aspects of temporal tables. The scale and precision of the valid timestamps can also be specified and later altered.

Restructuring The FROM clause in TSQL2 allows tables to be *restructured* so that the temporal elements associated with tuples with identical values on a subset of the columns are coalesced. For example, to determine when Tony made a Salary of $10,000, independent of who his manager was, the Employee table could be restructured on the Name and Salary columns. The timestamp of this restructured tuple would specify the periods when Tony made $10,000, information which might be gathered from several underlying tuples specifying different managers.

Similarly, to determine when Tony had LeeAnn as his manager, independent of his salary, the table would be restructured on the Name and Manager columns. To determine when Tony was an employee, independent of how much he made or who his manager was, the table could be restructured on only the Name column.

Restructuring can also involve *partitioning* of the temporal element or instant set into its constituent maximal periods or instants, respectively. Many queries refer to a continuous property, in which maximal periods are relevant.

Temporal Selection The valid-time timestamp of a table may participate in predicates in the WHERE clause by via VALID() applied to the table (or correlation variable) name. The transaction-time of a table can be accessed via TRANSACTION(). The operators have been extended to take temporal elements and instant sets as arguments.

Temporal Projection Conventional snapshot tables, as well as valid-time tables, can be derived from underlying snapshot or valid-time tables. An optional VALID or VALID INTERSECT clause is used to specify the timestamp of the derived tuple. The transaction time of an appended or modified tuple is supplied by the DBMS.

Update The update statements have been extended in a manner similar to the SELECT statement, to specify the temporal extent of the update.

Cursors Cursors have been extended to optionally return the valid time of the retrieved tuple.

Schema Versioning Schema *evolution*, where the schema may change, is already supported in SQL-92. However, old schemas are discarded; the data are always consistent with the current schema. Transaction time support dictates that previous schemas be accessible, which calls for *schema versioning*. TSQL2 supports a minimal level of schema versioning.

Vacuuming Updates, including (*logical*) deletions, to transaction time tables result in insertions at the physical level. Despite the continuing decrease in cost of data storage, it is still, for various reasons, not always acceptable that all data be retained forever. TSQL2 supports a simple form of *vacuuming*, i.e., physical deletion, from such tables.

System Tables The TABLE base table has been extended to include information on the valid and transaction time components (if present) of a table. Two other base tables have been added to the definition schema.

SQL-92 Compatibility All aspects of TSQL2 are pure extensions of SQL-92. The user-defined time in TSQL2 is a consistent replacement for that of SQL-92. This was done to permit support of multiple calendars and literal representations. Legacy applications can be supported through a default SQL92_calendric_system.

The defaults for the new clauses used to support temporal tables were designed to satisfy snapshot reducibility, thereby ensuring that these extensions constitute a strict superset of SQL-92.

Implementation During the design of the language, considerable effort was expended to ensure that the language could be implemented with only moderate modification to a conventional, SQL-92-compliant DBMS. In particular, an algebra has been demonstrated that can be implemented in terms of a period-stamped (or instant-stamped, for event tables) tuple representational model; few extensions to the conventional algebra were required to fully support the TSQL2 constructs. This algebra is snapshot reducible to the conventional relational algebra. Support for multiple calendars, multiple languages, mixed precision, and indeterminacy have been included in prototypes that demonstrated that these extensions have little deleterious effect on execution performance. Mappings from the data model underlying TSQL2, the bitemporal conceptual data model [1], to various representational data models have been defined [4].

Key Applications

TSQL2 continues to offer a common core for temporal database research, as well as a springboard for change proposals for extensions to the SQL standard.

Future Directions

Given the dramatic decrease in code size and complexity for temporal applications that TSQL2 and SQL/Temporal offers, it is hoped that other DBMS vendors will take Oracle's lead and incorporate these proposed language constructs into their products.

Lock tuning

Definition

Database systems implement concurrency control to give users the illusion that each transaction executes correctly, in isolation from all others. The concurrency-control algorithm in predominant use is two-phase locking. Tuning concurrency control consists in improving the performance of concurrent operations by reducing the number, duration and scope of the conflicts due to locking.

Historical Background

In 1976, Jim Gray et al. identified the fundamental concurrency control trade-off between correctness and performance. They discussed different lock granularities and introduced the notion of degrees of consistency.

Foundations

Database systems attempt to give users the illusion that each transaction executes in isolation from all others. The ANSI SQL standard, for example, makes this explicit with its concept of degrees of isolation. Full isolation or *serializability* is the guarantee that each transaction that completes will appear to execute one at a time, except that its performance may be affected by other transactions. Choosing a lower level of isolation will benefit performance, possibly at the cost of correctness. The value of serializability experiment (see below in experimental results) illustrates this performance/correctness trade-off. This entry discusses basic concurrency tuning techniques.

Leveraging Application Semantics

Efficient tuning often entails understanding application semantics. A frequently required feature is to assign consecutive key values to consecutive records (e.g., customer numbers, purchase order numbers). Consider a straightforward implementation.

In the following example, the COUNTER table contains the next value which is used as a key when inserting values in the ACCOUNT table.

```
begin transaction
  NextKey:=select nextkey from COUNTER;
  insert into ACCOUNT values (nextkey, 100, 200);
  update COUNTER set nextkey=NextKey+1;
end transaction
```

When the number of such transactions issued concurrently increases, COUNTER becomes a bottleneck because all transactions read and write the value of nextkey.

An alternative approach is to use the facilities that many systems offer that reduce the length of time counter locks are held. These facilities (sequences in Oracle, autoincrement in MySQL and identity in SQL Server, DB2 UDB and Sybase Adaptive Server) enable transactions to hold a latch (see the latch definitional entry) on the counter only while accessing the counter, rather than until the transaction completes. This eliminates the counter as a bottleneck but may introduce a small problem.

Consider an insert transaction T that increments the counter then aborts. Before T aborts, a second transaction T' may increment the counter further. Thus, the counter value obtained by T will not be associated with any data item. That is, there may be gaps in the counter values. Most applications can tolerate such gaps, but some cannot for legal reasons, e.g., tax authorities prefer that invoice numbers have no gaps.

Living Dangerously

Many applications live with less than full isolation due to the high cost of holding locks during user interactions. Consider the following full-isolation transaction from an airline reservation application:

```
Airline Reservation Transaction
  Begin transaction
    Retrieve list of seats available;
    Reservation agent talks with customer regarding
    availability;
    Secure seat.
  End transaction
```

The performance of a system built from such transactions would be intolerably slow, because each customer would hold a lock on all available seats for a flight while chatting with the reservations agent. This solution does, however, guarantee two conditions: (i) no two customers will be given the same seat, and (ii) any seat that the reservation agent identifies as available in view of the retrieval of seats will still be available when the customer asks to secure it.

Because of the poor performance, however, the following is done instead:

```
Loosely Consistent Airline Reservation
  Begin transaction
    Retrieve list of seats available;
    Reservation agent talks with customer regarding
    availability;
    Secure seat.
  End transaction
```

This design relegates lock conflicts to the secure step, thus guaranteeing that no two customers will be given the same seat. It does allow the possibility, however, that a customer will be told that a seat is available, will ask to secure it, and will then find out that it is gone.

General Rules of Thumb

By looking at blocking and (more rarely) deadlock statistics, an administrator or advanced application user can infer the existence of a concurrency control bottleneck. What should follow is careful analysis of the application to see (i) whether transactions can be redesigned to place accesses to hot items at the ends of the transactions, (ii) whether system facilities may help to reduce concurrency bottlenecks, (iii) or whether the application semantics allow a lesser form of concurrency correctness guarantee for the sake of performance. The general idea is to reduce the hold on the few critical resources that cause the concurrency bottleneck.

Key Applications

Concurrency control tuning is essential for applications having frequent modifications (inserts, deletes, and/or updates), because those applications entail lock conflicts.

Experimental Results

Value of Serializability

This experiment illustrates the correctness/performance trade-off associated to the two isolation levels, i.e., serializable and read committed. Consider a table of the form R(a int primary key, b int), on which an application executes two types of transactions: (i) a *sum* transaction that computes the sum of *b* values, and (ii) *swap* transactions that swap *b* values. The experiment consists in executing the two types of transactions concurrently. The parameters of the experiments are (i) the level of isolation, and (ii) the number of concurrent threads executing the swap transactions (note that the total number of transactions is kept constant throughout the experiment). Response time is measured for the total number of transactions.

The results presented below were obtained with MySQL SQL 6.0 (using InnoDB with a 1GB buffer pool), running on a Linux server equipped with an Intel Core 2 Duo processor (the cache is warm during this experiment). The SQL code and the data used for this experiment as well as the data set with the measurements are available at the URL listed at the end of this entry.

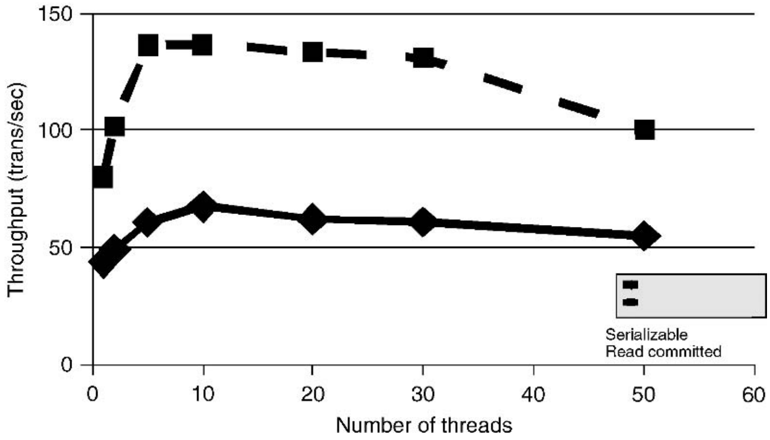
Interestingly, both the read committed and serializable isolation levels yield 100% correct answer regardless of the number of threads executing the *swap* transactions. The reason is that MySQL (like Oracle) implements snapshot isolation: the result of the *sum* transaction is obtained on the R table as it stood when that transaction began, i.e., the *swap* transactions do not impact the result of the *sum* transaction. When executed on database systems that do not implement snapshot isolation (e.g., SQLServer or DB2), only about 40% of the results were correct for the *sum* transaction [3].

Figure 1 traces throughput (i.e., total number of transactions/response time) for the serializable and read committed level as a function of the number of swap threads.

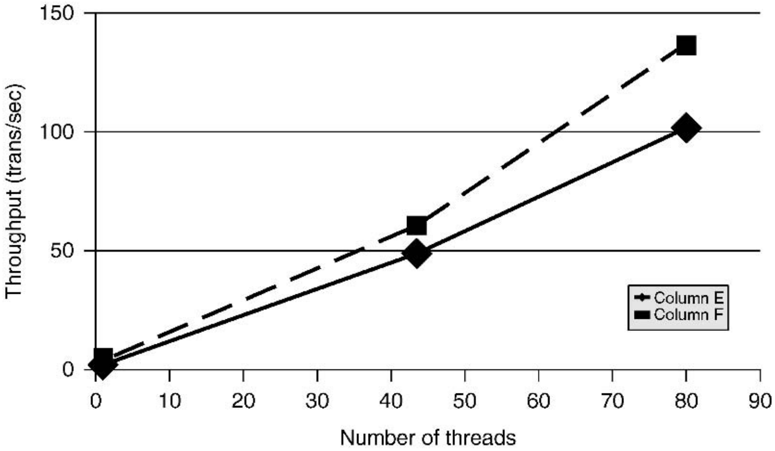
Read committed yields a higher throughput than serializable. The reason is that in the serializable isolation level, the *sum* transaction sets next-key locks while scanning the table, whereas at the read committed isolation level, the sum transaction relies on snapshot isolation, i.e., no read locks are used.

Counters

This experiment illustrates the benefit of using a system-defined counter as opposed to using an adhoc method based on a counter table. The experiment



Tuning Concurrency Control. Figure 1. Value of serializability experiment on MySQL 6.0.



Tuning Concurrency Control. Figure 2. Counter experiment on MySQL 6.0.

consists in running a fixed number of insert transactions concurrently. The number of threads used to run these transactions is the main parameter of this experiment. The experiment measures response time for the total number of transactions.

Figure 2 presents traces throughput (i.e., total number of transactions/response time) for the ad hoc and system implementation as a function of the number of swap threads. These results were obtained with the configuration used for the Value of Serializability experiment (see above). The SQL code and the data used for this experiment are available at the URL listed below.

In the experiment, the benefits of the system-based counter become more significant as the number of threads increases. The reason is that as the number of threads increase, the counter table becomes a hot spot and the benefits of using a latch released at the end of the statement (system method) over a lock held until the end of the transaction (ad hoc method) becomes significant. Note that the performance of the ad hoc method diminishes as the amount of processing in the transaction increases (i.e., as the time during which the lock is held increases).

Tuple-Generating Dependencies

RONALD FAGIN
IBM Almaden Research Center, San Jose, CA, USA

Synonyms

Equality-generating dependency (egd)

Definition

Tuple-generating dependencies, or *tgds*, are one of the two major types of *database dependencies* (the other major type consists of *equality-generating dependencies*, or *egds*).

To define tgds, the notion of an *atomic formula* is first needed, which is a formula of the form $P(x_1,...,x_k)$, where P is a k-ary relational symbol, and $x_1,...,x_k$ are variables, not necessarily distinct.

Then tgds are formulas of the form $\forall \mathbf{x}(\phi(\mathbf{x}) \rightarrow \exists \mathbf{y} \psi(\mathbf{x}, \mathbf{y}))$, where

1. $\phi(\mathbf{x})$ is a conjunction of atomic formulas, all with variables among the variables in $\mathbf{x}$.
2. every variable in $\mathbf{x}$ appears in $\phi(\mathbf{x})$ (but not necessarily in $\psi(\mathbf{x}, \mathbf{y})$).
3. $\psi(\mathbf{x}, \mathbf{y})$ is a conjunction of atomic formulas, all with variables among the variables in $\mathbf{x}$ and $\mathbf{y}$.

If $\mathbf{y}$ is empty, so that there are no existentially-quantified variables, then the tgd is called *full*.

Conditions (1) and (2) together are sometimes replaced by the weaker condition that $\phi(\mathbf{x})$ be an arbitrary first-order formula with free variables exactly those in $\mathbf{x}$.

Key Points

An example of a tgd is the formula

$$\forall x_1 \forall x_2 (R(x_1, x_1, x_2) \wedge S(x_2) \\ \rightarrow \exists y (R(x_1, y) \wedge T(x_2, y, x_1)).$$

Historically, tgds were introduced for the purpose of database normalization and design, with the first example being *multivalued dependencies* [2,5]. Fagin [3] defined the class of *embedded implicational dependencies*, which includes both tgds and egds, but he focused on the case where they are (i) unirelational (so that all atomic formulas involve the same relation symbol) and (ii) typed (so that no variable can appear in both the ith and jth position of an atomic formula if $i \neq j$). Beeri and Vardi [1] defined and named tgds and egds.

In recent years, tgds have been used to define *schema mappings* in *data exchange* [4], which describe how data structured under one schema (the *source schema*) is to be transformed into data structured under a second schema (the *target schema*). In this application, the atomic formulas in the premise $\phi(\mathbf{x})$ are all from the source schema, and the atomic formulas in the conclusion $\psi(\mathbf{x}, \mathbf{y})$ are all from the target schema.

Two-Dimensional Shape Retrieval

Lei Chen
Hong Kong University of Science and Technology,
Kowloon, Hong Kong, China

Definition

Shape is an important image feature, it is the geometrical information of an object after removing position, scale and rotational effects [3]. A shape is often represented by the contour map extracted from the images. Given a query 2D shape, *2D shape retrieval* retrieves a ranked list of similar 2D shapes from a collection of 2D polygonal models (contour points) based on the shape characteristics.

Figure 1 gives an example object shapes, which are represented by the extracted contour maps.

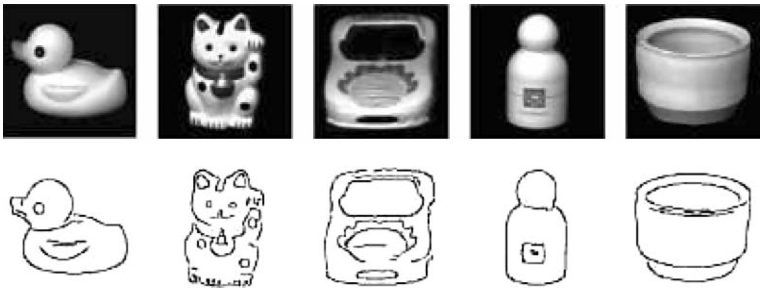
Historical Background

The study of shape retrieval can be traced back to 1980s. At that time, shape retrieval was treated as an key technique in object recognition of robot vision. Since then, shape retrieval has received much attention in the database domain due to its various application in biometrics, industry, medicine and anthropology.

Foundations

The shape retrieval problem is to retrieve shapes that are visually similar to the query shape. There are two key issues related to shape retrieval [6], *shape representation* and *similarity measure*. Given a shape, it should be represented in a form which is invariant to scaling, translation and rotation. For similarity measures, various measures are designed to meet application requirements. In fact, the two key issues are closely related to each other. Based on the different shape representations, different similarity measures are applied. Existing works represent shape in various ways including:

1. *Shape signature* is one-dimensional vector derived from the shape boundary coordinates. For example, the Euclidean distance between centroid point to the boundary points [8]. The shape of an object is represented by a set of normalized Fourier coefficients of the shape signature and the inner product



Two-Dimensional Shape Retrieval. Figure 1. Examples of shape of object represented by contour maps [4].

of the Fourier coefficients is used to measure the similarity between two shapes.

2. *Grid descriptor* is derived by overlaying the shapes with a coarse grid and assigning an '1' to a grid cell if more than 15% of the cell is covered by the shape, otherwise '0' [5]. Two shapes are compared by counting the number of different bits of corresponding normalized grid descriptors. The similarity measure conforms to human similarity perception, i.e., perceptually similar shapes have high similarity measure.
3. *Shape context* captures the distribution of the points relative to a reference point on the contour of an object, thus it offers a globally discriminative feature. Two shapes are similar if they have similar shape contexts. Therefore, the similarity between two shapes is computed by counting the number of matching corresponding points [2].
4. *Distance set* uses N nearest neighbors to represent each contour point [4]. The similarity between two shapes are measure by the cost of the cheapest correspondence relation of corresponding distance sets, which is computed by evaluating the minimum cost assignment in an associated bipartite graph.
5. *Curvature scale space* is formed by the positions of inflection points (x-axis) on the contours on every scale (y-axis) [7]. The shape representation is the positions of the maxima on these curves. The shape similarity is measures by relating the positions of the maxima of the corresponding curves.
6. *Symbolic features* refers to a shape which is represented in terms of multi-interval valued type features including shape centroid, extreme points, axis of least inertia with slope angle, and feature points on the axis of least inertia, etc. [1]. The similarity between two shapes is defined on these symbolic features as the average degree of similarity of all corresponding feature vector pairs.
7. *Shape space* refers a single point (vector) in a high-dimensional manifold. The vector is obtained by normalizing the landmark vector of the origin shape [9]. The similarity is measured as the geodesic distance between a shape and a model in the shape space.

In addition to the shape representation and similarity measure design, index structures should be built on the shape representations to allow shape similarity queries be answered efficiently.

Key Applications

Content Based Image Retrieval

Content-based image retrieval (CBIR), also known as query by image content (QBIC) and content-based visual information retrieval (CBVIR) is the application of computer vision to the image retrieval problem, that is, the problem of searching for digital images in large databases.

Visual Surveillance

Visual surveillance in dynamic scenes is an active research topics in computer vision. The aim of visual surveillance is to make it possible that the computer can watch or monitor a scene by automatic localization, tracking and recognition.

Future Directions

Effective and robust similarity measures and efficient indexing structures.

Two-Phase Commit

Yousef J. Al-Houmaily[1], George Samaras[2]
[1]Institute of Public Administration, Riyadh, Saudi Arabia
[2]University of Cyprus, Nicosia, Cyprus

Definition

Two-phase commit (2PC) is a synchronization protocol that solves the *atomic commitment problem*, a special case of the *Byzantine Generals* problem. Essentially, it is used in distributed database systems to ensure *global atomicity* of transactions in spite of site and communication failures, assuming that a failure will be, *eventually*, repaired and each site guarantees atomicity of transactions at its local level.

Historical Background

2PC is the simplest and most studied *atomic commit protocol* (ACP). It was first published in [9] and [4]. Since then, the protocol has received much attention from the academia and industry due to its importance in distributed database systems, and the research has resulted in numerous variants and optimizations for different distributed database environments. These environments include main memory databases (e.g., [10]), real-time databases (e.g., [5]), mobile database systems (e.g., [12]), heterogeneous database systems (e.g., [1]), Web databases (e.g., [15]), besides traditional (homogeneous) distributed database systems (e.g., [13,3]).

Foundations

In a distributed database system, a transaction is decomposed into a set of *subtransactions*, each of which executes at a single participating database site. Assuming that each database site preserves atomicity of (sub)transactions at its local level, global atomicity cannot be guaranteed without taking additional measures. This is because without global synchronization a distributed transaction might end-up committing at some participating sites and aborting at others due to a site or a communication failure. Thus, jeopardizing *global* atomicity and, consequently, the consistency of the (distributed) database.

To achieve atomicity at the global level, there is a need for a synchronization protocol that ensures a unanimous final outcome for each distributed transaction and regardless of failures. Such a protocol is referred to as an *atomic commit protocol* (ACP). An ACP ensures that a distributed transaction is either *committed* and all its effects become persistent across all participating sites, or *aborted* and all its effects are obliterated as if the transaction had never executed at any site. This is the essence of the two-phase commit (2PC) protocol.

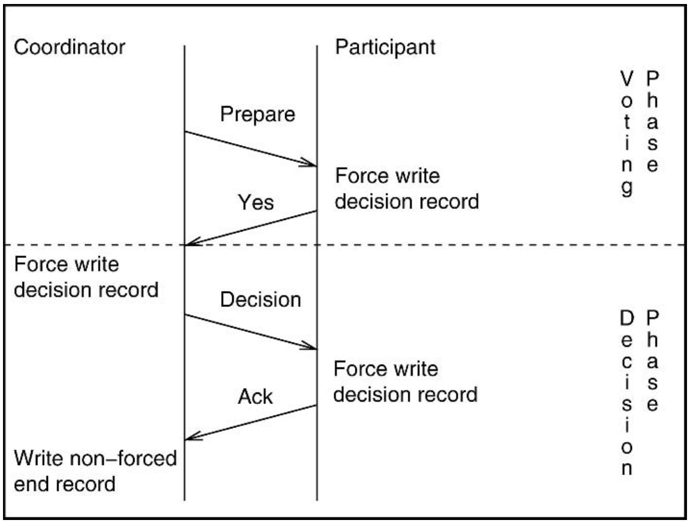
Dynamics of Two-Phase Commit

In 2PC, each transaction is associated with a designated site called the *coordinator* (or *master*). Although the coordinator of a transaction could be any of the sites participating in the transaction's execution, it is commonly the originating site of the transaction (i.e., the site where the transaction is first initiated). The rest of the sites are called *participants*, *subordinates*, *cohorts* or *slaves*. Once a transaction finishes its execution and indicates its termination point, through a commit primitive, to its coordinator, the coordinator initiates 2PC.

As the name implies, 2PC consists of two phases, namely a *voting phase* and a *decision phase*, as shown Fig. 1. During the voting phase, the coordinator requests all the sites participating in the transaction's execution to *prepare-to-commit* whereas, during the decision phase, the coordinator either decides to commit the transaction if *all* the participants are prepared to commit (voted "yes"), or to abort if any participant has decided to abort (voted "no"). On a commit decision, the coordinator sends out commit messages to *all* participants whereas, on an abort decision, it sends out abort messages to *only* those (required) participants that are prepared-to-commit (voted "yes").

When a participant receives a prepare-to-commit message for a transaction, it validates the transaction with respect to data consistency. If the transaction can be committed (i.e., it passed the validation process), the participant responds with a "yes" vote. Otherwise, it responds with a "no" vote and aborts the transaction, releasing all the resources held by the transaction.

If a participant had voted "yes", it can neither commit nor abort the transaction unilaterally and has to wait until it receives a final decision from the coordinator. In this case, the participant is said to be *blocked* for an indefinite period of time called *window of uncertainty* (or *window of vulnerability*) awaiting the coordinator's decision. When a participant receives the final decision, it complies with the decision, sends back an acknowledgement message (Ack) to the coordinator and releases all the resources held by the transaction.



Coordinator

Prepare
Force write decision record
Yes
Voting Phase
Force write decision record
Decision
Force write decision record
Ack
Decision Phase
Write non–forced end record

Two-Phase Commit. Figure 1. The two-phase commit protocol.

When the coordinator receives Acks from all the participants that had voted "yes," it *forgets* the transaction by discarding all information pertaining to the transaction from its protocol table that is kept in main memory.

The resilience of 2PC to failures is achieved by recording the progress of the protocol in the logs of the coordinator and the participants. The coordinator force writes a *decision* record prior to sending out its decision to the participants. Since a *forced write* of a log record causes a flush of the log onto a stable storage that survives system failures, the decision is not lost if the coordinator fails. Similarly, each participant force writes a *prepared* record before sending its "yes" vote and a *decision* record before acknowledging a decision. When the coordinator completes the protocol, it writes a non-forced *end* record in the volatile portion of its log that is kept in main memory. This record indicates that all (required) participants have received the decision and none of them will inquire about the transaction's status in the future. This allows the coordinator to (permanently) forget the transaction, with respect to 2PC, and garbage collect the log records of the transaction when necessary.

Recovery in Two-Phase Commit

Site and communication failures are detected by *timeouts*. When an operational site detects a failure, it invokes a recovery manager to handle the failure. In 2PC, there are four places where a communication failure might occur. The first place is when a participant is waiting for a prepare-to-commit message from the coordinator. This occurs before the participant has voted. In this case, the participant may unilaterally decide to abort the transaction. The second place is when the coordinator is waiting for the votes of the participants. Since the coordinator has not made a final decision yet and no participant could have decided to commit, the coordinator can decide to abort. The third place is when a participant had voted "yes" but has not received a commit or an abort final decision. In this case, the participant cannot make any unilateral decision because it is uncertain about the coordinator's final decision. The participant, in this case, is *blocked* until it re-establishes communication with the coordinator and, once re-established, the participant inquires the coordinator about the final decision and resumes the protocol by enforcing and, then, acknowledging the coordinator's decision. The fourth place is when the coordinator is waiting for the Acks of the participants. In this case, the coordinator re-submits its final decision to those participants that have not acknowledged the decision once it re-establishes communication with them. Notice that the coordinator cannot simply discard the information pertaining to a transaction from its protocol table or its stable log until it receives Acks from all the (required) participants.

To recover from site failures, there are two cases to consider: coordinator's failure and participant's failure.

For a coordinator's failure, the coordinator, upon its restart, scans its stable log and re-builds its protocol table to reflect the progress of 2PC for all the pending transactions prior to the failure. The coordinator has to consider only those transactions that have started 2PC and have not finished it prior to the failure (i.e., transactions that have decision log records without corresponding end log records in the stable log). For other transactions, i.e., transactions that were active at the coordinator's site prior to its failure without a decision record, the coordinator considers them as aborted transactions. Once the coordinator re-builds its protocol table, it completes the protocol for each of these transactions by re-submitting its final decision to all (required) participants whose identities are recorded in the decision record and waiting for their Acks. Since some of the participants might have already received the decision prior to the failure and enforced it, these participants might have already forgotten that the transaction had ever existed. Such participants simply reply with *blind* Acks, indicating that they have already received and enforced the decision prior to the failure.

For a participant's failure, the participant, as part of its recovery procedure, checks its log for the existence of any transaction that is in a prepared-to-commit state (i.e., has a prepared log record without a corresponding final decision one). For each such transaction, the participant inquires the transaction's coordinator about the final decision. Once the participant receives the decision from the coordinator, it completes the protocol by enforcing and, then, acknowledging the decision. Notice that a coordinator will be always able to respond to such inquires because it cannot forget a transaction before it has received the Acks of all (required) participants. However, there is a case where a participant might be in a prepared-to-commit state and the coordinator does not remember the transaction. This occurs if the coordinator fails after it has sent prepare-to-commit messages and just before it has made its decision. In this case, the coordinator will not remember the transaction after it has recovered. If a prepared-to-commit participant inquires about the transaction's status, the coordinator will *presume* that the transaction was aborted and responds with an abort message. This special case where an abort presumption is made about unremembered transactions in 2PC motivated the design of the *presumed abort* 2PC.

Underlying Assumptions

ACPs solve a special case of the problem of consensus in the presence of faults, a problem that is known in distributed systems as the *Byzantine Generals* problem [7]. This problem is, in its most general case, not solvable without some simplifying assumptions. In distributed database systems, ACPs solve the problem under the following general assumptions (among others that are sometimes ACP specific):

1. *Each site is sane*: A site is fail stop where it never deviates from its prescribed protocol. That is, a site is either operational or not but never behaves abnormally causing *commission* failures.
2. *Eventual recovery*: A failure (whether site or communication) will be, eventually, repaired.
3. *Binary outcome*: All sites unanimously agree on a single binary outcome, either commit or abort.

Performance Issues

There are three important performance issues that are associated with ACPs, which are as follows [3]:

1. *Efficiency During Normal Processing*: This refers to the cost of an ACP to provide atomicity in the absence of failures. Traditionally, this is measured using three metrics. The first metric is *message complexity* which deals with the number of messages that are needed to be exchanged between the systems participating in the execution of a transaction to reach a consistent decision regarding the final status of the transaction. The second metric is *log complexity* which accounts for the frequency at which information needs to be recorded at each participating site in order to achieve resiliency to failures. Typically, log complexity is expressed in terms of the required number of non-forced log records which are written into the log buffer (in main memory) and, more importantly, the number of forced log records which are written onto the stable log (on the disk). The third metric is *time complexity* which corresponds to the required number of rounds or sequential exchanges of messages in order for a decision to be made and propagated to the participants.
2. *Resilience to Failures*: This refers to the types of failures that an ACP can tolerate and the effects of failures on operational sites. An ACP is considered *non-blocking* if it never requires operational sites to

wait (i.e., block) until a failed site has recovered. One such protocol is 3PC.

3. *Independent Recovery*: This refers to the speed of recovery. That is, the time required for a site to recover its database and become operational, accepting new transactions after a system crash. A site can *independently* recover if it has all the necessary information needed for recovery stored locally (in its log) without requiring any communication with any other site in order to fully recover.

Most Common Two-Phase Commit Variants

Due to the costs associated with 2PC during normal transaction processing and the reliability drawbacks in the events of failures, a variety of ACPs have been proposed in the literature. These proposals can be, generally, classified as to enhance either (i) the efficiency of 2PC during normal processing or (ii) the reliability of 2PC by either reducing 2PC's blocking aspects or enhancing the degree of independent recovery. The most commonly pronounced 2PC variants are *presumed abort* (PrA) [11] and *presumed commit* (PrC) [11]. Both variants reduce the cost of 2PC during normal transaction processing, albeit for different final decisions. That is, PrA is designed to reduce the costs associated with aborting transactions whereas PrC is designed to reduce the costs associated with committing transactions.

In PrA, when a coordinator decides to abort a transaction, it does not force-write the abort decision in its log as in 2PC. It just sends abort messages to all the participants that have voted "yes" and discards all information about the transaction from its protocol table. That is, the coordinator of an aborted transaction does not have to write any log records or wait for Acks. Since the participants do not have to Ack abort decisions, they are also not required to force-write such decisions. After a coordinator's or a participant's failure, if the participant *inquires* about a transaction that has been aborted, the coordinator, not remembering the transaction, will direct the participant to abort the transaction (by presumption). Thus, as the name implies, if no information is found in the log of the coordinator of a transaction, the transaction is presumed aborted.

As opposed to PrA, in which missing information about transactions at a coordinator's site is interpreted as abort decisions, in PrC, a coordinator interprets missing information about transactions as commit decisions when replying to inquiry messages. However, in PrC, a coordinator has to force write a commit *initiation* record for each transaction before sending out prepare-to-commit messages to the participants. This record ensures that missing information about a transaction will not be misinterpreted as a commit after a coordinator's site failure without an actual commit decision is made.

To commit a transaction, the coordinator force writes a commit record to logically eliminate the initiation record of the transaction and then sends out commit messages. The coordinator also discards all information pertaining to the transaction from its protocol table. When a participant receives the decision, it writes a non-forced commit record and commits the transaction without having to Ack the decision. After a coordinator's or a participant's failure, if the participant *inquires* about a transaction that has been committed, the coordinator, not remembering the transaction, will direct the participant to commit the transaction (by presumption).

To abort a transaction, on the other hand, the coordinator does not write the abort decision in its log. Instead, the coordinator sends out abort messages and waits for Acks before discarding all information pertaining to the transaction. When a participant receives the decision, it force writes an abort record and then acknowledges the decision, as in 2PC. In the case of a coordinator's failure, the initiation record of an interrupted transaction contains all needed information for its recovery.

Table 1 summarizes the costs associated with the three 2PC variants for the commit as well as the abort case assuming a "yes" vote from each participant: "*m*" is the total number of log records, "*n*" is the number of forced log writes, "*p*" is the number of messages sent from the coordinator to each participant and "*q*" is the number of messages sent back to the coordinator. For simplicity, these costs are calculated for the flat (two-level) execution model in which, unlike the multi-level execution model, a participant never initiates (i.e., spawns) new (sub)transactions that execute at other participants, forming a tree of communicating participants.

Compatibility of 2PC Variants

ACPs are incompatible in the sense that they cannot be used (directly) in the same environment without conflicts. This is true even for the simplest and most

Two-Phase Commit. Table 1. The costs for update transactions in 2PC and its most commonly known two variants

	Commit decision						Abort decision					
	Coordinator			Participant			Coordinator			Participant		
2PC Variant	m	n	p	m	n	q	m	n	p	m	n	q
Basic 2PC	2	1	2	2	2	2	2	1	2	2	2	2
Presumed abort	2	1	2	2	2	2	0	0	2	2	1	1
Presumed commit	2	2	2	2	1	1	2	1	2	2	2	2

closely related variants such as the basic 2PC, PrA and PrC. The analysis of ACPs shows that incompatibilities among ACPs could be due to (i) the semantics of the coordination messages (which include both their meanings as well as their existence), or (ii) the presumptions about the outcome of terminated transactions in case of failures [1].

The *presumed any* (PrAny) protocol [2] interoperates the basic 2PC, PrA, and PrC. It was proposed in the context of multidatabase systems, a special case of heterogeneous distributed databases, to demonstrate the difficulties that arise when one attempts to interoperate different ACPs in the same environment and, more importantly, to introduce the "*operational correctness criterion*" and the notion of "*safe state*." Operational correctness means that all sites should be able, not only to reach an agreement but also, to forget the outcome of terminated transactions. On the other hand, the safe state means that, for any operationally correct ACP, the coordinator should be able to reach a state in which it can reply to the inquiry messages of the participants, in a consistent manner, without having to remember the outcome of terminated transactions forever.

In PrAny, a coordinator talks the language of the three 2PC variants and knows which variant is used by which participant. Based on that, it forgets a committed transaction once all PrA and 2PC participants Ack the commit decision, and forgets an aborted transaction once all PrC and 2PC participants Ack the abort decision. This is because only commit decisions are acknowledged in PrA whereas, in PrC, only abort decisions are acknowledged. However, unlike the other 2PC variants, in PrAny, a coordinator does not adopt a single presumption about the outcome of *all* terminated transactions. This is because, if it does so, the global atomicity of some transactions might be violated. For example, if the coordinator adopts for recovering purposes the abort presumption, it will respond with an abort message to a recovering PrC participant that inquires about a forgotten committed transaction. Similarly, if the coordinator adopts the commit presumption, it will respond with a commit message to a recovering PrA participant that inquires about a forgotten aborted transaction. Instead of using a single presumption, a coordinator in PrAny adopts the presumption of the protocol used by the inquiring participant. That is, if a participant inquires about a forgotten committed transaction, the participant has to be a PrC participant. This is because only PrC participants do not acknowledge commit decisions. Thus, the coordinator will reply with a commit message in accordance with PrC adopted by the participant. On the other hand, if a participant inquires about a forgotten aborted transaction, the participant has to be a PrA participant. This is because only PrA participants do not acknowledge abort decisions. Thus, the coordinator will reply with an abort message in accordance with PrA adopted by the participant. Knowledge about the used protocols by the participants could be recorded statically at the coordinator's site [2] or inferred dynamically by having a participant declares its used protocol in each inquiry message [15].

Key Applications

The use of 2PC (or one of its variants) is mandatory in any distributed database system in which the traditional atomicity property of transactions is to be preserved. However, the basic 2PC has never been implemented in any commercial database system due to its unnecessary costs compared to its two other most commonly known variants. Instead, PrA is considered the *de facto* standard in the industry and has been incorporated as part of the current X/Open DTP [14] and ISO OSI-TP [6] distributed transaction processing standards. PrA is chosen instead of PrC because (i) the cost of PrC for committing transactions is not symmetric with the cost of PrA for aborting transactions (which is highlighted in Table 1) and, more importantly, (ii) PrA is much cheaper to use with read-only transactions when complementing it with the traditional *read-only* optimization [13,3] (which is also part of the current database standards).

The above two reasons that favor PrA have been nullified with new 2PC variants and a read-only optimization called *unsolicited update-vote* (UUV). Thus, PrC is expected to become also part of future database standards, especially that the two variants can be incorporated in the same environment without any conflicts [1,15].

Two-Phase Commit Protocol

Jens Lechtenbörger
University of Münster, Münster, Germany

XA standard

Definition

The *Two-phase commit (2PC)* protocol is a distributed algorithm to ensure the consistent termination of a transaction in a distributed environment. Thus, via 2PC a unanimous decision is reached and enforced among multiple participating servers whether to commit or abort a given transaction, thereby guaranteeing atomicity. The protocol proceeds in two phases, namely the prepare (or voting) and the commit (or decision) phase, which explains the protocol's name.

The protocol is executed by a *coordinator* process, while the participating servers are called *participants*. When the transaction's initiator issues a request to commit the transaction, the coordinator starts the first phase of the 2PC protocol by querying – *via prepare messages* – all participants whether to abort or to commit the transaction. If all participants vote to commit then in the second phase the coordinator informs all participants to commit their share of the transaction by sending a *commit message*. Otherwise, the coordinator instructs all participants to abort their share of the transaction by sending an *abort message*. Appropriate log entries are written by coordinator as well as participants to enable restart procedures in case of failures.

Historical Background

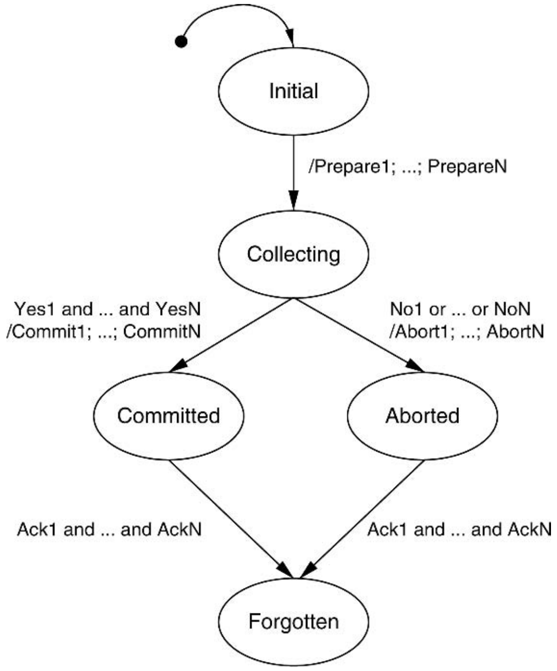
Essentially, the 2PC protocol is modeled after general contract law, where a contract among two or more parties is only established if all parties agree; hence, the underlying idea is well-established in everyday life. According to [3] the first known implementation in a distributed system was performed by Nico Garzado for the Italian social security system in the early 1970s, while the protocol's name arose in the mid 1970s. Early scientific presentations are given by Gray [2] and by Lampson and Sturgis [4]. Since then an API for the 2PC protocol has been standardized under the name XA within the X/Open Distributed Transaction Processing (DTP) model [7], and this API has been incorporated into several middleware specifications and implemented in numerous software components.

Foundations

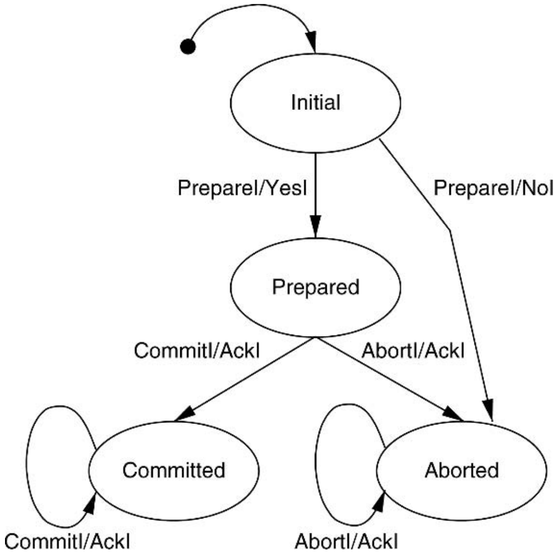
The 2PC protocol as described and analyzed in detail in [8] assumes that parts of a single (distributed) transaction involve resources hosted by multiple *resource managers* (e.g., database systems, file systems, messaging systems, persistent programming environments), which reside on possibly different nodes of a network and are called *participants* of the protocol. For every transaction one *coordinator* process, typically running on the node of that participant where the transaction was initiated, assumes responsibility for executing the 2PC protocol; alternative strategies for selecting (and transferring) the coordinator are discussed in [8]. The states through which coordinator and participants move in the course of the protocol are illustrated in Figs. 1 and 2, resp., and explained in the following. Such statecharts represent finite state automata, where ovals denote states, labeled arcs denote state transactions, and arc labels of the form "precondition/action" indicate that (i) the state transition is only enabled if the precondition is satisfied and (ii) the given action is executed when the state is changed.

Basic Protocol

As long as a transaction is still executing ordinary operations, coordinator as well as all participants operate in the Initial state. When the coordinator is requested to commit the transaction, it initiates the first phase of the 2PC protocol: To capture the state of the protocol's execution (which needs to be available in case of protocol restarts as explained below), the coordinator first forces a *begin log entry*, which includes a transaction identifier as well as a list of the transaction's participants, to a stable log. Afterwards, the coordinator sends a *prepare* message to every participant, enters the Collecting state and waits for replies.



Two-Phase Commit Protocol. Figure 1. Statechart for coordinator (given *N* participants).



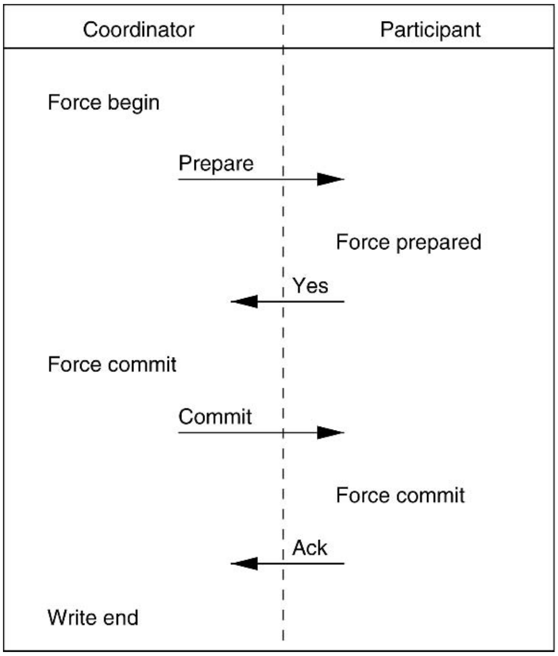
Two-Phase Commit Protocol. Figure 2. Statechart for participant *I*.

Upon receiving a prepare message, a participant decides whether it is able to commit its share of the transaction. In either case, suitable log entries for later recovery operations as well as a *prepared log entry* indicating the vote ("Yes" or "No") are forced to a stable log, before a response message containing the vote is sent back to the coordinator. In case of a No-vote, the participant switches into the Aborted state and immediately aborts the transaction locally. In case of a Yes-vote, the participant moves into the Prepared state. In the latter case the participant is said to be *in doubt* or *blocked* as it has now given up its local autonomy and must await the final decision from the coordinator in the second phase (in particular, locks cannot be released yet).

Once the coordinator has received all participants' response messages it starts the second phase of the 2PC protocol and decides how to complete the global transaction: The result is "Commit" if all participants voted to commit and "Abort" otherwise. The coordinator then forces a *commit* or *abort log entry* to the stable log, sends a message containing the final decision to all participants, and enters the corresponding state (Committed or Aborted).

Upon receipt of the decision message, a participant commits or aborts the local changes of the transaction depending on the coordinator's decision and forces suitable log entries for later recovery as well as a *commit* or *abort log entry* to a stable log. Afterwards, it sends an acknowledgment message to the coordinator and enters the corresponding final state (Committed or Aborted).

Once the coordinator has received all acknowledgment messages it ends the protocol by writing an *end log entry* to a stable log to enable later log truncation and enters the final state, Forgotten. The actions described for the overall process are summarized in Fig. 3 for the case of a transaction commit. (For multiple participants, the actions simply have to be duplicated; in case of abort, at least one of the participants votes "No", which implies that all occurrences of "commit" are replaced with "abort".)



Two-Phase Commit Protocol. Figure 3. Actions for transaction commit in the basic protocol.

Protocol Restart

The log entries seen so far are used to restart the 2PC protocol after so-called soft crashes of coordinators or participants, i.e., failures like process crashes which lead to a loss of main memory but which leave secondary storage intact. In particular, as participants always force log entries before sending replies, the coordinator never needs to resend messages for which replies have been received. Moreover, log truncation (garbage collection) may occur once all acknowledgment messages have arrived. Finally, every log entry uniquely determines a state, and the last log entry determines the most recent state prior to a failure. Clearly, failures in the final states (Forgotten for the coordinator and Committed or Aborted for a participant) do not require any action. For the remaining states, restart procedures are as follows:

If the coordinator fails in the Initial or the Collecting state, it simply restarts the protocol in the Initial state. (Coordinators writing received votes into the log could recover differently from the Collecting state.) If it fails in the Committed or in the Aborted state, it resends the decision message to all participants, and continues waiting for acknowledgments in the previous state.

If a participant fails in the Initial state it did not yet participate in the 2PC protocol and is free to decide arbitrarily when asked later on. If it fails in the Prepared state it either waits for the coordinator to announce the decision or actively queries the coordinator or other participants for the decision.

In addition to these restart procedures, coordinator and participants also need to be able to recover from message losses. To this end, standard timeout mechanisms are employed: Whenever a message is sent, a timer starts to run. If the timer expires before an appropriate answer is received, the message is simply resent (assuming that either original message or answer are lost; e.g., if the coordinator is missing some votes in the Collecting state, it resends a prepare message to every participant that did not answer in time). Finally, if repeated timeouts occur in the Collecting state the coordinator may decide to abort the transaction globally (as if an "Abort" vote was received), and a participant may unilaterally abort the transaction in the Initial state if no prepare message arrives.

Hierarchical and Flattened 2PC

New participants enter the 2PC protocol whenever they receive requests (e.g., to execute SQL statements) from already existing participants. In such a situation, the new participant can be regarded as child node of the requesting participant, and all such parent-child relationships form a *participant tree* with the transaction's initiator as root node. To execute the 2PC protocol, that tree may either be used directly or flattened as explained in the following.

For the *flattened* 2PC, one node in the participant tree, e.g., the root node, is chosen as coordinator, and this coordinator communicates directly with every participant contained in the tree to execute the basic 2PC protocol as described above. In contrary, in case of the hierarchical 2PC, the root node acts as global coordinator, the leaf nodes are ordinary participants, and the inner nodes are participants with respect to their parents as well as sub-coordinators for their children. Thus, when an inner node receives a 2PC message from its parent, the inner node first has to forward the message to its children before it responds on behalf of the *entire* subtree. For example, a prepare message is forwarded down the tree recursively, and an inner node first waits for all votes of its children before it decides, write a log entry, responds with a vote to the parent, and makes a transition to the Prepared (if all children voted to commit) or Aborted state.

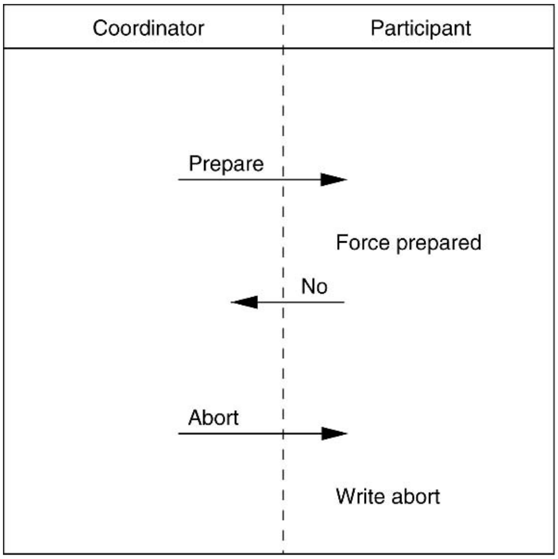
Optimizations

As the 2PC protocol involves costly operations such as sending messages and forcing log entries, several optimizations of the basic protocol have been proposed. In the following the most common variants based on *presumption* are sketched; further details and techniques such as real-only subtree optimization, coordinator transfer, and three-phase commit (3PC) to reduce blocking are presented in [8].

The key idea for presumption based optimizations is to write less log entries and send fewer messages in a systematic way such that in case of a failure the missing information can be compensated for by suitable presumptions concerning the transaction's state. As the basic protocol described above is not based on any presumptions, it is also called *presumed-nothing protocol*. In contrast, in the *presumed-abort protocol*, which aims to optimize the case of aborted transactions, the essential idea is to omit certain information concerning transaction aborts. If that information is needed but absent later on, abort is presumed. In fact, for the presumed-abort protocol the following information is omitted:

- The Coordinator's begin and abort log entries are omitted.
- The participants' abort log entries are not forced.
- Participants do not send acknowledgment messages before entering the Aborted state.

The actions required in case of a transaction abort are summarized in Fig. 4, which indicates significant



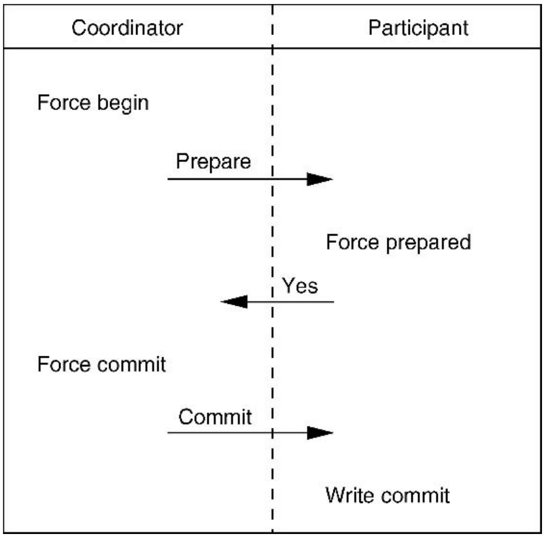
Two-Phase Commit Protocol. Figure 4. Actions for transaction abort in the presumed-abort variant.

savings when compared with the actions for the basic protocol shown in Fig. 3. In the presumed-abort variant, if a participant fails after receiving the abort decision from the coordinator and restarts without finding a log entry, it queries the coordinator for the decision. As the coordinator does not find the appropriate log entry (which has never been written) it presumes that the transaction should be aborted and informs the participant accordingly, which leads to a globally consistent decision.

Alternatively, in the *presumed-commit protocol*, which aims to optimize the case of committed transactions, the following information is omitted:

- The participants' commit log entries are not forced.
- Participants do not send acknowledgment messages before entering the Committed state.

The actions required in case of a transaction commit are summarized in Fig. 5, which again indicates significant savings in comparison to the basic protocol shown in Fig. 3. In this variant, log entries of committed transactions can be garbage collected as missing transactions are presumed to have committed. Thus, if a participant fails after receiving the commit decision from the coordinator and restarts without finding a log entry, it queries the coordinator for the decision. If the coordinator does not find any log entry it presumes that the transaction has committed and informs the participant accordingly, which leads to a globally consistent decision.



Two-Phase Commit Protocol. Figure 5. Actions for transaction commit in the presumed-commit variant.

Key Applications

While there is no single key application for the 2PC protocol, it is applicable wherever decentralized data needs to be shared by multiple participants under transactional guarantees, e.g., in e-commerce or e-science settings. More specifically, the 2PC protocol is widely implemented in database systems (commercial as well as open source ones), TP monitors, and message queue systems, where it is used in the background to provide atomicity for distributed transactions. In addition, the XA interface [7] for the protocol, more precisely for the hierarchical presumed-abort variant, has been adopted in the CORBA Transaction Service specified by the OMG [5] and is used as basis for the Java Transaction API (JTA) [6]. Furthermore, the 2PC protocol is also part of the Web Services Atomic Transaction specification [1] to enable the interoperable atomic composition of Web Service invocations.

Two-Phase Locking

Georg Lausen
University of Freiburg, Freiburg, Germany

Synonyms

Locking protocol; Isolation; Conflict serializability; Pessimistic scheduler

Definition

A locked transaction is a transaction which, in addition to read and write actions, contains lock and unlock operations to the data items. Lock and unlock operations enable a database system to control the order of read and write actions of a concurrent set of transactions. A locking policy is a set of rules which restrict the possible ways to introduce lock and unlock operations into a transaction. A locking policy is safe, if, whenever all the transactions conform to the policy, any history of the transactions is guaranteed to be serializable. Two-Phase Locking is a safe locking policy which is based on the simple rule saying a transaction is not allowed to further lock a data item once it has already unlocked some data item.

Historical Background

Two-Phase Locking was first described in [6]. Later the basic policy has been extended into several directions. In [1] ordered sharing of locks is proposed which allows more than one transaction to hold a lock on a data item as long as the actions are performed in the same order as the locks have been acquired. Altruistic locking has been proposed by [10]. A transaction may allow other transactions to access data items it has locked if it will not access these items later again. This protocol is designated to situations in which long and short transactions are running concurrently. Two-Phase Locking taking old values of a data item into account is described in [2]. Also hybrid protocols have been proposed which allow to apply other techniques than Two-Phase Locking simultaneously [5,8].

Foundations

Locking protocols are among the earliest mechanisms which have been developed for controlling a set of transactions to achieve serializability. The reason is not surprising, as locking is a very intuitive means to control transactions: the processing of an action may be either immediately allowed or delayed. Using locking, the critical actions for serializability are all those, whose order of processing might influence the effects of the transactions and thereby affect serializability. Such actions are called conflicting. Read and write actions are conflicting, whenever they refer to the same data item and at least one of them is a write action. The notion of serializability which is applicable under these assumptions is called conflict-serializability.

For the following, a database is a finite set $D = \{x, y, z, ...\}$ of disjoint data items. A transaction $t = (op_t, <_t)$ consists of a set of steps op_t which are assumed to be totally ordered by $<_t$. Read actions $r(x)$ and write actions $w(x)$ are steps, where x is the data item on which the respective action is processed. A history s of a set T of concurrent transactions is a pair $s = (op_s, <_s)$, where $op_s = \cup_{t \in T} op_t$ and $<_s$ is a total order on the steps in op_s which preserves $<_t$ for $t \in T$. $<_s$ also is called an interleaving of the transactions in T. For notational simplicity, total orders $<_t$ and $<_s$, $t \in T$, s a history of T, are also written as action sequences, where the total order is defined by considering a sequence from left to right. A history is called serializable, if it is equivalent to a serial, i.e., not interleaved history of the same set of transactions.

The decision whether or not a history is serializable can be based on an analysis of a so called conflict graph whose definition is based on the relative order of conflicting actions. Let $s = (op_s, <_s)$ be a history of a set of transactions T. The conflict graph $C(s)$ is a directed graph with set of nodes T and edges $t_i \rightarrow t_j$, $i \neq j$, whenever one of the following conditions is fulfilled:

$$\begin{array}{ll}
\textbf{RW}-\textbf{conflict:} & r_i(x) \in op_i, w_j(x) \in op_j, r_i(x) <_s w_j(x) \\
 & \text{and for all } w_k(x) \in op_s, i \neq k, j \neq k, \\
 & \text{there either holds } w_k(x) <_s r_i(x) \\
 & \text{or } w_j(x) <_s w_k(x), \\
\textbf{WR}-\textbf{conflict:} & w_i(x) \in op_i, r_j(x) \in op_j, w_i(x) <_s r_j(x) \\
 & \text{and for all } w_k(\mathrm{x}) \in op_s, i \neq k, j \neq k, \\
 & \text{there either holds } w_k(x) <_s w_i(x) \\
 & \text{or } r_{\mathrm{j}}(x) <_s w_k(x), \\
\textbf{WW}-\textbf{conflict:} & w_i(x) \in op_i, w_j(x) \in op_j, w_i(x) <_s w_j(x) \\
 & \text{and for all } w_k(x) \in op_s, i \neq k, j \neq k, \\
 & \text{there either holds } w_k(x) <_s w_i(x) \\
 & \text{or } w_{\mathrm{j}}(x) <_s w_k(x).
\end{array}$$

It is well known (e.g., [9,12]), whenever the conflict graph of a history is acyclic, then the history is serializable. However, this condition is not necessary, there may exist histories whose conflict graph is cyclic and still these histories are serializable. In practice, such histories are considered to be not of interest and, as a consequence, as correctness notion conflict-serializability (CSR) is used:

CSR : A history is conflict – serializable if and
only if its conflict graph is acyclic.

To keep the terminology simple, instead of conflict-serializability the notion of serializability will be used in the sequel. The serializability of a history $s = (op_s, <_s)$ of a set of transactions T depends on the relative ordering of the conflicting actions of the involved transactions. Consider two transactions t, t'. Let t, among others, contain actions p, q and t' actions p', q'. Now assume that p and p' are in conflict and q and q' as well. Let further $p <_s p'$ and $q' <_s q$. s is not serializable as the conflict graph $C(s)$ contains the cycle $t \rightarrow t' \rightarrow t$. This means that there cannot exist a serial schedule s^* containing t and t' with the same order on the conflicting actions. For such a schedule s^*, either $p <_{s^*} p'$ and $q <_{s^*} q'$, or $p' <_{s^*} p$ and $q' <_{s^*} q$; both orderings are not compatible to $<_s$. So why not enforce $q <_s q'$ once $p <_s p'$ has occurred? This means to ask for a transaction scheduler who is able to enforce certain relative orderings of conflicting actions such that not serializable orderings cannot occur. Two-Phase Locking, which is called 2PL for brevity in the sequel, is the most widely used technique which can be used to control the concurrent execution of transactions in a way which guarantees serializability.

To control a concurrent set of transactions 2PL uses lock and unlock operations. A locked transaction $t = (op_t, <_t)$ is a transaction which, in addition to the read and write actions, contains lock operations Lx and unlock operations Ux, where Lx, $Ux \in op_t$ and $<_t$ is a total order as before, however now ordering locks and unlocks as well. For a locked transaction $t = (op_t, <_t)$, whenever $p \in op_t$, $p \in \{r(x), w(x)\}$, the following conditions must hold: (i) $Lx, Ux \in op_t$, (ii) $Lx <_t Ux$ and (iii) $Lx <_t p <_t Ux$.

Let $t = r(x)w(x)r(y)w(y)$ be a transaction without any lock and unlock operations. Under the above conditions, there still exist many ways to insert lock and unlock operations into t, as it is demonstrated by the following examples:

$$\begin{aligned}
&(a) Lx\ r(x)\ w(x)\ Ux\ Ly\ r(y)\ w(y)\ Uy,\\
&(b) Lx\ r(x)\ w(x)\ Ly\ Ux\ r(y)\ w(y)\ Uy,\\
&(c) Lx\ r(x)\ w(x)\ Ly\ r(y)\ w(y)\ Ux\ Uy,\\
&(d) Lx\ Ly\ r(x)\ w(x)\ Ux\ r(y)\ w(y)\ Uy,\\
&(e) Lx\ Ly\ r(x)\ w(x)\ r(y)\ w(y)\ Ux\ Uy.
\end{aligned} \tag{1}$$

The idea of a lock operation Lx and the corresponding unlock operation Ux is to grant a transaction t the right of an exclusive access to data item x for the interval defined by the time of the processing of the lock and the processing of the succeeding unlock operation. The decision whether or not a lock can be granted typically is based on a so called lock table $\mathcal{L}$. Starting from an empty table $\mathcal{L}$, a lock operation Lx can only then be granted to a transaction t, if $\mathcal{L}$ does not contain an entry with respect to x. In that case (x, t) is inserted into $\mathcal{L}$. Otherwise transaction t has to wait until the condition is fulfilled. When later t processes the corresponding unlock operation Ux, the entry $(x, t)$is deleted from the lock table $\mathcal{L}$. Therefore, for any history s of locked transaction the following condition on locks and unlocks (LUL) must hold, where $t_1, t_2 \in T$:

LUL : If $L_1\, x <_s L_2\, x$, then $U_1\ x <_s L_2\, x$.

Locking by itself does not guarantee serializability. Consider the two transactions t_1, t_2:

$$\begin{aligned}
t_1 &: L_1x\ r_1(x)\ w_1(x)\ U_1x\ L_1y\ r_1(y)\ w_1(y)\ U_2y,\\
t_2 &: L_2x\ L_2y\ r_2(x)\ w_2(x)\ r_2(y)\ w_2(y)\ U_2x\ U_2y,
\end{aligned}$$

and a history s representing an interleaving of t_1 and t_2:

$$\begin{aligned}
s :& L_1x\ r_1(x)\ w_1(x)\ U_1x\ L_2x\ L_2y\ r_2(x)\\
& w_2(x)\ r_2(y)\ w_2(y)\ U_2x\ U_2y\ L_1y\ r_1(y)\ w_1(y)\ U_1y.
\end{aligned}$$

This schedule is not serializable; $w_1(x) <_s r_2(x)$ and $w_2(y) <_s r_1(y)$ force a cycle $t_1 \rightarrow t_2 \rightarrow t_1$ in the conflict graph which contradicts serializability. Therefore, rules are needed which define how locks and unlocks should be introduced into the single transactions such that, whatever other transactions are running concurrently, serializability is guaranteed. In other words, a locking policy has to be introduced. The most widely used locking policy is called Two-Phase Locking (2PL) and is expressed by the surprisingly simple sentence:

2PL : Whenever a transaction t has executed its *first* operation,no further lock operations *of* t are allowed.

All except the first transaction listed in (1) perfectly obey 2PL. The remaining four locked versions (b) – (e) implement different strategies for locking. Transaction (b) unlocks x as early as possible and locks y as late as possible. It therefore tries to minimize delay of other transactions by keeping the intervals of locked data items as small as possible. At a first glance, this seems to be an attractive approach. However, because of the early unlocking, another transaction may read the value written of x before the transaction has finished. Reading values of data items from transactions which have not yet reached their end is highly problematic for recovery reasons. Only after a transaction has executed its final commit successfully, a database system guarantees that the effects of the respective transactions are permanent and will survive system and transaction failures. Version (c) behaves more carefully and keeps all data items locked until the end of the transaction. The remaining versions (d) and (e) lock all data items in advance and unlock either as early as possible, respectively at the end of the transaction. Taking the possibility of failures into account, only versions (c) and (e) are acceptable. In practice, locks are kept until to the end of a transaction giving rise to the notion of strict 2PL. The following theorem states that 2PL indeed is a safe locking policy:

Theorem: *Let T be a set of transactions. If all* $t \in T$ *obey 2PL, then any history of the transactions in* T *is serializable.*

Proof: For any $t \in T$, the lock point of t is defined as t's last lock operation. Now consider a history s of the transactions in T such that all $t \in T$ obey 2PL. Under the assumption, that s is not serializable, a contradiction to 2PL can be derived thereby proving serializability of s which in turn proves the theorem.

If s is not serializable, then the conflict graph of $<_s$ contains a cycle, which, without loss of generality, is of the form $t_1 \rightarrow t_2 \rightarrow \ldots \rightarrow t_k \rightarrow t_1$. An edge $t \rightarrow t'$ can only then be part of the cycle, when there exists a data item x such that t and t' perform conflicting actions on x. As all transactions use locks, transaction t' can only then execute its action on x, after t has processed the unlock Ux. Before processing the respective action on x, t' has to lock x. Applying this observation on all edges of the cycle the following restrictions on the order $<_s$ can be concluded, where $x_1,\ldots,x_k$ are data items:

$$\begin{aligned} &U_1x_1 <_s L_2x_1,\\ &\vdots\\ &U_{k-1}x_{k-1} <_s L_kx_{k-1},\\ &U_kx_k <_s L_1x_k. \end{aligned}$$

Let l_i be the lock point of transaction t_i, $1 \leq i \leq k$. From the structure of $<_s$ it follows $l_1 <_s l_2,\ldots,l_{k-1} <_s l_k$ and $l_k <_s l_1$. Therefore it holds $l_1 <_s l_1$, which is a contradiction to the total order $<_s$.

2PL is optimal in the sense that for any locked transaction t_1 which does not follow 2PL, a locked transaction t_2 can be constructed such that for $T = \{t_1,t_2\}$ there exists a history which is not serializable. Consider the lock and unlock operations of t_1 be given by $L_1x <_{t_1} U_1x <_{t_1} L_1y <_{t_1} U_1y$ and the lock and unlock operations of t_2 be given by $L_2x <_{t_2} L_2y <_{t_2} U_2y <_{t_2} U_2x$. t_2 follows the 2PL policy, however t_1 does not. If both transactions are running concurrently, then the following order of locks and unlocks being part of a history s may happen:

$$L_1x <_s U_1x <_s L_2x <_s L_2y <_s U_2y <_s U_2x <_s L_1y <_s U_1y.$$

Obviously, if between any pair of lock and unlock operations Lx, Ux and Ly, Uy there exist read and write actions to the respective data items, conflicts happen and history s is not serializable. Therefore, t_1 has also to follow 2PL when serializability has to be guaranteed for arbitrary sets of transactions T, $t_1 \in T$.

However, optimality in the above sense does not imply that in every serializable history of transactions without locks and unlocks, locks and unlocks can be inserted according to 2PL in a way not violating LUL. Consider a serializable history s of $T = \{t_1,t_2,t_3\}$ with order of actions

$$r_1(x) <_s r_2(x) <_s w_2(x) <_s r_3(y) <_s w_3(y) <_s w_1(y).$$

It is impossible to insert lock and unlock operations into the transactions in T such that any $t \in T$ obeys 2PL and s fulfills LUL. Because of $r_1(x) <_s r_2(x)$ it must hold $U_1x <_s L_2\ x$ and because of 2PL it must hold $L_1y <_s U_1\ x$. However, as $w_1(y) <_s U_1y$, this implies $L_1y <_s r_3(y) <_s w_3(y) <_s U_1y$. Therefore, either $L_3y <_s L_1y <_s U_3y$, or $L_1y <_s L_3y <_s U_1y$. Both orderings contradict the basic locking condition LUL. Therefore, 2PL is a safe locking policy, however some serializable histories of a set of transactions T may be excluded. In other words, 2PL can only accept a strict subset of the set of all serializable histories, in general.

The model for locking presented so far is overly restrictive, as it does not distinguish between read and write actions. Serializability of a history is only then an issue, when some of the involved transactions modify the database, i.e., perform write actions. Therefore, when locking it should be possible to distinguish between locks for read actions $L^R x$ and locks for write actions $L^W x$. If a transaction reads and writes a data item x, then a single write lock is in order. It should be possible that arbitrarily many transactions may lock a data item for reading as long as there is no concurrent transaction writing the same data item. For any history s of locked transaction $t_1, t_2 \in T$ the following conditions on locks and unlocks (LUL^{RW}) must hold, which do not impose any restrictions on the ordering of read locks $L_1{}^R x$ and $L_2{}^R x$:

$$\mathbf{LUL^{RW}}: \begin{array}{l} \text{If } L_1^R x <_s L_2^W x, \text{ then } U_1 x <_s L_2^W x. \\ \text{If } L_1^W x <_s L_2^R x, \text{ then } U_1 x <_s L_2^R x. \\ \text{If } L_1^W x <_s L_2^W x, \text{ then } U_1 x <_s L_2^W x. \end{array}$$

When locking is used, deadlocks may occur. Consider transactions t_1, t_2 as follows: $t_1 = L_1 x\ r_1(x)\ L_1 y\ w_1(y)\ U_1 x\ U_1 y$ and $t_2 = L_2 y\ r_2(y)\ L_2 x\ w_2(x)\ U_2 y\ U_2 x$. A prefix s' of a history s cannot be continued to a complete history containing all the steps of t_1 and t_2, if, for example, $L_1 x <_{s'} L_2 y$ and s' does not contain $U_1 x$. To complete the prefix, $L_2 x$ and also $L_1 y$ have to be considered for $<_s$. However this is not possible, because otherwise the condition LUL would be violated. The problem of deadlocks is inherent to locking and practical systems solve deadlocks by aborting one of the involved transactions [12].

The transaction model abstracts away many aspects of real transactions running in practical systems. In particular, transactions are defined explicitly by a set of steps and not by a program whose concrete execution on a certain state of the database will define the transaction. Assume a program to process all data items which fulfill a certain predicate p. A transaction t resulting from executing the program will read all data items for which p is true. To guarantee serializability, in advance to reading such a data item, the item has to be locked. If concurrently, however later before t has finished, another transaction t' inserts a new data item x into the database which also fulfills predicate p, t has neither read nor locked x. In such situations serializability cannot be guaranteed by 2PL as described so far, because the relevant set of data items has not been locked by t. This problem is known as the phantom problem. Practical systems have found ways to live with phantoms. Instead of only locking data items, locking is applied on the set of objects fulfilling a predicate, on complete relations or index intervals.

Key Applications

For organizations of any kind database systems have become indispensable to maintain the operational data. Applications in this context typically are dominated by a potentially huge number of rather short transactions. In such a setting, commonly called online transaction processing (OLTP), reliable and efficient processing of transactions is required. 2PL has become a de facto standard in database systems for OLTP applications. However, 2PL is based on blocking transactions and therefore system throughput may be severely affected by the locking protocol. Fortunately, over the years several guidelines have been developed [3,7,11] which help a database administrator to tune the programming of the transactions and the implementation of 2PL in a way such that the requisite efficiency of the overall system can be achieved.

Two-Poisson model

Giambattista Amati
Ugo Bordoni Foundation, Rome, Italy,

Synonyms

Harter's model; Probabilistic model of indexing

Definition

The 2-Poisson model is a mixture, that is a linear combination, of two Poisson distributions:

$$\mathrm{Prob}(X = \mathbf{tf}) = \alpha \frac{\lambda^{\mathbf{tf}} e^{-\lambda}}{\mathbf{tf}\,!} + (1 - \alpha) \frac{\mu^{\mathbf{tf}} e^{-\mu}}{\mathbf{tf}\,!} \qquad [0 \leq \alpha \leq 1]$$

In the context of IR, the 2-Poisson is used to model the probability distribution of the frequency X of a term in a collection of documents.

Historical Background

The 2-Poisson model was given by Harter [5–7], although Bookstein [2,1] and Harter had been exchanging ideas about probabilistic models of indexing during those years. Harter coined the word "elite" to introduce his 2-Poisson model [5, pp. 68–74].

The origin of the 2-Poisson model can be traced back through all Luhn, Maroon, Damerau, Edmundson and Wyllys [3,4,5,6]. The first accounts on Poisson distribution modeling the stochastic behavior of functional words were given by Stone, Rubinoff and Damerau [3,11]. Stone, Rubinoff and Damerau observed that the words that have only a functional role in the text, can be modeled by a Poisson distribution.

Foundations

The 2-Poisson model is a probabilistic model of indexing, rather than a document retrieval model. The purpose of Harter's work is to identify the keywords likely to be informative for an arbitrary document that can be selected to build an index for a collection. Such words are called *specialty* words by Harter in contraposition to the other ones, the *non-specialty* ones, which instead are considered to occur at random in documents. In the works by Luhn, Maroon, Damerau, Edmundson and Wyllys it was observed that the divergence between the rare usage of a word across the document collection and the contrasting relative within-document frequency constitutes a revealing indication of the informative status of a word. Damerau suggests selecting the class of high status words of the index by making the assumption that Poisson distribution describes frequencies of words that are in the complementary class. If the Poisson probability of a term within a document is very small, then the word is marked as an index term. Obviously, not all words clearly fall either into one class or into the other. But nonetheless, many word tokens occur randomly in many documents while the same word tokens occur more densely and nonrational in a few documents. This set of documents called the *Elite set* of the term **t** is very likely to be the set of documents which extensively connects with the concept or the semantics related to the term. The Elite set $\mathbf{E_t}$ attracts the tokens with an expected rate $\lambda_{\mathbf{E_t}}$. Tokens fall randomly into the other documents with a lower rate $\lambda_{\overline{\mathbf{E_t}}}$. The final probability of occurrence of the term in any document is given by the mixture of these two Poisson distributions:

$$\mathrm{Prob}(X = \mathbf{tf}) = \alpha . \frac{e^{-\lambda_{\mathbf{E_t}}} \lambda_{\mathbf{E_t}}^{\mathbf{tf}}}{\mathbf{tf!}} + (1 - \alpha) . \frac{e^{-\lambda_{\overline{\mathbf{E_t}}}} \lambda_{\overline{\mathbf{E_t}}}^{\mathbf{tf}}}{\mathbf{tf!}} \qquad (1)$$

The probability of term **t** to appear **tf** times in a document **d** belonging to the Elite set $\mathbf{E_t}$ is given by the conditional probability

$$\begin{aligned}\mathrm{Prob}(\mathbf{d}\in\mathbf{E_t}|X=\mathbf{tf}) &= \frac{\mathrm{Prob}(X=\mathbf{tf},\mathbf{d}\in\mathbf{E_t})}{\mathrm{Prob}(X=\mathbf{tf})}\\ &= \frac{\alpha\cdot\frac{e^{-\lambda_{\mathbf{E_t}}}\lambda_{\mathbf{E_t}}^{\mathbf{tf}}}{\mathbf{tf!}}}{\alpha\cdot\frac{e^{-\lambda_{\mathbf{E_t}}}\lambda_{\mathbf{E_t}}^{\mathbf{tf}}}{\mathbf{tf!}}+(1-\alpha)\cdot\frac{e^{-\lambda_{\overline{\mathbf{E_t}}}}\lambda_{\overline{\mathbf{E_t}}}^{\mathbf{tf}}}{\mathbf{tf!}}}\end{aligned} \tag{2}$$

Thus, in the case that the word belongs to the non-specialty class:

$$\mathrm{Prob}(\mathbf{d}\in\mathbf{E_t}|X=\mathbf{tf}) = \frac{1}{1+\beta\cdot e^{\left(\lambda_{\mathrm{Et}}-\lambda_{\overline{\mathrm{Et}}}\right)}\left(\frac{\lambda_{\overline{\mathrm{Et}}}}{\lambda_{\mathrm{Et}}}\right)^{\mathbf{tf}}} \tag{3}$$

where $\beta=\frac{1-\alpha}{\alpha}$. The conditional probability of (3) is used by Harter to generate a ranking of the most informative words. However, the 2-Poisson model requires the estimation of three parameters for each word of the vocabulary, and this is a real drawback for any direct practical application of his model to term selection or term-weighting problems.

A last remark concerns the **N**-Poisson model, the generalization of the 2-Poisson model. Any probability distribution on $(0,\infty)$ can be defined as a mixing distribution of Poisons [10]. Therefore, it is true that every word follows a **N**-Poisson distribution for some N. **N**-Poisson models thus have a practical application only when N is small, that is the 2-Poisson model or the 3-Poisson model.

The 2-Poisson is illustrated with an example. A collection of ten documents contains a word **t** occurring respectively 4, 5, 6, 0, 1, 2, 0, 0, 0, 0 times within these ten documents, the first three documents having the highest frequency of term in the collection. A useful image for this configuration could be that the first three documents constitute an *elite* or *special* subset of documents for the term. Then, these data are fitted to the 2-Poisson model using the Expectation Maximization (EM) algorithm. To set the initial values α_0, λ_0 and μ_0 for the first step of the EM algorithm the assumption is that there is a Poisson distribution generating the frequency in the elite set of the word, with a mean term-frequency $\hat{\mu_0}=\frac{4+5+6}{3}=5$, and a second Poisson distribution generating the term-frequency in the rest of the collection with $\hat{\lambda}_0=\frac{0+1+2+0+0+0+0}{7}=0.4287$. Observe that the elite set is $\frac{3}{10}=0.3333$ of the entire collection, and thus $\hat{\alpha_0}=0.3333$ is initially set. Finally, the EM algorithm converges to the values $\hat{\alpha}=0.35$, $\hat{\mu}=4.5$ and $\hat{\lambda}=0.54$ with a confidence of 0.99. The probability that a document **d** belongs to the Elite set of a term occurring **tf** times in **d** is

$$\mathrm{Prob}(\mathbf{d}\in\mathbf{E_t}|X=\mathbf{tf}) = \frac{1}{1+1.86\cdot e^{3.96}0.12^{\mathbf{tf}}}$$

Key Applications

The 2-Poisson model is at the basis of two types of probabilistic models of IR: the BM25 model and the Divergence From Randomness models.

Type-based Publish/Subscribe

Hans-Arno Jacobsen
University of Toronto, Toronto, ON, Canada

Definition

Type-based publish/subscribe is an instance of the publish/subscribe concept, where publications are instances of application-defined types, subscriptions express interest in receiving publications of a specified type or sub-type, and publish/subscribe matching amounts to type conformance checking.

Key Points

The characterization of the type-based publish/subscribe class originated in the programming languages context with the objective of bridging the impedance mismatch in the integration of publish/subscribe abstractions into programming languages. For example, the representation of subscriptions as strings that are parsed, checked, and processed at runtime by the underlying publish/subscribe implementation, are frequent sources of errors that materialize too late due to the inability to properly type check the subscription string at the language level. To enable static type checking, type-based publish/subscribe includes subscriptions and publications as first class citizens into the language.

Publications become instances of language types. Arbitrary composite types, subject to the type definition capabilities of the host language, can be used to model application-defined events. Subscribers express interest in receiving publications of a specified type. Matching of publications against subscriptions amounts to type conformance checking. That is a publication matches a subscription, if the type of interest specified by a subscription conforms to the type of a publication, for some definition of type conformance. Matching is based on type determination, sub-type checking, and is-instance-of type checks. This is similar to topic-based publish/subscribe matching, except that a type is more general than a topic. Moreover, types may support operations that can model content-based predicates as tests on the instances of types. In this sense, type-based publish/subscribe can model content-based processing.

Several standards, such as the OMG Notification Service [2] and the OMG Data Dissemination Service [3] exhibit elements of type-based publish/subscribe, but do not directly follow the prescription of the type-based publish/subscribe model. The characterization of type-based publish/subscribe can be found in [1].

Uncertainty in Events

Segev Wasserkrug
IBM Research, Haifa, Israel

Synonyms

Event uncertainty

Definition

Uncertainty in events is uncertainty regarding either the occurrence of an event, or uncertainty regarding the data values associated with an event. This uncertainty is a result of a gap between the actual occurrences of events in the real world, and the availability of knowledge regarding the events.

Historical Background

The first event-based systems were active databases, in which automatic actions were carried out as a result of database queries. This was done using the *ECA* (Event-Condition-Action) paradigm. However, in many such database applications, the events of interest were not the results of single queries, (e.g., insertion or deletion of data), but rather could be deterministically inferred from several such queries. To facilitate such inferences, event inference languages were defined. Initially such languages were specific to active databases (e.g., SNOOP and ODE). However, more general languages were developed suitable for implementing such deterministic inferences in any event-based system. These general languages resulted from the need to enable event driven behavior in a wide variety of application domains and became part of a wider area known as Complex Event Processing (CEP). As event driven applications became more complex, it became necessary to handle uncertainty regarding the occurrence and inference of events.

Foundations

For a system to implement event driven behavior, the system must be able to recognize all events of interest. However, in many cases, there is a gap between the actual occurrences of events to which the system must respond and the data generated by monitoring tools regarding these events. This gap results in uncertainty.

To understand this, consider a thermometer that generates an event whenever the temperature rises above 37.5°C. The thermometer is known to be accurate to within ±0.2°C. Therefore, when the temperature measured by the thermometer is 37.6°C, there is some uncertainty regarding whether the event has actually occurred.

Another gap between the actual occurrence of events and the information available to the system is caused by the following: The information regarding the occurrence of some events (termed *explicit events*) is signaled by event sources (e.g., monitoring tools such as the thermometer described above), while for other events, explicit notification is never sent (*non-explicit events*). An example of a non-explicit event is insider trading. Although insider trading either does or does not take place, no explicit signal regarding such an event is generated.

For an event-based system to respond to non-explicit events, in many cases the occurrence of these events must be inferred based on the occurrence of other events. (The events based on such inference are termed *inferred events*.) To facilitate such inferences, several event composition languages have been defined that make it possible to infer non-explicit events based on a set of complex temporal predicates. In many cases, however, such inference cannot be carried out with certainty. To see an example, consider again the case of insider trading. While a single large sale of stock may not be indicative of anything suspicious, such a sale, together with a sharp change in stock prices of the company due to an announcement in the press may infer insider trading. However, such insider trading cannot always be said to have occurred whenever a combination of a sale event and a stock decline event occur.

Even when the inference rules may be deterministically stated, uncertainty associated with explicit events may also propagate to inferred events. To see this propagation of uncertainty, consider a rule (defined in an event composition language) that states that event e_3 must be inferred whenever an event of type e_2 occurs after an event of type e_1. Moreover, assume that it is known that both an event of type e_1 and an event of type e_2 have occurred, but there is uncertainty about the exact time of their occurrence because the occurrence of e_1 is known to be between time 2 and time 5, and the occurrence of e_2 is known to be between time 3 and time 7. Note that even though the rule is deterministic, the uncertainty regarding the occurrence times of e_1 and e_2, and the fact that the occurrence of e_3 must be inferred based upon these occurrence times, results in uncertainty with regards to the occurrence of the event e_3.

Dimensions of Event Uncertainty

It is useful to classify the uncertainty according to two orthogonal dimensions: *element uncertainty* and *origin uncertainty.*

Element uncertainty refers to the fact that event-related uncertainty may involve one of two elements:

1. *Uncertainty regarding event occurrence*: Such uncertainty is associated with the fact that although the actual event occurrence is atomic, (i.e., the event either did or did not occur) the event-based system does not know whether or not this event has, in fact, occurred. An example of this is insider trading. At any point in time, insider trading either was or was not carried out by some customer. However, an event-driven system can probably never be certain whether insider trading actually took place.
2. *Uncertainty regarding event attributes*: Even in cases in which the event is known to have occurred, there may be uncertainty associated with its attributes. For example, while it may be known that an event has occurred at some point in time, its exact time of occurrence may not be precisely known.

Origin uncertainty pertains to the two types of events (explicit and inferred) that exist in an event-based system. Due to these two types of events, there are two possible origins for uncertainty:

1. *Uncertainty originating at the event source*: When an event originates at an event source, there may be uncertainty associated either with the event occurrence itself or the event's attributes, due to a feature of the event source. An example is the limited precision thermometer described previously, where uncertainty regarding an event occurrence (i.e., the temperature being above 37°C) is caused by the limited measuring accuracy of a thermometer (i.e., the reading being accurate only to within ±0.2°C).
2. *Uncertainty resulting from event inference*: Due to some events being inferred based on other events, uncertainty can propagate to the inferred events. This is demonstrated by the rule previously described, which is used to infer events of type e_3 based on events of types e_1 and e_2. In the aforementioned case, uncertainty regarding the occurrence of event e_3 resulted from uncertainty regarding the time that events e_1 and e_2 occurred.

Based on the above two dimensions, it is possible to define four types of event uncertainty. These are the following:

1. Uncertainty regarding event occurrence originating at an event source;
2. Uncertainty regarding event occurrence resulting from inference;

3. Uncertainty regarding event attributes originating at an event source; and
4. Uncertainty regarding event attributes resulting from event inference.

These uncertainty types are depicted as quadrants in Fig. 1.

Causes of Event Uncertainty

There are many possible causes for event uncertainty. In addition, the uncertainty causes for explicit events are different from the uncertainty causes of inferred events.

These are the sources of uncertainty for explicit events:

1. *An unreliable source*: An event source may malfunction, indicating that an event has occurred even if it has not. Similarly, the event source may fail to signal the occurrence of an event which has, in fact, occurred. A source may also transmit erroneous information regarding one (or more) of the event's attributes.
2. *An imprecise event source*: An event source may operate correctly, but still fail to signal the occurrence of events due to limited precision (or may signal events that did not occur). Such a source may also be the cause of imprecision regarding an event's attributes.
3. *Problematic communication medium between the event source and the event-based system*: Even if the event source has full precision and operates correctly 100% of the time, the communication medium between the source and the event-based system may drop indications of an event's occurrence, generate indications of events that did not occur, or alter information regarding the event's attributes.

		Origin uncertainty	
		Event source	Inference source
Element uncertainty	Event occurrence	Event occurrence uncertainty quadrant	Inference occurrence uncertainty quadrant
	Event attribute	Event attribute uncertainty quadrant	Inference attribute uncertainty quadrant

Uncertainty in Events. Figure 1. Event uncertainty types.

4. *Uncertainty due to estimates*: In some cases, the event itself (or its attributes) may be the result of a statistical estimate. For example, it may be beneficial to generate an event whenever a network Denial of Service (DoS) event occurs, where the occurrence of such a DoS event is generated based on some mathematical model. However, as the mathematical model may produce erroneous results, this event also has uncertainty associated with it.
5. *Clock synchronization in distributed systems*: This is a cause of uncertainty regarding the occurrence time of events in a distributed system. This is due to the fact that in distributed systems, the clocks of various nodes are usually only guaranteed to be synchronized to within some interval of a global system clock. Therefore, there is uncertainty regarding the occurrence time of events as measured according to this global system clock.

These are possible causes of uncertainty of inferred events:

1. *Propagation of uncertainty*: There are cases in which an inferred event can be deterministically inferred based on other events. Even in such cases, there may be uncertainty regarding the inferred event, resulting from uncertainty regarding the events based on which the inference is carried out.
2. *Uncertain inference*: There are cases in which the inference is inherently uncertain. One example of this is insider trading, where events denoting suspicious purchases and sales of stock coupled with rapid price changes only serve to indicate the possible occurrence of an insider trading event. In such cases, an insider trading event cannot be inferred with certainty based on such suspicious transactions. An additional prominent example is when the event driven application is required to predict the occurrence of future events.

Note that for both explicit and inferred events, uncertainty regarding a specific event may be caused by a combination of factors. For example, for a specific event, it is possible that both the event source and communication medium simultaneously corrupt the information sent regarding this event.

Handling Uncertainty in Events

There is a spectrum of possibilities by which such event uncertainty may be handled. One end of this spectrum has methods that explicitly or implicitly ignore the presence of uncertainty. The other end is a complete and formal treatment of such uncertainty. Details about these two extremes are provided below. Obviously, solutions which lie between these two extremes are also possible.

The methods that explicitly or implicitly ignore such uncertainty usually rely on deterministic event composition languages to enable the event driven functionality required. In many cases, applications that ignore the uncertainty rely on a human being to make the final decision regarding whether or not an event of interest occurred. An example of such an application is credit card fraud detection. In many such systems, the system is expected to recognize suspicious patterns of credit card transaction events that may indicate fraud. Such indications are then used to alert a human operator, whose role it is to establish whether such a fraud indeed took place.

A full and formal treatment of such uncertainty is required in applications where automatic actions must be carried out as a result of events of interest. In such cases, the framework for dealing with event uncertainty must include the following components:

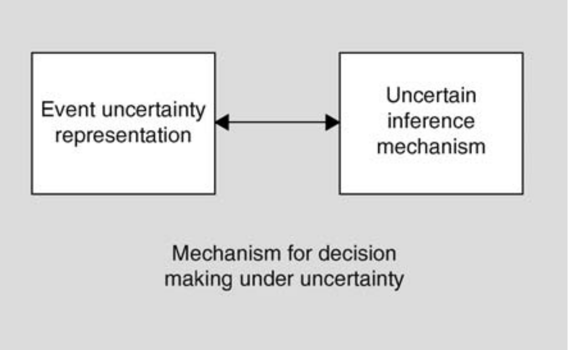
1. Mechanism for automatic decision making that can take uncertainty into account
2. Mechanism for enabling uncertain inference regarding events
3. Representation method of the uncertainty associated with each event

A depiction of such a framework appears in Fig. 2.

Example of Event Uncertainty Handling Framework

This section provides an example of an uncertainty handling framework that has the three components described in Fig. 2.

Underlying any framework for handling uncertainty in events is an uncertainty handling mechanism. Many such formalisms exist, including *Lower and Upper Probabilities*, *Dempster-Shafer Belief Functions*, and *Possibility Measures*. The framework discussed in this section is based on probability theory, which is the most well known framework for quantitative representation and reasoning about uncertainty.



Event uncertainty representation
Uncertain inference mechanism
Mechanism for decision making under uncertainty

Uncertainty in Events. Figure 2. Elements of event uncertainty handling framework.

In this framework, the uncertainty regarding an event is represented as follows: the event may have multiple sets of values associated with it. Each such set of values corresponds to possible attribute values of this event. The uncertainty is then quantified by probabilities for this set of values. For example, consider an event that either has not occurred, has occurred at time 5, or has occurred at time 10. This event has the set of values {*notOccurred*, 5, 10} associated with it. Furthermore, if the probability of the event not occurring is 0.5, the probability of the event having occurred at time 5 is 0.3 and the event having occurred at time 10 is 0.2. This is represented by {{*notOccurred*,0.5},{5,0.3},{10,0.2}}.

The framework enables uncertain inference by using a language that can specify uncertain rules together with an inference algorithm that enables the probabilities of interest to be calculated. The uncertain rules in the framework are of the form "If event e_1 and event e_2 occurred, then the probability of event e_3 occurring is 0.7." The inference framework ensures that the probabilities of the inferred events are taken into account in a manner consistent with probabilistic dependencies and independencies between the events.

The automatic decision making mechanism is based on utility theory.

Key Applications

Event driven functionality is required in almost all application domains. Therefore, the use of event-based systems is widespread. Two prominent examples of applications in which a complete treatment of uncertainty is required are security applications and sensor network applications.

In security applications, the response time available to respond to threats requires that automatic actions be carried out. An example is network security applications where it is important to respond quickly to Denial of Service (DoS) attacks. There is a need to provide a quick response (e.g., in milliseconds) to the threat, since waiting too long to respond may mean that the network may already be too saturated for a response to be of use. On the other hand, wrongly determining that a DoS attack has occurred and carrying out measures such as shutting down certain ports, may result in unjustifiable denial of service to legitimate network traffic. In such a case, an event driven framework for automatic decision making under uncertainty is required.

In sensor network applications, a large number of sensors continuously transmit relatively rudimentary data (in the form of events) to some central server. An example may be a monitoring application, in which sensors throughout a large office building constantly transmit the temperature of each room in the building. An application may then be required to detect the possibility of a fire occurring in the building based on the individual readings or to aggregate the individual readings.

Because of current technical limitations, each individual sensor is unreliable. Therefore, it is quite possible that a temperature reading is not transmitted by the sensor or that there is an error in the transmitted reading. Due to this unreliability, an explicit treatment of uncertainty is required in such domains.

Future Directions

While research in event-based systems and event driven applications has been ongoing for several years, relatively little research has been carried out on the explicit treatment of uncertainty in events. Moreover, most such research has been focused on specific domains such as sensor networks and security application. Therefore, much work remains in exploring new and formal approaches to such treatment. An additional important future direction is the implementation of a production level system that enables event inference under uncertainty in the general case.

Uncertainty Management in Scientific Database Systems

NILESH DALVI
Yahoo! Research, Santa Clara, CA, USA

Definition

Scientific databases often deal with data that comes from multiple sources of varying quality, is heterogeneous, incomplete and inconsistent, and ridden with measurement errors. Uncertainty management deals with a set of techniques for modeling and representing the various uncertainties that arise in scientific data and to enable users to query the data. This entry describes the UII system [10] that addresses the issue of managing uncertainty in integrating scientific databases.

Historical Background

Distributed data integration is becoming increasingly popular in biomedical research and in scientific research in general. Its popularity is based on the realization that combining sources frequently lead to novel scientific discoveries that cannot be concluded from any single source in isolation. However, as more and more scientific data is shared and as tools are built to provide a common query interface for them, the scientists face the major problem of dealing with information overload [19]. There are several factors that affect the quality of answers to the user queries: the quality of the data sources themselves, the quality of links across data sources, the alignment of data across sources, and so on. The data sources have a large variation in the quality of their data, caused by the curation method, provenance and the experimental protocols used in data collection. Some databases are nicely linked, with one containing foreign keys to other, while others have to be linked by matching tuples over text fields. The scientific data across sources is often not aligned, due to experimental errors and lack of common standards. Specialized algorithms exist to align scientific data, e.g., the BLAST [16] sequence alignment algorithm for aligning potentially similar proteins, but these algorithms are speculative at best. As a consequence, the user is left with the daunting task of searching for relevant answers among a vast number of spurious results.

Uncertain data management [15] has seen a recent renewed interest in the databases community. This is because of the thrust from applications that span not just scientific databases but several others that include exploratory queries in databases, novel IR-style approaches to data integration, information extraction from Web, sensor networks applications and data privacy analysis. There are efforts to build general purpose uncertain data management systems, e.g., MystiQ [2] and Trio [18]. In parallel, there are several efforts in the community to develop scientific data management systems and tools to ease the tasks of scientists and facilitating the process of sharing and reusing experimental data. This entry describes the application of uncertain data management techniques to scientific databases. It gives several examples of specific uncertainties that arise in managing scientific data and describes the UII system [10] that addresses these issues.

Foundations

This section provides examples of data uncertainties that arise in scientific data.

Uncertainties in Scientific Data

The uncertainties in scientific data can be classified into two broad categories:

1. *Inherent Data Uncertainties* Inherent data uncertainties are attributes of the data itself and not artifacts of its representation. Data generated from laboratory experimental methods often have inherent uncertainties. To illustrate an extreme case, two-hybrid screening assays, which are used to detect protein interactions, have error rates estimated to be close to 50% [2]. Experimental data can also be generated from computational experiments. The BLAST algorithm [3] searches in a database for sequences similar to a query sequence. The similarity between any two sequences is measured by the BLAST evalue, which is the degree to which the pairing could occur by chance. Additionally, uncertainties can be rooted in the ever-evolving nature of biological knowledge itself. For example, GenBank references sequences (RefSeqs) are assigned status codes which refer to the amount of evidence and expert curation attributed to a given sequence and its function [4]. These codes range from "inferred" where there is little support for a given sequence, to "reviewed" where substantial evidence exists and has been vetted by a biological domain expert. Status codes for sequences change over time as evidence for them accumulates.
2. *Data Representation Uncertainties* Data representation uncertainties result from the mapping of real world information onto a computable representation of this information. At last count there were over 600 online data sources in molecular biology [5]. Unfortunately, for all the data that is available there are no common standards for representing it (in part due to the evolving nature of biomedical knowledge). The result is the decentralized and heterogeneous nature of biological data sources which is an underlying source of many data uncertainties. For instance, there is no common identifier for a biological object [6] which make it difficult to query across data sources (manually or otherwise), a task which is commonly performed. Linkages between data records may then require string matches on text fields rather than more reliable "foreign-key" relationships. Additionally, data sources tend to represent data in idiosyncratic fashion. For

example, GenBank uses RefSeq status codes to represent the level of evidence for a particular gene but the Gene Ontology (GO) uses evidence codes [7]. Given evidence from both sources, it is sometimes difficult to make comparisons, such as determining which code provides the greater weight of evidence.

General Purpose Systems for Managing Uncertainty

The problem of managing uncertainty in databases has a long history [1,3,6,9] with a recent renewed interest, and several systems for managing uncertain data have been proposed recently in the literature.

Trio The Trio [18] system being developed at Stanford is a data management system that supports uncertainty and lineage. The focus of the system is on the representation formalisms for uncertainty and lineage as well as query languages over such data. Trio extends the relational database model with (i) *alternative values*, where tuple attributes may be assigned a set of possible values rather than a single value, (ii) *maybe* ("?") annotations, specifying that a tuple may not exist, (iii) optional *numeric confidences* attached to alternatives and (iv) *lineage*, connecting tuple-alternatives to other tuple alternatives from which they were delivered. The Trio query language extends SQL to support querying based on tuple-alternatives as well as lineage.

MystiQ The MystiQ [2] system from University of Washington is another general-purpose system which supports various constructs for handling uncertainty that include probabilities associated with tuples, approximate predicates in SQL queries and *soft views* over uncertain data. The focus of the system is on efficient query evaluation, and uses various techniques like *safe query plans* [4] and Monte-carlo approximations [11].

Other Systems The Orion system [14] at Purdue looks at uncertainty given by continuous-valued probability distributions. This is an important problem which is specially relevant to managing uncertainty in sensor networks, where the actual sensor readings often have continuous-valued uncertainty associated with it. The work looks at supporting aggregate queries over such data items. There is also very interesting research [5,7,12] being carried out on extending probabilistic databases to represent correlated tuples and graphical models.

Similarly, there are several systems that exist for Scientific data management. However, several challenges must be met to combine the uncertain data management techniques with these systems. First, it requires an analysis of various sources of uncertainties that arise in Scientific data management, and a principled way to quantify and represent these uncertainties. Secondly, the uncertain data management systems primarily use SQL queries over relational data. This model is unsuitable [13] for scientific databases as the scientists using the system are unfamiliar with the concepts of databases and SQL queries and prefer a simpler interface to browse and explore the data. The rest of this entry describes the UII system[10] which is a specialized scientific data management system with support for uncertainty.

The UII System for Managing Uncertainty in Scientific Data

UII is built on top of the BioMediator system [13,17], which is a mediated-schema distributed data integration system being developed at the University of Washington. The query model of BioMediator is designed to address the need of biologists, which supports poorly specified, exploratory kind of queries.

A user begins by issuing a simple query, called the *seed query*, which establishes the basic topic of interest. The user can then browse these results and explore any of the results further by finding information about it in other sources, a process called *query expansion*.

Figure 1 shows a sample seed query: `Gene` records containing a `Symbol` attribute with value `BRCA1`. The system determines which of the included data sources contain `Gene` information and then queries these sources for entries satisfying the specified constraints. The result is shown as a graph that contains one query node and several results node linked to it.

A user can expand a set of node by clicking them, which causes them to join with tuples from other data sources, using the information present in the nodes to be expanded. Such information may include foreign keys to other sources allowing direct look-ups. Often, in the absence of unique foreign keys, the joins involve partial matches over (multiple) free text fields. Figure 2 shows an example of a single step of query expansion. The one light node is expanded once resulting in two dark nodes.

Uncertainty Management in Scientific Database Systems. Figure 2. A single step in query expansion.

The browsing history of an user is abstracted in terms of a *browsing graph*. A browsing graph is a directed graph whose nodes are records from data sources, and edges correspond to node expansions. It has a distinguished query node, which in the seed query used to initiate the browsing. There can be multiple paths from the start node to a give node, which corresponding to multiple expansion paths to the same node.

Handling Uncertainty

The problem of searching for relevant query answers is exemplified by Fig. 3, which shows a fragment of browsing graph with over 5,000 results, derived by just two complete expansion steps (where in each step all the nodes are expanded) starting from the same seed query shown in Fig. 1. However, not all the nodes in the browsing graph are equally likely to be useful to the user. A node may be of low quality because of the data source that contributes that node. An expansion edge may be of low quality because it was joined using a partial match on a text field. The farther a node is from the start node, the less likely it is to be relevant to the user. The relevance of nodes to the user is assessed in two steps. In the first step, the browsing graph is annotated with *uncertainty metrics*, that describe the quality of each node and each edge in the graph. In the second step, these metrics are used to compute the relevance of each node to the user. The two steps are described below.

Uncertainty Metrics The following is a summary description of the four fundamental uncertainty metrics that capture all types of uncertainty in the UII system:

Ps Measure: Ps is a measure defined at the schema level. It is a quantification of user's prior belief in the quality of data records of a particular data type from a particular data source (e.g., Genes from Entrez Gene, Classifications from Entrez Gene, and Classifications from GO, are each assigned Ps values). For example, consider the comparison between proteins from

SwissProt and TrEMBL. SwissProt is a manually and carefully curated data source of protein functional information whereas TrEMBL contains only computational predictions which are deemed less reliable. The class of protein records from SwissProt therefore are assigned a higher Ps value than those from TrEMBL because SwissProt protein records are generally trusted to a greater degree.

Qs Measure: Qs is also defined at the schema level. It is a quantification of user's prior belief in the quality of links between to data types in two different data sources (e.g., Genes in Entrez Gene to Proteins in Entrez Protein). To elaborate, records in some sources, such as Gene records from Entrez Gene, contain references to records in another source, such as Protein records from Entrez Protein. In this example, these references are in the form of "accession" numbers which essentially correspond to unique identifiers (foreign keys). Records between other types and sources however may only be connected by non-foreign keys, e.g., text-string similarities such as is the case between Genes from Entrez Gene and Genes in OMIM. In this example, the relationship between Genes in Entrez Gene and Proteins in Entrez Protein is assigned a higher Qs value since these links are better in general than those between Genes in Entrez Gene and Genes in OMIM.

Pr Measure: This is defined at data level and is a quantification of user's belief in a particular data record. It is used to capture data uncertainties which differ between records of the same type and source.

Gene records in Entrez Gene, for example, are attributed with a Refseq status code which ranges in value from "inferred" to "reviewed." These status codes correspond to the amount of evidence for a given gene, therefore "reviewed" are assigned a higher Pr value than "inferred."

Qr Measure: Qr is also defined at the data level, and is a quantification of user's belief in a particular cross-reference (link) between two data records. It is dynamic (calculated at the time two linked results are returned by the system). For example, record cross-references using unique identifiers always receive a Qr of 1.0. Some records may reference others via the use of comparison algorithms such as BLAST. For BLAST cross-references, Qr scores are dynamically computed by converting the e-value from the BLAST algorithm into a numeric value between 0.0 and 1.0. BLAST comparisons that correspond to better matches between records (higher similarity) receive higher Qr values.

Probabilistic Query Evaluation Each query in UII system results in a set of nodes forming the browsing graph for the query. The objective is to find the relevance of each node in the browsing graph to the original seed query. This can be posed as a network reliability problem [8]. For each node in the graph, the quantity $Ps * Pr$ is interpreted as the probability that the node is correct. Similarly for each edge, $Qr * Qs$ is interpreted as the score that the edge is correct. Finally, the relevance of a node is simply the probability that the node is reachable from the seed query node in the browsing graph.

The exact relevance computation is an intractable problem [8]. However, the probabilities can be efficiently approximated to arbitrary precision using simulation algorithms. The following simulation algorithm can be employed, which is well suited for the needs of the problem. In a single pass, N trials (path traversals in the graph) are simulated where nodes and edges are included in the traversal with their associated probabilities. This is done by first storing a random N-bit vector with each node/edge, that denotes whether the node is in or out in the corresponding experiment. Finally, performing a single depth-first search and using these bit vectors, a final bit vector for each node is obtained that describes the trials where that node was reachable from the start node. The relevance for a node is then estimated using the quantity k/N, where k is the number of set bits in the node's final bit vector. The choice of N influences the error in the estimation, the larger the N the smaller the error. Also, for any fixed value of N, the larger the actual relevance of a node, the better the approximation. Thus, the simulation will correctly rank the most relevant answers, which the user cares about most, while the poorest results may be slightly out of order.

Key Applications

Uncertainty management techniques are fundamental to *Scientific Data Integration* applications.

Future Directions

Uncertainty is a fundamental issue in scientific databases, and there are several open and challenging problems which need to be addressed. One important problem is to assign meaningful probability scores to data in a principled way. While the current approach requires domain experts to specify Ps, Pr, Qs and Qr values, it would be more desirable to automatically ascribe them using machine learning techniques. Uncertainty management systems should also be able to relearn and update these scores based on users' feedback to query results. Another problem is to develop highly scalable and efficient query answering algorithms that go beyond the current simulation based techniques. A potential approach in this direction is to use the uncertainty scores to enable a focused expansion of the query rather than constructing the whole browsing graph a priori and ranking its nodes. Another important aspect of managing uncertainty in scientific data is keeping track of data provenance. As scientists use experimental data from different sources and their own experimental data to generate new data, it becomes important to track the provenance of data through these computing processes. The uncertainties in scientific data are often correlated in ways dictated by their provenance, and managing uncertainty along with the provenance information is a challenging and important future direction.

Unicode

Ethan V. Munson
University of Wisconsin-Milwaukee, Milwaukee,
WI, USA

Definition

Unicode is an international standard for representing text characters. Unicode supports the scripts of most languages in wide use and has a flexible design that is capable of supporting all known human languages and all of their variant scripts. The development of the Unicode standard is coordinated by the Unicode Consortium.

Key Points

Unicode's development is motivated by the need to encode characters in all languages without conflicts between the encodings for different languages. Obviously, the achievement of this goal is fraught with technical and political complexities.

Unicode has several different encodings. The most widely used is the 8-bit, variable-width UTF-8 encoding, which permits the encoding of many European languages in an efficient one-byte form and is backward compatible with both the ASCII and ISO-8859-1 character sets. UTF-16 is a 16-bit, variable-width encoding that is more suitable to languages with many characters, such as Chinese, Japanese and Korean. UTF-32 is a four-byte, fixed-width encoding that encompasses all Unicode characters.

The Unicode Consortium is supported by many well-known computer and software manufacturers. For the members of the consortium, the system internationalization problem is of compelling importance.

Unified Modeling Language

Martin Gogolla
University of Bremen, Bremen, Germany

Synonyms

UML; Unified modeling language; Unified modeling language

Definition

The Unified Modeling Language (UML) is a graphical language for visualizing, specifying, constructing, and documenting the artifacts of a software-intensive system. UML offers a standard way to write a system's blueprints, including conceptual things such as business processes and system functions as well as concrete things such as programming language statements, database schemas, and reusable software components [8].

Historical Background

The UML is based on earlier software design approaches, among them the Object Modeling Technique (OMT) [9], Object-Oriented Analysis and Design (OOAD) [1], and Object-Oriented Software Engineering (OOSE) [6] and other important techniques [5]. The UML was standardized in various versions by the Object Modeling Group (OMG) [8]. Authors of the predecessor techniques have published a comprehensive description of the UML [10]. Questions strongly related to UML are discussed at the UML and MODELS conferences [13]. Special issues with extended papers from that conference and other works strongly related to UML and modeling are published in [11].

UML is mainly a graphical language and offers different diagram types. Among the most important diagram types are the class, object, statechart, activity, sequence, communication, and use case diagram. UML includes the Object Constraint Language (OCL) which is a textual language for navigation in class diagrams and for expressing textual constraints like invariants, pre- and postconditions, or guard conditions. Many tools for UML, but fewer support for OCL is available, see e.g., [3,12], among other interesting work.

Foundations

UML Class and Object Diagrams

The main purpose of class diagrams is to capture the static structures and operations of a system. This section briefly explains the most fundamental features in class diagrams: classes and associations. More advanced features are also discussed.

Classes: A class is a descriptor for a set of objects sharing the same structure and behavior. In each (database) system state, a class is manifested by a set of objects. In the database context, concentration is upon structural aspects, although behavioral aspects may be represented in UML as well. Object properties can be described by attributes classified by data types like `String` or `Boolean`. Properties can also stem from roles in associations which connect classes.

Example: Figure 1 shows the classes `Supplier`, `Project`, and `Part` together with some basic attributes including their data types, e.g., one identifies `Supplier::Name:String` and `Project::Budget:Integer`. In this contribution, the general scheme for denoting properties (attributes and roles) is `Class::Property:PropertyType`.

Associations: An association represents a connection among a collection of classes and may be given a name. An association is manifested by a set of object connections, so-called links, sharing the same structure. A binary association can be defined between two different classes; objects of the respective classes play a particular role in the association. A binary association can also be defined on a single class; then objects of the class can play two different roles; such a binary association is called reflexive. A ternary association involves three roles. The notion n-ary association refers to a ternary or a higher-order association. Binary associations are usually shown with a simple line, and an n-ary association with a small rhomb-shaped polygon.

Example: Fig. 1 shows the binary association ProjectPart with roles project and part, the ternary association SupplierProjectPart with roles supplier, suppliedProject, and suppliedPart, and the reflexive association Component with roles parent and child.

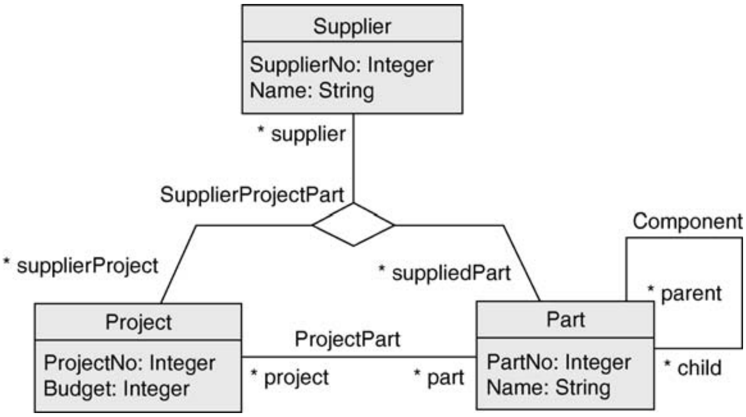
Objects and Links: Structural aspects in UML can also be represented in an object diagram showing objects, links, and attribute values as manifestations of classes, associations, and attributes. An object diagram shows an instantiation of a class diagram and represents the described system in a particular state. Underlining for objects and links is used in object diagrams in order to distinguish them clearly from class diagrams.

Example: Figure 2 shows an object diagram for the class diagram from Fig. 1. Objects, links, and attribute values correspond to the classes, associations, and attributes. There are two Project objects, two Supplier objects and five Part objects. Each Part object represents a piece of a software controller (Ctrl) being responsible for a particular portion of a car. The Component links express part-of relationships, for example, the Engine Code (engineCtrl) includes the Battery Code (batteryCtrl) and the Motor Code (motorCtrl).

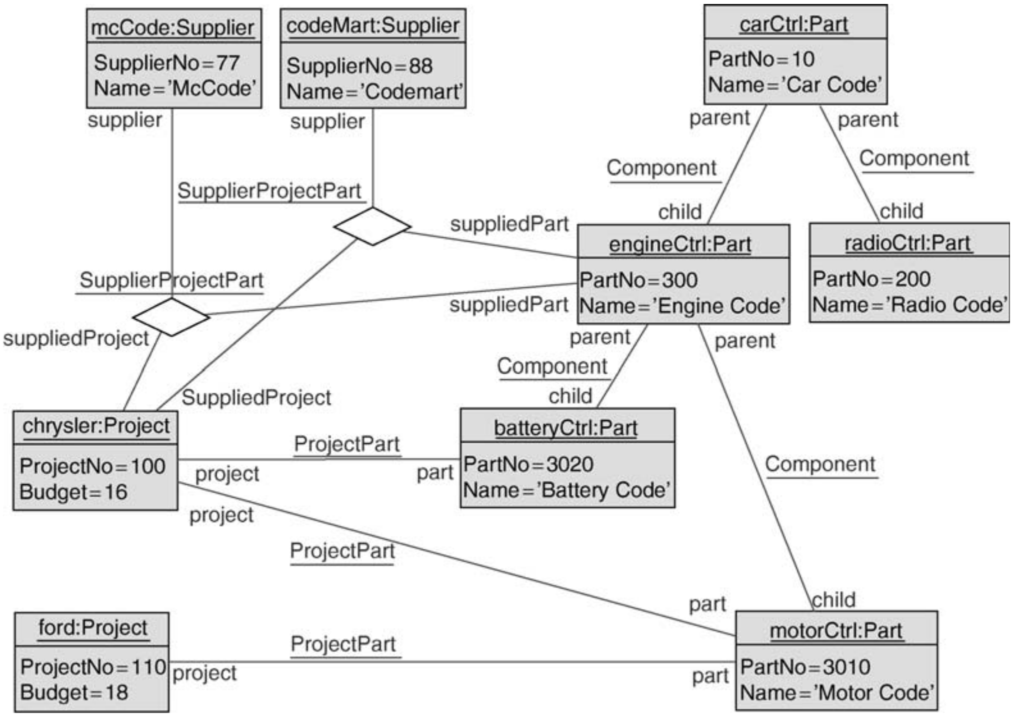
Roles: Proper roles must be specified on a class diagram in order to guarantee unique navigation. Navigation in a class diagram means to fix two classes and to consider a path from the first class to the second class by using association roles. The roles on the opposite side of a given class in an association also determine properties of the given class by navigating via the roles. Therefore, in UML the opposite side roles must be unique. Recall that properties can also come from attributes.

Example: Roles are captured on links. This is necessary in reflexive associations and in other situations, for example, if two associations are present between two given classes. For example in Fig. 2, if one considers the link between carCtrl and engineCrtl, without roles one could not tell which object plays the parent role and which one the child role. In the class diagram in Fig. 1, the class Project has two direct navigation possibilities to class Part: One via association ProjectPart and the other one via association SupplierProjectPart. One obtains therefore two properties of class Project returning Part objects: Project::part:Set(Part) from association ProjectPart and Project::suppliedPart: Set(Part) from association SupplierProjectPart. In the object diagram one obtains, for example, ford.part = Set{motorCtrl} as well as ford.suppliedPart = Set{}. In order to distinguish between these two navigations, the role name part and suppliedPart must be distinct.

Class Diagram versus Database Schema: In the database context, it is interesting to remark that the connection between a class diagram and its object diagrams resembles the connection between a database schema and its associated database states. The class diagram in general induces a set of object diagrams and the database schema determines a set of database states. Object diagrams and database states follow the general principles formulated in the class diagram and database schema, respectively. Because example object diagrams have to be displayed on a screen or on paper,



Unified Modeling Language. Figure 1. Example UML class diagram 1.



Unified Modeling Language. Figure 2. Example object diagram 1.

they tend to show less information than proper, large database states. They may however explain the principles underlying a class diagram pretty well if the examples are well chosen.

UML Class Diagram Features for Conceptual Schemas

Some of the more advanced features of conceptual database schemas in UML class diagrams are: object-valued, collection-valued and compound attributes, role multiplicities, association classes, generalizations, aggregations, compositions, and invariants.

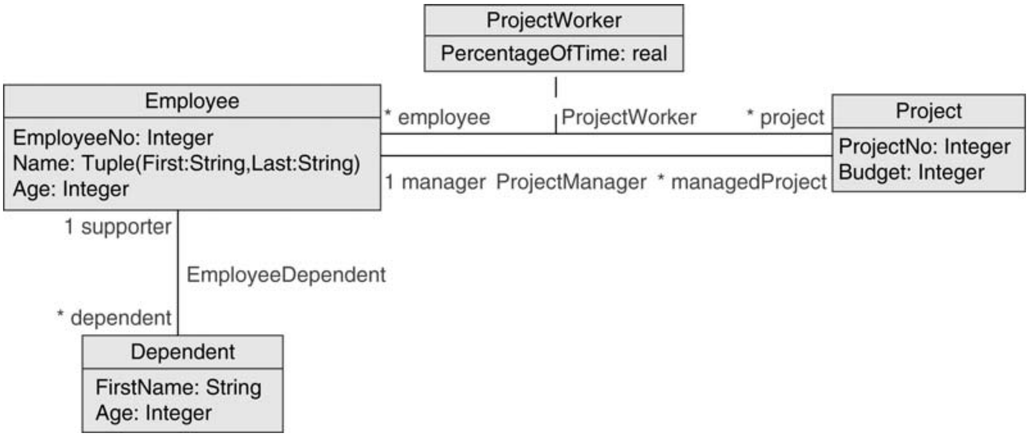
Object-Valued Attributes: Attributes in UML may not only be data-valued as above, but the attribute type may be a class as well which leads to object-valued attributes. Like associations, object-valued attributes also establish a connection between classes. However, an object-valued attribute is only available in the class in which it is defined. The information from that attribute is not directly present in the attribute type class. Thus an object-valued attribute may be regarded as a unidirectional association without an explicit name and where only one role is available.

Examples: The class diagram in Fig. 3 extends the class diagram in Fig. 1 by introducing the new classes `Employee`, `Dependent`, and `ProjectWorker`, and the associations `EmployeeDependent`, `ProjectManager`, and `ProjectWorker`. The fact that `ProjectWorker` is mentioned as a class as well as an association will be explained below. The object diagram in Fig. 4 shows an example state for the class diagrams from Fig. 3.

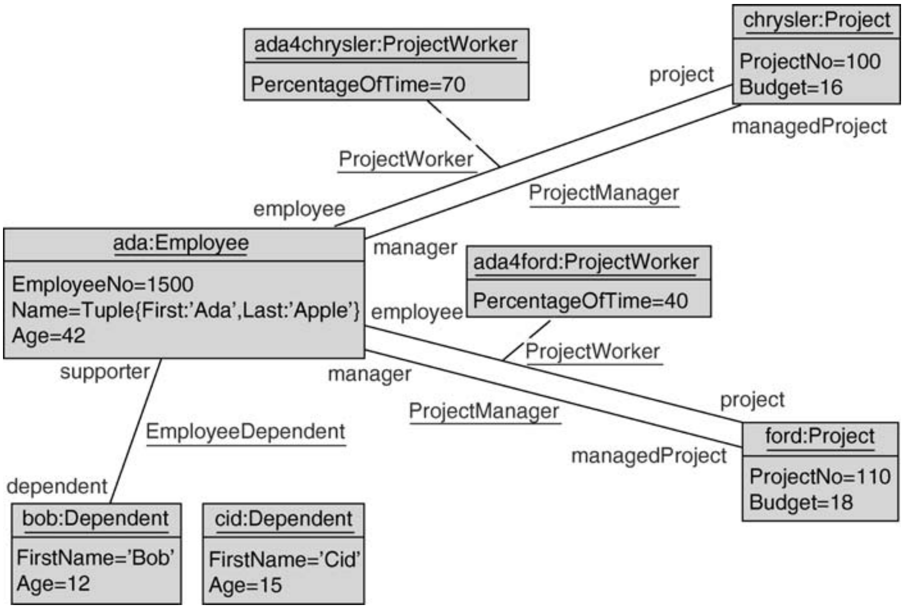
As an example for an object-valued attribute and as an alternative for the association `ProjectManager`, one could extend the class `Project` by an attribute `manager` with type `Employee`. This could be represented altogether as `Project::manager: Employee`.

Collection-Valued Attributes: The collection kinds set, bag, and sequence have already been introduced. These collection kinds can be used as type constructors on data types and classes. For building attribute types, the constructors may be nested.

Examples: An attribute could possess a type like `Set(Project)`. As an alternative for the association `ProjectManager` one could have one attribute `managedProject:Set(Project)` in the class `Employee` and another attribute `manager:Employee` in class `Project`. There is however a significant difference between the model with the association `ProjectManager` including the roles `manager` and



Unified Modeling Language. Figure 3. Example UML class diagram 2.



Unified Modeling Language. Figure 4. Example UML object diagram 2.

`managedProject` and the model with the two attributes `manager` and `managedProject`. In the model with the association, the roles `managedProject` and `manager` represent the same set of object connections, i.e., are inverse to each other:

```
    Employee.allInstances->forAll(e|e.
managedProject->forAll(p|p.manager=e))
Project.allInstances->forAll(p|p.manag-
er.managedProject->includes(p))
```

This is not required to hold in the model possessing the two attributes. In this case the two attributes `managedProject` and `manager` are independent from each other and may represent different sets of object connections.

Another useful application of collection-valued types are collections over the data types like the complex type `Set(Sequence(String))`. A value for an attribute typed in this way could be, for example, the complex value `Set{Sequence{'Rome','Euro'}, Sequence{'Tokyo','Yen'}}`.

Compound Attributes: Apart from using the collection constructors `Set`, `Bag`, and `Sequence` for attributes, one can employ a tuple constructor `Tuple`. A tuple has a set of components each possessing a component discriminator and a component type. The collection constructors and the tuple constructor may be nested in an orthogonal way.

Examples: The above value for the type Set(Sequence(String)) could be represented also with type Set(Tuple(Town:String,Currency:String)) and with the corresponding value Set{Tuple {Town:'Rome', Currency:'Euro'}, Tuple {Town:'Tokyo', Currency:'Yen'}}.

As a further example of a compound attribute using the Tuple constructor, one identifies in the class diagram in Fig. 3 the attribute Name in class Employee which is a compound attribute with type Tuple(First:String, Last:String).

Role Multiplicities: Associations may be restricted by specifying multiplicities. In a binary association, the multiplicity on the other side of a given class restricts the number of objects of the other class to which a given object may be connected. In a simple form, the multiplicity is given as an integer interval low..high (with low ≤high) which expresses that every object of the given class must be connected to at least low objects and at most high objects of the opposite class. The high specification may be given as * indicating no higher bound. A single integer i denotes the interval i..i and * is short for 0..*. The multiplicity specification may consist of more than one interval.

Examples: The multiplicity 1 on the role supporter indicates that an object of class Dependent must be linked to exactly one object of class Employee via the association EmployeeDependent.

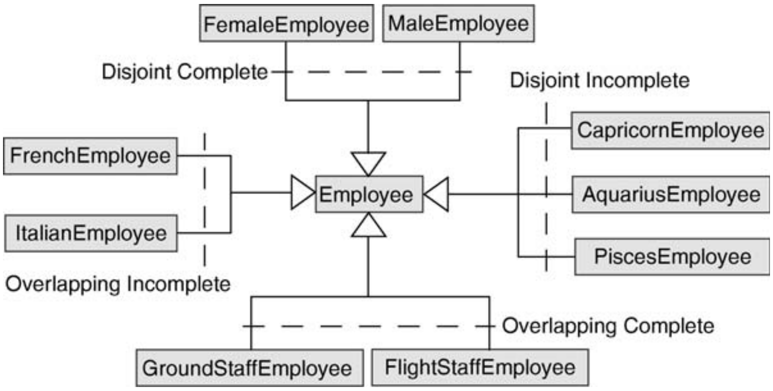
Association Classes: Associations may be viewed again as classes leading to the concept of an association class. Association classes are shown with a class rectangle and are connected to the association (represented by a line or a rhomb) with a dashed line. Association classes open the possibility of assigning attributes to associations.

Examples: The association ProjectWorker is modeled also as a class: ProjectWorker is an association class. This makes it possible to assign the attribute PercentageOfTime to the association ProjectWorker. In the class diagram, ProjectWorker is redundant as both the class name and the association name; the specification as the class name would be sufficient.

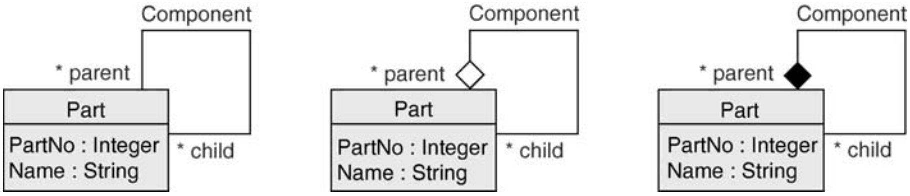
Generalizations: Generalizations are represented in UML with directed lines having an unfilled small triangle pointing to the more general class. Usually the more specific class inherits the properties from the more general class. Generalizations are known in the database context also as ISA (IS-A) hierarchies. In the programming language context often the notion of inheritance shows up. Viewed from the more general class its more specific classes are its specializations. In general, a class may have many specializations, and a class may have many generalizations. A set of generalizations may be restricted to be disjoint and a set of generalizations may be classified as complete. The classification disjoint means that any two specialized classes are not allowed to have a common instance. The label complete means that every instance of the general class is also an instance of at least one more specialized class. The explicit keywords overlapping and incomplete may be attached to sets of generalizations for which no respective restriction is made.

Examples: Figure 5 shows different specializations of the class Employee. The subclasses FemaleEmployee and MaleEmployee represent a disjoint and complete classification. The subclasses CapricornEmployee, AquariusEmployee, and PiscesEmployee classify employees according to their birthday (December 22–January 20, January 21–February 19, February 20–March 20, respectively). This classification is disjoint but incomplete. The subclasses GroundStaffEmployee and FlightStaffEmployeein the context of an airline company are labeled overlapping and complete, because each airline employee either works on the ground or during a flight and, for example, a flight accident is allowed to work on the ground during boarding and of course during the flight. The subclasses FrenchEmployee and ItalianEmployee are overlapping because employees may have two citizenships, but it is incomplete because, e.g., Swiss employees are not taken into account.

Aggregations: Part-whole relationships are available in UML class diagrams in two forms [6]. The first form represents a loose binding between the part and the whole, the second form realizes a stronger binding. Both forms can be understood as binary associations with additional restrictions. The first form called aggregation is drawn with a hollow rhomb on the whole side and is often called white diamond. The second form called composition is drawn with a filled rhomb on the whole side and is often called black



Unified Modeling Language. Figure 5. Different example generalizations and specializations in UML.



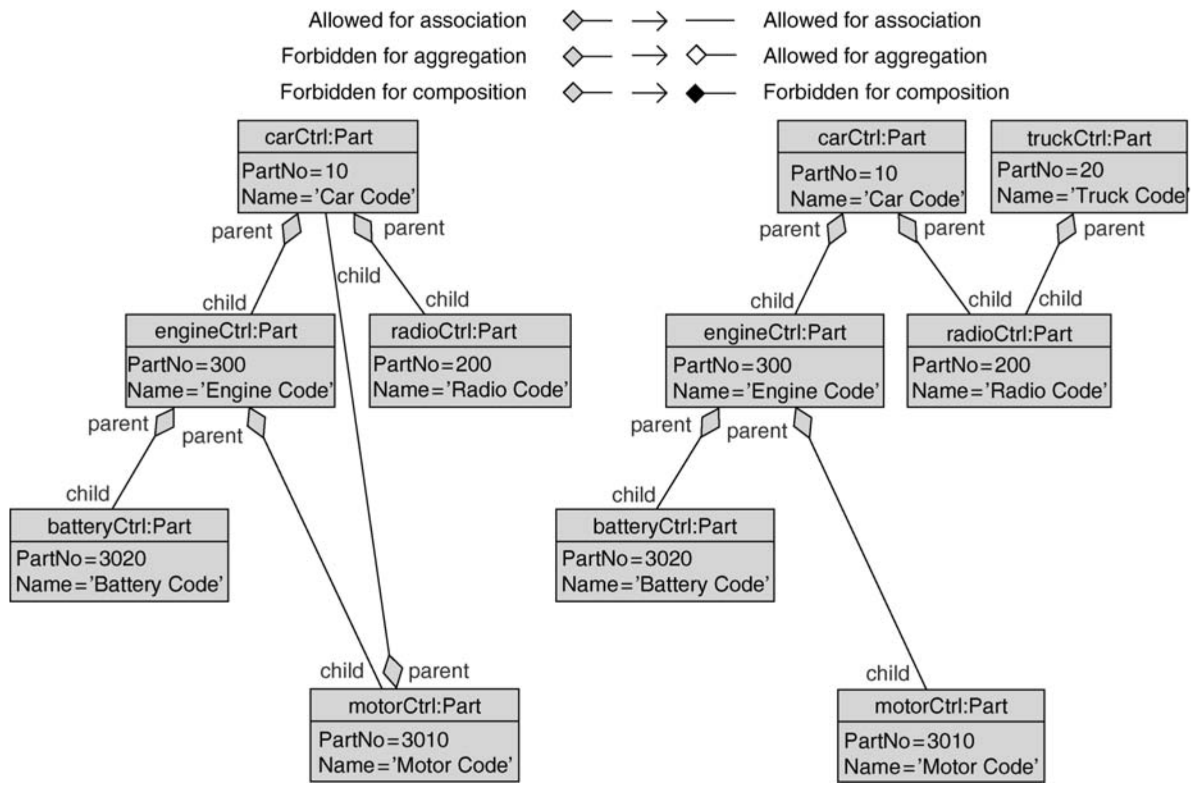
Unified Modeling Language. Figure 6. Component as association, aggregation, and composition.

diamond. The links in an object diagram belonging to a class diagram with a part-whole relationship must be acyclic if one regards the links as directed edges going from the whole to the part. This embodies the idea that no part can include itself as a subpart. Such cyclic links are allowed however for arbitrary associations. Part objects from an aggregation are allowed to be shared by two whole objects whereas this is forbidden for composition.

Examples: The class diagrams in Fig. 6 show on the left the association `Component` already introduced and on the right two alternatives in which the association is classified as an aggregation with a white diamond and as a composition with a black diamond. Recall that roles are essential in reflexive associations and therefore in reflexive part-whole relationships. Here the `parent` objects play the whole role and the `child` objects play the part role. The two object diagrams in Fig. 7 explain the differences between association, aggregation, and composition. The diamonds are shown as grey diamonds, a symbol which does *not* exist in the UML. If the grey diamond is substituted by a white diamond, the left object diagram is forbidden, because there is a cycle in the part-whole links which would mean that the object `carCtrl` is a part of itself. This would also hold for the other two objects on the cycle. Recall that if one would have a simple association instead of the grey diamond, this object diagram would be allowed. If the grey diamond is replaced by a white diamond, the right object diagram is an allowed object diagram. Here, the object `radioCtrl` is shared by the objects `carCtrl` and `truckCtrl`. Naturally, if the grey diamond would become an association, the right object diagram is allowed as well.

Compositions: Compositions pose further restrictions on the possible links in addition to the required acyclicity. Part objects from a composition cannot be shared by two whole objects. The table in Fig. 8 gives an overview on the properties of associations, aggregations, and compositions.

Examples: The discussion now turns to what happens in Fig. 7 if the grey diamond is substituted by a black diamond in order to represent compositions. If the grey diamond is replaced by a black diamond, the left object diagram is again forbidden, because there is a cycle in the part-whole links. If the grey diamond is replaced by a black diamond, the right object diagram is a forbidden object diagram for compositions, because sharing of objects is not allowed in that case.



Unified Modeling Language. Figure 7. Forbidden and allowed object diagrams for aggregation and composition.

	Acyclicity	Prohibition of sharing
Association	–	–
Aggregation	+	–
Composition	+	+

Unified Modeling Language. Figure 8. Overview on properties of associations, aggregations and compositions.

To show also a positive example for composition and aggregation, if the link from `motorCtrl` to `carCtrl` is removed in the left object diagram, it is a valid object diagram for compositions and aggregations.

Data Types And Enumeration Types: UML offers a collection of predefined data types with the usual operations on them. The data types include `Integer`, `Real`, `String`, and `Boolean`. Application dependent enumeration types can also be defined in a class diagram. The enumeration type name is followed by the list of allowed enumeration literals. Enumeration types can be used as attribute, operation-parameter or operation-return types.

Examples: Figure 9 shows two enumeration types useful in the context of the running example. The type `Gender` may represent the gender of an employee and the type `CivilStatus` its civil status.

Invariants: OCL allows invariants to be specified, i.e., conditions which must be true during the complete lifetime of an object (or perhaps more precisely, at least, in moments when no activity in the object takes place). Such invariants are implicitly or explicitly universally quantified OCL formulas introduced with the keyword `context`.

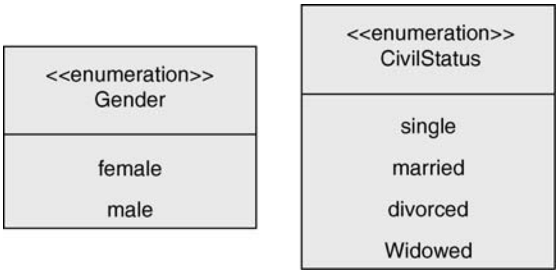
Example: In order to require that employees are atleast 18 years of age, one could state the following invariant.

context Employee inv EmployeeAreAtLeast18: Age>=18

This constraint has an implicit variable `self` of type `Employee` and is equivalent to:

context self:Employee inv EmployeeAreAtLeast18: self.Age>=18

Instead of `self` one could have used any other name for the variable, e.g., the variable `e`. The invariant



Unified Modeling Language. Figure 9. Enumerations in UML.

corresponds to the following OCL formula which must be true in all system states.

Employee.allInstances->forAll(selflself.age>=18)

Key Applications

UML class diagrams are widely used to describe structural aspects for databases (see [7,14], among other relevant papers). OCL constraints are applied for the specification of database integrity. OCL may also be regarded as an object-oriented navigation and query language.

Union

Cristina Sirangelo
University of Edinburgh, Edinburgh, UK

Synonyms

Union

Definition

The union of two relation instances R_1 and R_2 over the same set of attributes U – denoted by $R_1 \cup R_2$ – is another relation instance over U containing precisely the set of tuples t such that $t \in R_1$ or $t \in R_2$.

Key Points

The union is one of the primitive operators of the relational algebra. It is a natural extension of the set union to relations; the additional restriction is that it can be applied only to relations over the same set of attributes. However the union of two arbitrary relations having the same arity can be obtained by first renaming the attributes of one of the two relations.

As an example, consider a relation *Students* over attributes (*number, name*), containing tuples {(1001, *Black*), (1002, *White*)}, and a relation *Employees* over attributes (*number, name*), containing tuples {(1001, *Black*), (1003, *Brown*)}. Then the union *Students* ∪ *Employees* is a relation over attributes (*number, name*) with tuples {(1001, *Black*), (1002, *White*), (1003, *Brown*)}.

In the absence of attribute names, the union is defined on two relations with the same arity. The output is a relation with the same arity as the input, containing the union of the sets of tuples in the two input relations.

The union operator is commutative and associative. The number of tuples in the output relation is bounded by the sum of the number of tuples in the input relations.

Unnoticability

▶ Unobservability

Unobservability

Simone Fischer-Hübner
Karlstad University, Karlstad, Sweden

Synonyms

Unnoticability

Definition

Unobservability ensures that a user may use a resource or service without others, especially third parties, being able to observe that the resource or service is being used [1].

A corresponding, but more general definition is provided by [2]. Unobservability of an item of interest (e.g., a subject, messages, action) means that all uninvolved subjects cannot sufficiently distinguish whether or not it exists. Besides, anonymity of subjects involved in the item of interest is provided even against the other subjects involved in that item of interest.

Key Points

Whereas anonymity and pseudonymity protect the relationship of subjects to other items of interest (e.g., the fact that a specific user has sent a message), unobservability protects information about the very existence of the item of interest against uninvolved parties (e.g., the fact that a message was sent). With respect to the same attacker, if a subject's action is unobservable, then the user is also anonymous (see also [2]).

Consistency in peer-to-peer systems; Update propagation in peer-to-peer systems

Definition

In recent years, work on peer-to-peer systems has started to consider settings in which data is updated, sometimes in the form of atomic transactions, and sometimes by parties other than the original author. This raises many of the issues related to enforcing consistency using concurrency control or other schemes. While such issues have been addressed in many ways in distributed systems and distributed databases, the challenge in the peer-to-peer context is in performing the tasks cooperatively, and potentially in tolerating some variation among the instances at different nodes.

Historical Background

Early peer-to-peer systems focused on sharing or querying immutable data and/or files. More modern uses of peer-to-peer technology consider settings in which dynamic data and updates are being made in a distributed, autonomous context. A question of significant interest is how to define consistency in this model, while still allowing at least some autonomy among the sites.

Foundations

The database community has only recently begun to consider peer-to-peer architectures for applications beyond query answering, with recent work in peer data exchange [10] and collaborative data sharing [16]. However, a popular model has been that of *distributed stream processing*, in which streams of data (usually interpreted as insertions of new data) are processed in a distributed or peer-to-peer network [1,7]. Additionally, work in the distributed systems community, particularly on file systems, must consider many issues related to distributed replication and consistency with the granularity of updates typically being at the level of the file, or custom to an application. (See the entry on *peer-to-peer storage.*)

The work on updates and transactions in peer-to-peer systems can be classified based on who is allowed to modify it, and how conflicting modifications are resolved. This can be divided into the following categories:

Single Owner/Primary Copy is a setting in which each data item that originates from some source peer *p* can *only* be modified by (or through) *p* – i.e., no other peers are allowed to directly modify that data.

Owner-Resolver protocols allow multiple peers to modify the data, and they typically rely on the owner to resolve any conflicts. If resolution is impossible, they "branch" the data into fully independent instances.

Consensus protocols allow multiple peers to modify the data, and some set of nodes works together to determine how to arbitrate for consistency.

Partial Divergence schemes handle conflicts in a way that results in multiple divergent copies of the data, but they operate at a finer level of granularity than divergent replica protocols, and they allow some portions of the data instance to remain shared even after "branching" two instances.

The remainder of this entry provides more detail on the different approaches and their common implementations.

Single-Owner/Primary Copy

In the simplest schemes, each data item is owned by a single source, which may update that data. Many other nodes may replicate the data but may not change it (except, perhaps, by going through the *primary copy* at the owner). This is sometimes referred to as the *single-writer, multiple readers* problem. In this type of scheme, the owner of the data uses a timestamp (logical or physical) to preserve the serial order of updates, or to arbitrate among different verions of the data. Since there is a single owner and a single clock, any node can look at the data and deterministically choose an ordering.

In the database world, peer-to-peer stream processing or filtering systems, e.g., ONYX [7] and PIER [11], can be considered systems in which each data item (tuple or XML tree) has a single owner. When new data arrives on the stream, this appends to or replaces the previous data items from the same source.

P2P file systems have also employed a single-owner scheme that provides very interesting properties. In particular, CFS [5], PAST [8], and similar systems build a filesystem layer over distributed hash tables (DHash and Pastry, respectively), where every version of the file is maintained in the distributed hash table. In these approaches, a user must ask for a file by name *and version*; the latest version can be obtained from the file's owner or from a trusted third party. This model is exemplified by CFS, which retrieves the file as follows: first, it cryptographically hashes the filename and version, receiving a key from which the file's current block map can be fetched. This map contains an ordered list of keys corresponding to the individual blocks in the requested version of the file. Each block can be fetched using its key; the key actually represents the hash of the block's content. This content-based hashing scheme for blocks has a two key benefits: (i) if two files or file versions share a page with identical content, CFS will store only *one* copy of the page and will use it in both files; (ii) CFS will employ caching as blocks are requested, and the cache lookup mechanism can be based on hashing, rather than naming, content.

Owner-Resolver

Coda [12] relaxes the single-owner scheme described above, in allowing data to be replicated throughout a network, and for changes to be made to the replicas. Coda's focus is on allowing updates in the presence of network partition: nodes might need to make changes without having access to the primary copy. Once connectivity is restored, the newly modified replica must be reconciled with the original data and any other changed replicas; Coda does this by sharing and replaying logs of changes made to the different replicas. If Coda determines that multiple concurrent changes were made, then activates an application-specific *conflict resolver* that attempts to resolve the conflicts. In the worst case, the data may need to be branched.

Bayou [9] uses a very similar scheme, except that changes to replicas are propagated in pairwise fashion across the network (an *epidemic protocol*) instead of sent directly to each file's owner. Nodes maintain logs of the updates they know about, including other nodes' updates; as they communicate, they exchange logs and merge them in pairwise fashion (this is an *epidemic protocol*). If conflicts occur, an application-specific *merge procedure* is triggered. Eventually the logs reach a primary node, which determines the final order of updates.

Building even further on the notion of epidemic protocols, work by Datta et al. [6] focuses on settings in which conflicts are unlikely to arise at all. It adopts an epidemic protocol that provides eventual consistency across the network. In this model, a peer that makes an update pushes a notification to subset of its neighboring peers, who may in turn forward to additional peers. This is likely to keep many of the peers "relatively" up to date. When a peer has not received an update in a while, or if it comes back online, it tries to determine the latest state by executing a "pull" request.

Consensus

Coda and Bayou allowed for concurrent updates, but relied on the holder of the primary copy to resolve conflicts. An alternative is to reconcile conflicts through some sort of voting or consensus scheme. Like Bayou, Deno [4] uses an epidemic protocol, in which nodes share information in pairwise fashion about new updates. Here, updates are grouped into transactions that are to be atomically committed or aborted. For each transaction that is not *blocked* (i.e., waiting for another transaction to complete), a distributed vote is executed to determine whether the transaction should be committed. Nodes gossip by exchanging information about transactions and votes; ordering information is maintained using version vectors [15]. If a majority of nodes vote for the transaction, rather than any other transactions that have conflicting updates, then the transaction is committed.

A number of filesystems, including BFS [3], OceanStore [13], Farsite [2], make use of *quorums* of nodes that manage the sequencing on updates: these nodes essentially serve very similarly to the single owner schemes described previously, in that they must be contacted for each update in sequence, and they define the serialization order of updates.

Partial Divergence

Two more recent works – one focused on filesystems, and the other on database instances – enable a scheme for managing inconsistency based on peers' individual *trust policies*.

Like CFS, Ivy [14] is a filesystem built over the DHash distributed hash table. However, Ivy provides NFS-like semantics including the ability to modify files, and it does so in a novel way. Ivy has one update log per peer, and such logs are made publicly available through DHash. As a peer modifies a file, it writes these changes to its own update log (annotating them with version vectors [15] so sequencing can be tracked). As the peer *reads* a file, it may consult *all* logs; but it may also ignore some logs, depending on its local trust policy. However, Ivy assumes that it is highly undesirable for each peer to get a different version of a file (because this would prevent sharing); hence, sets of peers share a *view* of the file system – all files in the view have the same consistent version.

Finally, the Orchestra [16] *collaborative data sharing system* focuses on sharing different database instances in loose collaborations: here, multiple peers wish to share updates with one another, but each peer may selectively override the updates it receives from elsewhere. Each peer may adopt its own *trust policies* specifying (in a partial order) how much it trusts the other peers. Orchestra is specifically motivated by scientific data sharing: for instance, organizations holding proteomics and genomics data wish to import data from one another, and to refresh this imported data; however, since the data is often unreliable, each peer may wish to choose the version from the site it trusts most, and then independently curate (revise, correct, and annotate) the resulting data.

In Orchestra, as in Deno, all updates are grouped into atomic transactions. Here, each peer uses its local trust policies to choose among conflicting transactions – such a transaction will be *accepted* by the peer, and all conflicting transactions will be *rejected*. If a transaction *X* from a particular peer is rejected, then all subsequent transactions from that same peer that directly modified the results of *X* are also transitively rejected. In this trust model, the common case is that transactions come to a target peer *C* from a trusted peer and does not conflict with any others; hence they are immediately applied to *C*. Otherwise, trust composes as follows: as a transaction is propagated from peer *A* to peer *B* to peer *C*, it is only applied at *C* if it is the most trusted transaction at each step; if multiple conflicting transactions can be applied at *C*, then the one most trusted by *C* is applied. Orchestra allows instances to "partially diverge" where there are conflicts, while still maintaining sharing for portions of the data where there are no conflicts.

Key Applications

Recent applications of peer-to-peer technologies include distributed network monitoring, distributed stream processing, and exchange of data among collaborating organizations that host scientific databases. In all of these settings, data may be frequently updated.

Future Directions

One of the most promising directions of future study is the interaction between transactions and *mappings* or conversion routines: in many real-world applications, data is being shared between sites that have different data representations. There is some work (e.g., that related to view maintenance) that shows how to translate updates across mappings; but there is no scheme for mapping *transactions*.

Updates through Views

YANNIS VELEGRAKIS
University of Trento, Trento, Italy

Definition

Views are windows to a database. They provide access to only a portion of the data that is either of interest or related to an application. Views are relations without independent existence, as is the case of database tables created with the "create table" command. The contents of the instance of a view are determined by the result of a query on a set of database tables, typically referred to as *base tables*. Applications deal with views the same way they deal with any other relation. In fact, an application is rarely aware of whether a relation it is accessing is a base table or a view. This means that the application may issue updates on the view relation as it would have done with any other database table. Since the view instance depends on the instances of the base tables, to execute an update on the view one needs to find a number of base table modifications whose effect on the view instance is the modification described by the update command.

Historical Background

Views are one of the oldest concepts in computer science. They appeared almost at the same time with queries. In the early 1980s, as database vendors were moving towards the relational model, Codd introduced twelve rules that need to be satisfied by a database management system in order to be considered *relational*. Rule number six was referring to the concept of views and in particular, to the ability of the views to be updated when they are *theoretically updatable*, a concept that will be explained below.

The scientific literature contains different definitions (and uses) of the term "view," with two of them being dominant. The first is that a view is a relation whose instance depends (somehow) on the data of its base tables, and the second is that a view is a short-hand for a query. For query answering, those two definitions are equivalent, but for the purpose of updating, the definition that is considered makes a difference. They have different consequences. Considering the view as a query, implies that at any given point in time the instance of a view is fully specified by the results of the view query over the data, i.e., the set of possible instances of a view is the set of possible relations that can be generated as a result of the view query. A consequence of this is that the view might not be *theoretically* updatable, which means that there are updates on the view that cannot be translated to updates on the base tables. Recently, Kotidis et al. [8] have relaxed that requirement to accept views whose instance may be different from the result of their view query in order to allow arbitrary updates on the view.

Update propagation is one of the main issues in view updates. When multiple views share the same piece of data from the base tables, all these views should have consistent instances. This means that when some part of the data is updated, this change must propagate accordingly to the base tables and the other views. For the case of materialized views, and updates on the base tables, this is a well-studied problem, namely the view maintenance [10]. View maintenance has considered how to change the instances of the views in response to base table modifications.

However, updates on the views have not been studied to the same extend.

Foundations

A *database* D = <S, I> is a collection of data along with a description of its structure. The collection of data is referred to as the *database instance* I and the description of its data structures as the *database schema* S. In the relational model, a database instance is a set of relations, and the schema is the set of schemas of these relations. The contents of a relation, i.e., its instance, may be explicitly specified by a user or an application, or they may be derived from the contents of other relations. Relations of the first kind are those constructed using the "create table" command and are often referred to as *base tables*. Relations of the second kind are referred to as *views*. A view is accompanied by a query which is referred to as the *view query* and specifies how its contents will be derived from the contents of the base tables.

The term "update" on a relation implies an insertion, a deletion, or a value modification of one or more tuples. The literature often chooses to ignore modifications on the basis that a modification can be modeled as a deletion followed by an insertion. The same assumption is followed here.

Let U denote an update command on a relation R, |R| the instance of R and |U| the tuple(s) that need to be inserted in |R| (if U is an insert command) or deleted from |R| (if U is a delete command).

The *implementation* of an update U on a relation R is a new relation R′ such that:

- $|R|' = |R| - |U|$ if U is a delete command, and
- $|R|' = |U| \cup |R|$ if U is an insert command

In the case of a base table, the implementation of an update is straight forward (it is done by directly modifying the contents of the base table instance according to the update command). In the case of a view the situation is different. Since the view instance depends on the instances of its base tables an implementation is performed by translating the view update command into a series of updates on the base tables so that the requested update is observed in the view instance. Figure 1 provides a graphical representation of this notion. $Q_v(I)$ denotes the application of the view query Q_v on the database instance I. The result of this query is the instance |V| of the view V. Given an update command U on the view V, the *view update problem* is defined as the problem of finding an update W, referred to as the *translation* of U, on the instance I such that when the view query is applied on the new modified instance W(I), the new view instance $|V|' = Q_v(W(I))$ is an implementation of the update U.

For a given update U, there may be multiple possible translations. The following example illustrates such a situation. Consider a database instance that consists of a table *Personnel (Department, Employee)* with tuples {[Administration, Smith], [HR, Smith], [Research, Kole]} and the view

V_1: *select* Department *from* Personnel *where Employee* = "Smith"

The instance of view V_1 consists of the two tuples [Administration, Smith] and [HR, Smith]. Let U_1 be an update command that requests the deletion of tuple [Administration, Smith] from V_1. There are many possible changes that can be done on the instance of *Personnel* in order to make tuple [Administration, Smith] disappear from the instance of view V_1. The most obvious one is to simply delete tuple [Administration, Smith] from Personnel. Alternatively, one could update the value of its *Employee* attribute from "Smith" to *null* or to some value other than "Smith." Even changing the *Department* attribute from "Administration" to some other value "Y" will have the desired effect of removing tuple [Administration, Smith] from the view. Thus, each of the aforementioned changes constitutes an implementation of the view update U_1. They are not, however, equivalent. Each translation may be considered appropriate in different situations. The first translation, for instance, achieves the desired result and only this by deleting only one tuple from the database instance. The second achieves the result without reducing the number of tuples in the database instance, and the latter will cause the appearance of the additional tuple [Y, Smith] in the view, which makes the specific translation less appealing.

For the case of a view deletion, the first step in finding a view update translation is to find the provenance of the tuples that are to be deleted from the view, i.e., the tuples in the base tables that are responsible for the appearance in the view of the tuples that are to be deleted [4,5]. Researchers have concentrated their efforts in detecting the minimum number of changes that need to be made on the base tables in order to achieve the view update (*source-side-effect*). These changes, as mentioned previously through the example, may result in additional changes in the view instance apart from the one requested by the view update command. Thus, another important desideratum is to find translations that minimize the number of changes in the view (*view-side-effect*). In certain cases, these two desiderata may conflict.

Finding a translation of a view deletion that minimizes the changes in the base tables or/and the view is in general an NP-hard problem, even with monotone view queries. The complexity remains NP-hard even for the very restrictive classes of views with *select-project-join* or *select-join-union* view queries [4].

A different approach to the view update problem is to deal with it at the semantic level. This approach has been advocated by many early researchers [1]. Their position is that at the moment of view definition, the data administrator needs to specify how each update on the view will be translated to updates on the base tables. This is a safe approach that guarantees a semantically correct translation. However, this approach may be hard to apply in certain practical situations. One reason is that views may have been defined at a point in which updates were not of interest and the correct translation semantics may be difficult to infer. Furthermore, even if the data designer is aware of the existence of updates on the view, she may not be able to predict at the moment of view definition all the different semantics of the possible view update commands. For instance, the deletion of the [Administration, Smith] tuple in the example above may be simply because Smith stopped working for the Administration department, or because he moved from the Administration to another department. Another reason why this approach is difficult to implement is that views may have been introduced as replacements of tables in cases of physical or logical data reorganization, in which case again, more than one alternative translation may be semantically correct.

Keller [7] has provided a detailed classification of the different kinds of view update translations for projections, selections, select-project-join, and select-project-join-union views. Through an interactive procedure with the data administrator at the time of the view definition, the system tries to infer the right translation rules. At the other end, Dayal and Bernstein [6] have studied the classes of views for which the translation of an update is not ambiguous. For the case of translation ambiguity or the case in which it is possible to implement the update but with more changes in the view instance than those the view command requested, then the update may not be allowed.

$$\begin{tikzcd}
Q_V(I) \arrow[r, "U", ""{name=U, below}] & U(Q_V(I)) & Q_V(W(I)) \\
I \arrow[u] \arrow[rr, "W", ""{name=W}] & & W(I) \arrow[u]
\arrow[from=U, to=W]
\end{tikzcd}$$

Updates through Views. Figure 1. The updates through views problem.

A different approach in finding a view update translation is to reduce it to a constraint satisfaction problem [9]. Relational views can be represented as conditional tables and a view update can be translated into a disjunction of a number of constraint satisfaction problems (CSPs). Solutions to the CSPs correspond to possible translations. For the case of multiple candidate translations, semantic information to resolve ambiguity can be modeled as additional constraints.

The problem of updates through views appears also in other models, such as the object views or XML. Since most of the studies have been done for the relational model, one way to deal with the problem of updating object or XML views is to abstract it to the relational case [2,3].

Key Applications

Information Integration Systems. IIS are used to provide a unified view of data that is stored in multiple heterogeneous and physically distributed data sources. The majority of such systems are read-only, since data maintenance is considered to be an exclusive responsibility of the owner of each data source. This situation is gradually changing. Integrated views provide an excellent opportunity for detecting errors and inconsistencies among the different data sources. Once these inconsistencies are detected and corrected at the view level, the data in the sources will have to be accordingly updated.

Corporate Environments. Multiple different systems may operate in different parts of an organization, but centralized data management is crucial for decision making and policy implementations. Views provide the mean to propagate changes from the centralized level to the individual systems of the organization.

P2P. P2P systems use views to describe the relationships between the contents of one peer and its acquaintances. When a modification takes place in one of the peers, the views are used to determine its effects (if any) on the contents of its adjacent peers.

Database Management Systems. View support has been prevalent in Database Management Systems. They provide physical data independence, i.e., decoupling the logical schema from the physical design which is usually driven by performance reasons. By controlling access to the views, one can control access to different parts of the data and implement different security policies. It is not uncommon the case of databases that provide access to their data exclusively through views. For them the ability to perform arbitrary updates on the views is becoming a necessity since the only way to update the stored information is by issuing updates on the views.

WEB. The World Wide Web has evolved to be the world's largest database where organizations and individuals publish their information and data. Web users are then using applications and integration engines to query and retrieve that information. Since the users have no access to the individual sources, the web in its current form is a read-only system, restricting the potential of its million users. If the Web is to be brought from its read-only status into a full-fledged database, allowing updates on the web views to propagate to the sources is a fundamental requirement.

Usability

Nigel Bevan
Professional Usability Services, London, UK

Synonyms

User centered design

Definition

A product is usable if the intended users can achieve their goals with effectiveness, efficiency and satisfaction in a specified context of use [8]. Usability is achieved by taking a user-centered approach to design, and thus ensuring that the product incorporates characteristics that support usability.

Historical Background

Usability was adopted as a technical term to replace the phrase "user friendly," which by the early 1980s had acquired undesirably vague and subjective connotations. It is a goal for product design in the scientific fields of HCI, human factors and ergonomics. In 1985

Gould and Lewis [5] described the central principles of what became known as user-centered design [15]: (i) early focus on users and tasks., (ii) empirical measurement, (iii) iterative design.

Usability has since grown into an established discipline with the Usability Professionals Association founded in 1991, and the landmark book by Nielsen on Usability Engineering [13] published in 1993.

Although the field of usability overlaps with human factors and ergonomics, it tends to be associated with systems that have discretionary users. Human factors and ergonomics have traditionally focused on how human capabilities can be integrated into pre-defined tasks and work systems. Usability is more typically concerned with designing applications to support users and tasks that are often not well-understood.

Foundations

The broad interpretation of usability is the user's experience of the quality of the system in use [1]: to what extent the user is successful in achieving their goals (effectiveness), in an acceptable amount of time (efficiency), without undesirable side-effects (safety), and in a way that satisfies the user? While this interpretation is preferred by people working in the field, in systems development usability is often interpreted more narrowly as ease of use (as in the 1991 definition of usability in ISO 9126 [10]). More recently it has been appreciated that the prerequisites for achieving usability as a goal include not only software and hardware with appropriate functionality, reliability and ease of use, but also usable data [12].

The broad interpretation of usability is thus a black box view at the system level, measured in terms of success in achieving goals for effectiveness, efficiency, safety and satisfaction (Fig. 1). It is a result of the user's interaction with the product, and is facilitated by appropriate product characteristics.

In the context of databases, the major product characteristics for usability are software and data.

Software Usability

There are many well-established design principles and standards, both for general software usability, and for web usability. At a high level they include heuristics such as [13]:

- Use simple and natural dialogue, and speak the users' language.
- Minimize user memory load.
- Be consistent in screen and task design.
- Provide feedback in response to user input.
- Provide shortcuts and clearly marked exits.
- Prevent errors and provide informative error messages, help and documentation.

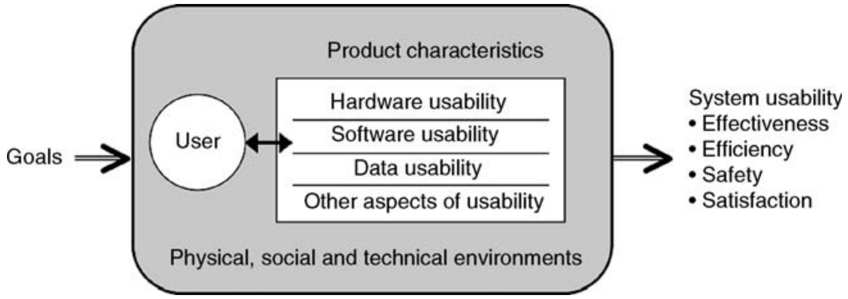
At a detailed level ISO 9241 [8] contains comprehensive interface guidelines, and the US Government has produced an authoritative and well-documented set of web design guidelines [18].

Data Usability

ISO is developing a model for data quality [7]. Data characteristics that contribute to overall system usability include completeness, depth of information, accuracy and understandability. Poor data quality makes it very difficult for users to achieve their goals, even if the user interface is easy to use.

For example, an online train timetable will have poor usability if the data is not usable, for example if:

- The destinations or types of ticket are *incomplete*.
- There is insufficient *depth of information* about the destinations or types of ticket



Usability. Figure 1. System usability.

- Any of the train times or ticket information are *inaccurate*
- The user cannot *understand* the names used for the destinations or types of ticket.

Key Applications

User Centered Design

A product will only be usable if the design and development process is based on an in depth understanding of the range and types of intended users, their task, and the physical, technical and social environments of use. Potential design solutions need to be continually evaluated from a user perspective from the earliest stages of design. The activities necessary to achieve user centered design are described at a high level in ISO 13407 [9], and in more detail in ISO 18529 [9].

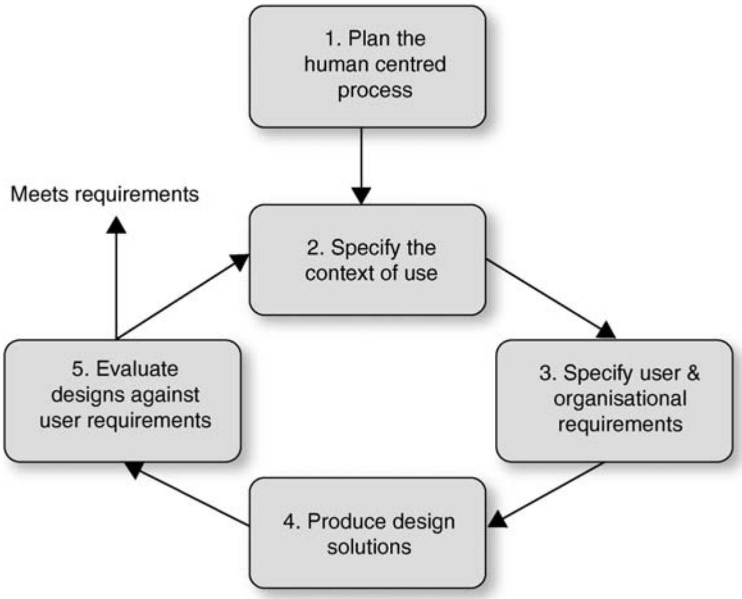
Key activities are illustrated in Fig. 2:

1. Planning. The nature and complexity of the user-centered activities should depend on the importance of usability, and a judgement on which particular activities are necessary for project success.
2. Context of Use. Detailed information about the context of use is an essential input to requirements, and provides a basis for prioritizing testing.
3. User and Organizational Requirements. These should be specified both at a high level in terms of user performance and satisfaction, and at a more detailed level of user interface characteristics.
4. Early design solutions should be produced as mock-ups, typically paper-based, simulations for exploratory testing [17]. Later in development, computer simulations can be used evaluate the user interface.
5. Designs should be evaluated from a user perspective using both expert and user-based methods, to obtain design feedback, and to establish whether requirements have been met.

Context of Use

The characteristics of the users, tasks and the organizational and physical environment define the context in which the system is used. It is important to gather and analyze information on the current context in order to understand and then specify the context that will apply in the future system. Analysis of existing or similar systems can provide information on a whole range of context issues including needs, problems and constraints that might otherwise be overlooked.

Methods for identifying the context range from collecting information in a workshop attended by the relevant stakeholders, to detailed field studies and task analysis.



1. Plan the human centred process
Meets requirements
2. Specify the context of use
5. Evaluate designs against user requirements
3. Specify user & organisational requirements
4. Produce design solutions

Usability. Figure 2. User centered design process.

User and Organizational Requirements

User needs should be identified in conjunction with identifying the context of use. The system requirements should include criteria for user performance, for minimization of adverse effects and for user satisfaction. These are most easily set in relation to baseline values for a comparable existing system. More detailed requirements should be developed iteratively incorporating feedback from early design solutions.

Design Solutions

Using simulations, mock-ups or prototype allows designers to communicate in a meaningful way what the proposed design is/would be like to users and other stakeholders. Paper prototypes can be very effective ingathering feedback [17]. The design should be consistent with established principles for software and data usability [8,12].

Usability Evaluation

Usability evaluation will reveal the strengths and weakness in the design solution and can indicate where the design should be improved.

Feedback from usability evaluation is particularly important because developers seldom have an intimate understanding of the user's perspective and work practices. Initial designs therefore very rarely fully meet user requirements. The cost of rectifying any divergence between the design and user needs increases rapidly as development proceeds, which means that user feedback should be obtained as early as possible. Without proper usability evaluation, a project runs a high risk of expensive rework to adapt a system to actual user needs.

Evaluation of overall system usability and of detailed product characteristics are complementary. Although a user-based evaluation is the ultimate test of usability, it is not usually practical to evaluate all permutations of user types, tasks and operational conditions. Evaluation of the detailed characteristics of the product or interactive system can anticipate and explain potential usability problems, and can be carried out before there is a working system. However evaluation of detailed characteristics alone can never be sufficient, as this does not provide enough information to accurately predict the eventual user behavior in every context.

The purpose of the evaluation may be primarily to obtain design feedback to identify and fix any obstacles to effective usability, or to validate the usability of a system. The most useful validation data are measures of user performance and satisfaction obtained from measuring system usability.

When to Use Methods for Design Feedback The most common type of usability evaluation is to improve a product by identifying and fixing usability problems. Evaluation of early mock-ups can also be used to obtain a better understanding of user needs and to refine requirements. An iterative process of repeated evaluation of prototypes can be used to monitor how closely the prototype designs match user needs. The feedback can be used to improve the design for further testing. Early evaluation reduces the risk of expensive rework. Usability evaluation is most effective when it involves a combination of expert and user-based methods.

When to Use Validation Methods In a more mature design process evaluation to obtain design feedback should be complemented by establishing usability requirements and testing whether these have been achieved by using a more formal method to validate usability. This reduces the risk of delivering a product that fails as a result of poor user performance.

Similar testing of an existing system can be used to provide baseline measures that can form the basis for usability requirements (i.e., objectives for human performance and user satisfaction ratings). A Common Industry Specification for Usability Requirements [14] has been developed to support iterative development and sharing of such requirements.

Validation tests at the end of development should have acceptance criteria derived from the usability requirements. Validation methods can be elaborated to also identify usability problems, but if prior iterative rounds of usability testing are performed, then typically there will be few usability surprises uncovered during this late stage testing.

Validity Usability testing should be carried out carefully and systematically, otherwise the resulting data may not be valid or reliable. O'Hara et al. [16] describe the need for the following types of validity:

- External validity: extent to which the context of use for the test is realistic.
- Construct validity: extent to which the measures are representative of user performance and satisfaction.

- Internal validity: extent to which the test is properly designed.
- Statistical validity: extent to which the statistical conclusions are valid.

Poor usability data may lead to poor design decisions and ultimately an error-prone and unsafe product. Therefore, usability testing protocols should be developed in collaboration with professional usability specialists. Non-specialists under the direction and training of professionals can handle the actual execution and reporting of the testing.

Cost Benefits

The objective of user centered design is to ensure that products can be used by real people to achieve their tasks in the real world. This requires not only easy-to-use interfaces, but also the appropriate functionality and support for real business activities and work flows. According to IBM [6], developing easy-to-use products "makes business effective. It makes business efficient. It makes business sense."

User centered design can reduce development and support costs, increase utilization, and reduce staff costs for employers [2]:

- Development costs can be reduced by fixing usability problems early in the development process, avoiding unnecessary functionality and minimizing documentation.
- Support costs can be reduced by minimizing help line, maintenance and training costs.
- Utilization of the system by individuals and organizations can be increased as a result of higher user success rates, productivity and satisfaction.

Usability of Digital Libraries

Digital libraries pose some particular challenges for usability, as a result of the large amount of information they contain, the difficult of determining what users want, and the need to cater for browsing and searching. Digital libraries demand more sophistication of query formulation than web search engines. Skills acquired in one library environment are often not easily transferred to another [3].

User-Defined Time

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Definition

The concept of *user-defined time* denotes time-valued attributes of database items with which the data model and query language associate no special semantics. Such attributes may have as their domains all domains that reference time, e.g., date and time. The domains may be instant-, period-, and interval-valued. Example user-defined time attributes include "birthday," "hiring date," and "contract duration." Thus, user-defined time attributes are parallel to attributes that record, e.g., salary, using domain "money," and publication count, using domain "integer." User-defined time attributes contrast transaction-time and valid-time attributes, which carry special semantics.

Key Points

The valid time and transaction time attributes of a database item are "about" the other attributes of the database item. The valid time records when the information recorded by the attributes is true in the modeled reality, and the transaction time captures when the data item was part of the current database state. In contrast, user-defined time attributes are simply "other" attributes that may be used for the capture of information with which valid time can be associated.

Conventional database management systems generally support a time and/or date attribute domain. The SQL2 standard has explicit support for user-defined time in its `datetime` and `interval` types.

Valid Time

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Real-world time; Intrinsic time; Logical time; Data time

Definition

The *valid time* of a fact is the time when the fact is true in the modeled reality. Any subset of the time domain may be associated with a fact. Thus, valid timestamps may be sets of time instants and time intervals, with single instants and intervals being important special cases. Valid times are usually supplied by the user.

Key Points

While other temporal aspects have been proposed, such as "decision time" and "event time," closer analysis indicates that the decision and event time of a fact can be captured as either a valid time or a transaction time of some related fact.

For example, consider a valid-time `Faculty` table with attributes `Name` and `Position` (that is, either Assistant Professor, Associate Professor, or Professor) that captures the positions of faculty members. The valid time then captures when a faculty member held a specific position.

The "decision time" of a faculty member holding a specific position would be the time the decision was made to hire or promote the faculty member into that position. In fact, there are generally several decision times for a promotion: recommendation by departmental promotion and tenure committee, recommendation by department chair, recommendation by college promotion and tenure committee, recommendation by Dean, and finally decision by Provost. Each of these decisions may be modeled as a separate fact, with an (event) valid time that captures when that decision was made.

Oracle explicitly supports valid time in its Workspace Manager. The support includes sequenced primary keys, sequenced uniqueness, sequenced referential integrity, and sequenced selection and projection.

The term "valid time" is widely accepted; it is short and easily spelled and pronounced. Most importantly, it is intuitive.

Concerning the alternatives, the term "real-world time" derives from the common identification of the modeled reality (opposed to the reality of the model) as the real world. This term is less frequently used. "Intrinsic time" is the opposite of extrinsic time. Choosing intrinsic time for valid time would require one to choose extrinsic time for transaction time. The terms are appropriate: The time when a fact is true is intrinsic to the fact; when it happened to be stored in a database is clearly an extrinsic property. However, "intrinsic" is rarely used. "Logical time" has been used for valid time in conjunction with "physical time" for transaction time. As the discussion of intrinsic time had to include extrinsic time, discussing logical time also requires the consideration of physical time. Both terms are used much less frequently than valid and transaction time, and they do not posses clear advantages over these. The term "data time" is probably the most rarely used alternative. While it is clearly brief and easily spelled and pronounced, it is not intuitively clear that the data time of a fact refers to the valid time as defined above.

Valid-time access methods

Definition

A valid-time index is a temporal index that enables fast access to valid-time datasets. In a traditional database, an index is used for selection queries. When accessing valid-time databases such selections also involve the valid-time dimension (the time when a fact becomes valid in reality). The characteristics of the valid-time dimension imply various properties that the temporal index should have in order to be efficient. As traditional indices, the performance of a temporal index is described by three costs: (i) storage cost (i.e., the number of pages the index occupies on the disk), (ii) update cost (the number of pages accessed to perform an update on the index; for example when adding, deleting or updating a record), and (iii) query cost (the number of pages accessed for the index to answer a query).

Historical Background

A valid-time database maintains the entire temporal behavior of an enterprise as best known now [13]. It stores the current knowledge about the enterprise's past, current or even future behavior. If errors are discovered about this temporal behavior, they are corrected by modifying the database. If the knowledge about the enterprise is updated, the new knowledge modifies the existing one. When a correction or an update is applied, previous values are not retained. It is thus not possible to view the database as it was before the correction/update. This is in contrast to a transaction-time database, which maintains the database activity (rather than the real world history) and can thus rollback to a past state. Hence, in a valid-time database the past can change, while in a transaction-time database it cannot.

The problem of indexing valid-time databases can be reduced to indexing dynamic collections of intervals, where an interval represents the temporal validity of a record. Note that the term "interval" is used here to mean a "convex subset of the time domain" (and not a "directed duration"). This concept has also been named a "period"; in this discussion, however, only the term "interval" is used.

To index a dynamic collection of intervals, one could use R-trees or related dynamic access methods. Relatively fewer approaches have been proposed for indexing valid-time databases. There have been various approaches proposed for the related problem of managing intervals in secondary storage. Given the problem difficulty, the majority of these approaches have focused on achieving good worst case behavior; as a result, they are mainly of theoretical importance.

For a more complete discussion the reader is referred to a comprehensive survey [12].

Foundations

The following scenario exemplifies the distinct properties of the valid time dimension. Consider a dynamic collection of "interval-objects." The term interval-object is used to emphasize that the object carries a valid-time interval to represent the temporal validity of some object property. (In contrast, and to emphasize that transaction-time represents the database activity rather than reality, note that intervals stored in a transaction time database correspond to when a record was inserted/updated in the database.)

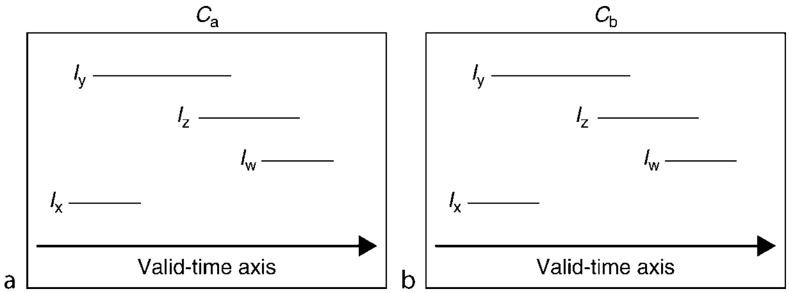
The allowable changes in this environment are the addition/deletion/modification of an interval-object. A difference with the transaction-time abstraction (the reader is referred to the Transaction-Time Indexing entry for more details) is that the collection's evolution (past states) is *not* kept. An example of a dynamic collection of interval-objects appears in Fig. 1. Assume that collection C_a has been recorded in some erasable medium and a change happens, namely object I_z is deleted. This change is applied on the recorded data and physically deletes object I_z. The medium now stores collection C_b, i.e., collection C_a is *not* retained. Note that when considering the valid time dimension, changes do not necessarily come in increasing time order (as is the case in transaction-time databases); rather they can affect *any* object in the collection. This implies that a valid-time database can correct errors in previously recorded data. However, only a single data state is kept, the one resulting after the correction is applied.

As a real-life example, consider the collection of contracts in a company. Each contract has an identity (*contract_no*) and an interval representing the contract's duration or validity. In collection C_a, there were four contracts in the company. But assume an error was discovered: contract I_z was never a company contract (maybe it was mistakenly entered). Then, this information is permanently deleted from the collection, which now is collection C_b.

The notion of time is now related to the valid-time axis. Given a valid-time instant, interval-objects can be classified as past, future or current as related to this instant, if their valid-time interval is before, after or contains the given instant. Valid-time databases can be used to correct errors anywhere in the valid-time domain (past, current or future) because the record of any interval-object in the collection can be changed, independently of its position on the valid-time axis. Note that a valid-time database may store records with the same surrogate but with non-intersecting valid-time intervals. For example, another object with identity I_x could be added in the collection at C_b as long as its valid-time interval does not intersect with the valid-time interval of the existing I_x object; the new collection will contain both I_x objects, each representing object I_x at different times in the valid-time dimension.

From the above discussion, an index used for a valid-time database should: (i) store the latest collection of interval-objects, (ii) support addition/deletion/modification changes to this collection, and (iii) efficiently query the interval-objects contained in the collection when the query is asked. Hence, a valid-time index should manage a *dynamic* collection of intervals.

Thus related is research on the interval management problem. Early work in main memory data-structures has proposed three separate approaches into managing intervals, namely, the Interval Tree, the Segment Tree and the Priority Search Tree [9]. Such approaches are focused on the "stabbing query" [6], i.e., given a collection of intervals, find all intervals



Valid-Time Indexing. Figure 1. Two valid-time databases.

that contain a given query point q. The stabbing query is one of the simpler queries for a valid-time database environment, since it does not involve any object key attribute (rather, only the object intervals).

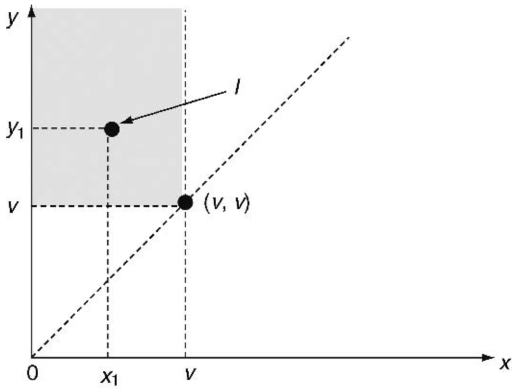
Various methods have been proposed for making these main-memory structures disk-resident. Among them are: the External Memory Interval Tree [1], the Binary-Blocked Interval Tree [4], the External Segment Tree [2], the Segment Tree with Path Caching [11] and the External Memory Segment Tree [1], the Metablock Tree [6], the External Priority Search Tree [5], and the Priority Search Tree with Path Caching [11]. Many of these approaches are mainly of theoretical interest as they concentrate on achieving a worst-case optimal external solution to the 1-dimensional stabbing query.

Recently, [8] presented the Relational Interval Tree (RI-tree) which is based on the original Interval Tree. In particular, the Interval Tree uses a backbone balanced binary tree structure that organizes the values of all the bounding points of the intervals. An interval (l, r) is registered in the highest node w of the backbone tree that it overlaps (that is, while descending the backbone tree, the first node w for which $l \leq w \leq r$). Each inner node w contains two sorted lists, one with the lower bounding points and one with the upper bounding points of the intervals assigned to this node. A "stabbing" query is answered by traversing one path of the backbone structure and accessing the lists in the nodes of this path. The RI-tree uses plain B+-trees to index these sorted lists, thus leading to fast query time. For n intervals stored in the RI-tree, the space used is linear $O(n/B)$ where B is the page capacity in records. If h corresponds to the height of the backbone structure, answering a stabbing query that returns s intervals takes $O(h \, logBn + s/B)$ page accesses.

Since intervals are 2-dimensional objects, a dynamic multi-dimensional index like an R-tree may be used. Moreover, the R-tree can also index other attributes of the valid-time objects, thus enabling queries involving non-temporal attributes as well. For example, "find contracts that were active on time t and had contract-id in the range $(r1,r2)$." While simple, the traditional R-tree approach may not always be very efficient. The R-tree will attempt to cluster intervals according to their length, thus creating pages with possibly large overlapping. It was observed in [7] that for data with non-uniform interval lengths (i.e., a large proportion of "short" intervals and a small proportion of "long" intervals), this overlapping is clearly increased, affecting the query and update performance of the index. This in turn decreases query and update efficiency.

Another straightforward approach is to transform intervals into 2-dimensional points and then use a Point Access Method (quad-tree, grid file, hB-tree, etc.). In Fig. 2, interval $I = (x_1,y_1)$ corresponds to a single point in the 2-dimensional space. Since an interval's end-time is always greater or equal than its start-time, all intervals are represented by points above the diagonal $x = y$. Note that an interval (x,y) contains a query time v if and only if its start-time x is less than or equal to v and its end-time y is greater than or equal to v. Then an interval contains query v if and only if its corresponding 2-dimensional point lies inside the box generated by lines $x = 0$, $x = v$, $y = v$, and $y = \infty$ (the shaded area in Fig. 2). This approach avoids the overlapping mentioned above. Long intervals will tend to be stored together in pages with other long intervals (similarly, for the short intervals). However, no worst case guarantees for good clustering are possible.

A related approach (MAP21) is proposed in [11]. An interval (l, r) is mapped to a point $z = (l \times 10^s) + r$, where s is the maximum number of digits needed to represent any point in the interval range. This is enough to map each interval to a separate point. A regular B$^+$-tree is then used to index these points. An advantage of this approach is that interval insertions/deletions are easy using the B$^+$-tree. To answer a stabbing query about q, the point closer but less than q is found among the points indexed in the B$^+$-tree, and then a sequential search for all intervals before q is performed. At worse, many intervals that do not intersect q can be found (this approach assumes that in

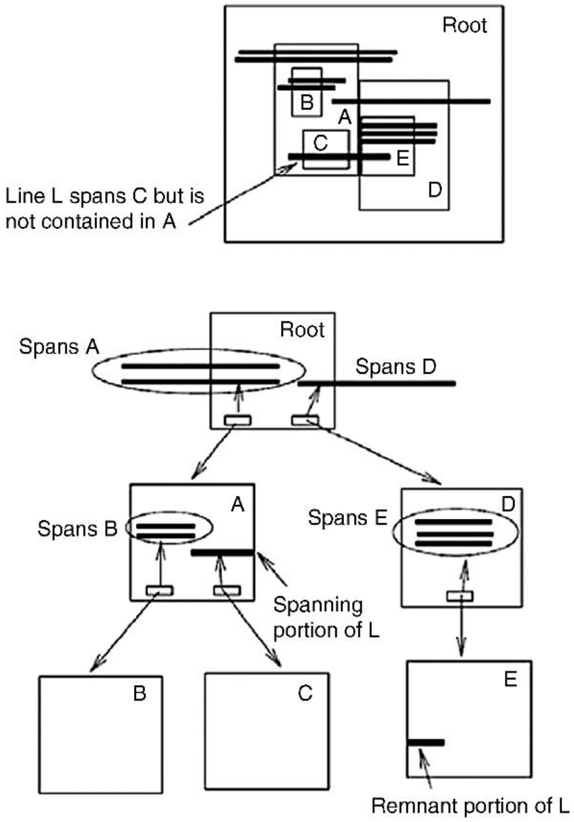


Valid-Time Indexing. Figure 2. An interval $I = (x_1,y_1)$ corresponds to a point in a 2-dimensional space.

practice the maximal interval length is known, which limits how far back the sequential search continues from *q*).

Another approach is to use a combination of an R-tree with Segment Tree properties. The Segment R-tree (SR-tree) was proposed in [11]. The SR-tree is an R-tree where intervals can be stored in both leaf and non-leaf nodes. An interval *I* is placed to the highest level node *X* of the tree such that *I* spans at least one of the intervals represented by *X*'s child nodes. If *I* does not span *X*, it spans at least one of its children but is not fully contained in *X*, then *I* is fragmented. Figure 3 shows an example of the SR-tree approach. The top rectangle depicts the R-tree nodes (root, A, B, C, D and E) as well as the stored intervals. Interval *L* spans the rectangle of node C, but is not contained in node A. It is thus fragmented between nodes A and E.

Using this idea, long intervals will be placed in higher levels of the R-tree. Hence, the SR-tree tends to decrease the overlapping in leaf nodes (in the regular R-tree, a long interval stored in a leaf node will "elongate" the area of this node thus exacerbating the overlap problem). However, having large numbers of spanning records or fragments of spanning records stored high up in the tree decreases the fan-out of the index as there is less room for pointers to children. It is suggested to vary the size of the nodes in the tree, making higher-up nodes larger. "Varying the size" of a node means that several pages are used for one node. This adds some page accesses to the search cost.



Valid-Time Indexing. Figure 3. An example of the SR-tree approach.

As with the R-tree, if the interval is inserted at a leaf (because it did not span anything) the boundaries of the space covered by the leaf node in which it is placed may be expanded. Expansions may be needed on all nodes on the path to the leaf, which contains the new record. This may change the spanning relationships since existing intervals may no longer span children, which have been expanded. In this case, such intervals are reinserted in the tree, possibly being demoted to occupants of nodes they previously spanned. Splitting nodes may also cause changes in spanning relationships as they make children smaller – former occupants of a node may be promoted to spanning records in the parent.

In contrast to the traditional R-tree, the space used by the SR-tree is no longer linear. An interval may be stored in more than one non-leaf nodes (in the *spanning* and *remnant* portions of this interval). Due to the use of the segment-tree property, the space can be as much as $O(n \log_B n)$. Inserting an interval still takes logarithmic time. However, due to possible promotions, demotions and fragmentation, insertion is slower than in the R-tree. Even though the segment property tends to reduce the overlapping problem, the (pathological) worst case performance for the deletion and query time remains the same as for the R-tree organization (that is, at worst, the whole R-tree may have to searched for an interval). The average case behavior is, however, logarithmic. Deletion is a bit more complex, as all the remnants of the deleted interval have to be deleted too. The original SR-tree proposal thus assumed that deletions of intervals are not that frequent.

The SR-tree search algorithm is similar to that of the original R-tree. It descends the index depth-first, descending only those branches that contain the given query point *q*. In addition, at each node encountered during the search, all spanning intervals stored at the node are added to the answer. To improve the performance of the structure, the *Skeleton SR-tree* has also been proposed [7], which is an SR-tree that prepartitions the entire domain into some number of regions. This pre-partition is based on some initial assumption on the distribution of data and the number of intervals to be inserted. Then the Skeleton SR-tree is populated with data; if the data distribution is changed, the structure of the Skeleton SR-tree can be changed too.

When indexing valid-time intervals, overlapping may also incur if the valid-time intervals extend to the ever-increasing *now*. One approach could be to use the largest possible valid-time to represent the variable *now*. In [3] the problem of addressing both the *now* and transaction-time Until-Changed (*UC*) variables is addressed by using bounding rectangles/regions that increase as the time proceeds. A variation of the R-tree, the GR-tree is presented. More details appear in [3].

Key Applications

The importance of temporal indexing emanates from the many applications that maintain temporal data. The ever increasing nature of time imposes the need for many applications to store large amounts of temporal data. Specialized indexing techniques are needed to access such data. Temporal indexing has offered many such solutions that enable fast access.

Value Equivalence

NIKOS A. LORENTZOS
Agricultural University of Athens, Athens, Greece

Definition

In temporal databases, the scheme of a temporal relation S has the form S(**E, I**) where **E** and **I** represent two disjoint sets of attributes, termed by some authors *explicit* and *implicit*, respectively. *Explicit* are the attributes in which ordinary data are recorded, such as Employee_Id, Name, Salary etc. *Implicit* are the attributes in which either *valid time* (one or more) or *transaction time* is recorded. Given two tuples ($\mathbf{e}_1$, $\mathbf{i}_1$) and ($\mathbf{e}_2$, $\mathbf{i}_2$) with the scheme of S, it is said that there is a *value equivalence* between them if and only if $\mathbf{e}_1 = \mathbf{e}_2$. Equivalently, it is said that ($\mathbf{e}_1$, $\mathbf{i}_1$) and ($\mathbf{e}_2$, $\mathbf{i}_2$) are *value equivalent*.

Example: Consider one tuple, (Alex, 100, d400, d799), with scheme SALARY(Name, Amount, Valid-Time), indicating that Alex's salary was 100 on each of the dates d400, d401,...,d799. Let also another tuple of the same scheme be (Alex, 100, d500, d899). For the given scheme, **E** = {Name, Amount} and

I = {ValidTime}. Given that both tuples have the same value for Name and Amount, they are value equivalent.

Key Points

The term has been introduced in the context of temporal databases, mainly in order to ease discussion on issues such as *temporal coalescing*.

Variable Time Span

Christian S. Jensen[1], Richard T. Snodgrass[2]
[1]Aalborg University, Aalborg, Denmark
[2]University of Arizona, Tucson, AZ, USA

Synonyms

Moving span

Definition

A span is *variable* if its duration is dependent on the assumed context.

Key Points

Given a specific setting, any span is either a fixed span or a variable span. An obvious example of a variable span is "1 month" in the Gregorian calendar. Its duration may be any of 28, 29, 30, and 31 days, depending on which particular month is intended. The span "1 h" is fixed because it always has a duration of 60 min.

Vector-Space Model

Massimo Melucci
University of Padua, Padua, Italy

Synonyms

VSM

Definition

The Vector-Space Model (VSM) for Information Retrieval represents documents and queries as vectors of weights. Each weight is a measure of the importance of an index term in a document or a query, respectively. The index term weights are computed on the basis of the frequency of the index terms in the document, the query or the collection. At retrieval time, the documents are ranked by the cosine of the angle between the document vectors and the query vector. For each document and query, the cosine of the angle is calculated as the ratio between the inner product between the document vector and the query vector, and the product of the norm of the document vector by the norm of the query vector. The documents are then returned by the system by decreasing cosine.

Historical Background

The use of vectors for modeling IR systems dates back to the early days of IR, especially as a tool for describing how a system should be designed and implemented. The popularity of the VSM is due to the intuitive yet formal view of indexing and retrieval – it should not come as a surprise that the VSM has attracted many researchers and newcomers since it was mentioned in [5], employed for indexing and clustering in [9], used as a framework for deciding whether a term should be stored in an index [10], and formulated in a comprehensive way in [6]. At the experimental level, the VSM has proved an effective and sound framework in retrieving documents in different languages, on different subjects, of different sizes, and of different media, thanks to a number of proposed and tested weighting schemes and applications (see [8] for a comprehensive evaluation). A perspective on the history of the VSM was illustrated in [2].

Despite its apparent simplicity, the mathematical properties of vector spaces can be used for advancing IR modeling. The hypothesis that the term-document frequency matrix contains information about the correlation among terms and among documents was cited in [7], stated in [13], developed in [6] and was further exploited in [1] in defining Latent Semantic Indexing (LSI). The latter is a technique based on Singular Value Decomposition (SVD) which aims at decomposing the term correlation matrix and at disclosing the principal components used to represent fewer independent concepts than many inter-dependent variables. A reconsideration of the potential of the vector spaces was presented in [12]. In that book, Hilbert's vector spaces, which is the mathematical tool of Quantum Mechanics, are used to see documents as vectors, relevance as a Hermitian operator, relevance statuses as the eigenvalues of this operator, and the computation of the probability of relevance of a document as the projection of the document vector onto the subspace of the eigenvalue of relevance. The idea of using the notion of basis of a vector space for representing context was proposed in [4].

Foundations

Basic Definitions

The VSM represents documents and queries as vectors of weights. A document vector is then

$$\mathbf{x} = (x_1,\ldots,x_k)$$

where x_i is the weight of index term i in the document and k is the number of unique index terms in the collection. Each weight is a measure of the importance of an index term in a document. A great deal of attention was paid in the past to the definition of the index term weights to be used in document vectors. An important example is

$$x_i = \mathrm{TF}_i$$

that is, the term frequency of i in the document. Of course, TF depends on the document. Another example is the binary weight,

$$x_i = \begin{cases} 1 & \text{if index term i occurs in the document} \\ 0 & \text{otherwise} \end{cases}$$

For an illustration of the term weighting schemes, see [8]. A query is represented as a vector of weights, too, for instance,

$$\mathbf{y} = (y_1,\ldots,y_k)$$

where y_i is the weight of index term i in the query. Each weight is a measure of the importance of an index term in a query – note that no Boolean operators are assumed. Also for queries, a great deal of attention has been paid in the past to the definition of the index term weights. An important example is

$$y_i = \mathrm{IDF}_i$$

where IDF stands for Inverse Document Frequency which is defined as

$$\mathrm{IDF}_i = \begin{cases} \log \frac{N}{n_i} & \text{if } i \text{ occurs in the query} \\ 0 & \text{otherwise} \end{cases}$$

where n_i is the number of documents indexed by i and N is the total number of documents in the collection. The binary weighting scheme can also be applied to queries.

At retrieval time, the documents are ranked by the cosine of the angle between the document vectors and the query vector. For each document and query, the cosine of the angle is calculated as the ratio between the inner product between the document vector and the query vector, and the product of the norm of the document vector by the norm of the query vector. The documents are then returned by the system by decreasing cosine. In a formal way,

$$\cos = \frac{\mathbf{x} \cdot \mathbf{y}}{||\mathbf{x}|| \; ||\mathbf{y}||}$$

where

$$\mathbf{x} \cdot \mathbf{y} = \sum_{i=1}^{k} x_i \; y_i \qquad ||\mathbf{x}|| = \sqrt{\sum_{i=1}^{k} x_i^2}$$

$$||\mathbf{y}|| = \sqrt{\sum_{i=1}^{k} y_i^2}$$

When the weights are binary, i.e., $x_i, y_i \in \{0, 1\}$, the vectors are representations of term sets and an alternative ranking function is Jaccard's coefficient defined as

$$\frac{\sum_{i=1}^{k} x_i \; y_i}{\sum_{i=1}^{k} x_i + \sum_{i=1}^{k} y_i - \sum_{i=1}^{k} x_i \; y_i}$$

When term frequency and inverse document frequency are used for weighting terms in the document and in the query, respectively the inner product between document and query vectors is

$$\sum_{i=1}^{k} \mathrm{TF}_i \; \mathrm{IDF}_i$$

where

$$\mathrm{TF}_i \; \mathrm{IDF}_i$$

is called TF-IDF weighting scheme. When different documents are considered, the notations $\mathbf{x}_n = (x_{1,n},\ldots, x_{k,n})$ and $\mathrm{TF}_{i,n}$ IDF_i are used for distinguishing documents $n = 1,\ldots,N$.

Mathematical Development

The VSM for IR considers a document collection as a vector space defined over the real field. The definition of a vector is given with respect to a basis, namely, a set of linearly independent vectors, called basis vectors – a set of vectors is independent when no vector of this set can be defined as a linear combination of the other vectors in the same set. The dimension of the space is the number of basis vectors. It is a fact from Linear Algebra that every vector of a space of dimension k is a linear combination of k basis vectors – for an introduction to the vector spaces see, for example, [3].

The VSM represents a collection index as a basis of a real vector space and a distinct index term is a basis vector. Moreover, every object managed by an IR system, e.g., document, query, sentence, cluster centroids, or terms, is a vector of this space. As every vector is a linear combination of a basis of the vector space, in the VSM the vector of any object is a linear combination of the basis vectors that represent the index terms. When non-textual media are to be represented, the basis vectors are a representation of content descriptors, yet the philosophy of the model remains unchanged. A basis plays an important role in expressing term correlations and in Latent Semantic Indexing.

Since there are infinite bases in a space, every vector has infinite numerical representations. To be precise, let k be the dimension of the space and $\{\mathbf{t}_1,\ldots,\mathbf{t}_k\}$ be a basis for this space. The representation of a document or a query is then a vector $\mathbf{x}$ such that

$$\mathbf{x} = \sum_{i=1}^{k} a_i \; \mathbf{t}_i.$$

where the a_{i} are real numbers. The numerical representations are provided by the a_{i}'s with respect to the basis $\{\mathbf{t}_1,\ldots,\mathbf{t}_k\}$. This entails that a change of basis determines a change of the numerical representation of $\mathbf{x}$; for example,

$$\mathbf{x} = \sum_{i=1}^{k} b_i \; \mathbf{u}_i,$$

where $\{\mathbf{u}_1,\ldots,\mathbf{u}_k\}$ is a different basis and the b_{i}'s provide a different representation of $\mathbf{x}$ – it follows that a vector can be assigned infinite representations, all being equivalent.

According to the basic definitions, the a_{i}'s are the weights used for measuring the importance of the index terms in documents and queries. Thus, TF-IDF is a possible scheme for defining the a_{i}'s.

The ranking function is based on the cosine of the angle between the query vector $\mathbf{y}$ and a document vector $\mathbf{x}$. The documents are then ranked by (decreasing) cosine with respect to the query. Formally, the cosine of the angle between the two aforementioned vectors is:

$$\frac{\mathbf{x}^\top \cdot \mathbf{y}}{||\mathbf{x}|| \; ||\mathbf{y}||}$$

where (The vectors are assumed to be column vectors and the symbol $^\top$ denotes transposition from a column (row) vector to a row (column) vector.):

$$\mathbf{x} = \sum_{i=1}^{k} a_i \; \mathbf{t}_i \qquad \mathbf{y} = \sum_{j=1}^{k} c_j \; \mathbf{t}_j \qquad \mathbf{x}^\top \cdot \mathbf{y} = \sum_{l=1}^{k} x_l \; y_l$$

After a few simple passages,

$$\mathbf{x}^\top \cdot \mathbf{y} = \sum_{i=1}^{k} \sum_{j=1}^{k} a_i \; c_j \; \mathbf{t}_i^\top \cdot \mathbf{t}_j$$

where $\mathbf{t}_i{}^\top \cdot \; \mathbf{t}_j$ is a measure of correlation between the basis vectors. The cosine is used as ranking function instead of the inner product at the numerator because the norms at the denominator of the formula make document ranking independent of document size. In contrast, the inner product would place long documents at the top ranks, while relevant, short documents would be penalized; however, see [11]. When the index terms are assumed to be uncorrelated, the basis vectors are orthogonal, namely,

$$\mathbf{t}_i^\top \cdot \mathbf{t}_j = \begin{cases} ||\mathbf{t}_i||^2 & i = j \\ 0 & i \neq j \end{cases}$$

It is customary to assume that the basis vectors are orthonormal, therefore,

$$\mathbf{t}_i^\top \cdot \mathbf{t}_j = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}$$

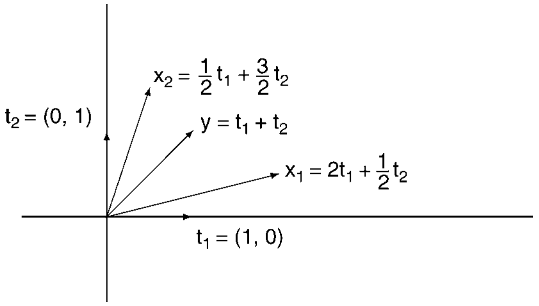
In practice, the basis is the canonical basis of a vector space, that is,

$$t_{i,j} = \begin{cases} 1 & i = j \\ 0 & i \neq j \end{cases}$$

where $t_{i,j}$ is the jth element of $\mathbf{t}_i$. In other words, the ith canonical basis vector has null elements except the ith element, which is 1. It follows that

$$\mathbf{x} = (a_1,\ldots,a_k)^\top \quad \mathbf{y} = (c_1,\ldots,c_k)^\top \quad \mathbf{x}^\top \cdot \mathbf{y} = \sum_{l=1}^{k} a_l\, c_l$$

when the canonical basis is used. Figure 1 gives a pictorial description of the VSM. The orthonormal basis ($\mathbf{t}_1$,$\mathbf{t}_2$) spans a two-dimensional spaces and every vector is thena linear combination of the basis vectors. In particular, $\mathbf{x}_1$ represents a document, $\mathbf{x}_2$ another document and $\mathbf{y}$ represents a query. After computing the cosine of the angle between the $\mathbf{x}_i$'s and $\mathbf{y}$,



$x_2 = \frac{1}{2}t_1 + \frac{3}{2}t_2$
$t_2 = (0, 1)$
$y = t_1 + t_2$
$x_1 = 2t_1 + \frac{1}{2}t_2$
$t_1 = (1, 0)$

Vector-Space Model. Figure 1. A pictorial description of the VSM.

$$\frac{\mathbf{y}^\top \cdot \mathbf{x}_1}{||\mathbf{y}||\,||\mathbf{x}_1||} = 0.86 \qquad \frac{\mathbf{y}^\top \cdot \mathbf{x}_2}{||\mathbf{y}||\,||\mathbf{x}_2||} = 0.89$$

If the basis is not orthogonal, for example, $\mathbf{t}_1 = (1, 0)^\top$ and $\mathbf{t}_2 = \left(\frac{1}{\sqrt{5}}, \frac{2}{\sqrt{5}}\right)^\top$, then, the numerical representation of the vectors and the cosines change; for example, the numerical representation of $\mathbf{x}_1$ is $\left(-\frac{1}{4}, \frac{5}{3}\right)^\top$.

Non-orthogonality has been employed for modeling relationships between index terms; for example, $\mathbf{t}_i{}^\top \cdot \mathbf{t}_j > 0$ for modeling that index term i is somehow related to index term j such that when i occurs, j also tends to occur – a negative value would model an inverse relationship. As a special, important case, non-orthogonality provides a principled way for modeling query expansion. Indeed, the cosine of the angle between $\mathbf{x}$ and $\mathbf{y}$ is in general affected by index term i when $a_i \neq 0$ or $c_i \neq 0$ – when the basis is orthogonal, the cosine is affected by i when $a_i \neq 0$ or $c_i \neq 0$ that is, when the index term occurs both in the document and in the query. Suppose, for example, $k = 2$ and the query contains term 1 only, that is, $c_1 = 1$ and $c_2 = 0$. Therefore,

$$\mathbf{x}^\top \cdot \mathbf{y} = a_1\; \mathbf{t}_1^\top \cdot \mathbf{t}_1 \; + a_2\; \mathbf{t}_2^\top \cdot \mathbf{t}_1$$

If $\mathbf{t}_2{}^\top \cdot \mathbf{t}_1 = 0.5$, that is, the terms are partially correlated, the distance between the document and the query is also affected by term 2, even though it does not occur in the query.

Latent Semantic Indexing (LSI) is a technique based on Singular Value Decomposition (SVD) which aims at finding a basis alternative to the canonical basis. The documents and the queries are then re-expressed with respect to this new basis. The potential of LSI is twofold. First, the document and the queries are vectors of a new space whose dimension is greatly reduced. Second, the new basis vectors no longer represent index terms, but sets of index terms that may be called "concepts," "clusters" or "aggregates" depending on the application domain.

Key Applications

The VSM has been subjected to an extensive evaluation and SMART is the best known experimental IR system. Thanks to the excellent results confirmed by several tests carried out within the Text Retrieval Conference (TREC), this model is presently the reference model for many applications whenever a best-match and weighted retrieval is required. The applications ranges in many tasks, including clustering, cross-language retrieval, summarization and personalization to name but a few. Salton and his colleagues' bibliography gives an idea of the broad range of applications.

Future Directions

The most challenging problem of Information Retrieval is to define a model that governs the complex interactions between the various components of a systems and the end users. An attempt in this direction has been made in [12], which has paved the way toward a new conception of the vector spaces and opened up some connections to other sciences.

Vertical Fragmentation

▶ Distributed Database Design

Vertically Partitioned Data

Jaideep Vaidya
Rutgers University, Newark, NJ, USA

Synonyms

Heterogeneously distributed data

Definition

Data is said to be vertically partitioned when several organizations own different attributes of information for the same set of entities. Thus, vertical partitioning of data can formally be defined as follows: First, define a dataset D in terms of the entities for whom the data are collected and the information that is collected for each entity. Thus, $D \equiv (E, I)$, where E is the entity set for whom information is collected and I is the feature set that is collected. Assume that there are k different sites, $P_1,\ldots,P_k$ collecting datasets $D_1 \equiv (E_1, I_1),\ldots,D_k \equiv (E_k,I_k)$ respectively. Therefore, data is said to be vertically partitioned if $E = \bigcap_i E_i = E_1 \bigcap\ldots\bigcap E_k$, and $I = \bigcup_i I_i = I_1 \bigcup\ldots\bigcup I_k$. In general, distributed data can be arbitrarily partitioned. Vertical partitioning can also be defined as a special case of arbitrary partitioning, where all of the partitions consist of information about the same set of entities.

Key Points

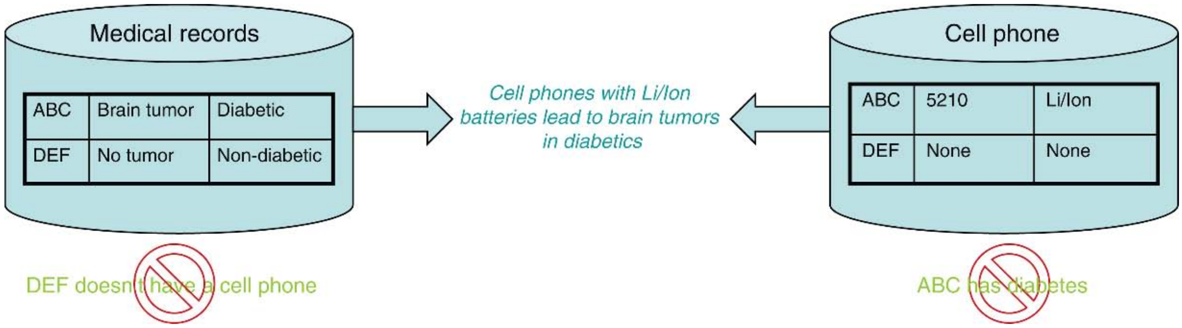
In general, data can be distributed in an arbitrary fashion. This means that different parties may own partial information about different sets of entities. While such arbitrary partitioning is possible, in practice, it rarely happens. Data is said to be vertically partitioned when different sites collect different features of data for the same set of entities. Integrating the local datasets gives the global dataset. Vertically partitioned data occurs naturally in many situations, and mining it can lead to unexpected insights. For example, consider the case of Ford and Firestone. Ford collects information about vehicles manufactured. Firestone collects information about tires manufactured. Vehicles can be linked to tires. This linking information can be used to join the databases. Why bring this up? In 2001, numerous accidents due to tread separation were reported. Initially both companies blamed each other. It turned out that it was only Ford Explorers with Firestone tires from the Decatur, Illinois plant, in specific situations that had these problems. If found out earlier, much loss could have been avoided. While both companies individually collect a lot of pertinent testing data, this was not shared due to commercial concerns. Mining of the global database had the potential to reveal this, which was otherwise impossible only with the local data.

Figure 1 demonstrates another example of vertical partitioning of data. There are two data sources – a hypothetical hospital/insurance company and a wireless service provider. The hospital collects medical records such as the type of brain tumor and diabetes (none if the person does not suffer from the condition). On the other hand, the wireless provider might collect other information such as the approximate amount of airtime used everyday, the model of the cellphone and the kind of battery used. Together, merging this information for common customers and running data mining algorithms might give completely unexpected correlations (for example, a person with Type I diabetes using a cell phone with Li/Ion batteries for more than 3 hours per day is very likely to suffer from primary brain tumors.). It would be impossible to get such information by considering either database in isolation. While this example is hypothetical, similar situations abound in practice.

In general, when data is vertically partitioned, more data significantly improves the quality of the models built from the dataset. Overall, the data analysis results are significantly more accurate and real. While this is also true of horizontally partitioned data (more data is always good), but it has a more critical impact with vertically partitioned data. This is because data from different parties give significantly different additional information about the entities. This is especially true with higher dimensional data.

The complexity of privacy-preserving data mining is also significantly increased due to the vertical partitioning of data. In contrast to horizontal partitioning of data, vertical partitioning of data raises several unique questions with respect to the way data is processed, results are obtained and shared. For example, consider the task of creating a decision tree classifier from some given vertically partitioned dataset. An immediate question is how is the final tree shared by the different parties? Since each party has knowledge of only some of the attributes, knowing the structure of the tree, and especially, knowledge of an unknown attribute and its breakpoints for testing – constitutes a violation of the privacy of the individual parties. Thus, completely revealing the tree is a bad idea from the security standpoint.

Indeed, in the best case, for no leakage of information, even the structure of the tree should be hidden, with an oblivious protocol for classifying a new instance. However, the cost associated with this is typically unacceptable. A compromise may be to



Medical records
Cell phones with Li/Ion batteries lead to brain tumors in diabetics
Cell phone
DEF doesn't have a cell phone
ABC has diabetes

ABC	Brain tumor	Diabetic
DEF	No tumor	Non-diabetic

ABC	5210	Li/Ion
DEF	None	None

Vertically Partitioned Data. Figure 1. A vertically partitioned dataset with hypothetical knowledge inferred from it.

cloak the attribute tests used in the tree while still revealing the basic structure of the tree. This way each site only need know the branch values for the decisions it makes, and the classification of a new instance would also have to be carried out in a distributed fashion by jumping from site to site. In general, it is necessary to carefully evaluate what may be the intermediate and final results, and only reveal as appropriate. Indeed, constructing the form of results is one of the major challenges, especially when one considers that multiple analyses may need to be carried out. [1] provides more details on problems, solutions and challenges in this area.

Synonyms

Rich media; Multimedia

Definition

Video, which means “I see” in Latin, is an electronic representation of a sequence of images or frames, put together to simulate motion and interactivity. From the producer’s perspective, a video delivers information created from the recording of real events to be processed simultaneously by a viewer’s eyes and ears. For most of time, a video also contains other forms of media such as audio.

Video is also referred to as a storage format for moving pictures as compared to image, audio, graphics and animation.

Historical Background

Video technology was first developed for television systems, but it has been further developed in many formats to allow for consumer video recordings. Generally speaking, there are two main types of video: analog video and digital video. Analog videos are usually recorded as PAL (Phase Alternating Line) or NTSC (National Television System Committee) electric signals following the VHS (Video Home System) standard, and stored in magnetic tapes. Digital videos, on the contrary, are usually captured by digital cameras and stored in digital video formats such as DVD (Digital Versatile Disc), QuickTime and MPEG-4 (Moving Picture Experts Group).

Launched in September 1976, VHS became a standard format for consumer recording and viewing by the 1990s. Since then, it has dominated both home and commercial video markets. In March 1997, the DVD format was introduced to American consumers, which gradually pulled consumers away from VHS in following years due to its much better quality. In June 2003, the DVD’s market share exceeded that of the VHS for the first time. Since then, it has been steadily expanding its consumer market, and by July 2006, most major film studios have stopped releasing new movie titles in VHS format, opting for DVD-only releases. Now, VHS is gradually disappearing from both rental and retail stores, and DVD has dominated the whole commercial market. Nevertheless, VHS is still popular for home recording of television programs, due to the large installed base and the lower cost of VHS recorders and tape.

For the last few decades, as video technology quickly advances and the cost of storage devices rapidly decreases, digital videos have become widely available in diverse application areas such as medicine, remote sensing, entertainment, education and online information services. This has thus led to very active researches in various video-related areas.

Foundations

The last three decades have witnessed a significant amount of research efforts on various aspects of video technologies. Roughly speaking, they fall into the following three general categories: video representation, video content analysis, and video application. Specifically, video representation deals with the way a video is represented, in another word, the file format. Video content analysis, on the other hand, aims to automatically structurize and ultimately understand the video by analyzing its underlying content. Due to the difficult nature of this problem, such process usually involves the analysis of multiple media modalities including visual, audio and text information. Finally, video application applies what's learned from the analysis engine, and facilitates various types of content access including video browsing, summarization and retrieval. A brief discussion on each of these three research domains is given below.

Video Representation

A video sequence with accompanying sound track can occupy a vast amount of storage space when represented in digital format. As estimated in [6], a 1-min video clip could possibly occupy up to 448 MB. Consequently, compression has been playing an important role in modern schemes for video representation.

A wide variety of methods have been proposed to compress video stream. Nevertheless, almost all of them build their approaches upon the fact that video data contains both spatial and temporal redundancy. Specifically, to reduce the spatial redundancy, an intra-frame compression is applied which registers differences between parts of a single frame. Such a task is more closely related to image compression. Likewise, to reduce the temporal redundancy, an inter-frame compression is exploited which registers differences between neighboring frames. This involves discrete Cosine transform (DCT), motion compensation and other techniques.

Some popular video compression mechanisms include H.261, H.263, H.264, MPEG-1, MPEG-2, MPEG-4 and MJPEG (Motion-Joint Photographic Experts Group). Specifically, H.261 is a 1990 ITU-T (Telecommunication Standardization Sector of International Telecommunication Union) video coding standard originally designed for transmission over ISDN lines. Later on, H.263 and H.264 which provide more capabilities and mainly target at video-conferencing applications, were standardized in 1995 and 2003, respectively.

In 1998, the Moving Picture Experts Group (MPEG) was formed to establish an international standard for the coded representation of moving pictures and associated audio on digital storage media. Currently, there have been three established MPEG standards from this effort: MPEG-1, MPEG-2, and MPEG-4. Each of them targets at different commercial applications. For instance, MPEG-1 is usually used as the Video CD (VCD) format, MPEG-2 for High Definition Television (HDTV), and MPEG-4 for streaming video applications.

Finally, to facilitate mobile appliances such as digital cameras, MJPEG was developed in 1990s which uses intra-frame coding technology that is very similar to those used in MPEG-1 or MPEG-2. However, it does not use inter-frame prediction, which on one hand, results in a loss of compression capability, yet on the other hand, it makes the degree of compression capability independent of the amount of motion in the scene. Moreover, it also eases video editing as simple edits can now be performed at any frame.

Video Content Analysis

Video is a type of rich media as it often consists of other media types such as audio and text. Consequently, research on video content analysis can be grouped into three classes: visual content analysis, audio content analysis, and audiovisual content analysis. A general goal of video content analysis is to extract the underlying video structure so as to facilitate convenient and nonlinear content access. Yet a more aggressive goal is to automatically understand video semantics so as to support applications such as video summarization and retrieval that require an in-depth understanding of the video content.

Visual Content Analysis

As the name implies, visual content analysis concentrates on processing the visual part of the video signal. Most existing work in this area falls into two directions, with one focusing on analyzing the image or frame content in the spatial domain, and the other on exploiting the temporal relationships between frames.

Visual feature extraction at different semantic levels are usually the major focus of those work in the first category. Popular features such as color, texture and motion, are low-level features, which while easy to extract, are not able to capture the video semantics. Therefore, most of recent work focuses on extracting mid to high level visual features, which can not only be derived from lower level features, but also capable of bridging the semantic gap by revealing the underlying content semantics to a certain degree. Such features include various types of video objects and semantic concepts such as sports, military, explosion and sky. Machine learning and content modeling are two popularly applied approaches to achieve such goal.

On the other hand, there is also a significant amount of work that attempts to capture both video syntax and semantics by exploring its temporal structure. Specifically, video shot change detection is usually the very first step towards this goal, where the entire video sequence is segmented into a series of cascaded shots. Shot forms the building block of a video sequence, and contains a set of frames that are continuously taken. For a comprehensive survey on various shot detection algorithms, readers can refer to [3].

Based on the syntactic shot structure, higher-level visual content analysis such as scene detection or extraction, could be subsequently carried out. Figure 1 shows a typical video content structure, which is represented by a hierarchical tree. As shown, for an incoming video stream, it is first segmented into a sequence of *shots*. Then, one or more of its frames (called *keyframes*) can be extracted to represent its underlying content. The next step is to build semantic video scenes upon the extracted shot structure. Specifically, a video *scene* is defined as a collection of semantically related and temporally adjacent shots that depicts and conveys a high-level concept or story. Consequently, a common solution to scene extraction is to group semantically related shots into a scene [14]. This process is similar to grouping words into sentences, where a sentence starts conveying meanings to readers. Finally, there could be one or more steps further from scene detection. One such effort is on event detection, where an *event* is considered as important scenes that contain particular thematic topics of interest such as dialogs, actions or something abnormal [3,5].

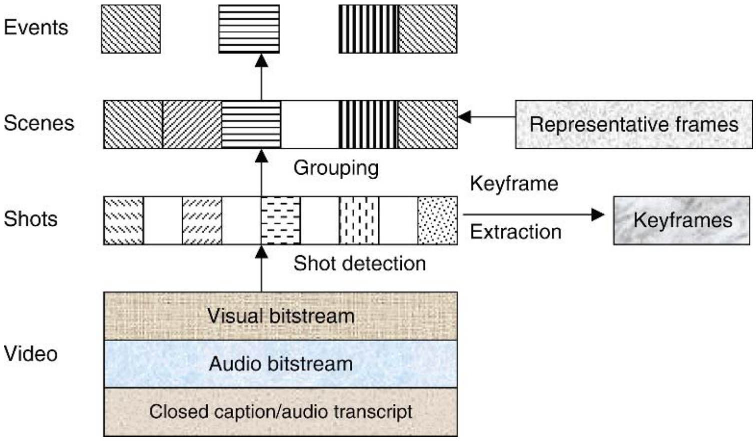
Audio Content Analysis

Audio, which includes voice, music and various kinds of environmental sounds, is an important type of media. A general approach to audio content analysis is to either classify or segment an audio clip into different homogeneous fragments with each fragment containing one particular audio type such as speech, music or silence [2]. Audio features such as short-time energy, short-time zero-crossing rate and short-time fundamental frequency, are usually extracted for this analysis purpose [15].

As a key ingredient of a video stream, the audio source could represent the story in a much simpler fashion than its pictorial counterpart. For instance, if people are only allowed to listen to a TV program without watching it, they can still get most of its meanings. Yet on the other hand, if they are only allowed to watch the program without listening to it, they may get lost easily. This shows that the audio source, especially the embedded speech cue, is critical to a human's content understanding. Moreover, audio is also essential to people's enjoyment of the video content.

Audiovisual Content Analysis

As automatic video content understanding is a very challenging task, thus most recent work tends to exploit all possible media cues to achieve such a goal. In particular, as audio and visual cues are two inseparable parts of a video stream, and usually complement with each other during the content creation, people tend to integrate them together during the content analysis.



Video. Figure 1. A hierarchical representation of video content.

A general solution to audiovisual content analysis is to first perform individual visual or audio content analysis to obtain two sets of analysis results, then combine them together using certain fusion rules or applying a probabilistic framework. Another popular way of media integration is to employ different information sources at different processing stages [4]. For instance, the visual cue is first employed to generate coarse-level results, then audio cues is introduced to refine the results. However, when and how to efficiently and effectively integrate multiple media sources still remains to be an open issue, and needs further study.

Video Application

Besides the large amount of research efforts on video content analysis, there are also many attentions on studying various video applications. After all, making the bulky and unstructured video content convenient and efficient to access, present, share, search and deliver is the ultimate goal of the entire research community in this area. Below, a brief introduction is given to three major types of video applications, namely, video indexing and browsing, video abstraction, and content-based video retrieval.

Video Indexing and Browsing

As analog to indexing a book, video indexing aims at facilitating non-linear access of the video content. It is thus very critical for efficient video retrieval. For instance, television and film archives usually contain a vast amount of audiovisual materials. If these materials are properly segmented and indexed, studios can conveniently produce a new video clip by finding and reusing some pre-produced segments. Moreover, in audiovisual libraries or family entertainment applications, it would be very desirable if the needed video segments from a large video collection could be quickly located.

Video browsing refers to the activity where a user watches through a video to get quick ideas of its underlying content [11]. Video browsing can also assist users in query forming for video retrieval purpose. For instance, when the user lacks a clear idea of what he wants from a large video collection, he can gradually conceptualize his needs by browsing through the video clips to find the one that stimulates his desire. Once such clip is located, he can further submit it as a query seed to obtain more related clips.

Video Abstraction

Video abstraction, as the name implies, generates a short summary for a long video document. Specifically, a video abstract is a sequence of still or moving images, representing the video content in a way such that the target party is rapidly provided with concise information about the content, while the essential message of the original is well preserved [12]. Video abstraction is primarily used for video browsing, and is an inseparable part of a video indexing and retrieval system.

Theoretically, a video abstract can be generated both manually and automatically, but due to the huge volumes of video data and limited human power, it is getting increasingly important to develop fully automated video analysis and processing tools so as to reduce human involvement in the video abstraction process.

There are two fundamentally different kinds of video abstracts: still- and moving-image abstracts. The still-image abstract, also known as static storyboard or *video summary*, is a small collection of salient images (also called keyframes) extracted or generated from the underlying video source. The moving-image abstract, also known as moving storyboard or *video skim*, consists of a collection of image sequences, as well as the corresponding audio abstract extracted from the original sequence. Thus, it is itself a video clip but is of a considerably shorter length.

There exist some significant differences between video summary and video skim. First, a video summary can be built much faster, since generally only visual information is utilized and no handling of audio and textual information is needed. Also, once composed, it can be displayed more easily since there are no timing or synchronization issues. Second, more salient images such as mosaics could be generated to better represent the underlying video content. Third, the temporal order of all extracted representative frames can be displayed in a spatial order so that the users are able to quickly grasp the video content. Finally, all extracted stills could be easily printed out when needed.

There are also advantages in using video skim. Compared to the still-image abstract, a moving-image abstract usually makes more sense to users since it preserves part of the original audio track. Moreover, the possibly higher computational effort during the abstracting process pays off during the playback time: it is usually more natural and more interesting for users to watch a trailer than watching a slide show, and in many cases, the motion is also information-bearing.

A comprehensive survey of various video summarization and video skimming techniques could be found in [3].

Content-Based Video Retrieval

By definition, a content-based video retrieval system (CBVRS) aims at assisting a human operator or user to retrieve a video sequence within a potentially large collection based on certain criteria. Generally speaking, there are three major aspects regarding a CBVRS, namely, *query formation*, *feature space selection*, and *similarity measurement*. In particular, the query formation deals with formulating a meaningful and clear query which faithfully captures what the user is looking for. Once the query is submitted, potential candidates will be evaluated within certain feature space, and the similarity between the query and candidate is measured. Such a process usually results in a ranked list of retrieved sequences sorted from the most similar to the least. Below gives a brief discussion on each of the above three aspects.

To formulate a query, the user can either submit still images (*a.k.a.* keyframes), short video sequence, textual keywords, or a combination of the above as the search seeds. Query formation is not as easy a task as it appears to be. One major reason for this is due to the semantic gap between the user's true intention and the constrained way of representing it. For instance, when the user submits a video sequence as a query example, he or she may mean to find some videos that present similar color schemes, motion, events, or objects, yet such intention is hard to be captured or understood by the system as it is embedded in the query and is highly subjective. To close such a semantic gap, one way is to use textual keywords in queries that precisely describe what the user is looking for. Nevertheless, this would require a thorough and correct textual annotation of the entire collection, which is not only very tedious but in fact, impossible for humans to perform. Recently, there have been some ongoing research efforts on automatic video annotation [10], yet many challenging issues still remain to be solved.

As another effort on bridging such a semantic gap, people have been introducing the so-called relevance feedback mechanism into the system, where the user interacts with the system by giving negative or positive feedback on the retrieved results [13]. The system then performs an online learning of the user's expectations by possibly adjusting or updating the weights of different features, the similarity metrics, and the learning algorithms. While there has been an increasing amount of work on this subject, how to design an efficient, effective and user-friendly relevance feedback system still deserves further study.

Once the query is formulated and submitted, the next step is to measure the similarity between the query example and possible candidates within certain feature space. Undoubtedly, finding a good set of features to represent the query is very critical to the success of the search. So far, various features at different semantic levels have been proposed including color, texture, motion, audio, object, scene, event etc. in both spatial and temporal domains [16].

Finally, a metric is required to measure the similarity, which produces a distance that would account for both the spatial and temporal differences between the two video sequences. Ideally, such metric should be jointly defined with the particular feature set that is applied in the system for a better result [1].

In a word, while at a first glance, a content-based video retrieval system is a natural extension of a content-based image retrieval system, it is in fact, far more complex due to the excessive dimensionality of the search space induced by the inherent temporal information in videos.

Key Applications

In October 1998, MPEG started a new work item called the "*Multimedia Content Description Interface*," or in short "MPEG-7," which aims to specify a standard set of descriptors and description schemes that can be used in describing various types of multimedia information [9]. This description shall be associated with the content itself, to allow fast and efficient search for materials of users' interests. The major objective of MPEG-7 is to make audiovisual material as searchable as text [8].

Various cases of professional and consumers applications have been identified and targeted by MPEG-7, which can be categorized into either *pull* or *push* applications [7]. Specifically, typical pull applications that are more related to video include: (i) storage and retrieval of video databases; (ii) delivery of pictures and video for professional media production, and

(iii) movie scene retrieval by memorable auditory events. In contrast, push applications follow a paradigm more akin to broadcasting and webcasting. Some key applications include: (i) user agent driven media selection and filtering; (ii) personalized television services; (iii) intelligent multimedia presentation; (iv) bio-medical applications; (v) remote sensing applications; (vi) semi-automated multimedia editing; (vii) educational applications, and (viii) surveillance applications.

Undoubtedly, with the amount of audiovisual information rapidly increasing and becoming widely available from many sources around the world, a lot more new applications will emerge so as to satisfy various urgent needs related to important academic, social and economic issues.

Synonyms

Video analysis; Video content processing; Semantic analysis of video

Definition

Video content analysis deals with the extraction of metadata from raw video to be used as components for further processing in applications such as search, summarization, classification or event detection. The purpose of video content analysis is to provide extracted features and identification of structure that constitute building blocks for video retrieval, video similarity finding, summarization and navigation. Video content analysis transforms the audio and image stream into a set of semantically meaningful representations. The ultimate goal is to extract structural and semantic content automatically, without any human intervention, at least for limited types of video domains. Algorithms to perform content analysis include those for detecting objects in video, recognizing specific objects, persons, locations, detecting dynamic events in video, associating keywords with image regions or motion patterns, identifying visible actions or behaviors, and labeling scenes, activities, genres. The analysis may be performed on single frames (images), sequences of frames indicating change or motion by the camera or the subject, audio analysis through speech recognition and non-speech sound characterization as well as any combinations of still image analysis, image sequence analysis and audio analysis.

Historical Background

Digital video has proliferated dramatically since the 1990s, ranging from ever-growing personal video collections to professional news and documentary archives. As bandwidth and disk space accessible to users is increasing, video is becoming the most rapidly proliferating type of data on the Internet. Fueled by the popularity of social media sharing in the Web 2.0 paradigm, there has been exponential increase in videos available on the internet. With the availability of large amounts of multimedia data, there comes an urgent need for good video content analysis.

The first attempts at image and video content analysis were made in the 1960s and 1970s, with applications mostly in video compression and videophones. By the mid 1990s, a number of research systems that could perform video content analysis on sequences longer than a few minutes were introduced. With the widespread introduction of fast computers in the twenty-first century, digital video content analysis has become common, but is frequently not accurate enough for widespread commercial use, and the more sophisticated approaches are still too computationally complex to be applied to every frame in the video.

Video content analysis has become the only feasible way to analyze larger video collections for search, summarization, navigation, and re-use in other applications. Social media tagging has allowed collections on the internet to be searchable through text tags and comments, but these searches rely on precision, and reasonable tagging, which is often not the case, especially for some of the less popular video files.

Foundations

Video content analysis algorithms are usually built within a machine learning framework, where the system is first provided with a set of training instances that represent the type of analysis to be performed (e.g., soccer goal scoring), as well as negative training instances (normal play) and any of a large set of machine learning techniques is used to automatically determine which video analysis features are useful to predict this higher level analysis. However, the most impressive results in video content analysis are achieved when judicious constraints, rules or heuristics exploit the particular characteristics of the analysis to be performed, limiting the number of features that are considered and improving the accuracy of the analysis or classification result.

V

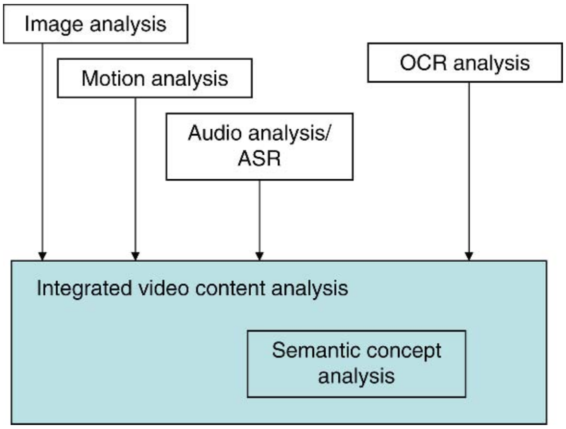
Much of the most interesting video content analysis is based on a fusion of analysis results at different levels of the different modalities (image, audio, motion, OCR). This type of content analysis has produced the most interesting results in sports video analysis, where the crowd and announcer noise indicates an interesting event on the field, while the image and motion analysis gives a clue to the type of event, and the OCR might indicate the players involved as well as the score.

Similarly, for broadcast video, a combination of image analysis for faces, audio analysis and camera analysis can determine which shots contain interviews with news subject, and OCR together with face recognition provides the identify of the person in the news. Video content analysis combining image similarity based on duplicate detection, identification of news studio shots and news anchor scenes can be used to provide the building blocks for news story segmentation. In order to summarize and browse through "scenes" or stories quickly, it is convenient to assign them to particular topic classes, which can again be done be integrating the results of different components of video content analysis.

In many ways, video content analysis fundamentally builds on image content analysis. Each frame in a video can be considered an image by itself, so all aspects of an image retrieval system can be applied. Text annotations may be available and can be searched as well. But video offers additional challenges and opportunities.

Video consists of additional types of information (e.g., audio sounds, human speech, motion) beyond what one might find in pure still image data. While a collection of a million images is considered quite large, just 10 h of video at 30 frames per second would provide a million frames (images). Of course, consecutive frames are often strongly related, providing high similarity and numerous slightly different versions of the same content in adjacent frames. However, the large amount of data, puts the burden on video content analysis to provide effective abstractions. The purpose of video content analysis is to provide extracted features and identification of structure that constitute building blocks for video retrieval, video similarity finding, summarization and navigation (Fig. 1).

Broadcast video consists of edited programs, whose structure can be exploited. Thus, news video consists of anchors, news stories, reporters, advertisements, etc. with each category providing context and constraint to what might be of use in further analysis. Videos can generally be partitioned temporally into keyframes, scenes, stories, and programs.



Video Content Analysis. Figure 1. Integrated video content analysis builds on Image, audio, motion and OCR analysis.

Partitioning Video

One of the earliest and most successful applications of video content analysis was the detection of shot boundaries. Shot boundary segmentation involves the identification of cuts, fades, and dissolves as typical editing effects added to video. Most techniques use sudden color, texture or edge changes and feature point tracks over various window sizes to determine shot breaks. In *movie or television video*, additional segmentation may aggregate several related shots into a scene or video paragraph, based on the similarity between sequences of shots.

In the case of *broadcast news video*, it is usually possible to segment a news story as a possible semantic unit, based on consistency in the text transcript, detection of news anchors, audio speaker analysis, and similarity in the news story footage. Special segmentation techniques involving black frames and rapid scene changes are used to identify commercial advertisements. Program or station logos, special transition effects, and recognition of distinctive backgrounds such as weather maps can also help determine news story boundaries.

Surveillance video has very different characteristics, since there are no editing artifacts, such as shot boundaries. Here, keyframe extraction is still desirable, but keyframes are usually selected from sections of video that contain motion, detected objects and people. In surveillance video, the best representative keyframe captures an unusual event or a person/object when it is most clearly visible (largest) in the frame.

Audio Analysis

Audio analysis provides one component of video content analysis, supplementing visual analysis. From the audio track, it is possible to automatically generate a transcript to enable text-based retrieval from spoken language documents. Audio analysis can also identify changes in speakers and identify individual speakers.

Speech Recognition for Video Content Analysis and Retrieval The consensus from a number of published experiments in the area of automatic speech recognition for broadcast retrieval applications is that as long as speech recognition has a word error rate less than 35%, then information retrieval from the transcripts of spoken documents is only 3–10% worse than information retrieval on perfect text transcriptions of the same documents. The most accurate recognizers to date produce a word error rate under 20% for broadcast news, suitable for very accurate text-based retrieval.

Speaker and Audio Type Identification Another component of video content analysis is the use of audio features and speaker labeling. Many systems use audio analysis techniques to automatically extract additional metadata providing a description of the content of the audio channel. Audio processing can be used to detect music and other non-speech sounds, e.g., laughter and applause. Audio processing techniques can also be used to distinguish male versus female speakers, so that the respective audio regions can be passed to more accurately trained gender-specific speech recognizers. Existing audio analysis systems also identify well-known speakers for which a significant amount of training data is available, or group speakers across different speaker turns. Thus, for example, the techniques could identify the US President as well as most news anchors. Infrequently appearing speakers can be tracked when reappearing at different times within a video broadcast, although not labeled by name. This speaker change classification can be used to help break the video into coherent segments, and in general to characterize the audio channel of the data. Thus, video where one talker speaks for a long time can be labeled as a "speech," whereas an "interview" consists of two people switching back and forth, while a "forum" discussion includes many speakers. For broadcast data, it is possible to detect which speaker remains present throughout the entire audio data, thus identifying the anchor or narrator.

Content Analysis from Individual Image Frames

Most image content analysis for video usually happens on extracted keyframes. The full palate of image content analysis techniques can be applied, including low-level image content analysis, mid/high-level content analysis, image content modeling, image salient point extraction and representation, image segmentation and images similarity analysis, as described in the relevant sections.

Metadata Extraction Unique to Video

There are several types of content analyses that are unique to video.

Motion Feature Analysis One additional feature type not present in images is related to *motion*. There are several types of motion estimators that can be extracted, the motion blocks typically used in MPEG-style compression, the overall kinetic energy in the image and a fine-grained motion analysis based on optical flow. MPEG motion vectors can be directly extracted from the compressed result of an MPEG encoding process. These motion vectors can be aggregated and used for object and camera motion assessment. Kinetic energy measures the pixel variation within the shot. Optical flow algorithms typically warp one frame into another frame. They estimate the movements of high intensity interest points between two image frames as the motion vectors. While expensive to compute, optical flow analysis tends to provide the most refined estimates of object motion.

Recognizing object motion in video sequences is an important component in many applications. For example, in computer vision systems it enables the identification and tracking of the objects that make up a scene; while in video data compression it provides a means of reducing redundancy – knowing the motion of an object allows its position in successive frames to be predicted, removing the need to retransmit identical frame data and leading to a reduction in the bit rate required to transmit the video. Other applications include the generation of panoramic images, and recovery of 3-dimensional structure.

Recovering detailed motion from video sequences is a non-trivial effort. Factors such as the ambiguity resulting from 3-D action recorded as a 2-D projection by the camera, poor contrast, and low spatial or temporal resolution, require sophisticated techniques to obtain reliable motion information. The range of approaches used includes affine models to estimate and track complex 2-D motions and techniques to deal with multiple component motion regions.

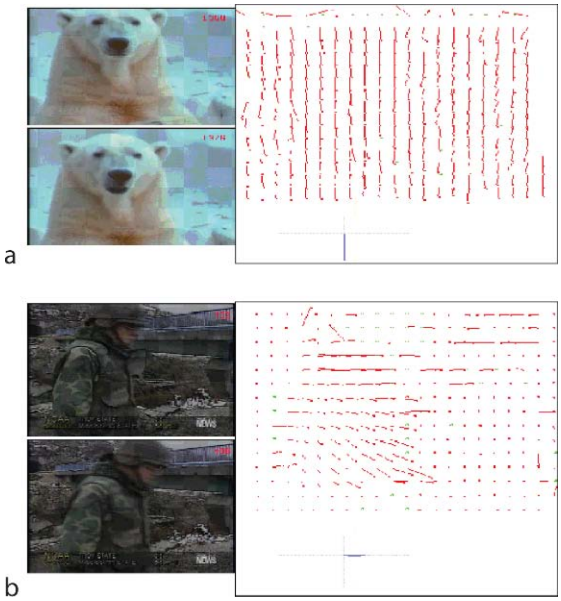
It has become popular in sports motion analysis to videotape subjects with markers placed on critical body parts, joints or equipment. The markers are used in each movement as references to the particular point of interest. Typically, the camera is carefully calibrated and distance markers placed in the field of view to allow accurate estimates of motion distances and velocities. This motion analysis allows customized systems to create models of motion and performance analysis relative to a specific sports activity. The motion may be translated into either 2-dimensional or 3-dimensional models and compared to reference motions.

Camera Motion Analysis One facet of video content analysis is concerned with analysis of camera motion, which includes pan (left/right), tilt (up/down), and zoom motions. More subtle analysis tries to distinguish dolly and boom motion, where the camera is physically moved from one place to another from the situation where the camera stays in place. Even further refinement of camera motion analysis tries to detect camera "shake," used for image stabilization. In principle, camera motion can also include rotation around a focal point; however this is a relatively infrequent event.

A wide variety of techniques exist for estimating the camera motion, most of which depend on the comparison between adjacent frames, based either on all pixels in the image or particularly salient pixels or regions. Since these pixels or regions only move slightly from frame to frame, their difference can be interpreted as a "track." From the overall patterns of tracks, models can be built to estimate if the motion pattern is more consistent with object motion, or camera shake, or camera pan/tilt/zoom, etc.

Most methods approach the problem of camera motion by deriving parameters proportional to the zoom, pan, rotate and tilt given a set of motion tracks. The methods usually determine an empirical threshold that classifies the derived parameters as representative for a particular camera motion. Optical flow analysis methods computed between consecutive images rely on tracking a large number of characteristic points across adjacent frames. Other methods use the MPEG motion vectors which encode one quantized motion vector per macro-block of pixels as an alternative to optical flow. Though these motion vectors are not directly equivalent to the true motion vectors of a particular pixel in the frame, there are typically enough motion vectors to robustly estimate camera motion parameters (Fig. 2).

Video OCR (VOCR) A somewhat different representation is derived by interpreting the text that is present in video images using optical character recognition (OCR). However, reading text present in the video stream requires a number of processing steps in addition to mere character recognition (see Fig. 3). First the text must be detected as present in a wide variety of scenes and backgrounds. Then it must be extracted from the image and finally converted into a binary (black and white) representation, since the commercially available OCR engines do not recognize colored text on variably colored background. The video OCR is further complicated because the text has very low resolution, frequently only about 10 pixels of height per character. Unlike text printed on white paper, the background of the image tends to be complex, with the character hue and brightness very near the background values. Among the solutions to these problems are



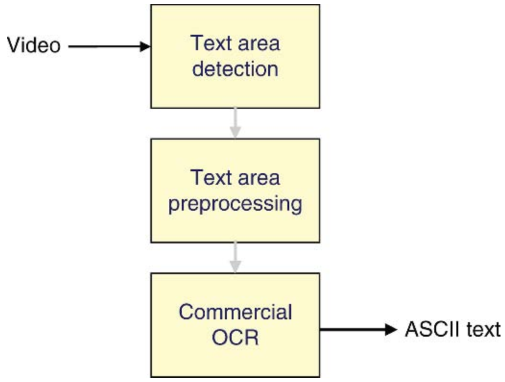
Video Content Analysis. Figure 2. Camera motion analysis for camera pan/tilt versus object motion using MPEG motion vectors.

interpolation filters, the integration of images across multiple frames and combinations of filters.

A text region detection is performed first, searching for horizontal rectangular structures of clustered sharp edges using variable orientation differential filtering techniques. Text boxes are identified based on their aspect ratio, absolute size and the fill factor of the bounding boxes.

Once a text area is detected, enhancement takes place. Multi-frame integration looks at the potential bounding boxes over several frames and finds the minimal (white) pixel values across that range. Potential text regions are sequentially filtered across consecutive frames, effectively increasing the resolution of each caption. Sub-pixel interpolation is performed to increase resolution without incurring jagged edges as artifacts (Fig. 4).

Adaptive thresholding on the gray-scale histogram is then used to create binarized black on white text before submitting it to an optical character recognition package. Systems will run OCR on multiple consecutive frames where text was detected, obtaining several nearly identical OCR results for a single occurrence of text on the screen that might last for a few seconds. These results can then be merged together for a single estimate. Once text is recognized, post-processing can correct some of the inevitable errors, e.g., using dictionary spelling correction.



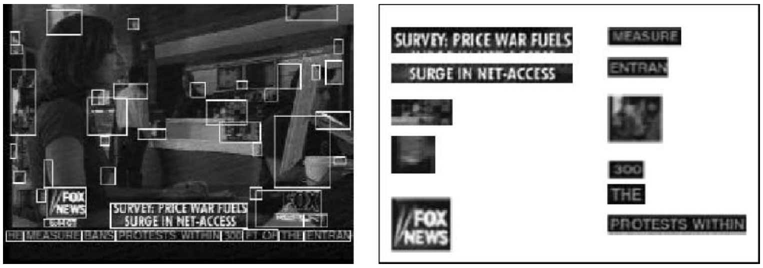
Video Content Analysis. Figure 3. Video OCR block diagram consisting of text area detection, text area preprocessing, and commercial OCR.

Combination of Audio Analysis, Image Analysis, and Motion Analysis for Semantic Content Analysis

Ultimately, video content analysis tries to achieve many of the same goals as mid-level and high level image analysis, except that the low level features available come from any number of modalities (audio, image, motion) and have already been performed at low, mid or high levels for this modality. The main task for video content analysis is then to fuse or combine these building blocks into a new characterization of the video.

Semantic Concepts as Mid or High-level Video Features. The effectiveness of low-level image analysis to represent image or video content is usually limited. The representations typically result in the notorious semantic gap between what users or applications expect and what content analysis systems can return, due to the systems' inability to capture the semantic meaning of the video content.

To provide a more semantic content analysis in video, an intermediate (mid to high-level) layer of hundreds of semantic concepts has been introduced in an effort to capture the semantic content of multimedia documents. The typical concepts includes a wide range of topics such as those related to people (face, anchor, etc.), objects (cars, buildings, bridges, graphics), location (outdoors, city, office setting), and genre (weddings, meetings, sports). Beyond the semantic concepts that are common to still image content analysis, semantic concepts for video can include temporally defined



Video Content Analysis. Figure 4. Candidate text regions as detected in a single frame of a video and some of the extracted individual text line.

events, such as an airplane landing, a vehicle stopping, etc. The successes of automatic semantic concept detection in recent years have demonstrated that a large number of high-level semantic concepts can be derived from the low-level multi-modal features with reasonable detection accuracy.

Detectors or classifiers for such semantic features are usually built off-line using large amounts of labeled training data combined with a number of machine learning approaches. Accuracy of the detectors depends critically on the number of training examples available as well as the difficulty of the semantic concept to be detected, e.g., a "left thumb" would be much more difficult to detect than a face. Face detection has been most effective for image and video retrieval, and significant added benefit can be gained from accurate face recognition, depending on the quality of the available images.

More recently, it has been proposed to combine these intermediate level semantic concepts into an ontology, which defines the relationships between concepts, their taxonomic structures and constraints. While researchers have shown some benefit to retrieval accuracy when using ontologies for limited domains, it is still unclear if a general-purpose ontology of visual concepts can be built and successfully applied. Similar efforts in the text analysis area have not yielded the expected results so far.

Key Applications

Search, browsing and summarization in video archives, real-time surveillance monitoring.

Video data modeling

Definition

Video Content Modeling refers to representing the content of video data for search later on. Specifically, the content of video data includes the visual features, the temporal features, the contained objects, and the semantic concepts. With an effective modeling technique, people cannot only browse the video data, but also search the video with the specific features. Video content modeling is the basic for video data indexing and retrieval.

Historical Background

Video, as a popular type of multimedia, has been widely used by movie/TV industries and individuals. In the earlier 90s, people started search video data through annotated text information [20,21,23]. However, the low efficiency of manual annotation techniques prevents the text-based retrieval techniques applying to video data on a large scale. Thus, content-based video retrieval was proposed and studied. For the purpose of conducting effective and efficient search, significant works have been conducted on modeling video content. These techniques can be classified into three categories:

Segmentation-based models [24,18,12,8].
Video are recursively broken down into *scenes*, *shots* and *frames*. Key frames are extracted from shots and scenes to represent them, and visual features are extracted from key frames as indexes to key frames.

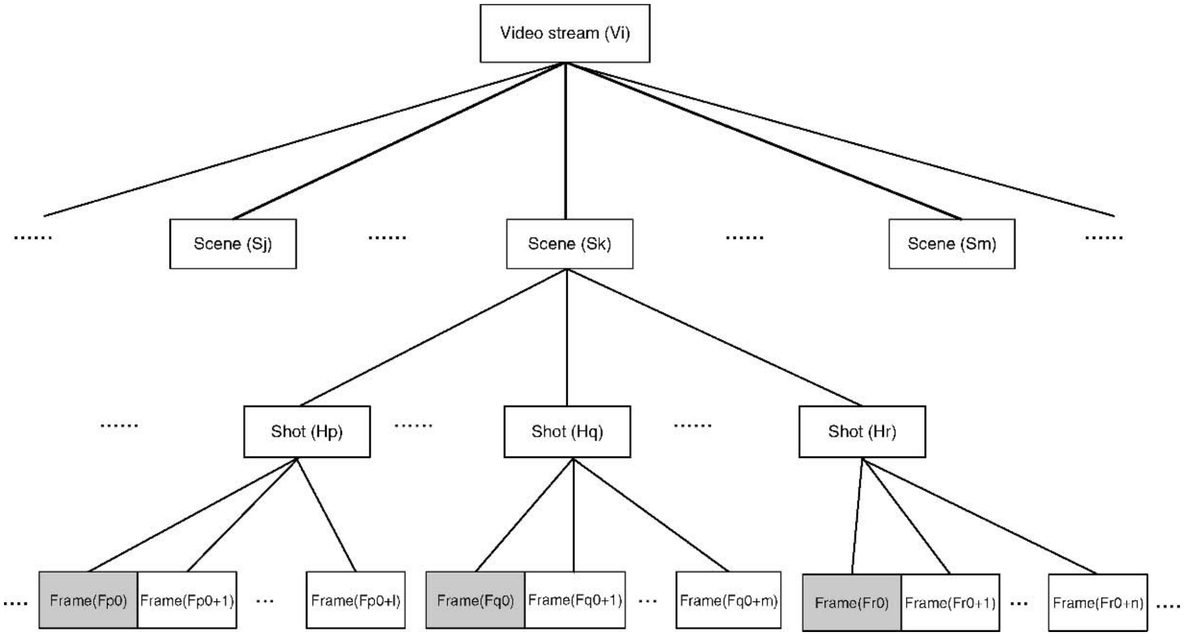
- Annotation-based models [20,23,22,14,3].
  In this model, a content description (annotation) layer is put on top of the video stream. Each annotation can be associated with a logical video sequence or physically segmented shots or scenes. An annotation describes the events or semantics of a video sequence.
- Salient object-based models [13,4,10,16,5,19]. Salient objects are extracted from video, and their audio-visual features and spatio-temporal relationships among them are described to express events or concepts.

Foundations

- Segmentation-based video data modeling:
  Modeling video data based on segmentation can be divided into three steps. First, video is segmented into *shots* (sometimes called *clips*); second, key frames are selected to represent the shots; finally, based on these shots, *scenes* or *story units* are constructed. During the last step, keyframes may also be selected to represent scenes and story units. Usually,visual features are extracted from the key frames as indexes to the video data. A video data model based on video segmentation possess a hierarchical structure (Fig. 1): a video stream contains several scenes or story units, each scene contains a set of shots and each shot contains asequence of video frames. The shaded frames in Fig. 1 are examples of key frames. The definition of shots, key frames and scenes are as follows [18]:
  - A shot is an unbroken sequence of frames recorded from a single camera.
  - A key frame is the frame selected from a shot which can represent the salient content of that shot.
  - A scene is a sequence of shots which conveys a concept or story.

The techniques for shot detection, key frame selection and scene construction, as briefly reviewed, follows:

- Video shot detection
  There are two basic types of video shot transitions: *abrupt* and *gradual* [24]. Abrupt transitions (cuts) occur when stopping and restarting cameras. Gradual transitions are introduced when two shots are artificially combined together by applying cinematic effects (fade-in, fade-out, dissolve, etc) [24]. Compared to the abrupt shot transitions, the gradual shot transitions are much more difficult to detect, because camera operations and big object movements may cause temporal variance similar to gradual shot transitions.
- Key frame selection
  Key frames provide a suitable abstraction and framework for video indexing, browsing and retrieval [1]. Users can get an overview of the video by only browsing the key frames. Furthermore, using key frames greatly reduces the amount of data required in constructing higher level video structure units (e.g., scenes, story units). Most of the key frame selection techniques are based on shot detection; in other words, key frames are mainly defined at the shot level. In order to select key frames, the video stream is first partitioned into shots, and different techniques are applied to extract key frames for each shot [25].



Video Content Modeling. Figure 1. A hierarchy structure of video data.

  - Scene construction from shots

    Individual shots are fundamental representation units of a video. However, in a normal video stream, there are thousands of shots, and usually a single shot conveys very little semantics. Shots can be grouped into higher-level segments to form *scenes*, which can convey much more semantics than shots [18]. All the scene construction algorithms follow similar steps: (1) Shots are clustered together based on the similarity which is computed from some visual features (e.g., color, texture, edge, etc.), (2) Clusters that are temporally close to each other are grouped into scenes.

- Annotation-based video data modeling

  Annotation-based video modeling techniques associate annotations (keywords or free text) to video sequences. These annotations describe the semantics of the video sequences. Based on the structure of annotations, an annotation-based video data model can be classified into: a *single value annotation structure* and an *attribute-value pair structure.*

  - Single value annotation structure approach

    In this model, annotations are associated to logical [20,23] or physical [11] frame sequences directly.

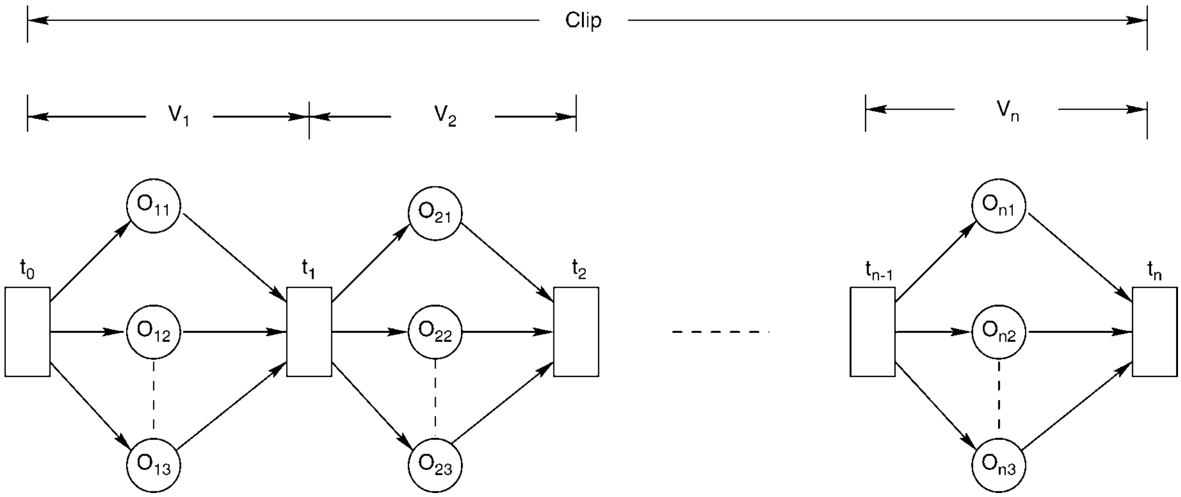
    - Annotations to logical frame sequences. Smith et al. [20] proposed a layered annotation representation model called the stratification model that segments the contextual information of the video. The stratification model divides the video sequence into a set of overlapping strata. A stratum consists of descriptive information such as title, keywords and the boundaries it represents. The strata may be contained in other strata and may encompass a multitude of other descriptions. The content information is derived by examining the union of all the contextual descriptions that are associated with it. Each stratum is logically independent and will make its contribution to the content when its descriptive information meets the user requirements.

    - Annotations to physical frame sequences

      Different from the stratification system which directly links the logical video segment to the raw video data at frame level, a generic video model [11] is developed which incorporates a segmentation-based video data model to associate text to a well defined structure. Hjelsvold's model supports sharing and reuse of the video data, temporal interval operations and structure abstraction. However, the arbitrary definition and reuse of a frame sequence introduces complicated relationships between structure units and thematic annotations.

- Attribute-value pair structure approaches
  Instead of using the single value for annotations, attribute-value pairs are adopted to annotate the logical video segments. Attributes define the types, ranges and semantics of the values [17].

- Salient object-based video modeling
  Events that happen in a video such as dialogs, explosions, car chases are considered basic semantic units that the video intends to express. Through analysis of characteristics of video content, the event can be expressed by describing spatio-temporal relationships among the *video objects* that appear in that video. The models of this category can be further divided into *motion segmentation-based* and *spatio-temporal relationship-based*.
  - Motion segmentation-based approaches
    Motion based approaches try to model video data through investigating motion directions, trajectories and velocities of video objects. These motion parameters are extracted together with video objects from video data and stored together. Motion segmentation-based approaches can befurther divided into *graph-based* approaches and *motion vector-based* approaches.
    - Graph-based approaches
      Approaches in this category use a graph to describe moving objects, their trajectories and spatio-temporal relations with other moving video objects [9,13,15].
    - Motion vector-based approaches
      Instead of using a graph, motion vector-based approaches model moving video objects with a set of motion vectors [6].
  - Spatio-temporal relationship-based approaches
    Motion segmentation-based approaches only address motion parameters of video objects. However, the spatial and temporal relationships among video objects (not only moving video objects [15,13]) possess many more semantics. Several approaches have been proposed and they can be classified into two categories: *spatio-temporal logic-based* and *graph model-based.*
    - Spatio-temporal logic-based approaches
      Del Bimbo et al. [4] propose a Spatial-Temporal Logic (STL) language to describe the spatio-temporal relationships among video objects within image sequences.
    - Graph model-based approaches
      Different graphs are used in these approaches to model the spatio-temporal relationships among the video objects. From the point of view of dealing with semantic heterogeneity of video data, Day et al. [10] propose a Video Semantic Directed Graph (VSDG), which is used to construct users' heterogeneous views of the video data. VSDG is created to model spatio-temporal interactions between video objects. An example of a VSDG is shown in Fig. 2. A video clip is composed of n video segments, labelled $V_1,V_2,...V_n$. Each video



Video Content Modeling. Figure 2. VSDG representation of a clip.

object $(O_{11},O_{12},...O_{nn})$ has attributes that describe the duration of its appearance in the video segments and its motion vector. Each rectangular node corresponds to an event in the video clip whenever a new physical object appears.

From the point of view of multimedia presentation, two other approaches have been proposed to model the spatio-temporal relationships among the video objects. HPNs [2] use Hierarchical Petri nets to capture the multi-level content of video data, which includes motion trajectories of moving objects and spatial temporal relationships among video objects. Chen et al. [7] model the salient objects, their content, and their spatio-temporal relationships in a hierarchy model and propose a video query language for users to search related contents.

Key Applications

Content Based Video Retrieval

Content-based video retrieval (CVIR) is the the problem of searching for videos that have similar content to the query video in a large database.

Video Databases

With a proper video content modeling technique, the video data can be stored in a database for efficient retrieval and analysis later on.

Video structuring; Video structure analysis

Definition

Mining video content structure is an elementary step of video content analysis. Direct access to a video without indexing is usually not an easy task, due to its length and unstructured format. On the other hand, analogous to text documents that can be decomposed into chapters, paragraphs, sentences and words, videos can be segmented into units like scenes, shots, and keyframes. The analysis of video content structure can be viewed as the process of hierarchically decomposing videos into units and building their relationships. Through such a process, a table-of-content can be constructed for each video, which facilitates the access and manipulations of the video data. For example, the keyframes extracted from the video can be used as its entries for indexing and browsing.

Historical Background

More and more *video* data has become available to ordinary users due to the advances in storage devices, networks and compression techniques. However, the efficient access to an unstructured video is a challenging task due to the huge number of frames. Video structuring is proposed to tackle this difficulty. In [14], Zhang et al. first proposed the scheme that partitions videos into shots, and then selects the first frame of each shot as the keyframe for indexing. From 2001, the National Institute of Standard and Technology (NIST) has established video shot detection as a evaluation task in the TREC Video Retrieval Evaluation (TRECVID) benchmark (http://www.itl.nist.gov/iaui/894.02/projects/trecvid/). In [10], Rui et al. proposed to group shots into scenes, such that the video content can be structured at a higher level. For several video genres, such as news and movies, "story" is also widely applied as the unit for content organization. Kim et al. [6] proposed a method to further segment shots into subshots in order to facilitate more detailed implementations. For each shot or subshot, one or more keyframes can be extracted to represent its content. Thus, as illustrated in Fig. 1, generally a video can be structured in a hierarchical form as "video → scenes → shots → subshots → keyframes," and it can also be segmented into stories if it belongs to certain genres, such as news video. The definitions of these terminologies are as follows:

Shot: a shot is an uninterrupted clip recorded by a single camera. It is a physical entity and often forms the building block of video content.

Scene: a scene is defined as a collection of semantically related and temporally adjacent shots, depicting and conveying a high-level concept or story. A scene usually consists of a series of consecutive shots that are recorded in the same location.

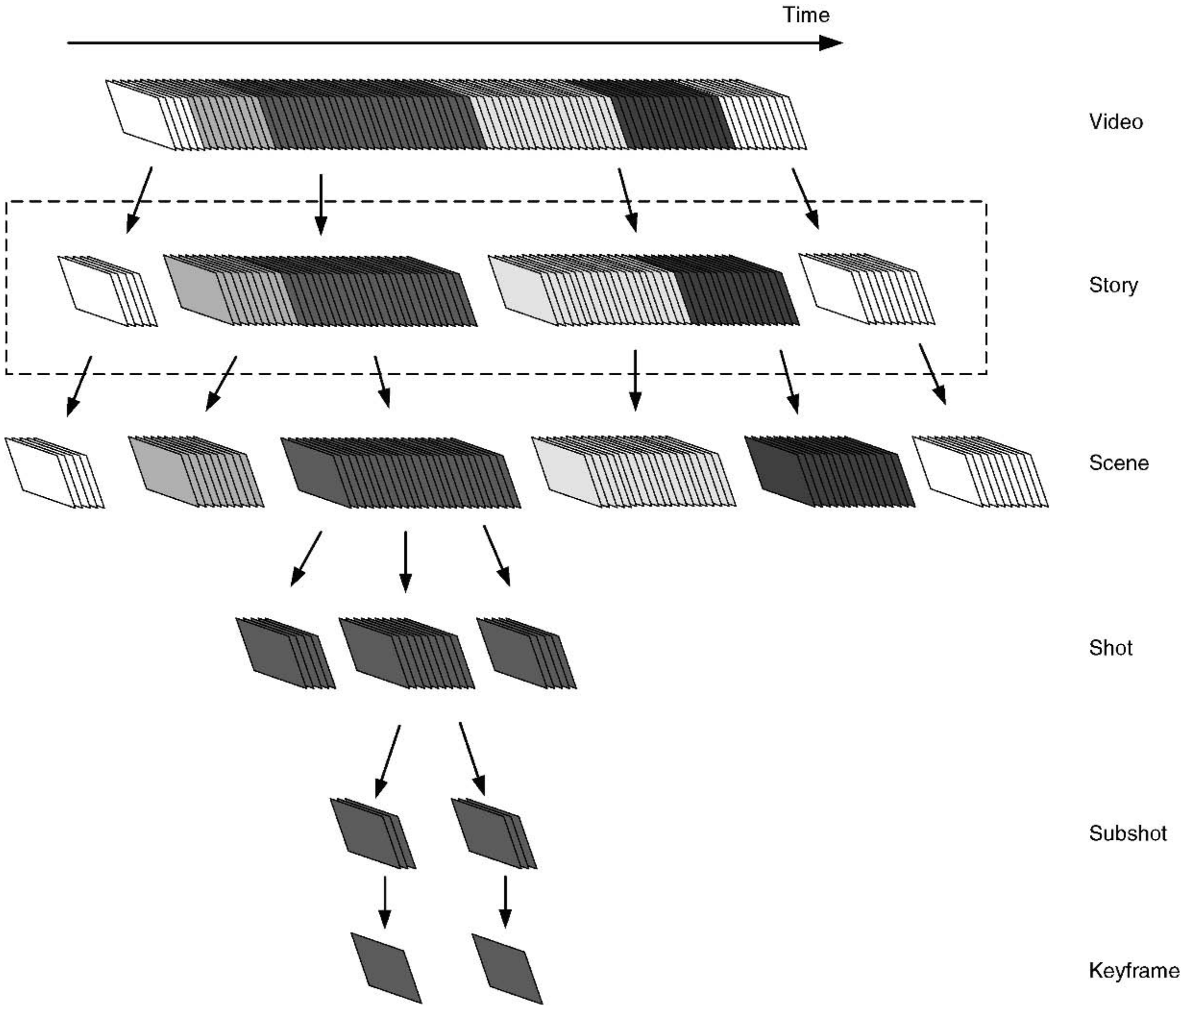
Story: a story is referred to as a clip that captures a continuous action or a series of events, and it may be composed of several scenes and shots. Note that the story lines are usually only clear for rigidly structured videos. Currently, most story identification methods are developed for news videos. Thus, here only "news story" is considered. A definition of a news story in TRECVID is "a segment of a news broadcast with a coherent news focus which contains at least two independent, declarative clauses."

Subshot: subshot is a segment within a shot that corresponds to a unique camera motion. A shot can be divided into one or more consecutive subshots according to the movement of the camera.

Keyframe: a keyframe is the frame which best represents the content of a shot or a subshot. According to the content complexity, one or more keyframes can be extracted for each shot or subshot. Keyframes can be used as the entries of the video data for manipulations, such as indexing and browsing.

Foundations

As previously introduced, the analysis of video content structure may involve five techniques, namely, shot detection, scene grouping, story identification, subshot segmentation, and keyframe extraction.



Video Content Structure. Figure 1. Hierarchical decomposition and representation of video content.

Shot Detection

Shot detection is the process of identifying the boundaries between two consecutive shots, such that the frame sequence can be grouped into a set of shots. According to the transition style of the consecutive shots, the shot boundaries can be mainly categorized into two types, i.e., cut and gradual transitions. Cut indicates that the change between the two shots is abrupt, whereas the gradual transition means that there is a gradual special effect in the transition of the two shots. Many different shot detection methods have been proposed (including the detection and categorization of gradual transitions), and a most straightforward approach to shot detection is to measure the change between every two consecutive frames and a shot boundary can be declared if there is a significant change. Yuan et al. have provided a comprehensive survey on shot detection in [13], and more details about this technique can be found in the entry *Video Shot Detection*.

Scene Grouping

Scene grouping is usually implemented based upon the results of shot detection. From a global point of view, scene grouping can be viewed as a shot *clustering* task. With an appropriate pairwise similar definition, many different clustering algorithms can be applied to accomplish this task. Intuitively, two criteria should be considered in a scene grouping algorithm, namely, content similarity and temporal continuity. Content similarity means that the shots within the same scene should have similar content, whereas the temporal continuity indicates that these shots should be close to each other temporally. The content similarity is usually defined based on a low-level feature space, and many different features can be applied, including visual, audio and text features (the text features can be extracted by several existing techniques such as “Automatic Speech Recognition” and “Optical Character Recognition”).

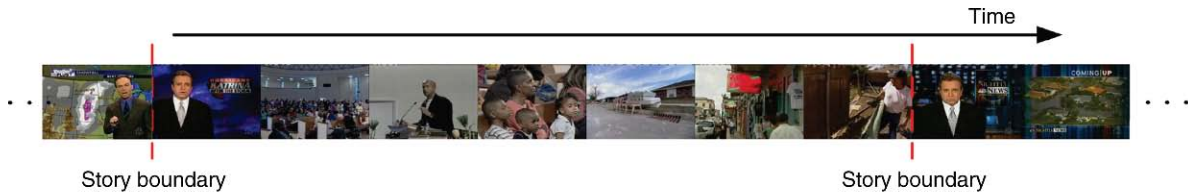
Gu et al. [3] have categorized the existing scene grouping methods into three approaches: merging-based, splitting-based, and model-based. The merging-based approach groups shots in a bottom-up way. In [10], the scene grouping is implemented via a two-step process: (i) assign the shots into groups according to their visual similarities and temporal continuities; and (ii) merge similar groups into a unified scene. Rasheed et al. proposed another two-step scene grouping process in [9]: (i) cluster shots according to Backward Shot Coherence (BSC); and (ii) merge the clusters into scenes based on an analysis of the shot length and the motion content in the potential scenes.

As opposed to the merging-based approach, splitting-based scene grouping methods are implemented in a top-down style, i.e., a video is split into a set of coherent scenes in turn. In [8,12], two different graph-based splitting methods are proposed. In these two methods, a video is represented by a graph, in which the vertices are denoted by the shots and the edges are determined by the similarities of the shots and their temporal localities. A graph is then partitioned into several subgraphs and each subgraph can be regarded as a scene. In [12], the graph is named as a Scene Transition Graph (STG), and it is partitioned into several subgraphs with the complete-link method, whereas in [8] the graph is named as a Shot Similarity Graph (SSG) and it is partitioned by the normalized cuts method.

Different from the above two approaches, model-based methods group shots into scenes with statistical models. Tan et al. [11] implemented scene grouping using the Gaussian Mixture Model (GMM), with each Gaussian component indicating the distribution of a scene, and the number of scenes can be determined by the Bayesian Information Criterion (BIC) method. Recently, Gu et al. [3] proposed an energy minimization scheme, in which the constraints of time and content of scene grouping are indicated by energy items. It is able to take both the global and local constraints into consideration, and the number of scenes can be established by the Minimum Description Length (MDL) principle.

Story Identification

Story identification needs more semantic understanding of video content (Fig. 2), and it is usually only applied for certain rigidly structured video genres such as news video. In TRECVID 2003 and 2004, news story identification was established as an evaluation task. The existing story identification methods can be mainly classified into two categories, i.e., rule-based and learning-based. The rule-based story identification methods are usually based on certain domain knowledge. For example, it has been observed that many news stories begin with an anchorperson shot and end with the start of another anchorperson shot. In [15], the pattern of news stories has been analyzed, and the task of story identification is accomplished via detecting the shots of certain types, such as anchorperson shot. However, such an approach highly depends on the adopted knowledge, and can hardly handle diverse video sources with different features and production rules. The learning-based approach is able to tackle this difficulty. In typical learning-based story identification methods, a set of story boundary candidates is first established (such as the shot boundaries and audio pauses), and then each candidate is classified as “story boundary” or not according to the model learned from a training set [1]. More details about these story identification methods can be found in [1,15] and references therein.



Video Content Structure. Figure 2. A typical news story in a video. The keyframes of the video have been illustrated, and the story boundaries can be identified according to the anchorperson analysis.

Subshot Segmentation

Subshot is a sub segment within a shot. Generally, a subshot is defined to contain a unique camera motion. Thus, subshot segmentation can be accomplished through camera motion detection. For example, consider a shot in which the camera moves as follows: zoomed out, then panned from left to right and zoomed in to a specific object, and then stopped. This shot then comprises three subshots, including one zoom out, one pan to right, and one zoom in. The camera motion between two adjacent frames can be estimated based on a two-dimensional affine model, in which the motion vector (v_x, v_y) at pixel (x, y) can be expressed as

$$\begin{pmatrix} v_x \\ v_y \end{pmatrix} = \begin{pmatrix} a_1 \\ a_4 \end{pmatrix} + \begin{pmatrix} a_2 & a_3 \\ a_5 & a_6 \end{pmatrix} \begin{pmatrix} x \\ y \end{pmatrix} \tag{1}$$

where $a_i(i = 1,2,...,6)$ denote the motion parameters. The motion parameters can be represented by a more meaningful set of terms as follows

$$\begin{cases} pan = a_1 \\ tilt = a_4 \\ zoom = \frac{a_2+a_6}{2} \\ rot = \frac{a_5-a_3}{2} \\ hyp = \frac{|a_2-a_6|+|a_3+a_5|}{2} \end{cases} \tag{2}$$

where *pan* corresponds to the pan movement of camera, *tilt* corresponds to tilt and boom, *zoom* corresponds to dolly and the change of focus, *rot* corresponds to roll, and *hyp* indicates that object motion is predominant. For more details about video motion analysis, please refer to [6].

Based on the analysis of camera motion, the subshot segmentation can be implemented and each subshot will be categorized into one of the following six classes: *pan*, *tilt*, *zoom*, *rot*, *objectmotion*, and *static*. For an individual frame, its motion category can be determined by thresholding the related terms in Eq. (2). However, it is observed that generally a camera movement will be maintained for a period of, say, at least a half second [6]. Thus, a typical subshot segmentation process consists of three steps, i.e., frame-level motion detection, segment-level motion detection, and post-processing. More details can be found in [6]. Figure 3 illustrates an example, in which the shot can be segmented into seven subshots.

Keyframe Extraction

Keyframes are the frames in the video sequence that can best preserve the content of shots or subshots. They can be used as the entries of the videos for access. The most widely-applied methods for this task can be categorized into two approaches, i.e., analysis-based and clustering-based. The analysis-based methods extract keyframes by analyzing video content, such as the quality and the attractiveness of frames. For example, in [7], Ma et al. adopted an attention model, and the frames that attract the most user attention are extracted as keyframes. In the clustering-based approach, a clustering process is carried out, and then the cluster centroids can be established as keyframes. In [4], Hanjalic et al. adopted a partitioning-based clustering method, and the number of clusters (i.e., the number of keyframes) can be determined by a cluster-validity approach.

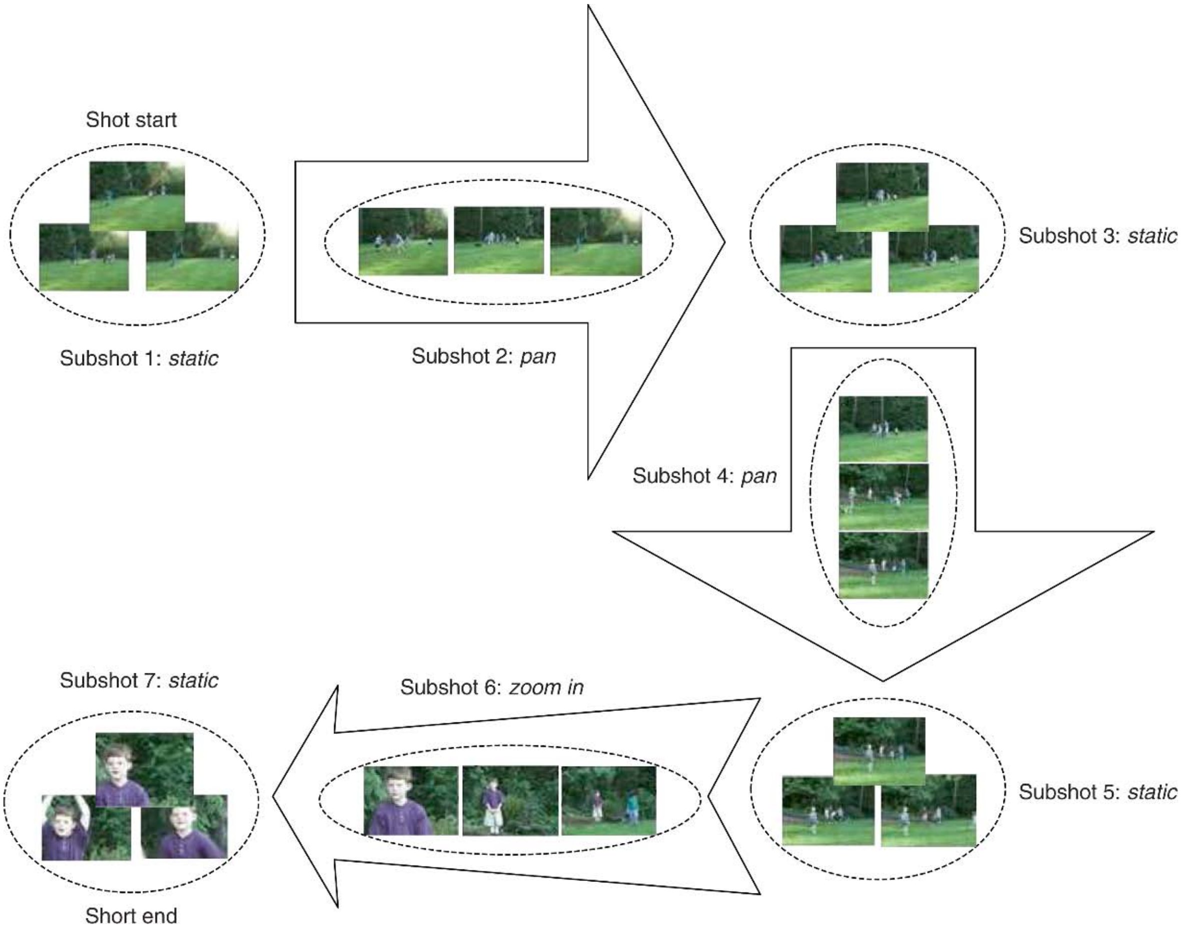
A recent development in keyframe extraction is to formulate it as a learning task [5]. It is observed that the representativeness of a video frame involves several elements, such as its image quality, user attention, and visual details. Thus, the frame representativeness can be modeled through a training set that regards these elements as features. This learning process is able to simulate a human's perception on keyframe extraction. The method in [5] builds a model based on four elements extracted from each frame, including *frame quality*, *visual details*, *content dominance* and *attention measurement*, and encouraging results have been reported in both subjective and objective evaluations.

Key Applications

As previously mentioned, analyzing video content structure is the first step of *video content analysis*, and it is thus a prerequisite for many video applications, such as *video abstraction*, *video summarization* and *content-based video retrieval.*

Future Directions

The existing video structuring methods are mainly carried out based on low-level features. However, from the above introduction it can be found that several structuring techniques involve the understanding of video content. For example, for scene grouping, it is better to group shots with coherent semantic concepts rather than those with close low-level features. Thus, it is believed that better structuring performance can be achieved by leveraging semantic features in the existing algorithms. This can be named as "semantic-based video structuring"



Video Content Structure. Figure 3. An illustrative example of subshot segmentation.

approach. For details about the application of semantic features (or semantic feature space), please refer to [2]. It is worth noting that structuring is currently always regarded as an independent and preliminary step of video semantic analysis. To use semantic features for structuring, the semantic analysis and structuring may have to be integrated or unified.

Experimental Results

Generally, for each presented method, there is an accompanying empirical evaluation in the corresponding reference. For shot detection and story identification, the results achieved in TRECVID can be found in the corresponding notebook papers which can be downloaded from the TRECVID website (http://www-nlpir.nist.gov/projects/tvpubs/tv.pubs.org.html).

Definition

Digital video is recorded in two different image capture formats: interlaced and progressive scan. Interlaced video establishes an image by recording alternating sets of lines, where one set of odd or even lines is referred to as a "field," and a consecutive pairing of two fields of opposite parity is called a frame. In a progressive digital video each frame is recorded in a distinct manner, with both fields being identical. Both operate at the same number of frames per second, which is in NTSC roughly 29 images and in Pal around 25 images per second. As of 2007, the highest resolution demonstrated for digital video generation is 33 megapixels (7,680 × 4,320) at 60 frames per second ("UHDV").

Metadata is data about data of any sort in any media, describing an individual datum, content item, or a collection of data including multiple content items. In that way, metadata facilitates the understanding, characterization, use and management of data.

Video metadata is structured, encoded data that describes content and representation characteristics of information-bearing video entities to facilitate the automatic or semiautomatic identification, discovery, assessment, and management of the described entities, as well as their generation, manipulation, and distribution.

Historical Background

In the late 1970s to the early 1980s of the twentieth century the first digital video production equipment, such as time base correctors (TBC) and digital video effects (DVE) units, were developed. This type of equipment was, however, not part of the general production flow, as the digitized and processed video still needed to be converted back to standard analog video.

Digital video was first introduced commercially in 1986 with the Sony D-1 format, which recorded an uncompressed standard definition component video signal in digital form. Due to its costs, the D-1 was primarily used by large television networks. Over the years it was replaced by cheaper systems, such as Sony's Digital Betacam, which were still expensive so that they were mainly used as a field recording format by professional television producers.

Consumer digital video first appeared in 1991 in the form of QuickTime, Apple's framework for time-based and streaming data. Shortly after, Microsoft's AVI format followed and then MPEG-1, MPEG-2 and MPEG-4 (the basis of MPEG-4 was QuickTime) formats gained popularity. The introduction of the DV tape in 1996 gave digital video another acceptance push as it allowed recording directly to digital data and thus simplified the editing process, allowing non-linear editing systems to be deployed wholly on desktop computers (e.g., FAST 601, Softimage DS, Appel's Final Cut line).

The work on video codec technology from the early 1990s allowed a great deal of research directed on computer environments that seek to interpret, manipulate or generate digital video either in a manual, semi-automatic, or automatic way [1–6]. In all these research projects the description of video content in form of metadata played a central role. The steady infiltration of those technological advances in everyday production finally allowed the general public to really include video into their everyday communication. Examples of such infiltrated technologies are simple non-linear video editing systems, environments for new media authoring (e.g., Director/Shockwave, Flash), and web authoring environments (e.g., Dreamweaver, Frontpage, and SMIL).

The rapid growth of professionally created and exploited video databases, as well as the slow but steady growth of user-generated video material on the web (the growth was much slower than the one of images), forced research to address similar problems as those already explored for digital image databases, namely how to efficiently search and then exploit video databases. Over the years a number of metadata standards have been developed, which address various aspects of video data, such as the Dublin Core Metadata Initiative (http://www.dublincore.org/), the Society for Motion Pictures and Television Engineering (SMPTE) (http://www.smpte.org/home/), the Moving Picture Expert Group (MPEG) (http://www.chiariglione.org/mpeg/), the TV-Anytime Consortium (http://www.tv-anytime.org/), and the International Press Telecommunications Council(IPTC) (http://www.iptc.org/pages/index.php). The common definition language between all these languages has been in one way or another the Extensible Markup Language (XML) [7], defined by W3C.

The most relevant initiative for addressing segmentation, indexing and content-based retrieval of digital video based on low-level features, usually automatically extracted from the content, is the TrecVid series (http://trecvid.nist.gov).

The by far largest contribution to digital video was provided by the three ISO standards MPEG-4 [8], MPEG-7 [9] and MPEG-21 [10]. With MPEG-4 the group entered the realm of media content, arisen due to the growing need for content manipulation and interaction. MPEG-4 expanded MPEG-1 to support video "objects," 3D content, low bitrate encoding and support for Digital Rights Management. Yet, MPEG-4 lacked the means to identify video objects on a semantic level – a necessary element for efficient search in and the manipulation of video. Addressing this problem, the MPEG-7 standard was started in the late 1990s. One core part of MPEG-7 (Part 3: Video – and also larger sections of Part 5: The Multimedia Description Schemes) is devoted to video annotation only. The beginning of the twenty-first century established an even faster exchange of multimedia data via the web, as higher bandwidth as well as access to high quality data became a commodity. Media businesses, such as the film industry, feared, due to peer-to-peer technology for their markets and requested strict digital rights management enforcement. MPEG reacted with MPEG-21, defined as the multimedia framework.

Since 2005 the web saw an exploitation of video content. The main reasons were:

- Easy access to digital video cameras
- The provision of Adobes Flash player, which can be easily integrated into web pages
- Easy ways of sharing enabling technology, of which YouTube (http://www.YouTube.com), among others, is the most well-known example

The relevance of YouTube is not so much grounded in its technology advances (YouTube plays back videos limited in size (320 × 240 pixel) and quality (a bitrate of around 314 kbit/s with a frame rate depending on the uploaded video), but rather on the distribution of content. YouTube lets their clientèle act as they please, without enforcing editorial decisions or odds and ends such as copyright. As many Web2.0 applications YouTube applies folksonomy tagging (also known as collaborative tagging, social classification, social indexing, and social tagging) a method of collaboratively creating and managing tags to annotate and categorize content. In folksonomy tagging metadata is not only generated by experts but mainly by creators and consumers of the content, where a tag is a keyword or term associated with or assigned to a piece of information (a picture, a map, etc.), which enables keyword-based classification and search. The advantage of tagging is its ease of use – creating a vocabulary based on freely chosen keywords instead of a controlled set of terms and structures. This approach, though highly popular, carries serious problems. Typically there is no information about the semantics of a tag, no matter if it is a single tag or a bag of tags. Additionally, different people may use drastically different terms to describe the same concept. This lack of semantic distinction can lead to inappropriate connections.

The success of YouTube, which consumed in 2007 as much bandwidth as the entire Internet in 2000, and similar sites let the W3C start a new video on the web initiative in 2008, which will address the access of video on the web (http://www.w3.org/2008/WebVideo/Activity.html).

Foundations

The description of video content is to some extent very similar to the one of images, simply because a video is the representation of single images over time. The following text, therefore, only addresses those issues of video content representation that are not already addressed in the "Image Metadata" entry of this encyclopedia. As applications like YouTube reestablished the question of rights management on a large scale, this section also addresses this problem in some detail.

The two essential aspects of video that enhance its "meaning making" over that of an image is the concept of a shot and the sequence of shots, or time and structure of time.

Shot Description

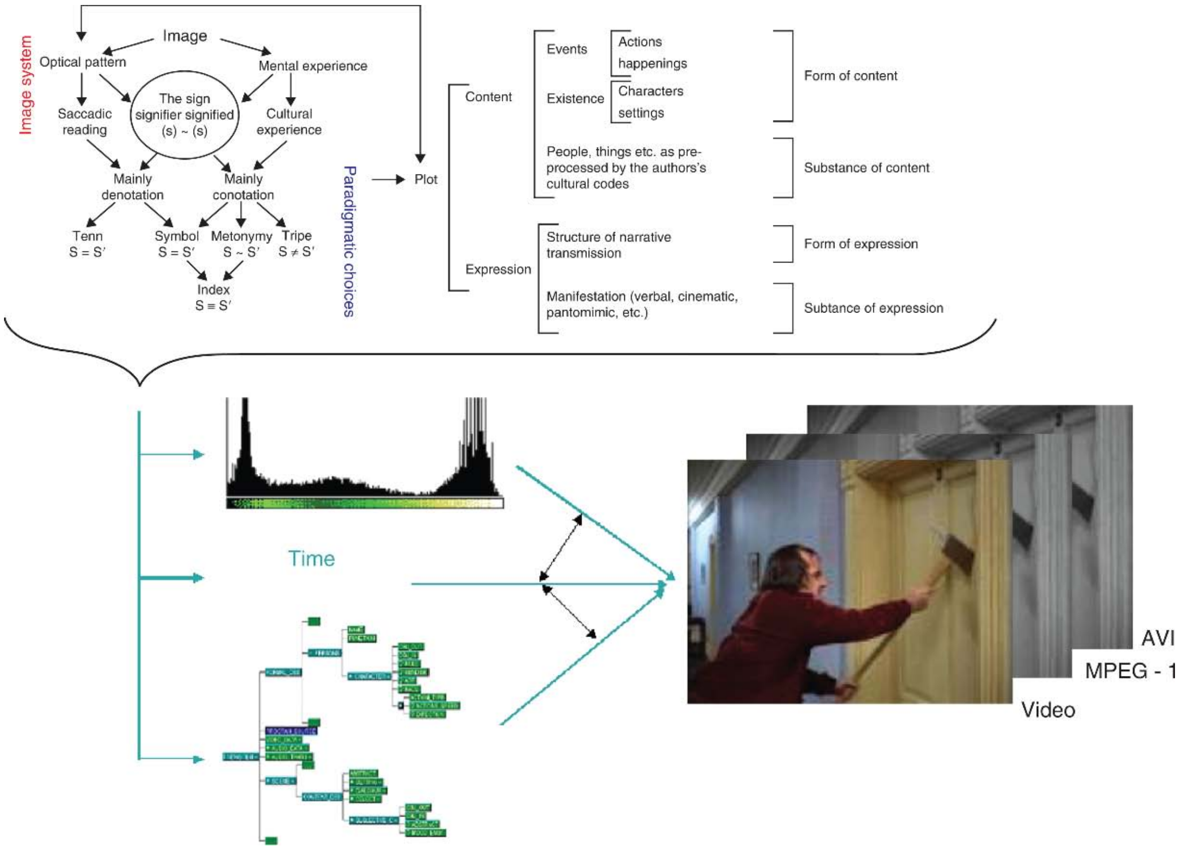
A shot is a single piece of film, however long or short, without cuts, exposed continuously. The significant additional element here is time, which provides the basis for the understanding of action, distance and the relationship among characters, based on the relationship between frames within a shot and their rhythmical variations. The compositional use of *focus*, for example, through which the foreground, middle ground or background are emphasized, is one way to guide the perception of a shot. If all planes are represented in focus, they are attributed with the same level of importance, whereas emphasis can be achieved by use of focus for a part of a frame. Of even stronger impact than focus is *camera movement* around the imaginary vertical axis (pan), the horizontal axis (tilt), and the longitudinal axis (distance from lens to the subject). The *tilt*, for example, presents the eye-level from which a scene is perceived and thus can affect the importance ascribed to an object (for example, high-angle shots may diminish the perceived importance of an object). The *tempo* of a shot can also provide information. The intense feeling of fast movement may excite, while calm movement expressed, for example, through the slow rolling of waves filmed from a static camera position, may encourage feelings of relaxation. Related to tempo, is the *perceived duration* of the shot. The actual duration of a long shot full of people and action may well be identical to one of the close-up of a face, and yet the latter will be perceived as being longer. Hence, the organization of perceived duration is more complex than the actual duration of a shot.

There are, on the perceptional level, various automatic methods to extract shot boundaries, namely the border between two different shots, forms of transitions between shots, as well as temporal or conceptual concepts (color, shape or texture-based). A good summary of these methods can be found in [11]. The advantage of automatic extraction is its low costs. The disadvantage, similar to the problems in automatic image indexing, is that it is exclusively organized around the sensory surface structures of media, i.e., the physical features, which are able to grant access to the representation of conceptual items but not to the higher semantics users wishes to access. Detailed description of schemata, that allow high-level semantic descriptions, namely for the essential content categories actor, appearance (features of a character), action (chronology of, or direction of, the action) location, and cinematographic devices (e.g., camera and lens movement, camera position, etc) are described in [3], which also establishes an icon based annotation method, and [4]. Both approaches make use of hierarchical schemata structures.

Important for all of these annotation forms, might they be automatic, semi-automatic or manual, is a proper representation of time. The current ways or representing time are either based on:

- Physical time (full clock value (e.g., 7:45:23.76, where the last two items present ms), partial clock values (any sort of short base notation), time count values (numbers with a additional type string, e.g., 10S for "ten seconds"), and time context values, which are represented in three parts: a date field (YYY:MM:DD), a time field, and a timezone field). These descriptions allow the location of an annotation based on the start- and end-frame.
- Logic descriptions, as best described by [12], which are useful for a symbolic representation of a time relation instantiation in a triple structure, as requested by the Resource Description Framework (RDF) [13].
- Or as a hierarchical ontological description, that describes time not on its physical form but rather on its relevance for the shot content, e.g., The presented epoch (e.g., seventeenth century), season (e.g., Summer), or daytime (e.g., Midday) [3].

The essential concepts of video metadata are summarized in Fig. 1. The upper left corner describes the possibilities of interpretation of an image, the upper right part outlines the structural elements of a story (of which the visual information forms a subpart). Both together form the schematic basis for the annotation process, which can be performed in an automatic, semi-automatic or manual fashion, as described in the lower left part of Fig. 1, which are performed on various instantiations of the same content material in form of differently coded digital video, as outlined in the lower right part.



Video Metadata. Figure 1. Essential metadata concepts for the description of video content.

Sequence

The final level of generating meaning with video material to be considered is the way in which content of a shot can be affected by other shots.

- The meaning of a shot depends on the context in which it is situated.
- A change in the order of shots within a scene changes the meaning of the shot as well as the meaning of the scene.

Important is that not every combination of shots creates a meaning, but there are restricted conventions that can help create larger meaningful entities. The key elements for creating meaning by joining shots are *assertions* and *associative cues* [14].

An assertion is the relationship between two elements. There are many different types of such relationships. For example, the description of an attribute (such as *red* for a car) could be as important as a simple action (two men shaking hands).

Associative cues result from the combinations of the indicators that make the creation of meaning possible. One essential cue was already discussed, namely human action. The other one is surrounding space. Most human activities, human roles or objects are associated with specific locations. The conceptualization of space is, therefore, an elementary principle of the analysis and organization of video material. The sequential structures built up through juxtaposition provide the complex and intricate syntax for film narrative. The two essential works for structural metadata concepts for video are described by Aguierre Smith et al. [1] and in the MPEG-7 part 5 [15].

Aguierre-Smith designed the Stratification System to support an anthropological video study in the state of Chiapas, Mexico. The idea was to provide a number of researchers with random access to a video archive, in which video could be annotated with complementary or even contradictory descriptions. The video material was stored on a laserdisc. The annotations used in the Stratification System were keywords organized in hierarchical classes which were implemented as directory trees in UNIX. The novel feature introduced by Aguierre-Smith was the multiple partially overlapping annotation, where each annotation is related to a precise time index (begin and end frame). To provide a visual representation of the distinct layers of the representation, the Stratification System used a histogram, where the keyword classes are displayed as buttons along the *y*-axis and the time code (frame numbers on the laserdisc) form the *x*-axis. Aguierre-Smith's stream-based content representation for video enables the dynamic development of context while maintaining the completeness of the original footage. The notion of multiple partially overlapping annotations establishes the Stratification System as a breakthrough in the effective representation of video content, despite its weaknesses, i.e., the keyword approach and the lack of a true representation of the semantics of the video.

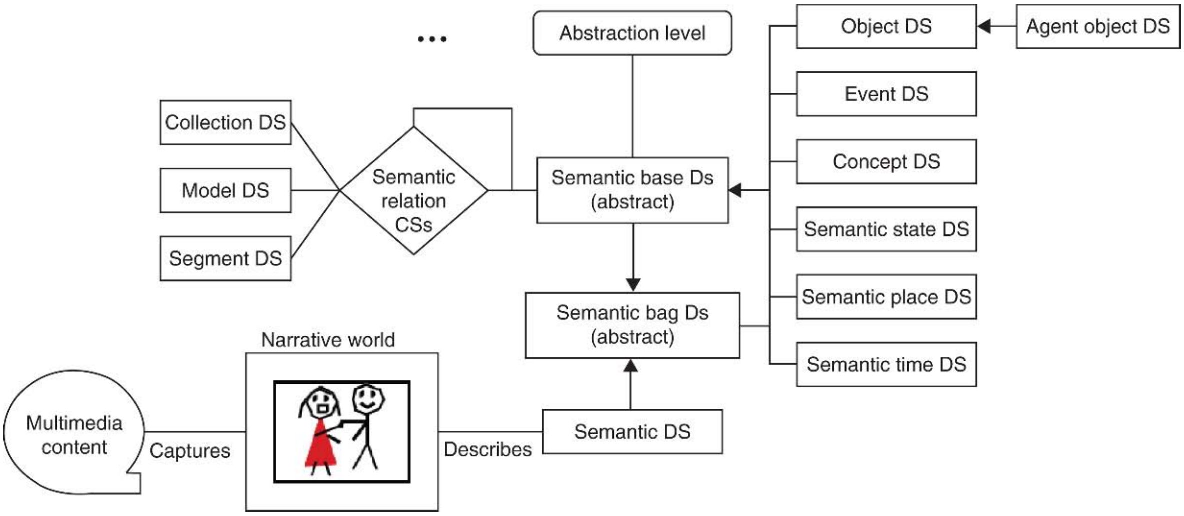
In MPEG-7's Part 5: Multimedia Description Schemes (MDS) the organization structure follows the overall hierarchical document structure, which at the end is instantiated as an XML schema file. Figure 2 visualizes description schemata that can be used to describe real-life concepts or narratives, which include objects, agent objects, events, concepts, states, places, times, and narrative worlds, all depicted by or related to video content. This means that the description schemata can be used to annotate the narrative in the video or the narrative world of the video, which then can be linked to the video.

The most relevant description schemata in Fig. 2 are:

- Semantic DS, which describes narrative worlds that are depicted by or related to the video content.
- Object DS, which describes objects in a narrative.
- AgentObject DS, which describes objects that are persons, organizations, or groups of people in a narrative.
- Event DS, which describes events in a narrative.
- Concept DS, which describes abstract semantic entities that cannot be described as abstractions of any objects, events, times, places, or states.
- SemanticState DS, which describes states or parametric attributes of semantic entities and semantic relations, at a given time or location in a narrative.
- SemanticPlace DS, which describes locations in a narrative.
- SemanticTime DS, which describes times in a narrative.

As often in MPEG-7, the description options are flexible, which allows the user to establish complex annotation structures. Yet, the taken approach also carries a number of problems, essentially:

- There are a great number of abstract elements, which are used to establish class structure. However,



Video Metadata. Figure 2. Illustration of the relationships of the tools for describing the semantics of video content.

abstract elements cannot appear in instantiations. When an element is declared to be abstract, a member of that element's substitutable class must appear in the instance document. To indicate that the derived type is not abstract, the XML namespace mechanism is used (xsi:type). Thus, a thorough understanding of schemata development is required, which makes instant schemata development for distinct domains hard, especially if the required schemata should cover simple descriptions, where the theoretical overhead is actually not required.

- The interlocked nature of schemata, providing an ontology-like yet general set of schemata for describing media semantics, makes it very difficult for a user to identify the appropriate schemata and to use them in isolation.
- Due to the lack of a fundamental data model the structures provided show inconsistencies and duplications, which makes manual schemata generation difficult.

There are, however, projects in real world domains, such as the TV Anytime Forum, that give an indication of how media-aware semantic structures, such as those provided by MPEG-7, will be used in the future. The TV Anytime Consortium (http://www.tvanytime.org) developed specifications for services based on consumer digital storage devices. The semantic structures, all written in XML Schema, are proprietary and cover the essential aspects of media description, i.e., content description, content referencing and location, rights management and protection, systems and transport. Though the TV Anytime schemata are similar to the equivalent structures in MPEG-7, they are less complex in their organizational structure. TV Anytime includes, for example, the MPEG-7 schemata on user-modeling, though without incorporating the complete MPEG-7 organizational overhead. Rather, TV Anytime uses MPEG-7 as a namespace and is thus able to incorporate only the required schemata.

Rights Management

MPEG-21 [10] addresses, among others, two important aspects when it comes to user interaction with video content (in fact MPEG-21 describes that for all types of multimedia): first the identification and declaration of video items, and second the description and protection of rights.

MPEG-21 is understood as a framework that supports users to access, exchange, trade and consume digital media. The basic unit for MPEG-21 is the Digital Item (DI) which can be distributed and on which transactions can be performed. The DI is defined as a "virtual container" for metadata (created based on MPEG-7) and content (in MPEG-1, MPEG-2 or MPEG-4 format). The Digital Item Declaration (DID) defines the resources (e.g., MPEG-4 files) and the related metadata (e.g., Dublin Core) which the author identified to be part of the DI. The Digital Identification framework then supports devices to uniquely identify various objects and items of the DI.

The provision of DIs only makes sense if there are mechanisms that allow to exploit those structures. For that MPEG-21 developed the Rights Expression

Language (REL), which is an XML-based machine-readable language that allows the specification of specific rights and conditions associated with the distribution of say video content. REL does not aim for replacing legal rights methods but rather specifies a grant specifying that a "principal" has a "right" over a "resource" under certain "conditions." REL is based on the Extensible Rights Markup Language (XCML) 2.0 which was selected by MPEG due to its expressiveness and unambiguaty. In addition MPEG-21 has designed the Rights Data Dictionary (RDD), which contains the key terms required to describe rights. Finally, the Intellectual Property Management and Protection Component (PMP) was established, which uses again metadata to allow the inclusion of protected and governed content into a DI. This mechanism facilitates terminals to process protected content. As MPEG-21 is at time of writing still relatively new the future has to show if that framework is functioning and thus will be accepted by the public.

Key Applications

The annotation of video is useful for the retrieval, reuse, manipulation, generation and distribution of video for domains, such as medicine, entertainment, distributed games, all sort of experience related applications and education.

Video Querying

Ichiro Ide
Nagoya University, Nagoya, Japan

Synonyms

Image Querying; Query by Example; Similarity in Video; Near-duplicate Video Retrieval

Definition

Video querying is a way to issue a query for retrieving video data from a database without explicitly expressing the contents of the video-in-search by high-level semantics, such as keywords. It, instead, expects that a user issues a query as a video segment in hand. The system will then search and retrieve similar video data from the database. Since video data is composed of sequences of still frame images, the search for similar video data in a database necessarily requires a huge computation cost when comparing the query with the data in the database. Thus, the main issue when processing a video query is to reduce both the computation time for the search itself, and for the comparison of image sequences, to evaluate the similarity of the video segments. Video querying is an efficient way to issue a query when a user already has in hand an exact or an extremely relevant segment of the video in-search. For specific genres of video data, such as those obtained from a fixed surveillance camera or sports programs, querying based on certain motions, gestures or trajectories can be useful. This kind of querying can also be considered as a kind of video querying in the sense that it handles a query as a time-sequence transition of an interest point. In most other cases, keyword-based querying can be more efficient and realistic in general.

Historical Background

Although there are some academic works that make use of video segments as queries [3], video querying is still not widely employed for the purpose of video retrieval in general. It has, however, been a key technology for some real-world problems.

Most early works that make use of video segments as queries, aim to detect advertisements from a broadcast video stream; when a source video segment (an advertisement) is given, the system returns where it appears (repeatedly) in the archived long video stream [4,6]. This is often used by commercial sponsors to monitor if a television broadcaster has actually aired an advertisement at specific hours and/or for specific times, according to the contract.

Recently, the technology has started to be applied by copyright holders for monitoring video data illegally distributed on the internet. While the advertisement monitoring task requires exact matching, this task needs to handle near-duplicate video data, which are almost identical but may have slightly changed from the original data during the distribution process. The changes may include size, frame rate, compression, editing (ex. insertion of captions and logos) and so on.

The easiest approach to compare a pair of video data is to do so frame-by-frame. This approach is, however, highly expensive in computation cost; not only that the comparison needs to be done as many times as the number of the frames, but also the cost to compare each frame is itself relatively high compared to audio or text data. Thus, the key to realize this technology in a realistic speed is to reduce the size of the feature, and also to reduce the times of comparison.

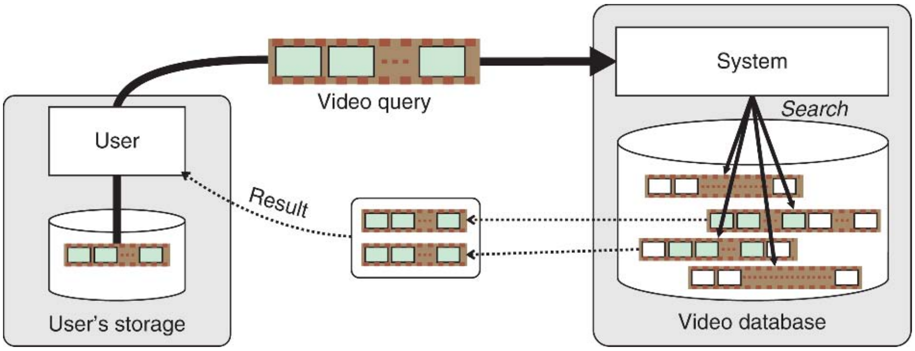
Foundations

Figure 1 shows the process flow of video querying. A user issues a query in the form of a video segment to a video database system. The query video segment should be readily available at the users hand, but it can also be provided externally through an interactive interface with a search function. For specific purposes such as action detection from fixed surveillance video, sports video, and so on, querying by motion, gesture, or trajectory [1, 2] can also be considered as a kind of video querying.

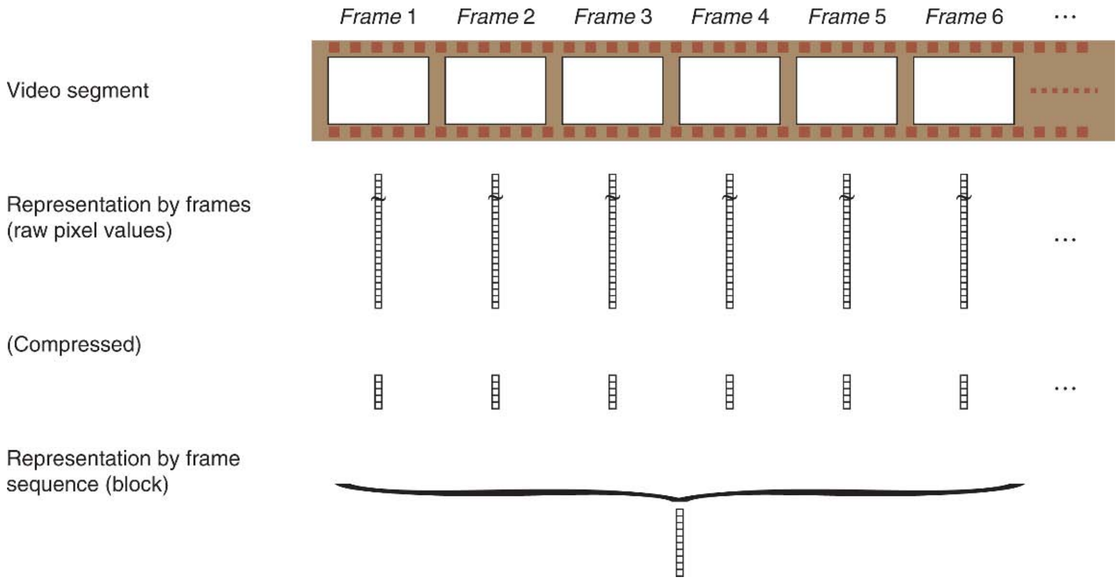
In order to process a video query, evaluation of the similarity between the query and the video data in the database is necessary.

The first question here is how to represent a video segment. Figure 2 shows an illustration of three representations explained below.

The simplest representation of a video segment is as a sequence of still frame images. Each image is represented by a feature vector composed of raw pixel values of all pixels in the frame image. It is, however, rarely the case



Video Querying. Figure 1. Process flow of video querying.



Video Querying. Figure 2. Representations of a video segment.

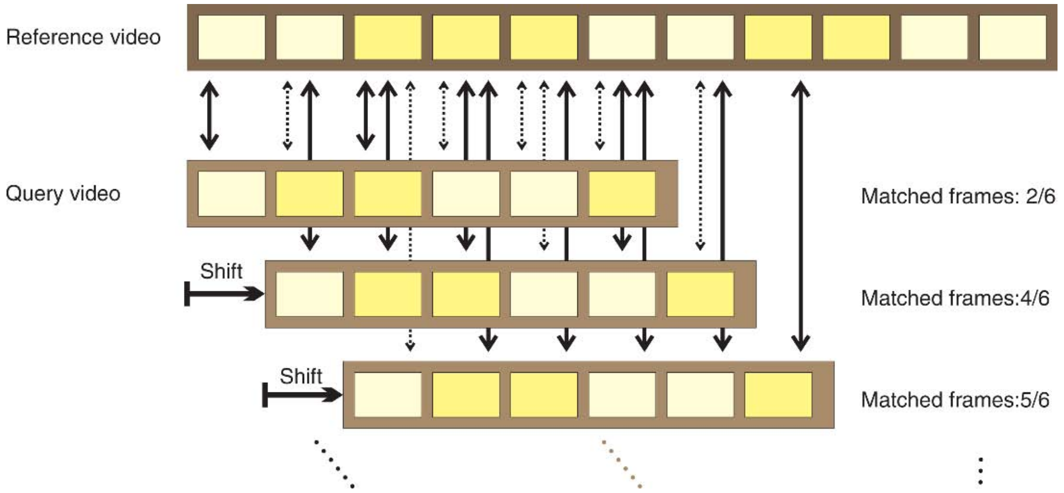
that exact pixel values between two video sequences are identical, due to noise, slight change of size / ratio, color adjustment, and so on. To cope with this problem, the image and the color resolutions are usually reduced, which is also the case for the original frame image used in the following two representations. Using raw pixel values is accurate, but the size of a feature vector tends to be large.

Since comparing large vectors is computationally expensive, it is better to reduce the size of a feature vector; the dimension of a feature space. Reduction of the dimension of a feature space can be done in various ways; from random sampling to hashing, signatures and transformations that preserve the original feature better by principal component analysis, and so on. On the other hand, the feature used to represent a frame can be more abstract features than the raw pixel values, such as edge, color histogram, or combinations of these features. In any case, representation in the compressed feature space does not usually guarantee the same distinguish ability as in the original feature space. When an identical result is needed, comparison in the original feature space after obtaining candidates in the compressed feature space is needed as a post-process in order to eliminate false positives. Note that in order to ensure that no false negative (oversight) exists among the candidates, the vector comparison method (distance measure) needs to theoretically guarantee it.

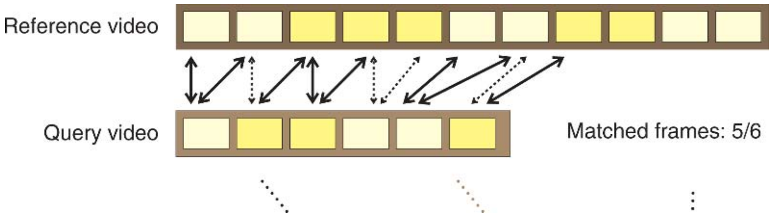
While the above two representations consider the feature of a video segment by a sequence of frame-wise features, it is more natural to represent a video segment by blocks of successive frames. In this case, image features from a fixed number of multiple successive frames represent a video segment. Ways to represent a block of frames can be a simple concatenation of frame-wise features (usually compressed afterwards), or can be more sophisticated features that make use of the redundancy of video data such as those used for video compression (MPEG and so on). This representation usually makes the comparison more robust and fast than the previous two representations, but it cannot represent, and accordingly compare and retrieve shorter segments than the block size.

The next question is how to compare the segments. Figures 3–5 show illustrations of the comparison methods explained below.

As shown in Fig. 3, the simplest method to compare the query video segment to the video data in the database (hereafter, “reference video”) is to compare it against all possible segments in the reference video. In this case, the query video is compared by shifting it frame by frame against the reference video until it reaches the end. For each iteration of the comparison, all frames are sequentially compared. This method is not robust even against slight change in the frame sequence; frame-rate, and editorial effects such as slow-motioning or fast-forwarding.



Video Querying. Figure 3. Simple frame-by-frame comparison.



Video Querying. Figure 4. Frame-by-frame comparison by continuous dynamic time warping (DTW), also known as DP-matching.

An improved version of this method that takes the above-mentioned weak-point in consideration, is the method that employs continuous Dynamic Time Warping (DTW; also known as DP-matching). This method allows the comparison of a query video frame to multiple (usually a fixed number of frames after the frame matched in the previous iteration) reference video frames. As shown in Fig. 4, the method could cope, to some extent, with temporal expansion and contraction in both sides of the comparison.

Although there are many works on speeding-up the above-mentioned methods, they essentially require large computation costs due to the frame-by-frame shift and comparison approach.

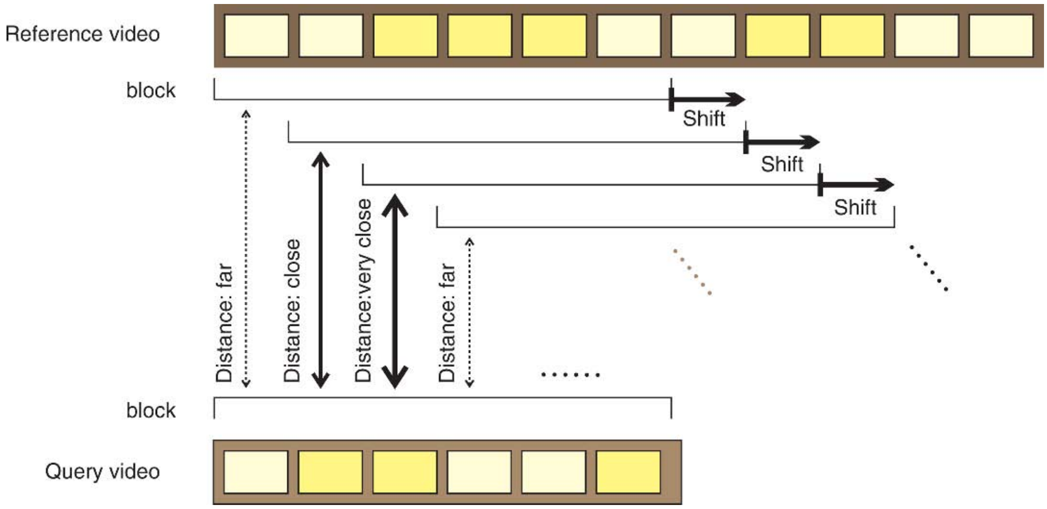
A different approach is to compare the video data as blocks of sequential frames. It does not necessarily have to be a simple concatenation of frame-wise features, but can be an integrated feature that represents the image features in the block. Block-wise comparison is robust to slight change of features in a frame sequence. Although in practice, it can tolerate time-wise expansion and contraction to some extent, it is mainly not due to the nature of the method, but rather due to the continuous nature of video contents. One of the fastest algorithm that takes this approach for video querying is the Time-Series Active Search method proposed by Kashino et al. [4], which reduces the computational cost by skipping the comparison under certain criteria.

Key Applications

As mentioned in the "Historical Background," the technology has been used by commercial sponsors of television programs and copyright holders of video contents.

Future Directions

Future applications include online retrieval of near-duplicate video data available on the internet. This application can be used not only for detecting illegal posting of copyrighted video data on the internet, but also for retrieval of web contents based on the video querying technology.



Video Querying. Figure 5. Comparison by block.

Another challenging task is to retrieve near-duplicate video segments from a video query based on feature points matching. This technology enables the retrieval of video segments shooting the same target from a different video camera, but current technology does not allow such processing in realistic time.

Video Representation

Ying Li
IBM T. J. Watson Research Center, Hawthorne, NY, USA

Synonyms

Video format; Video compression

Definition

Video representation, as the name implies, specifies a way of representing a video. While some work refers to video representation as the way to present or express video content through some extracted or summarized content units such as scenes or objects, the majority regard it more as the way the video content is stored. In other words, it is about *video format* which describes the sequence, structure and content of frames that create the moving video image, along with any possible audio or text (closed caption) information.

Historical Background

A video can be represented in either analog or digital formats. Typical analog formats include NTSC (National Television System Committee), PAL (Phase Alternating Line) and SECAM (Séquentiel couleur à mémoire, French for "Sequential Color with Memory,") which are commonly used in the domain of commercial broadcast. On the other hand, due to the rapid development of computer technologies, the continuously improved transmission rate and the increasing ubiquity of digital video capturing devices such as digital cameras and camcorders, digital videos have become widely available. This has entailed the development of various kinds of digital video formats suited for various purposes. Some of the most popularly used ones are DVD (Digital Versatile Disc), QuickTime, H.261, H.263, H.264, MPEG-1 (Moving Picture Experts Group), MPEG-2, and MPEG-4.

Digital video was first introduced commercially in 1986 with the Sony D-1 format, which recorded an uncompressed standard definition component video signal in digital form instead of the high-band analog forms that had been commonplace until then. Due to the expense, D-1 was used primarily by large television networks. It was eventually replaced by cheaper systems using compressed data.

Consumer digital video first appeared in the form of QuickTime around 1990, which is Apple Computer's architecture for time-based and streaming data formats. Also around the same time, the ITU-T (Telecommunication Standardization Sector of International Telecommunication Union) Video Coding Experts Group (VCEG) developed H.261 standard which aims for video transmission over ISDN (Integrated Services Digital Network) lines whose data rates are multiples of 64 kbit/s [6]. Based on the experience from H.261, H.263 was developed, which is a low-bitrate compressed format for video-conferencing [7]. Its first version was completed in 1995 and provided a suitable replacement for H.261 at all bit rates. The next enhanced compression mechanism developed by ITU-T VCEG is the H.264 standard, also known as AVC (Advanced Video Coding) and MPEG-4 part 10. H.264 provides a significant improvement in capability beyond H.263 [8]. Now, most new video-conferencing products include H.264 as well as H.263 and H.261 capabilities.

Along the same direction, but targeting at different commercial applications, the Moving Picture Experts Group (MPEG) was formed in 1998 to establish an international standard for the coded representation of moving pictures and associated audio on digital storage media. So far, there have been three established MPEG standards: MPEG-1, MPEG-2, and MPEG-4. Specifically, MPEG-1 was originally designed to achieve VHS-video quality at 1.5 Mbit/s data rate [2]. MPEG-1 video is usually used for the Video CD (VCD) format. Compared to MPEG-1, MPEG-2 targets at a very high bandwidth with up to 40 Mbits/s data rate, and is widely used as the format of digital television signals that are broadcast by terrestrial (over-the-air), cable, and direct broadcast satellite TV systems [4]. It also specifies the format of movies and other programs that are distributed on DVD and similar disks. In late 1998, an effort on MPEG-4 was initiated which added many new features such as VRML (Virtual Reality Modeling Language) support for 3D rendering, object-oriented composite files (including audio, video and VRML objects), support for externally-specified Digital Rights Management (DRM) and various types of interactivity, besides absorbing many features from MPEG-1 and MPEG-2 [5]. Major MPEG-4 applications include streaming media on web, video-phone and broadcast television.

Foundations

Basics of Video Representation

Frame is the fundamental building block of a video, which is basically a rectangular image consisting of a series of lines, known as scan lines. A scan line contains a given number of pixels, and a pixel is represented by a certain number of bits (*a.k.a.* bits per pixel or bpp). A frame can consist of two or more fields, which are sent sequentially and displayed over time to form a complete frame. This kind of assembly is known as interlace. An alternative way is to send the entire frame as a single entity, which is known as a progressive scan frame.

The basics that are needed to represent a video or to define a video format is listed below.

- *Video resolution*, which equals the frame size measured in pixels.
- *Aspect ratio*, which describes the dimensions of video screens and video picture elements or pixels. The screen aspect ratio of a traditional television screen is 4:3, while a high definition television is 16:9. On the other hand, while pixels on computer monitors are usually square, pixels used in digital videos usually have non-square aspect ratios.
- *Color space*, which specifies the video's color representation. For instance, the YUV color model where Y stands for the luma component (the brightness) and U and V are the chrominance (color) components, is used in the PAL, NTSC, and SECAM composite color video standards. Other popularly

used color models include RGB (Red, Green and Blue components) and YCbCr (Y for luma component, Cb and Cr for the blue and red chroma components).

- *Depth of color*, which indicates the number of distinct colors that could be represented by a pixel. This depends on the number of bits per pixel (bpp).
- *Interlacing* or *progressive*. Interlacing was invented as a way to achieve good visual quality within the limitations of a narrow bandwidth. The horizontal scan lines of each interlaced frame are numbered consecutively and partitioned into two fields: the odd field (upper field) consisting of the odd-numbered lines and the even field (lower field) consisting of the even-numbered lines. NTSC, PAL and SECAM all use interlaced formats. In contrast, with progressive scan systems, each refresh period updates all of the scan lines. This results in a higher perceived resolution and a lack of various artifacts that can make parts of a stationary picture appear to be moving or flashing.
- *Frame rate*, which indicates the number of frames per time unit of the video. PAL and SECAM standards specify 25 frames per second (fps), while NTSC specifies 29.97 fps. Film is shot at a slightly lower frame rate of 24 fps. Generally speaking, the minimum frame rate for achieving an illusion of moving images is about 15 fps.
- *Bit rate*, which measures the rate of the information content in a video stream. Bit rate is only defined for digital videos, and is usually quantified in units of bit per second (bit/s or bps) or Megabit per second (Mbit/s or Mbps). A higher bit rate generally indicates a better video quality. For instance, VCD has a bit rate of about 1 Mbps while DVD, which has a much better quality, has a bit rate of around 20 Mbps. Variable bit rate (VBR) is a strategy to maximize the video quality and minimize the bit rate. For fast motion scenes, VBR uses more bits than it does for slow motion scenes of similar duration to achieve a consistent visual quality. However, for real-time and non-buffered video streaming applications where the available bandwidth is fixed, *e.g.*, for video-conferencing delivered on channels of fixed bandwidth, a constant bit rate (CBR) must be used.

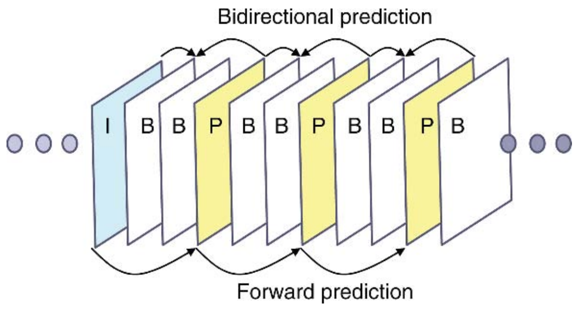
Video Compression

A video can occupy a vast amount of storage space when represented in digital form. For instance, suppose the video frame is of size 360 pixels by 288 pixels, and each pixel uses three color primaries with 8-bit precision for each color component, then each frame will occupy approximately 311 Kbytes. Further assume that the video is sent uncompressed at 24 frames/s, then the raw data rate for the video will be about 60 Mbps, which quickly amounts to 448 Mbytes for a 1 min video clip [10]!

Undoubtedly, there is a need of some techniques to compress or reduce the amount of video data so that videos can be conveniently and efficiently stored, transmitted and delivered, while retaining the original video quality as much as possible. Many research efforts on video compression started to emerge in 1990s. However, while there have been various kinds of compression techniques being proposed and standardized for various different application areas, most of them are based upon the same fact that video data contains both spatial and temporal redundancy. Specifically, to reduce the spatial redundancy, an intra-frame compression is applied which registers differences between parts of a single frame. On the other hand, to reduce the temporal redundancy, an inter-frame compression is exploited which registers differences between neighboring frames.

Below the basic spatial and temporal compression techniques that are applied in MPEG-1 video, are briefly discussed. Many other popularly used video compression standards such as H.261, H.263, H.264, MPEG-2 and MPEG-4, are more or less built upon similar techniques with certain improvements, extensions and modifications so as to meet different application requirements. These compression, together with the corresponding decompression algorithms are generally implemented in computer softwares as video codecs.

Frame Types in MPEG-1 There are basically three different types of frames in MPEG-1, namely, I-frame, P-frame and B-frame. Specifically, I-frames, also known as intra-coded frames, are coded independently without reference to any other frames. In contrast, P-frames (predictive-coded frames) obtain predictions from temporally preceding I- or P-frames in the sequence, which is known as forward prediction. Between the I- and P-frames, there may be zero or more bidirectionally predictive-coded frames, or B-frames. B-frames are interpolated between the preceding and/or upcoming I- or P-frames in the sequence. Figure 1 shows a group of pictures consisting



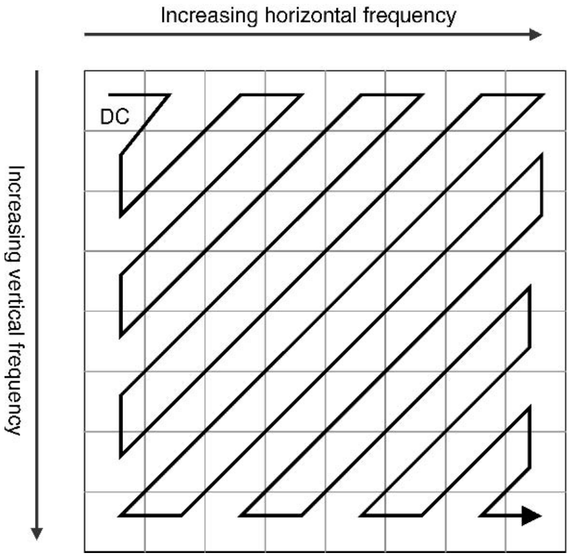
Video Representation. Figure 1. A typical group of pictures in display order in MPEG-1.

of one or more pictures of the three different types of frames.

Two different compression techniques are thus developed to code these three different types of frames. Specifically, intra-frame compression is applied to code I-frames, while inter-frame technique is applied to P- and B-frames. Both techniques are briefly discussed in the following sections.

Intra-Frame Compression *Macroblock*, which is a very important concept in MPEG coding, forms the basic building block of a coded frame. Specifically, a macroblock consists of a 16 sample array of luminance (grayscale) samples together with one 8 × 8 block of samples for each of two chrominance (color) components. The 16 sample array of luminance samples is actually composed of four 8 × 8 blocks of samples, which form the units of data that are actually fed to the compression models. Notice that a lower resolution is used for the chrominance blocks because the human eyes resolve high spatial frequencies in luminance better than in chrominance.

At the heart of both intra-frame and inter-frame coding in MPEG is a mathematical transform known as discrete cosine transform (DCT). DCT transform is a mapping function from time or space domain to frequency domain. Given an 8 × 8 image block, a DCT transform will convert it into 64 DCT coefficients. Among them, the first coefficient is called *DC coefficient* or DC term, and the others, *AC coefficients.* Specifically, the DC coefficient contains the block's average intensity, *i.e.*, the low frequency information, while the rest 63 AC coefficients contain high frequency information. Figure 2 shows the zigzag ordering which approximately orders the DCT coefficients in ascending spatial frequency.



Increasing horizontal frequency
Increasing vertical frequency
DC

Video Representation. Figure 2. Zigzag scanning order of DCT coefficients.

The advantages of applying DCT in the compression models are twofold: i) it de-correlates the original signal. That is, the 64 DCT coefficients are independent of each other, thus they can be coded separately; ii) it distributes the signal energy to only a small set of coefficients. Generally speaking, after the transform, many AC coefficients in high frequencies will be very small, which may be discarded without, or with little, loss of visual quality.

After each of the four 8 × 8 blocks of luminance samples and two 8 × 8 blocks of chrominance samples of a macroblock is processed by the DCT, a quantization process is carried out on the obtained DCT coefficients, which aims to represent the coefficients of high spatial frequencies with less precision. Specifically, it divides and truncates each of the transformed coefficients by individual quantization values. These values are usually given in a quantization matrix, which typically contains higher values towards the lower right, thus giving several of the less important coefficients at high spatial frequencies a zero value. This allows the encoder to selectively discard non-important high frequency activity that the human eye cannot readily perceive.

The next step is to code the resulted DC and AC coefficients. Specifically, as there could be some correlation between the DC coefficients of neighboring blocks, the DC term is coded separately from the AC terms using a predictive DPCM (differential pulse code modulation) technique. As for AC terms, they are first arranged qualitatively from low to high spatial frequency following the zigzag scan order as shown in Fig. 1. Such zigzag scan approximately orders the coefficients according to their probability of being zero. Finally, each nonzero AC coefficient is coded using a so-called *run-level* symbol structure where run refers to the number of zero coefficients before the next nonzero coefficient, and level refers to the amplitude of the nonzero coefficient. For more details on this part, please refer to [10].

Inter-Frame Compression Compared to the intra-frame compression, the inter-frame compression codes the difference between a frame and its reference frames, thereby exploiting the similarities or temporal redundancy from one picture to the next.

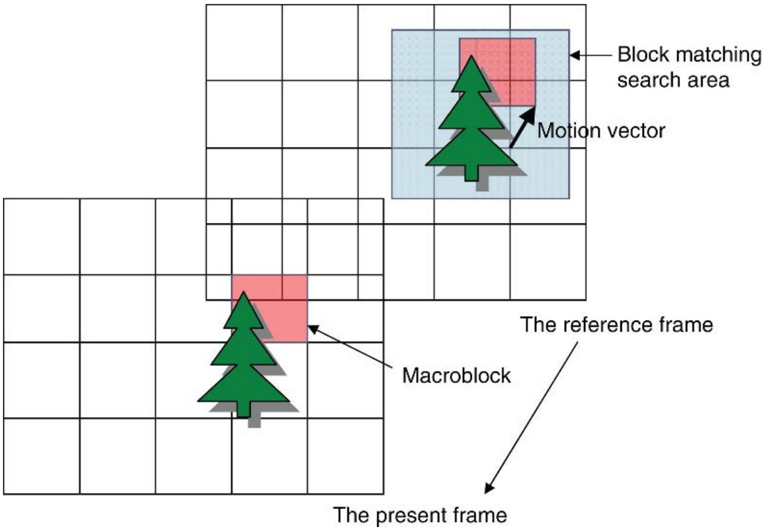
The most important concept in inter-frame compression is *motion estimation*. Specifically, motion estimation refers to the determination of the motion displacement between two frames which is expressed by motion vectors. In real video scenes, motion can be a complex combination of translation and rotation, which could be very difficult to estimate and may require large amount of processing. Nevertheless, translational motion could be easily estimated and has been successfully used for motion compensated coding.

There are two main classes of motion estimation techniques, namely, *pel-recursion* and *block matching*. Pel-recursion techniques are used primarily for systems where the motion vectors can vary from pixel to pixel. In contrast, in block matching techniques, there is only one single motion vector applied to a block of pixels. Due to its simple hardware realization and less computational complexity, the block matching approach has been more popularly used.

Figure 3 shows the basic idea of the block matching approach. Specifically, for each macroblock in the present frame, it is matched against a candidate block within a search area on the reference frame. If a good match is found based on certain criterion such as MSE (mean square error) and MAD (mean absolute distortion), the current macroblock will be represented by a motion vector pointing to the reference block, along with the DCT-coded residual. Otherwise, the macroblock will be intra-coded. Note that for B-frames, there are even more options for coding a macroblock, it could be forward predicted using the preceding I- or P-frame as the reference, backward predicted using the next I- or P-frame, and bidirectionally predicted using both preceding and succeeding I- or P-frames. Moreover, to achieve an even higher compression ratio, some macroblocks can be skipped.

Audio Compression

When a video stream also contains audio information, some kind of audio compression algorithm is usually



Video Representation. Figure 3. Block matching based motion estimation.

applied to condense the audio data, in addition to the aforementioned video compression. Generally speaking, many video codecs such as those introduced earlier (MPEG-1, MPEG-2, H.263 and H.264) also have corresponding specifications on encoding the embedded audio signals. For instance, MPEG-1 has defined three layers of audio coding in the ascending order of coding complexity: MPEG-1 Audio Layer 1 (MP1), Audio Layer 2 (MP2) and Audio Layer 3 (MP3) [3]. Below, a very high-level discussion on audio coding is given.

As with image or video compression, both lossy and lossless compression algorithms are used in audio compression. In both cases, techniques such as coding, pattern recognition and linear prediction are applied to reduce the amount of redundant information within the data. However, while lossless compression is good for the archival purpose, it generally produces much lower compression ratios due to the nature of audio waveforms and the fast-changing values of audio samples. Consequently, the lossy audio compression is much more popular. So far, it has found applications in video DVDs, digital television, streaming media, satellite and cable radio.

The key breakthrough in lossy audio compression is to rely on psychoacoustic models to identify the important audio signals that must be preserved, while throwing away unimportant ones. For instance, signals that can be perceived by the human auditory system must be kept, while perceptually irrelevant sounds could be ignored or coded with decreased accuracy as they are anyway very hard to hear. Typical examples of such sounds are those that have very high frequencies, or those that occur at the same time with other much louder sounds.

In particular, the following four human hearing characteristics, as recognized by the psychoacoustic model, are exploited in audio compression: *human hearing sensitivity*, *frequency masking*, *temporal masking* and *critical bands*. Specifically, by carefully conducting experiments, it is found that the general range of human hearing is from 20 Hz to 20 kHz, and the most sensitive range is from 2 kHz to 4 kHz. By frequency masking, it refers to the phenomenon in which a weak signal is made inaudible (*i.e.*, masked) by a simultaneously occurring stronger signal. In contrast, the temporal masking indicates the phenomenon in which a soft tone could not be heard immediately when there is a loud sound nearby. Finally, critical bands are obtained using a bandwidth classification scheme such that within each band, the width of frequency masking region is approximately uniform. As it could be seen that, by relying on these four characteristics, the compression algorithm could save bits on signals that are either out of human hearing ranges, temporally masked, or frequency masked within a critical band. During the actual coding, specific masking thresholds will be calculated by the psychoacoustic model to determine the audibility of each spectral component within particular critical band.

There are two general types of audio coding schemes, one in the frequency domain and the other, the time domain. Transform coding and subband coding belongs to the first category, while PCM (pulse code modulation), DPCM (differential pulse code modulation) and ADPCM (adaptive differential pulse code modulation) are in the second category.

Streaming Videos

Since the late 1990s, there have been some great advances in computer networking such as a higher network bandwidth, an increased access to networks, especially, the Internet, a widely accepted use of standard protocols and formats including TCP/IP (transmission control protocol/Internet protocol), HTTP (hyper text transfer protocol), and HTML (hyper text markup language), and the commercialization of the Internet. These advances, combined with increasingly powerful home computers and modern operating systems, have made streaming media practical and affordable for ordinary consumers.

By definition, streaming videos are the videos that are continuously received by and displayed to the end-users while the videos are being delivered from the providers. The name "streaming" refers to the delivery method of the medium rather than the medium itself. A video stream can be either *on demand* or *live*. On demand streams are stored on a server for a long period of time, and are available to be transmitted at a user's request. Live streams are only available at one particular time, such as the video stream of a live sporting event.

Some popular streaming video and streaming media technologies include Microsoft Windows Media, RealMedia from RealNetwork, Quicktime, MPEG-4, and Adobe Flash. And some major streaming video content providers include YouTube, Google Video, Netflix, Stage 6, and Metacafe.

Key Applications

With the proliferation of videos across the world, how to efficiently and effectively store, process, transmit, deliver and present them to end users has become an increasingly popular research topic. Video representation is undoubtedly one of these important issues. On one hand, the wide availability of videos has motivated the development of advanced video compression techniques, yet on the other hand, accomplishment achieved in the compression areas has made videos further distributed.

The benefits brought by efficient video representation are significant. Some popular applications that take advantage of advanced video compression techniques include: (i) HDTV and mobile broadcast terrestrial digital television (DTV); (ii) gaming consoles; (iii) network database services such as video library and video information provider; (iv) video on demand (VOD); (v) digital storage media such as CD-ROM videos, DVD movies and digital recorders; (vi) interactive communications such as two-way video phones, video-conferencing and videotex; and (vii) video surveillance.

Future Directions

Approximately every 3 to 4 years, a significantly new standard on video compression is developed. The latest generation is the MPEG-4 Part 10 advanced video coding (AVC). This is also known as the H.264 standard and is developed to achieve broadcast-quality video at much lower bit rates. The algorithm offers compression percentages that are twice as much as those offered by MPEG-4 Part 2 with the same image quality. It is also designed for a wide variety of consumer and pro AV (audiovisual) applications including TV set-top boxes and DVD players. MPEG-4 Part 10 (or H.264) improves older compression schemes by using significantly more sophisticated predictive coding, as well as variable block-size motion compensation and variable block-size integer discrete cosine transform [8]. However, the not-so-good news about MPEG-4 AVC is that it is extremely computation-intensive and requires a very high horsepower hardware platform to correctly implement it [9].

H.264 is now still in its preliminary stage in terms of adoption, although many vendors and analysts believe that it will eventually grab a big market share. It is expected that H.264 will be used by many digital video delivery networks and the new DVD standards such as high definition (HD)-DVD and Blu-Ray.

Another two directions to watch for future video compression are object-based video coding and scalable video coding (SVC). The basic idea of object-based video coding is to first segment a video scene into objects, then code them separately. MPEG-4 has actually explored such idea in its video codec, nevertheless, as object segmentation is a fairly challenging task and remains to be an open research topic, such object-based video coding still has a long way to go before it can truly take off. As for the scalable video coding, it is sort of a natural follow-on of H.264. In particular, it aims to provide a better way for dealing with wild cards such as disparate network types and different endpoint abilities, including display resolution and processing power [1].

In a word, while the network bandwidth has constantly increased in recent years, the emerging of high-definition videos effectively cancels out some of these gains. Moreover, considering the formidable high bit-rate of raw video data, video compression techniques are bound to be in great need for the future.

Video scene and event extraction

Definition

A video scene, also called a Logical Story Unit [7] or simply a story unit, can be defined as a semantically related consecutive series of image frames that depicts and conveys a high-level concept such as *event*, *topic*, *object*, *location*, and *action*, which constitutes a story in a video. Especially, an event can be defined as an incident or situation, which occurs in a particular place during a particular interval of time, for example – homerun in a baseball game, actor's entrance on stage, car explosion on a highway, etc. Under these definitions, video scene and event detection is to find all video intervals corresponding to a specific event from a given video.

Historical Background

Video scene and event detection has been an active research area in the community of multimedia signal processing and computer vision, and has attracted much interest in many applications such as multimedia information retrieval, video archive indexing and management, real-time adaptive streaming, and security monitoring.

For example, in sports videos, various score event scenes, e.g., touchdown in American football, homerun in baseball, and 3-point shoot in basketball are actually what viewers want to watch. Video retrieval based on such events is a typical example of multimedia information retrieval. Real-time adaptive streaming can also be achieved by transmitting only these score event scenes with full motion audio-video, while transmitting other irrelevant video segments with less information such as only keyframes. In addition, *annotations* of each event scene about "Five Ws and One H" – who, when, where, what, why, and how – are of much importance because such data enables efficient and effective video archive indexing and management. Event detection provides when and what attributes, e.g., *the homerun* in *the top of the 8th inning*. As another example, the security monitoring can be realized by detecting unusual events in surveillance videos in order to reduce the volume of data presented to security personnel. As can be seen, video scene and event detection is one of the most important tasks in video content analysis.

Foundations

Video scene and event detection requires both video scene detection and event detection. Here, note that the target events can be categorized into two types: *known* and *unknown* events. For both types of event, shot detection, where a *shot* is defined as a set of contiguously recorded image frames, is usually the first step towards video scene and event detection. For unedited continuously captured videos, this can be realized by segmenting the video into fixed-length units. After that, there are mainly two types of approach: i) detecting events and scenes simultaneously based on heuristically/statistically determined rules, and ii) detecting scenes first and then classifying the detected scenes into predefined event classes. Both approaches can be applicable to detect known events, while the latter approach is usually used for detecting unknown events. More details are discussed below.

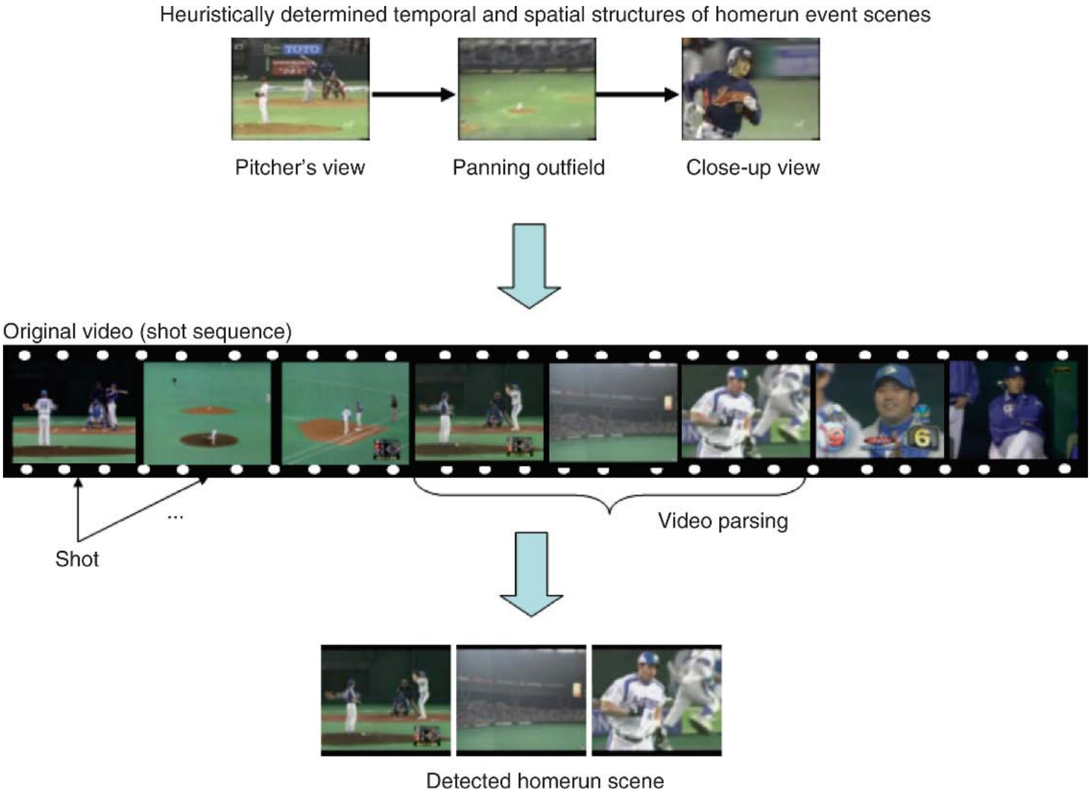
The primary event detection approach is to detect known event scenes based on heuristically determined rules. An example of known events is *homerun* in a baseball game. Broadcast baseball videos usually have

V

well-defined structures, for example, a typical home-run event usually consists of three or more shots, which starts from a pitcher's view, followed by a panning outfield and audience view in which the video camera tracks the flying ball, and ends with a global or close-up view of the player running to home base. These elemental shots consist of characteristic low- to mid-level image features such as color, texture, shape, motion, object trajectories, and human faces. Therefore, according to such *domain knowledge*, a series of certain types of shots is heuristically predefined as the temporal and spatial structures of the event scene, and then a video is parsed to find the corresponding event scenes as shown in Fig. 1.

It is noted that the approach discussed above focuses on single modality of the video data, in this case, the image stream. The single modality based approaches have low computational load, but the accuracy of event detection is low, as only using single modality is not able to fully characterize the events. For example, there are several cases for touchdown in American football games, such as the touchdown by pass, by running, and after turnover. It is not easy to construct a compact visual model that covers a number of cases of concern.

Alternatively, great emphasis has been placed on multimodality of the videos in recent years [2,3,8,11,13]. As is well known, the video data is composed of temporally synchronized *multimodal streams*: visual, auditory, text, and graphics streams, which are closely related to each other. The visual stream is a sequence of image frames, and the auditory stream is a mixture of a couple of auditory sources such as speech, music, and sound. In addition, the closed caption (CC) text, which is a transcript of the speech part of the auditory stream, can be viewed as the text stream for broadcast videos. The graphics stream is a sequence of overlays or video captions that have rich information about the content of the video data. The aim of multimodality based approaches is to improve the reliability and efficiency in analyzing the semantic content of videos. Although the computation for analyzing the visual stream is most costly, the use of other streams may be capable of reducing it. It should also be added that external metadata such as scenarios and web-cast game statistics is often used as one of the multimodal



Heuristically determined temporal and spatial structures of homerun event scenes

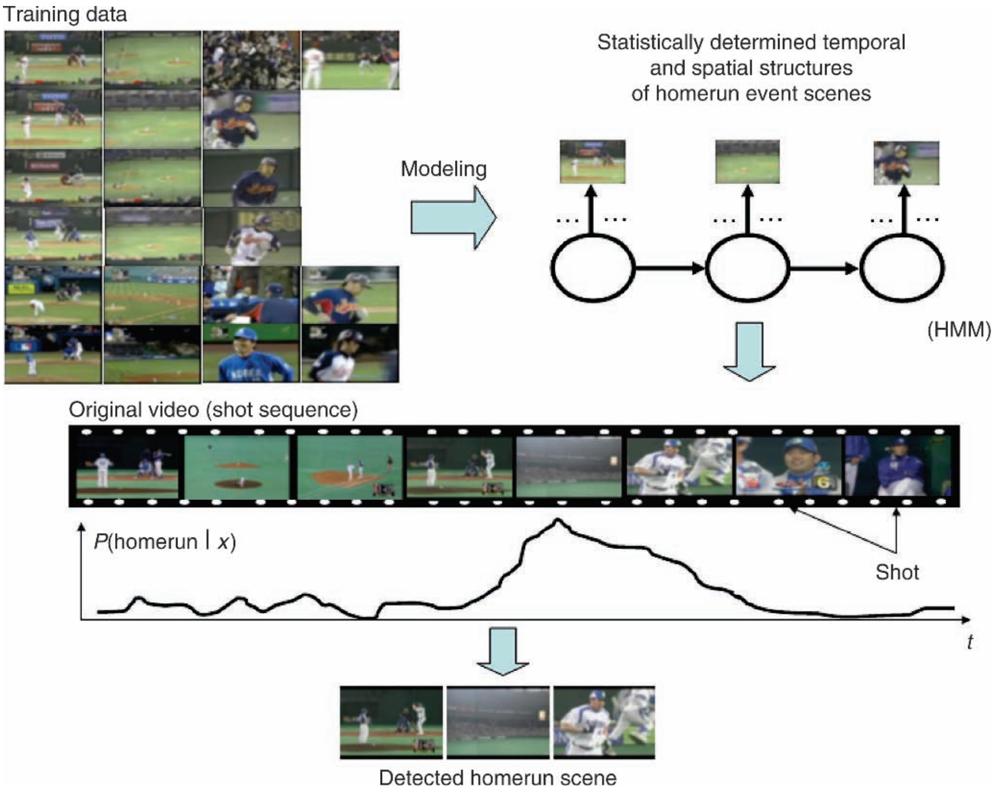
Detected homerun scene

Video Scene and Event Detection. Figure 1. Heuristically determined rule-based approach for known events.

streams [4]; however, since the metadata is generally created independently from the video, it needs to be synchronized with other streams according to the semantic content at some point. Note that these multimodal streams are also used for other types of approaches described later.

These traditional rule-based approaches, where humans have to discover the domain knowledge and encode it into a set of programming rules, are too costly and incompetent for multimedia content analysis because knowledge for recognizing high-level events could be very complex, vague, or difficult to define. Therefore, on alternative solution is to use statistical models to learn the temporal and spatial structures of the event scene from training data which is given beforehand as shown in Fig. 2. Hidden Markov Models (HMMs), being a popular choice for probabilistic representation of sequences, are often used to learn these structures of a specific event and to detect the corresponding scenes from the video [15]. Several effective extensions to HMMs have been used to model more complex structures and to achieve better performance; especially, the coupled HMM (CHMM) has been developed to model interacting processes of multimodal streams.

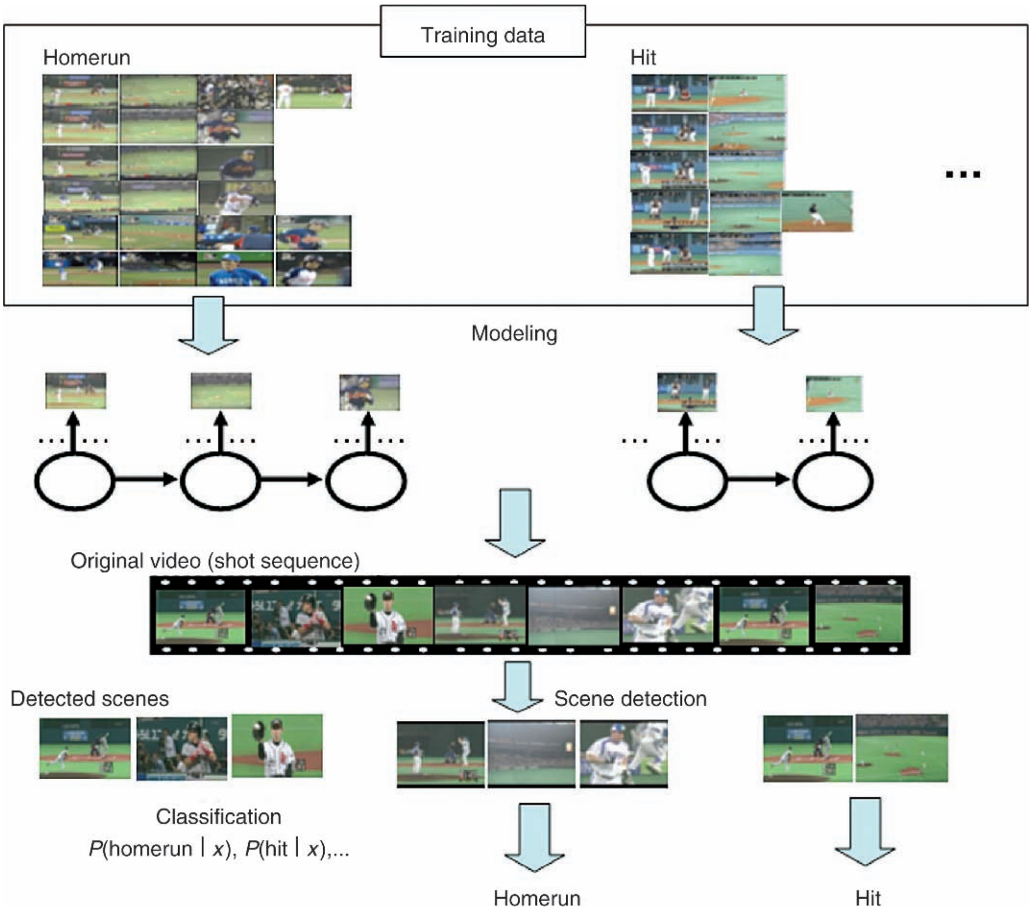
Now, there is a different type of solution for event detection, which is to firstly detect scenes and then classify the detected scenes into predefined event classes. In this case, semantically related shots are firstly grouped into a scene under the assumption that semantically related shots are usually temporally close to each other and have visual/audio similarity [7,9,10,12]. For example, if a person is talking in different shots, his/her speeches in these shots should present similar audio characteristics and these shots can be grouped as a scene. Then, the detected scenes are classified into a certain number of event classes based on the statistical model of each event [1]. More precisely, given a finite set of event classes $C = \{1,2,\ldots,K\}$ and a scene s, probabilistic classification methods typically compute the probabilities $P(k|s)$ that s belongs to class $k \in C$, and then classify



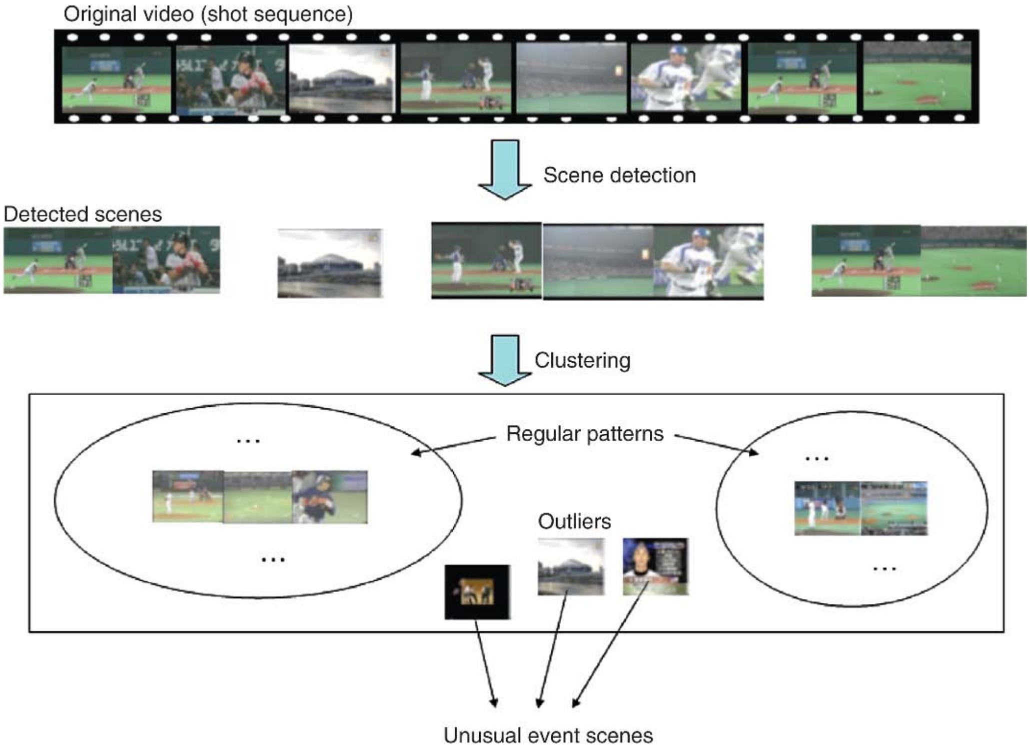
Video Scene and Event Detection. Figure 2. Statistical model-based approach for known events (with scene segmentation).

s into the class l that has the highest conditional probability $l = \mathrm{argmax}_k\, P(k|s)$. Figure 3 shows the schematic diagram of this approach. In general, there are two ways of learning $P(k|s)$: generative and discriminative. Discriminative models strive to learn $P(k|s)$ directly from the training set without the attempt to model the observation s. Generative models, on the other hand, compute $P(k|s)$ by first modeling the class-conditional probabilities $P(s|k)$ as well as the class probabilities $P(k)$, and then applying the Bayes' rule as follows: $P(k|s) \propto P(s|k)P(k)$. Popular generative models include HMMs, while representative discriminative models include Support Vector Machines (SVMs) [6].

Although high classification accuracy can often be achieved by these statistical model-based approach, the drawback is that the model developed for one application usually does not fit for others. For example, the homerun model developed for baseball games is obviously not suitable for detecting the 3-point shoot scenes in basketball videos. Similarly, when detecting unknown events, it is quite unnatural to have their statistical models created from the training data since there would be so much variety for unknown events. Recently, much work has been done to detect unusual events as unknown events. The basis of detecting unusual events is the notion of usual events and an underlying distance/similarity metric. The existing work mainly solves this problem by finding regular patterns, which are typically found with clustering operations on a given dataset, as usual events. Here, unsupervised classification methods automatically partition the given data set into the predefined number of clusters. Some methods are even able to automatically guess the optimal number of clusters into



Video Scene and Event Detection. Figure 3. Statistical model-based approach for known events (without scene segmentation).



Video Scene and Event Detection. Figure 4. Statistical model-based approach for unknown events.

which the given data set should be partitioned. Then, unusual events are detected by finding outliers that do not fit the current set of usual event clusters [5] as shown in Fig. 4.

Key Applications

Video Indexing Systems: are used to insert metadata about events for the corresponding video scenes so that they can be easily found at a later time.
Video Scene Retrieval Systems: are used to find one or more media clips that match an event-based user query, which can be specified in a variety of ways, such as text and some media examples.
Video Summarization Systems: are used to represent one media clip or a collection of clips in a condensed form. The presentation style includes the *storyboard*, where the representative images of all/important events are displayed in the spatial layout, and *skims*, where only the important event scenes are concatenated. Event metadata can help decide which part of the content shall be presented or emphasized in a concise and coherent manner.

Future Directions

Despite a great amount of research efforts, the success of video scene and event detection methods is limited due to the big *semantic gaps* between the low-level features used by these systems and the high-level semantics of events, that is, the low-level features such as color, texture, and motion are insufficient to capture the intrinsic nature of events even throughout the videos of the same genre, mainly due to the differences of their recorded situation. Therefore, a conclusion that can be drawn here is that the key to the success of video scene and event detection systems lies in the degree to which the semantic gaps can be bridged.

Experimental Results

Common evaluation measures for event detection are:

$$precision = \frac{the\ number\ of\ correctly\ detected\ events}{the\ number\ of\ all\ detected\ events}$$

$$recall = \frac{the\ number\ of\ correctly\ detected\ events}{the\ number\ of\ the\ events\ that\ should\ be\ detected}.$$

In general, for most existing methods, there are accompanying experimental evaluations with these measures; however, it is quite difficult to compare their performances since a different dataset is used in these experiments.

Data Sets

The TREC Video Retrieval Evaluation (TRECVID) [14], sponsored by the National Institute of Standards and Technology (NIST) and other U.S. government agencies, has been used as a benchmark dataset to encourage research in video content analysis. Although video scene and event detection has not been explicitly stated as their tasks, there are some related tasks, e.g., story segmentation can be considered as the equivalence to scene detection and high-level feature extraction includes the detection of events such as Monologue, Physical violence, People walking, and Airplane takeoff. Further usage of such benchmark datasets is expected for video scene and event detection in order to create objective measurements of the performance of each approach.

Definition

Video (temporal) segmentation is the process of partitioning a video sequence into disjoint sets of consecutive frames that are homogeneous according to some defined criteria. In the most common types of segmentation, video is partitioned into *shots*, *camera-takes*, or *scenes*. A *camera take* is a sequence of frames captured by a video camera from the moment it starts capturing to the moment it stops. During *montage*, camera takes are trimmed, split, and inserted one after the other to compose an *edited version* of a video. The basic element of an edited video is called *shot*. A *shot* is a contiguous sequence of frames belonging to a single camera take in an edited video. Content-wise, shots usually possess some degree of visual uniformity. A *scene* is a group of contiguous shots that form a semantically meaningful set.

If a video V is represented as a finite sequence of frames $V = (f_1,\ldots,f_n)$, the temporal segmentation $S(V)$ of a video is a partition of the video into non-overlapping *video segments* v:

$$S(V) = \{v_1, v_2,\ldots,v_m\},$$

with $v_i \cap v_j = \phi$ and $\cup v_i = V \quad \forall i,j \in [1,\ldots,m]$, where a *video segment* is a finite sequence of consecutive frames $v = (f_p,\ldots,f_q\} \quad 1 \leq p \leq q \leq n.$

Historical Background

There have been many reports in the literature on methods for video shot-cut detection. The first report was published in 1992 (from a conference held in 1991) by Nagasaka et al., and described a way of indexing video objects by first detecting video cuts and then finding important objects in those frames [6]. Some of the reported methods worked on various ways of comparing pixel differences between frames. The methods presented in [5–7] operated in the spatial domain. In order to analyze an MPEG or motion JPEG stream, the frames in the stream would have to be fully decompressed, which was very computationally expensive. Later, other techniques have been applied in the compressed domain [2,12]. Some of these techniques require images obtained from an uncompressed stream to be fully compressed to take advantage of some of their special features. A method that was introduced by Swanberg et al. [7] actually went beyond the notions at that time that "cutting" and boundaries have to be at a consecutive frame level. The conceptual notion of "video parsing" was introduced where "video" is a multimedia language conveying more than the sum of the individual pixels and signals.

A model driven approach to digital video segmentation is presented by Hampapur and his colleagues in [5]. The paper deals with extracting features that correspond to cuts, spatial edits, and chromatic edits. The authors present extensive formal treatment of shot boundary identification based on models of video editing effects.

Arman et al. [1] have used a DCT approach on both JPEG and MPEG streams. For MPEG streams, only I-frames are analyzed. This implementation employed a two step approach. The first pass compares the images based on using selected DCT coefficients from selected blocks. Video frames are represented by a vector of this subset of DCT coefficients. Then the normalized inner product is subtracted from one another and compared to a threshold. If a potential cut is detected, the images can be decompressed for further processing.

A similar multi-pass approach has been used by Zhang et al. but their technique also analyzes the B and P frames in an MPEG stream [12]. The first pass compares the images based on DCT coefficients. The DCT comparison is based on a pair-wise block comparison algorithm which compares the DCT coefficients of corresponding blocks of consecutive video frames. For example, if block n in frame i has a DCT coefficient $C_{n,k}(i)$ where k is from 1 to 64 and n depends on the frame size, then the difference between two frames which are j frames apart is:

$$Diff_n = \frac{1}{64}\sum_{k=1}^{64}\frac{|C_{n,k}(i) - C_{n,k}(i+j)|}{\max(C_{n,k}(i), C_{n,k}(i+j))}$$

If $Diff_n$ is greater than some threshold t, then the block is different between the two frames. If the percentage of blocks changed is greater than some threshold t_b, it is considered to be a shot-cut. It is reported that t tends not to vary across video sources and can be easily experimentally determined. However, t_b is computed from the overall statistics for the values of the percentage of blocks that have changed which exceed the mean by approximately five standard deviations. In the second pass the number of motion vectors is compared to a threshold. If there are less motion vectors than some threshold, a shot-cut is determined to occur. This is based on the fact that if there are high residual errors, then there are no motion vectors, consequently, this block is sufficiently different and can not be predicted. If a large number of blocks can not be predicted, than it probably is a shot-cut. The performance of this method depends to a certain extent on the quality of the encoding scheme. An encoder with poor motion estimation may lead to poor shot-cut detection performances.

Yeo et al. have investigated using only the DC values of the DCT coefficients for comparing frames in the compressed domain [9]. They sum the DC difference between successive frames. If the difference is the maximum and n times larger than the next largest peak in a sliding window of frames, then it is a cut. They also detect "gradual transitions" such as dissolves and fades, by comparing each frame to the subsequent *k*-th frame over some time interval.

An alternative shot segmentation method was proposed by Zabih et al. in [11]. Their approach is based on the observation that, during shot-cuts, new edges appear far away from old ones, and old edges disappear in locations far away from new ones. Shot-cuts are detected by counting the number of edges *entering* and *exiting* pixels in consecutive frames.

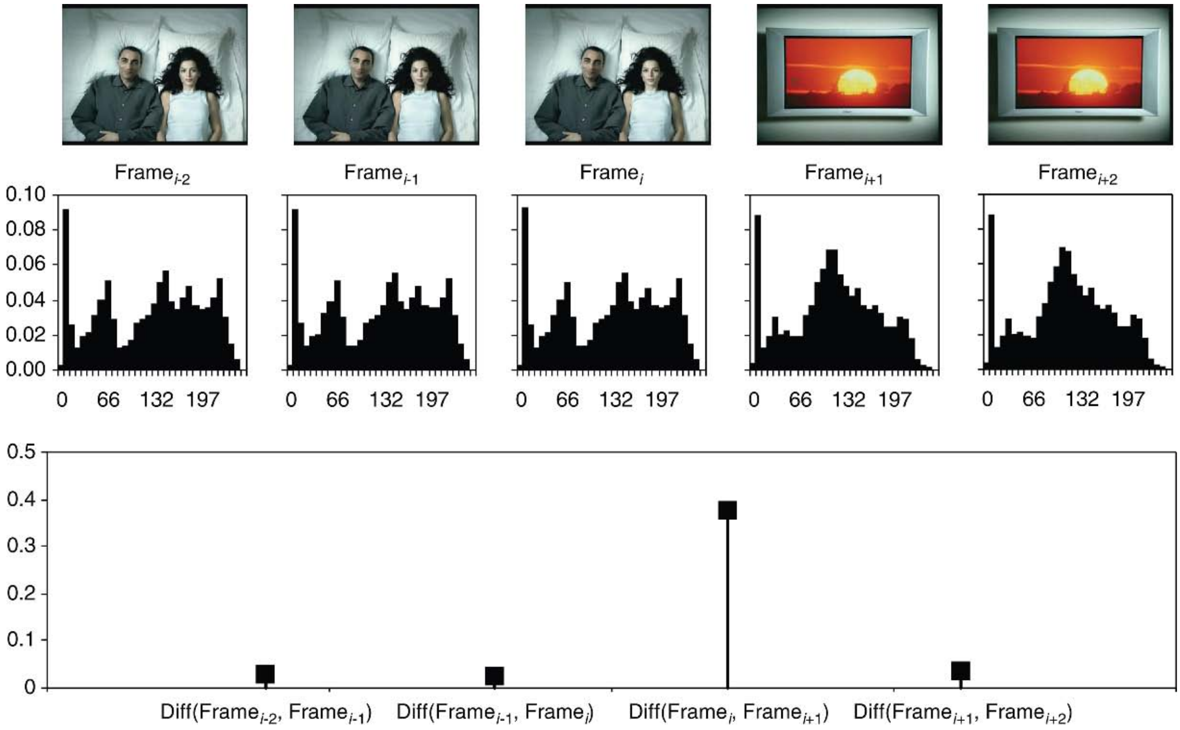
All of the above techniques have reported good results for shot-cut detection. However, a comparison of algorithms to detect shots boundaries has been performed by Boreczky and Rowe [2]. They selected and implemented some of the above algorithms. Their results showed that the simplest algorithms outperformed the more complicated methods and that DCT based algorithms had the lowest precision for a given recall.

Foundations

Shot-Cut Detection

Video segmentation aims at finding the temporal boundaries that separate visually homogeneous sequences of frames. The basic idea used by most methods for video segmentation is to compare subsequent frames for determining (based on some kind of threshold) when a significant change in the content occurs. For this purpose, it is necessary to define a metric for the comparison of subsequent frames and a thresholding method.

The key concept is visualized in Fig. 1. On the top of the figure, five frames across a shot boundary are shown. Below each frame, the corresponding luminance histogram is plotted. The plot shows on the horizontal axis the luminance values (from 0 to 255), and on the vertical axis the fraction of the pixels (from 0 to 1) in the frame image that have a particular luminance value. In this case, the metric for comparing two subsequent frames is the difference between the luminance histograms. The value of such distance is plotted in the graph at the bottom of the figure. As it can be seen in the histogram difference plot, the distance between the histograms of frames *i* and *i*+1 is considerably higher than



Video Segmentation. Figure 1. Example of a basic method for shot cut detection.

the differences between the histograms of other pairs of frames. The shot boundary located between the frames *i* and *i*+1 is easily detectable by means of a threshold located, for example, at 0.3.

A very simple metric for comparing frames is the *pixel-wise frame difference* consisting in the absolute difference of the intensity of the pixels between two consecutive frames. If $Y(x,y,n)$ and $Y(x,y,m)$ indicate the intensities of the pixels at position (x,y) in the frames n and m, the pixel-wise frame difference $\Delta_{n,m}$ is defined as follows:

$$\Delta_{n,\,m} = \sum_{x,\,y} |Y(x, y, n) - Y(x, y, m)|,$$

where the summation extends to the whole frame.

The pixel-wise frame difference is sensitive to noise, object and camera motion, and can lead to a high number of false detections. Better performances can be achieved by performing block-based differences instead of comparing single pixels.

Even better performances can be achieved by comparing image histograms. With respect to comparing pixels of consecutive frames, the histogram of a digital image increases robustness to noise, object and camera motion and is rotation invariant. Although image histograms do not retain any spatial information, they represent a good compromise between computational cost and performance for shot-cut detection.

If $H(i,\ n)$ represents the i-th histogram value for frame n and $H(i,\ m)$ represents the i-th histogram value for frame m, a simple but effective comparison metric is the *bin-to-bin* difference:

$$\Delta_{n,\,m} = \sum_{i} |H(i, n) - H(i, m)|$$

Shot-cuts are detected whenever the *bin-to-bin* difference exceeds a threshold. Other comparison metrics for histograms are the *intersection*, the *chi-square test* and the *correlation* defined as follows:

Histograms intersection	$\Delta_{n,\,m} = 1 - \sum_{i} \min(H(i,n), H(i,m))$
Chi-square test	$\Delta_{n,\,m} = \sum_{i} \frac{[H(i,n) - H(i,m)]^2}{[H(i,n) + H(i,m)]^2}$
Histograms correlation	$\Delta_{n,\,m} = 1 - \frac{\sum_{i} [H(i,n) - \mu_n][H(i,m) - \mu_m]}{\sigma_n \sigma_m}$

where μ_n and σ_n represent the mean and the standard deviation, respectively, of the histogram of the frame *n*.

The choice of a thresholding method is critical regardless of the comparison metric used. A too low threshold may create a high number of false detections, while a too high threshold may lead to many missed detections. A fixed threshold can be easily determined experimentally for one video. However, different videos might require different threshold values. To limit this problem, techniques have been proposed that link the threshold value to the mean and standard deviation of the distribution of frame differences across the whole video. Other methods use running averages in windows of multiple frames to detect shot-cuts.

Scene Boundary Detection

The methods described above typically use the differences in contiguous frames to detect shot boundaries. In order to detect scene boundaries, groups of shots are determined that contain semantically related information such as the same physical location, or the same action. While a shot boundary is defined rather unambiguously, scene boundaries are much more difficult to capture. Different individuals tend to identify scenes in videos in different ways. This makes obtaining ground truth for the scenes a non-trivial task.

An overview and a benchmark of different methods for scene boundary detection are presented in [8]. Common techniques used for scene boundary detection use audio analysis and shot clustering [10].

One of the methods to automatically detect scene boundaries is by means of *superhistograms* [3]. Using this method, first the color histograms for individual frames are computed, and then they are merged into a single cumulative histogram called a *family histogram* based on a comparison measure. As new frames are added, the family histogram accumulates the new colors from the respective frames. However, if the histogram of a new frame is different from the previously constructed family histograms, a new family is formed. In the end, there are a few families of histograms to represent the entire video. This set of families is ordered with respect to the length of the temporal segment of video that they represent. The ordered set of family histograms is called superhistogram.

When computing the family histograms there are several dimensions to think about when making comparisons between frames based on (i) the amount of memory (time) (ii) contiguity of compared families, (iii) the representative structure for a family. Memory can be thought as one-dimension, that is, how much history of the computed family histograms is kept: a process that has "zero memory" and compares only the current frame with a previous frame histogram vs. a process with infinite memory that compares the current frame with all the previous family histograms. As shown in Fig. 2, the results can be quite different. Another dimension is time, which means whether contiguous or noncontiguous comparisons are made. The third dimension is the determination of a representative histogram for the family. This can be the average histogram or the histogram of a selected frame (e.g., the last frame). There are different

Video Segmentation. Figure 2. Merging strategies for creating family histograms.

merging strategies [15]: contiguous vs. noncontiguous comparison and comparison with a short term and longer term memory:

1. Contiguous with zero memory: A new frame histogram is compared with the previous frame histogram. This strategy allows to keep a pan sequence in a single family as the addition of new colors happens slowly and the difference between consecutive frames (in case the last frame is compared) is very small.
2. Contiguous with limited memory: Contiguous families are produced by comparing the new frame histogram only with the previous family histogram. For commercial detection applications such strategy needs to be used because, otherwise, many families would be created during the commercials when new colors are introduced with each shot. This enables the differentiation of commercials from regular programs where the families are usually longer.
3. Noncontiguous with infinite memory with family histogram comparison: This is useful to capture the global colors of a complete program. For applications for characterization of videos for clustering and retrieval, this strategy needs to be used as it captures all the colors present in the video in the least number of clusters possible. A new frame histogram is compared with all previous family within the same video.
4. Hybrid: First a new frame histogram is compared using (3) above and then the generated family histograms are merged using (1) or (2). This enables the combination of global information that is preserved when using the (3) strategy to the local information that is achieved by combining the families using strategies (1) or (2). In this case, the family histograms that are produced by (3) effectively become the frame histograms. These are now merged with each other to generate a hierarchical picture of the video. This enables to cluster colors that are repeated at regular intervals throughout the program while keeping pans etc. together in a single family.

An example of the results obtained using these four strategies is shown in Fig. 2 for a portion of a news video program.

Key Applications

Video segmentation is usually the first step in content-based automatic video indexing and retrieval. It is also widely used for video browsing and automatic video summarization. Additionally, another field of application is the object-based video compression. To correctly detect and track objects in video, a temporal segmentation step is in general needed.

Video Sequence Indexing

Heng Tao Shen
The University of Queensland, Brisbane, QLD,
Australia

Synonyms

Video retrieval; Video search; Video indexing

Definition

A video is usually defined as a sequence of high-dimensional feature vectors. Video sequence indexing consists of describing the content of video sequences from a video database to allow effective and efficient search and retrieval. Given a query video sequence, video sequence indexing aims to find its similar video sequences from a video database quickly. Typically, it includes the following major components: effective summarization of the high-dimensional sequence, effective access method for indexing the obtained summarization, and efficient query processing method.

Historical Background

Video feature extraction and content analysis have been studied for several decades since the emergence of video data. Recently, video sequence indexing has attracted plenty of attention because of the huge amount of video data. With ever more heavy usage of video devices and advances in video processing technologies, the amount of video data has grown rapidly and enormously for various usages, such as filming, advertising, news video broadcasting, personal video archive, medical video data, and so on. Based on the statistics from Berkeley's "How Much Information" project 2003, 5,660 motion pictures are produced every year, amounting to almost 6,078 h. 21,264 television stations broadcast for about 16 h/day, producing 31 million hours of original programming annually, and huge amount of personal and organizational video data stocks are accumulating. Interestingly, the popularity of WWW enables enormous video data to be published and shared. The mainstream media is moving to the web. The media content online and video streaming is growing aggressively. While the pool of video data is super large, such as millions of videos currently available in web, video search engines provide users convenient ways for finding videos of their interests. Consequently, video sequence indexing has become a key part of the future of digital media [1].

The goal of video sequence indexing is to quickly find the similar videos to a query, and a video is usually represented by a sequence of high-dimensional frame feature vectors at a frame rate of 25–30/s. Due to the high complexity of video data, early work mainly focused on reducing the temporal redundancy of video data by identifying the shot which is the basic unit in video data. Shot detection is a fundamental task in video content manipulation. Representing the video by a small number of shots can reduce the data complexity in temporal dimension significantly. One central task in annual TRECVID evaluation is the shot boundary detection [2]. Many shot detection methods have been proposed and the field has matured [2,3]. Beside shot representation, recent work also considered the closeness of frames within a video across different shots and summarized similar frames into a compact representation [4,5]. Typically, temporal information is ignored for such aggressive summarizations. As the amount of video data increases explosively, there is also a trend to investigate various high-dimensional indexing methods to effectively manage and organize the video summaries for fast retrieval [5,6].

Foundations

Figure 1 shows the generic architecture for video sequence indexing. Given a collection of videos, their visual frame features, such as colour, tensity, and texture, is first extracted. Semantic features like objects and motions can also be further extracted from frame features. The sequence of frame features for each video is further summarized into compact representations which are indexed for fast retrieval. Given a query video, its features are first extracted and used to generate compact summarization. A similarity search is then performed on the indexed summary collection. The video similarity is approximated based on their compact representations.

To achieve efficient retrieval, most existing works emphasize on the summarization step to reduce the video data complexity and can be categorized into content-based and semantic-based approach. Content-based approach deals with frame visual features. In literature, two types of summarization techniques have been proposed: summarize the sequence as a statistical distribution and summarize the sequence into fewer representatives. The first type typically assumes that the frames are distributed in a model like Gaussian, or mixture of Gaussian [7]. In the second type, keyframe is often used [8]. Video signature introduces a

Video Sequence Indexing. Figure 1. A generic architecture for video sequence indexing.

randomized summarization method which randomly selects a number of seed frames and assigns a small collection of closest frames to each seed [4]. However, the selection of seeds may sample non-similar frames from two almost-identical sequences. Video Triplet (ViTri) models a cluster of similar frames as a tightly bounded hypersphere described by its *position*, *radius*, and *density* [5]. The ViTri similarity is measured by the volume of intersection between two hyper-spheres multiplying the minimal density, i.e., the estimated number of similar frames shared by two clusters. The total number of similar frames is then estimated to derive the overall similarity between two video sequences.

The semantic-based approach typically handles the motion trajectory of objects in a video sequence. Motion trajectories suggest the temporal movement of objects. Moving objects are first detected and segmented, and the motion trajectories of objects are then detected by analyzing inter-frame correspondences. Videos are represented based on these raw motion trajectories within a shot [8,9]. However, this approach is limited by the accuracy of object detection and only applicable so applications where the objects can be clearly identified.

In content-based image retrieval, the similarity/ distance of two images is typically computed by the Euclidean distance. When extending the distance function to video sequences, many proposals have been proposed. One widely used video similarity measure is the approximate percentage of similar frames shared by two sequences [4,13]. Some studies also take temporal information into consideration. In [5], a time warping based approach is proposed to deal with video temporal variations, including local shifting. Hausdorff distance is used to measure the maximal dissimilarity between two shots [2]. The Earth Mover's Distance was introduced in computer vision to better approach human perceptual similarities. It models similarity as the amount of changes necessary to transform one image feature into another one. A tight and computationally simple approximation of the Earth Mover's Distance was proposed for matching video sequences [1]. Other measures widely used in time series, such as Longest Common Subsequence [15], Edit Distance and its extensions [3], can also be extended for comparing video sequences. However, all these measures need to compare most, if not all, frames pairwise. The full similarity computation requires storage of the entire sequence and time complexity is typically quadratic.

To index low-dimensional video trajectories, trajectories are typically first split into segments which are typically represented by Minimum Bounding Rectangles (MBR) [11]. The obtained MBRs can then be indexed by some tree structures like Trajectory Bundle Tree (TB-tree) [10]. Efficient query processing typically deploys the GEMINI-like framework which pruning the search space by the established lower bound lemma. When temporal information is not considered, existing high-dimensional indexing structures and their query processing methods can be directly applied [4,13].

Key Applications

There are many applications for video sequence indexing. Typically applications include video search, video monitoring, video copy detection, video annotation, video digital library, etc.

Future Directions

The indexing structures that are used to manage high-dimensional video sequences have not been well explored in the database community. There is the also an urgent need for online monitoring, indexing and searching, as the media content online and video streaming is growing aggressively.

Experimental Results

In general, for every presented method, there is an experimental study in the corresponding reference.

Data Sets

TRECVID provides reasonably large video data sets for testing and experimental purposes [14].

URL to Code

Published code for video sequence indexing is rather limited in the database society.

Video Shot Detection

Chong-Wah Ngo
City University of Hong Kong, Hong Kong, China

Synonyms

Shot boundary detection; Camera break detection

Definition

Shot is a contiguous sequence of video frames with smooth and continuous camera motion. Shot can thus be viewed as an uninterrupted video frame sequence of space, time, and graphical configuration. The boundary between two shots is called a camera break (or video edit). Based on the transitional properties of video edits, there are two major types of camera breaks: *cut* and *gradual transition*. A camera cut is an instantaneous change from one shot to another. The gradual transition can further be categorized as *wipe* and *dissolve*. A wipe is the moving transition of a frame (or a pattern) across the screen that enables one shot to gradually replace another. A dissolve superimposes two shots, where one shot gradually appears while the other fades out slowly. Fade-in and fade-out can be considered as the special cases of dissolve, by replacing one of the shots as a constant image sequence (e.g., black image sequence). In contrast to cut, wipe and dissolve involve gradual transitions with no drastic changes between two consecutive frames, and hence, are relatively difficult to identify by computer.

Historical Background

Shot is regarded as the elementary unit of video structure, often serving as the basic component for video indexing, browsing and retrieval. Shot detection has been extensively studied since the emergence of the topic: content-based video retrieval in mid 1990. The early researches are unified under the theme of *video structuring and representation*, which targets for decomposing videos into smaller unit facilitating content analysis and understanding [15]. The scope of studies includes the detection of cut and gradual transition [15], detection efficiency [11], feasibility of thresholding [10], compressed versus uncompressed domain [11], and framework of detection [13].

Shot detection is mostly based on the analysis of visual information, or more precisely the changes of visual signal over time. For instance, an abrupt change of signal between frames can imply a camera cut. To date, there exist numerous approaches for shot detection which can be broadly classified according to the visual features being used and the type of camera breaks being analyzed. Based on feature, the existing approaches can be categorized as pixel-based, block-based, color-based, texture-based [14], motion-based [2], and slice-based [8]. These approaches can operate in either a compressed or uncompressed domain with slight modification. Uncompressed domain detection refers to the pixel-to-pixel processing of video frames to extract the desired features for analysis. Compressed domain detection refers to the direct processing of compressed information without explicitly decompressing video signals. The compressed features popularly used are DCT coefficients and MPEG motion vectors. Since the amount of information to be processed is relatively small, compressed domain detection has the advantage of speed efficiency. For instance, in [15], DC images which are the thumbnail version of original video frames are extracted directly from MPEG videos for rapid shot detection. In [15], motion vectors of P- and B- frames are extracted directly from MPEG videos for analysis.

Compared to cut, gradual transition (GT) is difficult to detect due to the absence of sharp signal changes. While cut normally involves only two frames, GT involves a sequence of frames ranging from several to even hundreds of frames. The first algorithm for GT detection is twin-comparison [15], which utilizes two thresholds to locate GTs. Another well-known algorithm is based on the video production model proposed in [1], which model the distribution of GT signals for detection by reversing the linear equation used to synthesized GTs in video production. GT detection has also recently been cast as a pattern analysis and learning problem. In [5–7,13], various classifiers are learned to recognize different types of GTs.

TRECVID has been the rendezvous where researchers meet and compete their shot detection algorithms since early 2000 [9]. The series of activities, over the past few years, have led to several sophisticated frameworks that perform reliably and excellently for the detection of camera cuts and GTs [9,13]. Based on the reported results, the best performing systems can always achieve more than 80% of recall and precision for cut and GT detection. Most systems also run faster than real-time.

Foundations

Cut

Camera cut is the most common type of shot boundary. In contrast to gradual transitions, most cuts involve no transitional frame. Thus, direct comparison between two frames is usually sufficient to attain satisfactory performance. A straightforward approach is to compute the mean absolute change of intensity between two frames at time t and t + 1. This simple approach, however, is sensitive to object and camera motion. An alternative version is to compute the energy changes of DC frames, which is the smaller and smoothed version of the original frames, extracted from MPEG videos to reduce the sensitivity [11]. In [8], the sequence of DC frames is further sub-sampled along the time dimension to form spatial-temporal slices. This approach detects cuts by analyzing the changes of temporal patterns in slices.

The most popular approach perhaps is via the comparison of intensity or color histograms between two contiguous frames. Color histogram quantizes the color space and captures the ratio of color components in a frame as a distribution. As a result, the histogram-based approaches are more invariant to local and global motion changes. To also capture spatial information in a color histogram, a more popular version is the block-based histogram: divide frames into blocks and compute a histogram for each block.

Other visual features being considered for cut detection include edge information, which captures the structural discontinuity of frames. In [14], edge change ratio is used to model the discontinuity by computing the number of edge pixels entering and existing between two frames. In addition, motion discontinuity is also studied in [2]. The cut detection is conducted by computing the global dominant motion of frames and accounting the number of points that do not fit the computed motion model. This approach can also be used for detecting gradual transitions.

Dissolve

Some existing works on the detection of dissolve transitions are based on the video production model [1]:

$$f(x,y,t) = (1-\alpha(x,y,t))g(x,y,t) + \alpha(x,y,t)h(x,y,t) \qquad (1)$$

where f is a dissolved frame superimposed by two frames g and h at time t. Typically, g and h are frames from two different shots. The transition function α characterizes, either linearly or non-linearly, how f is dissolved over time as a result of mixing g and h. Usually $0<\alpha(x, y, t) < 1$ with the condition $\alpha(x, y, t) \leq \alpha(x, y, t + 1)$. Since (1) is irreversible, apparently, detecting and classifying dissolves is a difficult task. To simplify the problem of detection, various assumptions have been made on (1). These assumptions can lead to plateau a effect [11] and parabolic curve of variance [1]. Take $\alpha(x, y, t) = \alpha(t)$, $g(x, y, t) = g(x, y)$ and $h(x, y, t) = h(x, y)$, (1) becomes

$$f(x,y,t) = (1-\alpha(t))g(x,y) + \alpha(t)h(x,y) \qquad (2)$$

In other words, f is a dissolved sequence of two static shots g and h in $t = [t_1, t_2]$. Let $\mathcal{F}(t) = f(x,y,t)$, by taking the frame difference, the following can be derived:

$$\frac{\mathcal{F}(t)-\mathcal{F}(t+k)}{\mathcal{F}(t-k)-\mathcal{F}(t)} = \beta(t,k) \qquad (3)$$

where $\beta(t,k) = \frac{\alpha(t+k)-\alpha(t)}{\alpha(t)-\alpha(t-k)} > 1$ and $t = [t_1 + k, t_2 - k]$. If $k > t_2 - t_1 + 1$, plateau effect will be exhibited and this effect can be exploited effectively for dissolve detection [11].

Equation(2) can be further simplified by assuming $\alpha(t)$ as a linear function, $\alpha(t) = \frac{t-t_1}{t_2-t_1}$ for instance. This terms leads to a formula in terms of variance:

$$\sigma_f(t) = (\sigma_g + \sigma_h)\alpha^2(t) - 2\sigma_g\alpha(t) + \sigma_g \qquad (4)$$

where $\sigma_f(t)$, σ_g and σ_h are the variances of, $g(x, y)$ and $h(x, y)$. Since $\sigma_f(t)$ is a concave upward parabolic curve, dissolves can be detected simply by locating parabolic curves [1,8]. The limitations of (3) and (4) are mainly due to the linearity assumption of α(t) and the static sequence assumption of shots g and h. As a result, most detectors are generally very sensitive to noise, camera and object motions.

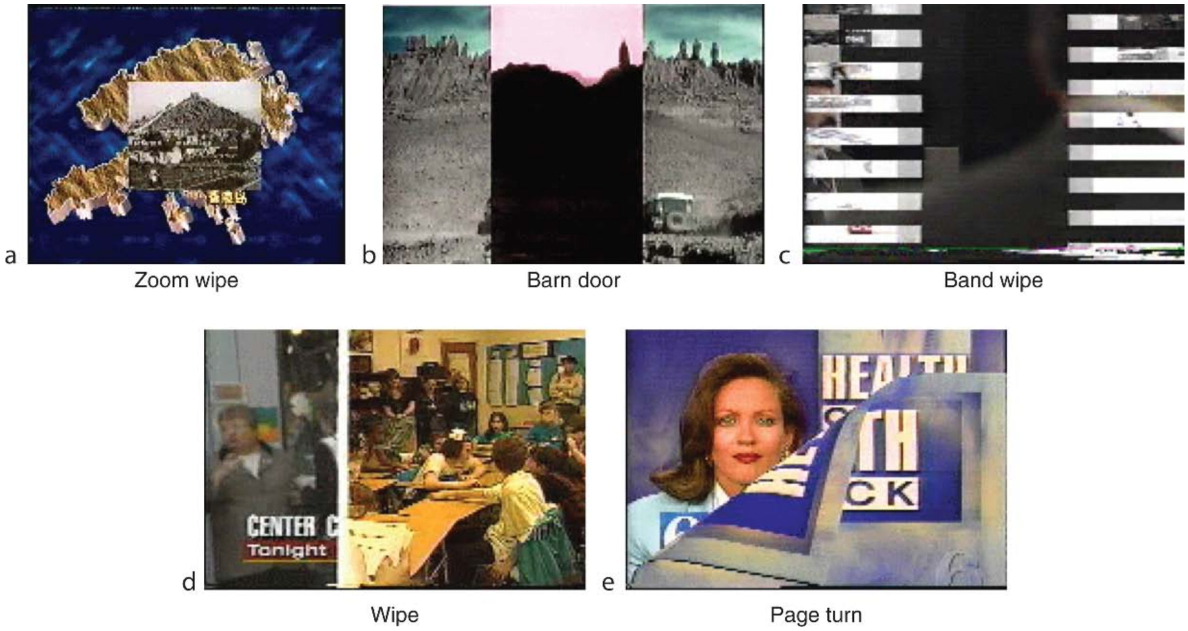
Recently, dissolve detection is also considered as a pattern classification problem, and various machine learning algorithms are brought in for this task [3]. For instance, in [6], multiple independent FSM (finite state machine) based detectors are used for detecting different types of shot boundaries. Together with classifiers, multiresolution analysis is also adopted by [5,7,13]. In [7], dissolve detection is reduced to the cut detection problem by projecting the spatio-temporal slices to lower temporal resolution scale. The detected cuts at lower resolution are further classified in the higher resolution space by machine learning. In [13], multi-resolution features are extracted for active learning of SVM (support vector machines) to detect dissolves.

Wipe

Wipe is also a common shot boundary transition frequently found, for example, in sport and news videos. There are lots of fancy wipe transitions being used by video editors today. Figure 1 shows a few examples of wipe. As each transition exhibits its own unique transition patterns, wipe patterns, compared to dissolves, are relatively hard for machines to learn. Early works are mostly based on frame differencing and edge detection to trace the moving boundary lines created by wipes. For instance, the works in [8] detect the edge patterns formed by wipes in spatial-temporal slices. The recent work in [4] analyzes the independence and completeness properties of wipe transitions. A cost function utilizing the MPEG motion vectors is derived to model these two properties for reliable wipe detection.

General Challenges

As a fundamental building block to support other video applications, shot detection has been extensively studied in the literature. The challenges that are not completely solved for cut detection include abrupt illumination change (e.g., flashlight) and large object/camera movement, which could trigger abrupt changes of video signal and generate false alarms. For gradual transition (GT), on the other hand, the



Video Shot Detection. Figure 1. Various wipe transition.

major difficulties are the slow evolution of signal that is hard to observe. Furthermore, the temporal duration can vary greatly while the patterns could appear similar to slow camera/object movement, making GT detection a very challenging problem. For both cut and GT detection, a fundamental issue is the thresholding heuristic – mostly relying on empirical setting. Over the years, the thresholding techniques have also been evolved from simple global threshold setting, to the adaptive thresholding [10] and learning-based heuristics [3,5,13].

Key Applications

Shot detection is a fundamental task of video content manipulation. Shots are often served as the basic unit for video browsing, indexing and search. An interesting application of shot detection is that, by knowing the type, speed and frequency of shot transitions, the pace, mood, style and highlight of the underlying video events can be modeled for affective computing.

Experimental Results

The evaluations commonly used are recall and precision, defined as:

$$\text{Precision} = \frac{\text{Number of Transitions Correctly Detected}}{\text{Number of Transitions Detected}} \qquad (5)$$

$$\text{Recall} = \frac{\text{Number of Transitions Correctly Detected}}{\text{Number of Transitionsarray}} \qquad (6)$$

Precision and recall are in the interval of [0,1]. Low precision hints the frequent occurrence of false positives, while low recall indicates the frequent occurrence of false negatives. As gradual transition involves multiple frames, frame precision and recall are also used in order to evaluate the accurate localization of transitions,

$$\text{Frame Precision} = \frac{\begin{array}{c}\text{Number of Frames Correctly Located}\\ \text{in the Detected Transitions}\end{array}}{\begin{array}{c}\text{Number of Frames Located in}\\ \text{the Detected Transitions}\end{array}} \qquad (7)$$

$$\text{Frame Recall} = \frac{\begin{array}{c}\text{Number of Frames Correctly Located}\\ \text{in the Detected Transitions}\end{array}}{\text{Number of Frames in the Transitions}} \qquad (8)$$

Data Sets

The popular datasets always experimented are TRECVID benchmarks [9].

Video abstraction; Video skimming

Definition

Video summarization is to generate a short summary of the content of a longer video document by selecting and presenting the most informative or interesting materials for potential users. The output summary is usually composed of a set of keyframes or video clips extracted from the original video with some editing process. The aim of video summarization is to speed up browsing of a large collection of video data, and achieve efficient access and representation of the video content. By watching the summary, users can make quick decisions on the usefulness of the video. Dependent on applications and target users, the evaluation of summary often involves usability studies to measure the content informativeness and quality of a summary.

Historical Background

Due to the advance of web technologies and the popularity of video capture devices in the past few decades, the amount of video data is dramatically increasing. This creates a strong demand for efficient tools to browse, access, and manipulate large video collections. The most straightforward and simplest way for quick browsing of video content is to speed up the play of video by frame dropping or re-encoding. As studied in [6], the entire video could be watched in a shorter amount of time by fast playback with almost no pitch distortion using the time compression technology. This kind of approach is easy to implement and preserves most information while shortening the time of watching videos. However, without comprehensive understanding of the original video content, the selection of video materials is impossible, and thus almost all redundant information still has to be watched. This limits further shortening of summary duration and its enjoyability. Meanwhile, the ratio of time compression is also limited.

Since the 1990s, *video content analysis* has attracted a lot of research attention. Different approaches have been proposed for automatic structuring and understanding of video content. This enables video summarization by measuring and selecting the most informative materials based on more comprehension of the video content. Video summarization can be seen as a general term of video abstraction and video skimming. In some works, they are distinguished by little difference in the composition of the output. For instance, video skims are mainly composed of the short clips skimmed from the original video. Video summary and abstraction could be a set of keyframes, clips or even other media (e.g., texts) created to describe the video content. Nowadays, video summarization has become the key tool to facilitate efficient browsing and indexing of large video collections.

Foundations

In the past two decades, a lot of research efforts have been devoted to video summarization. A systematic review of these works can be found in [10]. According to the definition, a summary should be as short or concise as possible to support efficient video browsing. On the other hand, it should be informative so that as much interesting and useful materials as possible will be included. Thus, the key of video summarization is how to measure the importance of different video clips and select the most useful ones so as to achieve both elegancy and informativeness. For this purpose, there are mainly two issues concerned: *video content analysis* and summary generation by selecting appropriate materials. *Video content analysis* enables the understanding and comprehension of the original video content. Different features are then extracted to structure and describe the video. Based on *video content analysis*, a shorter summary is generated by selecting and presenting the most important materials to users. Meanwhile, to cope with the characteristics of different video domains, many algorithms are proposed to achieve better results for the summarization of specific video domains by employing domain-specific knowledge.

Features for Content Analysis

Along with the advances in *video content analysis*, more and more features are employed in video summarization. According to the features adopted for video content analysis, the algorithms can be categorized as shot detection based [15], motion based [3], audio based [9], and multi-modality based [4,11]. In recent years, most algorithms tend to integrate multiple features to better describe the video content. Besides the visual-audio features, especially with the dramatic increasing of web videos, the metadata, context, social, and log information are being explored for video summarization of video corpus, e.g., the video clips that are watched by the most users may be more important and interesting. What features to use is usually dependent on the requirements of specific applications.

Importance Measure for Summary Generation

How to decide the importance and usefulness of video segments are essential for summary generation. During the past two decades, different approaches have been proposed. The first kind of approach is based on *video shot detection.* Shot detection is one of the fundamental techniques for video structuring. In each segmented shot, one or several keyframes are selected and presented for users to effiently browse and index the video content in order to find the interesting video segments for further exploration. In [15], several keyframes are extracted by detecting visual changes using color histogram inside each shot. In [2], to eliminate the possible redundancy among extracted keyframes, fuzzy clustering and data pruning methods are employed based on color information to obtain a set of non-redundant keyframes as the summary of the video. These approaches just employ limited low-level visual features. For the selection of keyframes or video segments, the main idea is to reduce the redundancy and maximize the visual difference in the generated summary to show more information measure by low-level features.

In the second kind of approach, importance measure is based on some pre-defined rules. In [8], a set of rules are defined to select the most useful frames or video segments. For instance, images between similar scenes that are less than 5 seconds apart, are used for summarization; short successive shots are considered to introduce a more important topic. With prioritized video frame from each shot, another set of high order rules are then used to compose the selected clips for summary generation. For instance, the duration of each clip is at least 60 frames based on empirical and user studies of visual comprehension in short video sequences. Similar rules can also be used in query-based or domain-specific video summarization. For instance, given a soccer video, the users may be just interested in the shots of goal. In this case, to make a summary, the events of goal should be first detected and then shown to the users. In this kind rule-based approaches, the importance of video segment is manually assigned by the predefined rules. This may be useful for some specific video domains and applications. However, the rules are usually subjective. Considering the variations of video content, to make desirable summaries, more and more detailed rules are required to cope with different scenarios. This becomes almost impossible in general videos.

Today many approaches try to numerically measure the importance of video segments and model video summarization in a computational way. In [4], a user attention model utilizing a set of audio-visual features is proposed. Attention is a neurobiological conception. It implies the concentration of mental powers upon an object by close or careful observing or listening, which is the ability or power to concentrate mentally. When watching a video, human attention is always attracted by different information elements such as face, text, object and camera motion, and so on. In [4], attention models are first computed based on different visual/audio features. A user attention curve is then generated by linear combination fusion scheme. The crests of the curve are more likely to attract the viewers' attentions. Keyframes or video skims are extracted from these crests. Similarly, in [14], a perception curve that corresponds to human perception changes is constructed based on a number of visual features, including motion, contrast, special scenes, and statistical rhythm. The frames corresponding to the peak points of the perception curve are extracted for summarization. This kind of approach usually integrates multiple modalities from video documents and human perception cue to depict the curve of video importance numerically for summarization. However, there are still manually defined rules used such as the selection and the weights of different modalities.

Domain-Specific Video Summarization

According to the target video domains, video summarization can be categorized into general videos and domain-specific videos, such as music video, news video, sports video, and rushes video.

General video: The algorithms for general video summarization employ features available in all types of videos, and usually do not consider any domain-specific knowledge. In [5], a video is represented as a complete undirected graph and the normalized cut algorithm is employed to partition the graph into video clusters. The resulting clusters form a directed temporal graph and a shortest path algorithm is proposed to detect video scenes. The attention values are computed and attached to the scenes, clusters, shots and subshots. Thus, the temporal graph can describe the evolution and perceptual importance of a video. A video summary is generated from the temporal graph to emphasize both content balance and perceptual quality. The advantage of this kind of approach is that no prior knowledge is used and the algorithms can work for most videos. However, when watching videos of different domains, the users' attentions are quite different. By treating all videos in the same way, these algorithms usually cannot produce satisfactory results for videos of specific interest. Thus, a lot of works focus on specific video domains and make use of domain-specific knowledge in order to improve the summary qualities.

Music video: In music video, the music plays the dominant role. Thus, music video summarization is mainly based on music analysis. In [13], the chorus is detected and used as a thumbnail for music content. The analysis of visual content such as shot classification and text (lyrics) recognition are employed for music-visual-text alignment so as to make a meaningful and smooth music video summary.

Sports video: When watching sports videos, people are more interested in the exciting moments and great plays. Thus, the highlight detection and event classification are usually involved in order to make a good summary. In [1], a multi-level representation for sports video is proposed. Based on low-level features, different semantic shots (e.g., Audience, Player Close-up, and Player Following) are classified at mid-level. For different sports games, the corresponding interesting objects and events (such as the football and a goal event in a soccer video) are detected at high-level. The interesting events can then be selected for summary generation.

News video: In daily news videos, a topic is usually composed of a story chain during the topic evolution. The dependencies among related stories are important to summarize a news topic. A feasible solution for rapid browsing of news topics is by threading and autodocumenting news videos [12]. In [12], the duality between stories and textual-visual concepts is first exploited to cluster the stories of the same topic. The topic structure is then presented by exploring the textual-visual novelty and redundancy of stories. By pruning the peripheral and redundant news tories in the topic structure, a main thread is extracted for autodocumentary.

Rushes video: Rushes are the raw materials captured during video production. Being unedited, rushes contain a lot of redundant and junk information which is intertwined with useful stock footage. In [11], stock footage is first located by motion analysis, repetitive shot detection, and shot classification. The most representative video clips are then selected to compose a summary based on object and event understanding.

Key Applications

Video summarization can be used in many applications.

Multimedia Archives Indexing and Retrieval

Nowadays more and more video documents are being digitized and archived worldwide. Video summarization can be used to index and retrieve a large video collection, and thus facilitate efficient access of video content. For instance, the online summarization can support journalists when searching old video material, or when producing documentaries. Another example is the wide use of web videos, where the index could easily be realized by automatically generated video summaries.

Movie Marketing

In the broadcasting and filmmaking industries, a lot of raw footage (extra video, B-rolls footage) is used to generate the final products such as TV programs and movies. Twenty to forty times as much material may be shot as actually becomes part of the finished product. The "shoot-to-show" ratio, such as in BBC TV, ranges from 20 to 40. The producers see these large amount of raw footage as cheap gold mine. Video summarization can be used to find the stock footage from the heavily redundant materials for potential reuse.

Home Entertainment

For instance, one can easily have a brief overview of what happened in a television series that may have been missed.

Future Directions

Performance evaluation

Despite the advance achieved in video summarization, a fundamental problem, i.e., performance evaluation, is yet to be solved. Today, the evaluation is mainly carried out by subjective scoring based on the users' personal judgment or few predefined criterions. This limits effective comparison between different approaches.

Comprehensive understanding and modeling of video content

In the existing approaches, neither the rule-based nor computational models can fully grasp the content and the storyline of the video. Besides more powerful approaches for *video content analysis*, the modeling of multimedia information is also essential for video summarization.

From large-scale video summarization to search and browsing

The existing works mainly focus on the summarization of a single video document or a small video cluster, where the information inside a video or dependency between videos can be relatively easily modeled. With the dramatic increasing of video data (e.g., web videos), how to summarize a huge group of videos, for instance, by structuring the relationship among the diversity of videos is a big challenge. Besides video content dependency, context and social information are cues that could be explored for this type of summarization in large-scale. In addition, the exploitation of summarization for large-scale video search and browsing remains an area yet to be studied.

Experimental Results

In TRECVID Workshop 2007 on Rushes Summarization [7], there were 22 runs submitted for evaluation on the same benchmark. Different criteria such as IN (inclusion of groundtruth objects/events), EA (easy to understand), and RE (redundancy of the summary) were assessed. Runs generated by CityUHK, NII, and LIP6 were verified by [7] as significantly better than two baselines from CMU. The baselines were generated by evenly sampling frames and shot clustering, respectively.

Data Sets

Rushes Videos by TRECVID Workshop.

Since 2004, the annual TRECVID Workshop provides a benchmark for rushes video exploitation and summarization. The dataset is composed of 100 h's raw video materials produced during news video and film production.

View Adaptation

Kenneth A. Ross
Columbia University, New York, NY, USA

Synonyms

Materialized view redefinition

Definition

Small changes to the definition of a materialized view are often needed in database systems. View adaptation is the process of keeping a materialized view up-to-date when the definition of the view is changed. View adaptation aims to leverage the previously materialized view to generate the new view, since the cost of rebuilding the materialized view from scratch may be expensive.

Key Points

View adaptation is related to the question of *answering queries using views*. The new view can be thought of as a query, with the old view available to help compute it. However, view adaptation also admits in-place changes that are not possible using a query-answering approach. For example, if a redefined view contains most but not all of the records from the original view, then view adaptation could be achieved by deleting the records that no longer qualify.

A variety of adaptation techniques are presented in [2,3], allowing changes to the SELECT, FROM, WHERE, GROUPBY and HAVING clauses. UNION and EXCEPT views are also considered. In some cases, multiple changes to a view definition can be handled in a single pass, without materializing intermediate results for each change. Experimental results show the value of adaptation, particularly the in-place methods, relative to recomputation. Extensions of view adaptation to more general contexts, such as distributed databases, have also been proposed [1,4].

Data warehouses and decision support systems often employ materialized views to speed up query processing. Applications in which a user can change queries dynamically and see the results fast, such as data visualization, data archeology, and dynamic query processing can also benefit from view adaptation.

View expression

Definition

The definition of a view consists of the name of the view and of a query, whose result is used to determine the content of the view.

Key Points

A view is a virtual relation. Its content depends on the evaluation of a query over a set of base tables or other views in the database. This query is part of the view definition and is, typically, recomputed every time the view is referenced. In some cases, for efficiency, the tuples of a view may be materialized as a separate table in the database.

In relational systems, a view is defined using the **create view** command:

create view < v > **as** < *query expression* >

The name of the view in the above example is < v > and the schema and content of the view are derived on-demand by the evaluation of < query expression >, which should be a legal expression supported by the database management system. Different vendor systems may impose some constraints on the form of < query expression >, for instance they may disallow references to temporary tables. When the data in the table(s) mentioned in < query expression > changes, the data in view < v > changes also.

Consider the following view definitions:

create view v1 as select Name, Age from Personnel where Department = "Sales"
create view v2 as select Wages.Name,Wages.Salary
from Personnel, Wages
where Personnel.Name = Wages.Name and Personnel.Department = "Sales"

The first expression defines a view termed *v1* that contains the name and age attributes from database table *Personnel*. The instance of view *v1* consists of the subset of personnel data restricted to those working at department *Sales*. View *v2* defined by the second expression, contains the result of the join between tables *Personnel* and *Wages* for employees working at the same department.

View update; Materialized view maintenance

Definition

View maintenance typically refers to the updating of a *materialized view* (also known as a derived relation) to make it consistent with the base relations it is derived from. Such an update typically happens *immediately*, with the transaction that updates the base relations also updating the materialized views. However, such immediate updates impose significant overheads on update transactions that cannot be tolerated by many applications. *Deferred view maintenance*, on the other hand, allows the view to become inconsistent with its definition, and a *refresh operation* is required to establish consistency. Typically, under deferred maintenance, a view is *incrementally* updated only just before data is retrieved from it (i.e., on-demand, just before a query is performed on the view).

Historical Background

Early systems that supported views did so in their "pure form," i.e., by storing just the view definition and using query rewriting to take advantage of views in other queries [11].

Incremental view maintenance is introduced in [1] through a technique to efficiently detect relevant updates to materialized views, thus streamlining their maintenance.

Deferred view maintenance is introduced in [10] as a scheme for materializing copies of views on workstations attached to a mainframe that maintains a shared global database. The workstations update local copies of the views while processing queries. In [7], deferred view maintenance is defined as the application of incremental view maintenance whenever desired, unlike the immediate view maintenance, where any database update triggers the incremental view maintenance algorithm. [5] has a nice survey of view maintenance techniques.

Foundations

Algorithms and techniques for maintenance of materialized views can be classified according to three different criteria:

- Whether the view is recomputed from scratch or not: *recomputation* versus *incremental* maintenance.
- Whether the view is updated whenever the base data change or not: *immediate* versus *deferred* maintenance.
- Whether queries can be executed while the view is being updated or not: *online* versus *offline* maintenance.

All the above dimensions are typically orthogonal. We explain the different options below.

View Recomputation

Recomputing a materialized view from the base relations it is derived from is the most general technique of updating. As such, it can be applied on any type of view, regardless of the complexity of the query definition. The disadvantage is that, in most cases, such recomputation is costly, and, in many cases, the view can be updated *incrementally* instead, at a fraction of the cost.

Incremental View Maintenance

It is possible to update a materialized view *incrementally* for many types of view definitions (i.e., queries). One such class is the general case of SPJ views (i.e., views whose definition is just a select-project-join query).

For example, assume that we have a view V defined over two relations R and S through a natural join (i.e., $V = R \bowtie S$; for simplicity of the presentation we ignore the selection and projection operators). Further, let us assume that we have a set of deleted tuples from relation R, denoted as R_D; a set of inserted tuples into relation R, denoted as R_I (i.e., $R^{'} = R \cup R_I - R_D$). Also, assume a set of deleted tuples from relation S, denoted as S_D; and a set of inserted tuples into relation S, denoted as S_I (i.e., $S^{'} = S \cup S_I - S_D$). We trivially represent base relation updates as pairs of deletions and insertions.

Given the above, the updated version of V, i.e., $V^{'}$, should be $V^{'} = R^{'} \bowtie S^{'} = (R \cup R_I - R_D) \bowtie (S \cup S_I - S_D)$. By expanding this further, and grouping all the deletions from V as V_D and all the insertions to V as V_I, we have that: $V_D = (R_D \bowtie (S \cup S_I)) \bowtie ((R \cup R_I) \bowtie S_D)$, and $V_I = (R_I \bowtie S) \cup (R \bowtie S_I) \cup (R_I \bowtie S_I)$, so that $V^{'} = V \cup V_I - V_D$. This, incrementally computed formula, should be less costly to compute than recomputing the entire join from scratch.

The problem of incrementally updating materialized views is difficult in the general case, but there are additional classes of queries (i.e., besides SPJ views) that it can be solved for [6].

Immediate View Maintenance

The default way of updating materialized views is to do so *immediately*, i.e., batch together, in a single transaction, the updating of the base relations and the updating of the materialized views that are derived from these relations. However, many applications cannot tolerate this delay, especially if they are interactive and users are expecting an answer at transaction commit.

Deferred View Maintenance

Incremental deferred view maintenance requires (i) techniques for checking what views are affected by an update to the basic tables, (ii)auxiliary tables that maintain certain information like updates and deletes since the last view refresh and finally (iii) techniques for propagating the changes from the base tuples to the view tuples without fully recomputing the view relation.

First, Buneman in [2], proposes a technique for the efficient implementation of alerters and triggers that checks each update operation prior to execution to see whether it can cause a view to change. In [1], an efficient method for identifying updates that cannot possibly affect the views is described. Such *irrelevant updates* are then removed from consideration while differentially updating the views.

In [7], the hypothetical relations technique developed in [12] is adapted to the purpose of storing and indexing the deltas to the base tables. The main idea is to use a single table *AD* that stores deletions and insertions for the base tables (updates can be modeled as a deletion followed by an update). Whenever a view is accessed, the base tables and the *AD* table need to be accessed (in order to check for new or deleted tuples). A bloom filter however, is used to check if a tuple from the base relation exists in *AD* significantly reducing irrelevant accesses to *AD*.

In [4], the authors demonstrate that the ordering of the updates from the base tuples to the view tuples is critical and call this phenomenon *state bug*. Typically, an "incremental query" – during the refresh operation – avoids recomputing the full view and only incrementally computes the delta view to bring it up to date, based on updates/deletes made to the base tables. Such incremental queries can evaluated in two states: The *pre-update state*, where the base table updates have not been applied yet or the *post-update state* where changes have been applied. In most techniques a pre-update state is assumed which severely limits the class of updates and views considered. The post-update state allows for a much larger class of view to be deferred maintained, however direct application of pre-update techniques results in incorrect answers (state bug) and new techniques are proposed.

Offline View Maintenance

Typically, maintaining materialized views is done *offline*, without allowing queries to the materialized view to execute concurrently with the processing of the materialized view updates. This simplifies the view maintenance algorithms significantly, at the expense of delaying queries. Traditionally, in data warehousing environments [3], updates of materialized views are performed at night, thus minimizing the possibility of delaying user queries.

Online View Maintenance

The need of most companies for continuous operation (especially in the presence of the Web), has precipitated the need for *online view maintenance*, where queries can be answered while the materialized views are being updated.

In a centralized setting, this is typically achieved through some sort of multi-versioning, either as *horizontal redundancy*, where extra columns are added to hold the different versions [9], or as *vertical redundancy*, where extra rows are needed to hold the different versions [8]. In a distributed setting, this is typically achieved through determination of additional queries to ask of the data sources [13].

Key Applications

Materialized views help speed up the execution of frequently accessed queries, giving interactive response times to even the most complex queries. The cost of maintaining materialized views is typically amortized over multiple accesses (i.e., queries to the view). This has been utilized/transferred in many different application domains, from data warehousing to web data management. Beyond efficient algorithms and techniques to update materialized views, special attention has also been given to the *view selection* problem: how to identify which views should be materialized, and also to the issue of how to effectively use materialized views to answer other queries (i.e., by utilizing subsumption or caching).

View Maintenance Aspects

Antonios Deligiannakis
University of Athens, Athens, Greece

Definition

Database systems often define *views* in order to provide conceptual subsets of the data to different users. Each view may be very complex and require joining information from multiple *base relations*, or other views. A view can simply be used as a query modification mechanism, where user queries referring to a particular view are appropriately modified based on the definition of the view. However, in applications where fast response times to user queries are essential, views are often materialized by storing their tuples inside the database. This is extremely useful when recomputing the view from the base relations is very expensive. When changes occur to their base relations, materialized views need to be updated, with a process known as view maintenance, in order to provide fresh data to the user.

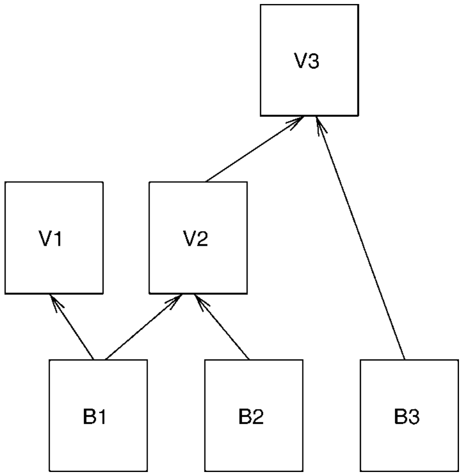
Historical Background

The use of relational views has long been proposed in relational database systems. The notion of materialized views, or *snapshots*, was first proposed in [1]. A snapshot represents the state of some portion of the database at the time when the snapshot was computed. Since the publication of [1], a large number of mechanisms for refreshing materialized views has been proposed. These mechanisms mainly involve either the time of refreshing the materialized views, or how such a refresh operation can be performed (i.e., through a re-computation of the view, or in an incremental manner). While each policy has its own advantages and drawbacks, ADMS was the first system that realized the importance of having multiple maintenance policies within the same database [11,12]. An excellent classification of the view maintenance problem was presented in [4].

Foundations

Materialized views are used in order to provide faster response times to user queries. Figure 1 depicts a sample *view-dependency graph* of three materialized views (namely, V1, V2 and V3) defined over three base relations (denoted as B1, B2 and B3). If a view V contains in its definition a reference to a base relation (or another view) B, then there exists a directed edge in the view-dependency graph from B to V. Given this explanation, please note that V3 in the sample view-dependency graph is expressed in terms of a base relation (B3) and another materialized view (V2). However, the ultimate set of base relations that are used to derive V3 are B1, B2 and B3.

When the underlying data of the base relations changes, the materialized views contain stale data, until the materialized view is refreshed. The view maintenance can be performed either through a re-computation of the view or, if possible, through an incremental procedure. An incremental update policy is often faster, and is thus in many cases desirable, if the base relations have been modified only by a small portion. However, when a large portion of some base relations is updated (i.e., most tuples of a base relation are deleted), then a complete re-computation may actually be faster. The process of maintaining a materialized view can be classified based on five main dimensions.



View Maintenance Aspects. Figure 1. An example of a view-dependency graph.

Time Dimension

Every update transaction incurs a time penalty, thus slowing down queries performed during the update process. On the other hand, some applications (i.e., applications regarding stock data) cannot tolerate viewing stale data.

Depending on when a materialized view is updated, three main policies for view maintenance can be defined [2]:

1. Immediate Views: Upon an update to a base relation, the materialized view is updated immediately. This is often accomplished using database triggers.
2. Deferred Views: Updating the materialized view is deferred until the first time when the view is queried.
3. Snapshot Views: The view is updated periodically (i.e., at daily intervals) by an asynchronous process.

Each of the aforementioned policies has some advantages and drawbacks, and each may be the policy of choice, depending on the characteristics of the targeted application. Immediate views incur an update penalty even if the updated tuples are never queried. Deferred views incur this update cost only at the first time when the view is queried after its base relations have been updated. Thus, deferred views incur a lower update overhead, but also worse query performance, since the query evaluation process may have to wait for some views to be updated, when compared to the immediate views policy. The snapshot views policy leads to faster query performance, since typically no updates are performed in parallel to the user queries, and to better update performance, since the updates are batched. Thus, snapshot views represent an attractive choice when the application may tolerate reading stale data.

Expressiveness of View Definition Language

Algorithms proposed for the maintenance of a materialized view can often handle only views expressed as a subset of SQL. For example, some techniques may only be able to handle views defined as select-project-join (SPJ) queries. However, a view definition may be much more complex, as it may contain (amongst others) duplicates, arithmetic operations, aggregate or ranking functions, nested subqueries, set operations such as calculating the union or difference amongst two sets, outer-joins, recursion etc.

View maintenance algorithms often seek to derive formulas for determining the update to a view, and thus avoid recalculating the entire view from scratch, based on the updates to its base relations. For example, for the sample dependency graph presented in Fig. 1, let view $V2$ be calculated as: $V2 = B1 \bowtie_{JC} B2$, where JC denotes the join condition in the definition of $V2$ between relations $B1$ and $B2$. If $\Delta B1$ and $\Delta B2$ represent the inserted (deleted) tuples to relations $B1$ and $B2$, then the inserted (deleted) tuples $\Delta V2$ to view $V2$ can be calculated as:

$$\Delta V2 = (\Delta B1 \bowtie_{JC} B2) \cup (B1 \bowtie_{JC} \Delta B2) \cup (\Delta B1 \bowtie_{JC} \Delta B2)$$

Updates can be modeled as deletions followed by insertions. Deriving such formulas for computing the incremental update operations on a view typically becomes harder, or even impossible, as the expressiveness of the view definition language is increased. Thus, maintenance algorithms often first check whether a view can be incrementally maintained, and then proceed to decide how to actually maintain it.

Available Information

When maintaining a materialized view, we do not always have access to both the materialized view and its base relations. For example, when one of the base relations represents a data stream, as in the case of Chronicle Views [7], the entire relation cannot be stored and is, thus, unavailable during the maintenance process. Thus, during the view maintenance process one may, or may not, have access to the materialized view itself, to its base relations, or to information regarding the presence of keys and referential integrity constraints. Depending on the amount of information available, different algorithms can be used for maintaining a view.

Supported Modifications

The view maintenance algorithms can also be classified based on types of modifications to the base relations that they can handle. Not all algorithms handle both insertions and deletions to base relations. Some algorithms handle sets of modifications (i.e., insertions and deletions) in a single pass, as in [6], while others require one pass for each different modification set. Some algorithms handle updates directly, while other algorithms model them as deletions followed by insertions. Finally, not all view maintenance algorithms can handle more complex modifications, such as modifications to the view definition. Even when such modifications are handled, the view maintenance can be achieved by different techniques that either recompute the view, or try to *adapt* the view, so that the old view can be used to materialize the new view [5].

Algorithm Applicability

View maintenance algorithms should be able to be applied to all possible data stored in the database tables, and to all instances of a particular modification (i.e., insertion, deletion, update etc). Techniques that operate correctly but only on specific database instances, or on specific only modification instances are less desirable.

Figure 2, originally presented in [4], summarizes some areas of the problem space for three of the five dimensions described above, namely for the expressiveness of the view definition language, for the available information and for the supported modifications dimensions. The remaining two dimensions have been omitted for ease of presentation.

Key Applications

Data Warehousing

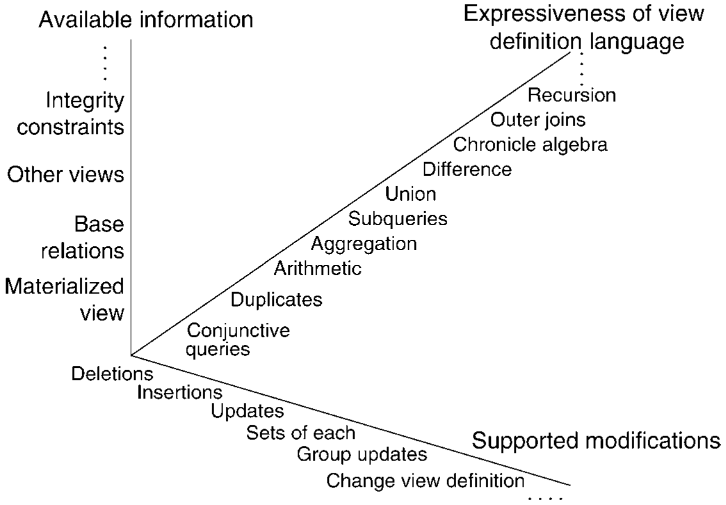
Materialized views are frequently used in data warehouses to provide personalized behavior to users, store frequently queried data derived from multiple relations, and to encapsulate different views of local or even remote data and databases. Materialization allows for significantly better query performance [8], while view maintenance, in the case of Immediate or Deferred Views, allows users to access fresh data.

Data Streams

Banking, billing, networking and stock applications often generate infinite streams of data. View maintenance algorithms can help answer complex queries over such infinite data streams without requiring access to the entire stream.

Caching

Cached data can be refreshed quickly using techniques developed for view maintenance when only a small portion of the cache has become stale. The cached



View Maintenance Aspects. Figure 2. The problem space, as presented in [4].

content may also involve dynamically generated web page fragments. In this case, the notion of WebViews [9,10] can be used to decide which such fragments to materialize, and how to determine a schedule for updating them.

Mobile Applications

If data needs to be transmitted in cases of bandwidth constraints, as in applications of mobile clients holding a cell phone or a GPS system, then only the data altered between the last transmission needs to be transmitted. Similar techniques that transmit only the changes in the computed data can also be used in other bandwidth-constrained applications as well, such as in transmitting smaller amounts of data to/from sensor nodes [3].

View-based Data Integration

Yannis Katsis, Yannis Papakonstantinou
University of California-San Diego, La Jolla, CA, USA

Definition

Data Integration (or *Information Integration*) is the problem of finding and combining data from different sources. *View-based Data Integration* is a framework that solves the data integration problem for *structured* data by integrating sources into a single unified view. This integration is facilitated by a declarative *mapping language* that allows the specification of how each source relates to the unified view. Depending on the type of view specification language used, view-based data integration systems (VDISs) are said to follow the *Global as View (GAV)*, *Local as View (LAV)* or *Global and Local as View (GLAV)* approach.

Historical Background

Data needed by an application are often provided by a multitude of data sources. The sources often employ heterogeneous data formats (e.g., text files, web pages, XML documents, relational databases), structure the data in different ways and can be accessed through different methods (e.g., web forms, database clients). This makes the task of combining information from multiple sources particularly challenging. To carry it out, one has to retrieve data from each source individually, understand how the data of the sources relate to each other and merge them, while accounting for discrepancies in the structure and the values, as well as for potential inconsistencies.

The first to realize this problem were companies willing to integrate their structured data within or across organizations. Soon the idea of integrating the data into a single unified view emerged. These systems, to be referred to as view-based integration systems (VDISs) would provide a single point of access to all underlying data sources. Users of a VDIS (or applications) would query the unified view and get back integrated results from all sources, whereas the task of combining data from the sources and resolving inconsistencies would be handled by the system transparently to the applications.

The VDISs made their first appearance in the form of multidatabases and federated systems [11]. Subsequently, the research community dived into the problem of specifying the correspondence between the sources and the unified view. The outcome were three categories of languages to express the correspondence (GAV, LAV and GLAV), together with several related theoretical and system results. The industry also embraced the view-based integration framework by creating many successful VDISs (e.g., BEA AquaLogic, IBM WebSphere).

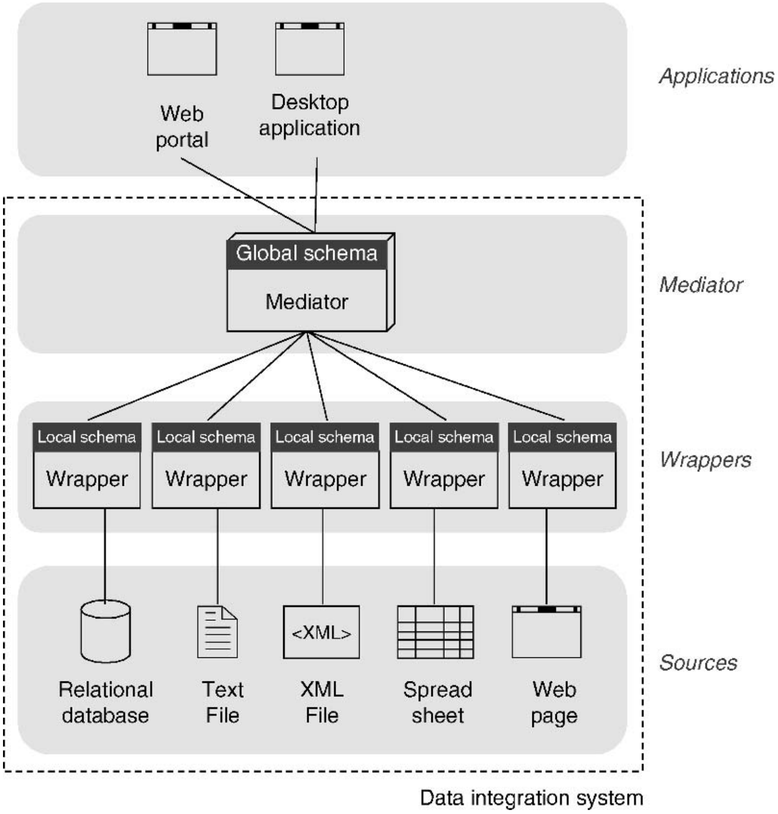
Foundations

Abstracting out the differences between individual systems, a typical VDIS conforms to the architecture shown in Fig. 1. Sources store the data in a variety of formats (relational databases, text files, etc.). Wrappers solve the heterogeneity in the formats by transforming each source's data model into a common data model used by the integration system. The wrapped data sources are usually referred to as local or source databases, the structure of which is described by corresponding local/source schemas. This is in contrast to the unified view exported by the mediator, also called global/target database. Finally, mappings expressed in a certain mapping language (depicted as lines between the wrapped sources and the mediator) specify the relationship between the wrapped data sources (i.e., the local schemas) and the unified view exported by the mediator (i.e., the global schema).

Given a VDIS, applications or users retrieve data from the sources indirectly by querying the global schema. It is the task of the mediator to consult the mappings to decide which data to retrieve from the sources, and how to combine them appropriately in order to form the answer to the user's query.

VDISs can be categorized according to the following three main axes:

1. *Common data model and query language.* The data model and query language that is exposed by the



View-based Data Integration. Figure 1. View-based Data Integration System (VDIS) architecture.

wrappers to the mediator and by the mediator to the applications. Commonly used data models include the relational, XML and object-oriented data model.

2. *Mapping language.* The language for specifying the relationship of sources with the view. Languages proposed in the literature fall into three categories; *Global as View (GAV)*, *Local as View (LAV)* and *Global and Local as View (GLAV)*. Being one of the most important components in a VDIS, these are discussed in detail below.
3. *Data storage method.* The decision on the place where the data are actually stored. The two extremes are the materialized and the virtual approach (see [14] for a comparison). In the materialized integration (also known as eager, in-advance or warehousing approach), all source data are replicated on the mediator. On the other hand, in the virtual mediation (e.g., Infomaster [6]) (or lazy approach), the data are kept in the sources and the global database is virtual. Consequently, a query against the global database cannot be answered directly, but has to be translated to queries against the actual sources. Finally, some systems employ hybrid policies, such as virtualization accompanied by a cache.

Specifying the Relationship of the Sources with the Unified View

To allow the mediator to decide which data to retrieve from each source and how to combine them into the unified view, the administrator of the VDIS has to specify the correspondence between the local schema of each source and the global schema through mappings.

The mappings are expressed in a language, corresponding to some class of logic formulas. Languages proposed in the literature fall into three categories: *Global as View (GAV)*, *Local as View (LAV)* and *Global and Local as View (GLAV)*. In GAV the global database (schema) is expressed as a function of the local databases (schemas). LAV on the other hand follows the opposite direction, with each local schema being described as a function over the global schema. Therefore, LAV allows to add a source to the system independently of other sources. Finally, GLAV is a generalization of the two. This section presents each of these approaches in detail and explains their implications on the query answering algorithms. Essentially, each of them represents a different trade-off between expressivity and hardness in query answering.

Running example. For ease of exposition, the following discussion employs a running example of integrating information about books. The example employs the relational data model for both the sources and the global database. Moreover, the query language used by the users to extract information from the global database, and in turn by the mediator to retrieve information from the sources, is the language of conjunctive queries with equalities ($CQ^{=}$); a subset of SQL widely adopted in database research.

Figure 2 shows the employed local and global schemas. Relations are depicted in italics and their attributes appear nested in them. For instance, the global schema $\mathcal{G}$ in Fig. 2b consists of two relations Book and Book_Price. Relation Book has attributes ISBN, title, suggested retail price, author and publisher, while Book_Price stores the book price and stock information for different sellers. Data is fueled into the system by two sources; the databases of the bookstore Barnes & Noble (B&N) and the publisher Prentice Hall (PH), with the schemas shown in Fig. 2a. Note that there are two versions of the PH schema, used in different examples.

Global as View (GAV)

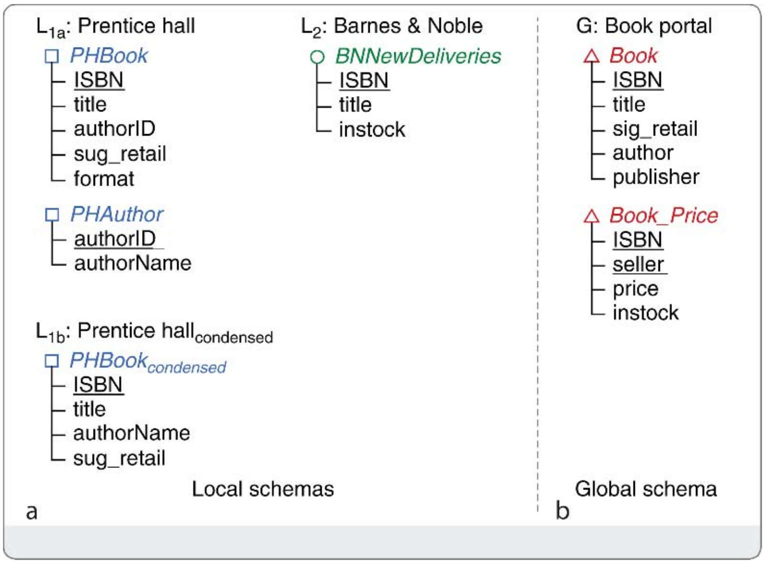
Historically, the first VDISs followed the Global as View (GAV) approach [7,12], in which the global schema is described in terms of the local schemas. In such systems the contents of each relation R in the target schema $\mathcal{G}$ are specified through a query (view) V over the combined schemas of the sources.

Thus, in GAV the correspondence between the local schemas and the global schema can be described through a set of mappings of the form:

$$V_i \rightarrow I(R_i)$$

one for each relation R_i of the global schema, where V_i is a query over the combined source schemas. $I(R_i)$ is the identity query over R_i (i.e., a query that returns all attributes of R_i). The symbol → can represent either query containment ($\subseteq$) or query equality ($=$). This leads to two different semantics, referred to in the literature as the open-world and the closed-world assumption, respectively.

Example: Consider the following two GAV mappings (For the examples, the identity query I over some relation is considered to return the attributes of that relation in the same order as they appear on the schema in Fig. 2).



View-based Data Integration. Figure 2. Local and global schemas of the running example.

$M_1 : V_1 \rightarrow I(Book)$
$M_2 : V_2 \rightarrow I(Book\_Price)$

where

$V_1(ISBN, title, sug\_retail, authorName, \text{"PH"})$:-
$PHBook(ISBN, title, authorID, sug\_retail, format)$,
$PHAuthor(authorID, authorName)$

and

$V_2(ISBN, \text{"B\&N"}, sug\_retail, instock)$:-
$PHBook(ISBN, title1, authorID, sug\_retail, format)$,
$BNNewDeliveries(ISBN, title2, instock)$

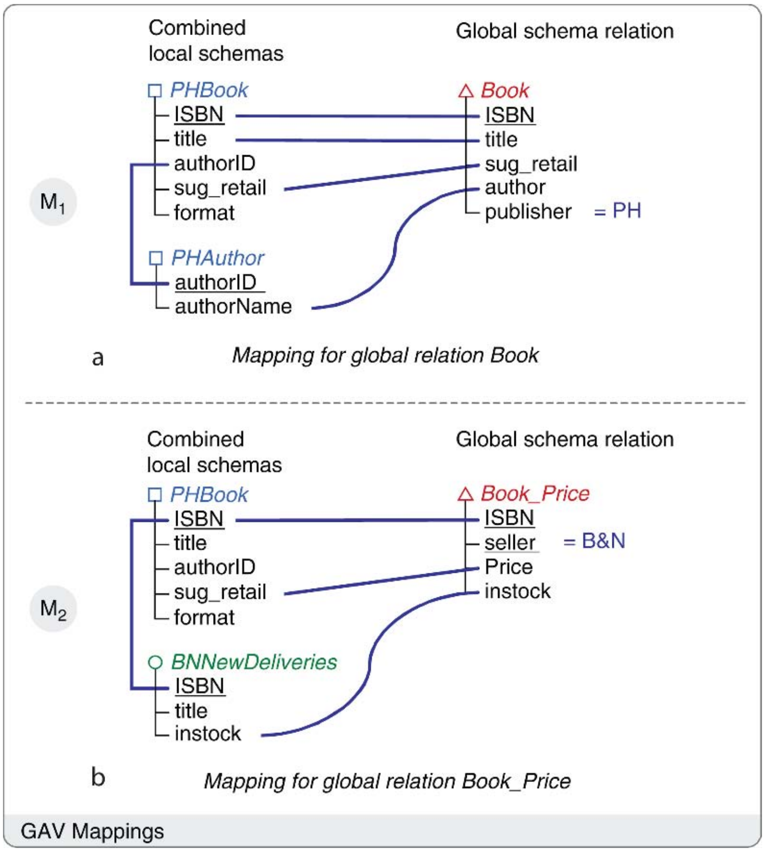
The mappings are graphically depicted in Fig. 3a and b, as described in [9]. This is similar to the way most *mapping tools* (i.e., tools that allow a visual specification of mappings), such as IBM Clio and MS BizTalk Mapper, display mappings.

Mapping M_1 intuitively describes how Book tuples in the global database are created. This is done by retrieving the ISBN, title and sug_retail from a PHBook tuple, the author from the corresponding PHAuthor tuple (i.e., the PHAuthor tuple with the same authorID as the PHBook tuple), and finally setting the publisher to "PH" (since the extracted books are published by PH).

Similarly, mapping M_2 describes the construction of the global relation Book_Price. This involves combining information from multiple sources: the price from the suggested retail price information provided by PH and the inventory information from B&N, because B&N's administrator knows that B&N's sells its books at the suggested retail price.

Query Answering in GAV. GAV mappings have a *procedural* flavor, since they describe how the global database can be constructed from the local databases. For this reason, query answering in GAV is straightforward, both in the materialized and in the virtual approach.

In the materialized approach, the source data are replicated in the global database by executing for each mapping $V_i \rightarrow I(R_i)$ the query V_i against the local databases and populating R_i with the query results.



View-based Data Integration. Figure 3. Example of GAV mappings.

Subsequently, an application query Q against the global schema is answered by simply running Q over the materialized global database.

On the other hand, in the virtual approach, data are kept in the sources and thus a query against the global schema has to be translated to corresponding queries against the local schemas. Due to the procedural flavor of GAV, this can be done through view unfolding (i.e., replacing each relational atom of the global schema in the query by the corresponding view definition). Intuitively, whenever a query asks for a global relation R_i, it will instead run the subquery V_i over the local schemas, which, according to the mapping $V_i \rightarrow I(R_i)$, provides the contents of R_i.

Advantages. The simplicity of the GAV rules together with the straight-forward implementation of query answering, led to the wide adoption of GAV by industrial systems. From the research sector representative GAV-based VDISs systems are MULTIBASE [11], TSIMMIS [5] and Garlic [2].

Disadvantages. GAV also has several drawbacks:

First, since the global schema is expressed in terms of the sources, *global relations cannot model any information not present in at least one source.* For instance, the Book relation in the example could not contain an attribute for the book weight, since no source currently provides it. In other words, the value of each global attribute has to be explicitly specified (i.e., in the visual representation all global attributes must have an incoming line or an equality with a constant).

Second, as observed in mapping M_2 of the running example, *a mapping has to explicitly specify how data from multiple sources are combined to form global relation tuples.* Therefore, GAV-based systems do not facilitate adding a source to the system independently of other sources. Instead, when a new source wants to join the system, the system administrator has to inspect how its data can be merged with those of the other sources currently in the system and modify the corresponding mappings.

Local as View (LAV)

To overcome the shortcomings of GAV, researchers came up with the Local as View (LAV) approach [7,12]. While in GAV the global schema is described in terms of the local schemas, LAV follows the opposite direction expressing each local schema as a function of the global schema. LAV essentially corresponds to the "source owners view" of the system by describing which data of the global database are present in the source. Using the same notation as in GAV, local-to-global correspondences can be written in LAV as a set of mappings:

$$I(R_i) \rightarrow U_i$$

one for every relation R_i in the local schemas, where U_i is a query over the global schema and I the identity query.

Example: Figure 4 shows the following two LAV mappings for the running example:

$M'_1 : I(PHBook_{condensed}) \rightarrow U_1$
$M'_2 : I(BNNewDeliveries) \rightarrow U_2$

where

$U_1(ISBN, title, author, sug\_retail)$:-
  $Book(ISBN, title, sug\_retail, author, \text{"}PH\text{"})$

and

$U_2(ISBN, title, instock)$:-
  $Book(ISBN, title, sug\_retail, author, publisher)$,
  $Book\_Price(ISBN, \text{"}B\&N\text{"}, sug\_retail, instock)$

For instance, M'_1 specifies that $PHBook_{condensed}$ contains information about books published by PH. Similarly, M'_2 declares that *BNNewDeliveries* contains the ISBN and title of books sold by B&N at their suggested retail price and whether B&N has them in stock.

In contrast to GAV mappings, LAV mappings have a *declarative* flavor, since, instead of explaining how the global database can be created, they describe what information of the global database is contained in each local database.

Advantages. LAV addresses many of GAV problems with the most important being that sources can register independently of each other, since a source's mappings do not refer to other sources in the system.

Disadvantages. LAV suffers from the symmetric drawbacks of GAV. In particular, it cannot model sources that have information not present in the global schema (this is the reason why the example above used the condensed version of PH's schema that did not contain the attribute format, which is not present in the global schema). Furthermore, due to LAV's declarative nature, query answering is non-trivial any more, as described next. Mainly because of its technical implications to query answering, LAV has been extensively studied in the literature. Representative LAV-based systems include Information Manifold [10] and the system described in [13].

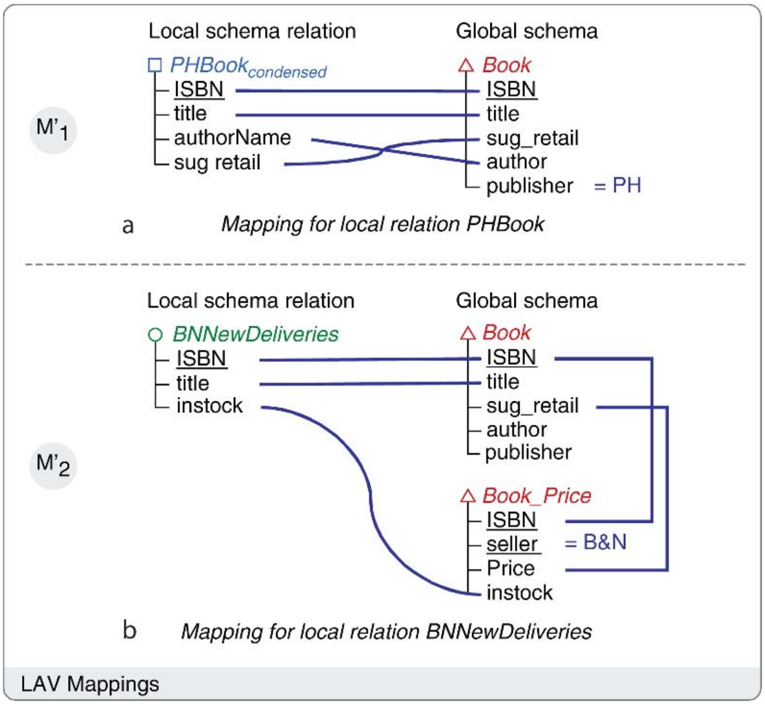
Query Answering in LAV. Since LAV mappings consist of an arbitrary query over the global schema, they may leave some information of the global database unspecified. For instance, mapping M'_2 above only states that B&N sells its books at the suggested retail price, without specifying the exact price. Thus, there might be infinitely many global databases that could be inferred from the sources through the mappings (each of them would make sure that each pair of Book and Book_Price tuples created from a BNNewDeliveries tuple share the same value for price, but each such global database might choose a different constant for the value). These databases are called *possible worlds*. Their existence has two important implications:

First, since a unique global database does not exist, it cannot be materialized and therefore LAV lends itself better to virtual mediation. However, there is still a way of replicating source information in a centralized place. This involves creating a "special" database that intuitively stores the general shape of all possible worlds. This "special" database is called *canonical universal solution* and can be built through procedures employed in data exchange [3].

Second, since many global databases exist, the query answering semantics need to be redefined. The standard semantics adopted in the literature for query answering in LAV-based systems are based on the notion of *certain answers* [1,8]. The certain answers to a query are the answers to the query, which will always appear regardless of which possible world the query is executed against (i.e., the tuples that appear in the intersection of the sets of query answers against each possible world). Intuitively, certain answers return information that *is guaranteed* to exist in *any* possible world.

Example: If in the integration system of Fig. 4 a query asks for all ISBNs that are sold by some seller at their suggested retail price, it will get back all ISBNs stored in relation BNNewDeliveries, because for each of them, any possible world will contain a pair of Book and Book_Price tuples with the same ISBN and the same prices (although these prices will have different values between possible worlds). On the other hand, if the query asks for all books sold at a specific price, it will not get back the ISBNs from BNNewDeliveries, because their exact prices are left unspecified by the mapping M'_2 and will therefore differ among possible worlds.

In order to compute the certain answers to a query in a virtual integration system following the LAV approach, the query against the global schema has to be translated to corresponding queries against the local schemas. This problem is called *rewriting queries using*



View-based Data Integration. Figure 4. Example of LAV mappings.

views (because the query over the global database has to be answered by using the sources which are expressed as views over it), and is also of interest to other areas of database research, such as query optimization and physical data independence (see [8] for a survey). In contrast to GAV, it is a non-trivial problem studied extensively by researchers.

Global and Local as View (GLAV)

To overcome the limitations of both GAV and LAV, [4] proposed a new category of mapping languages, called Global and Local as View (GLAV), which is a generalization of both GAV and LAV. GLAV mappings are of the form:

$$V_i \rightarrow U_i$$

where V_i, U_i are queries over the local and global schemas, respectively.

GLAV languages can trivially express both GAV mappings and LAV mappings by assigning to U_i a query returning a single global relation or to V_i a query asking for a single local relation, respectively. However, GLAV is a strict superset of both GAV and LAV by allowing the formulation of mappings that do not fall either under GAV or under LAV (i.e., mappings in which V_i and U_i both do not return just a single local or global relation).

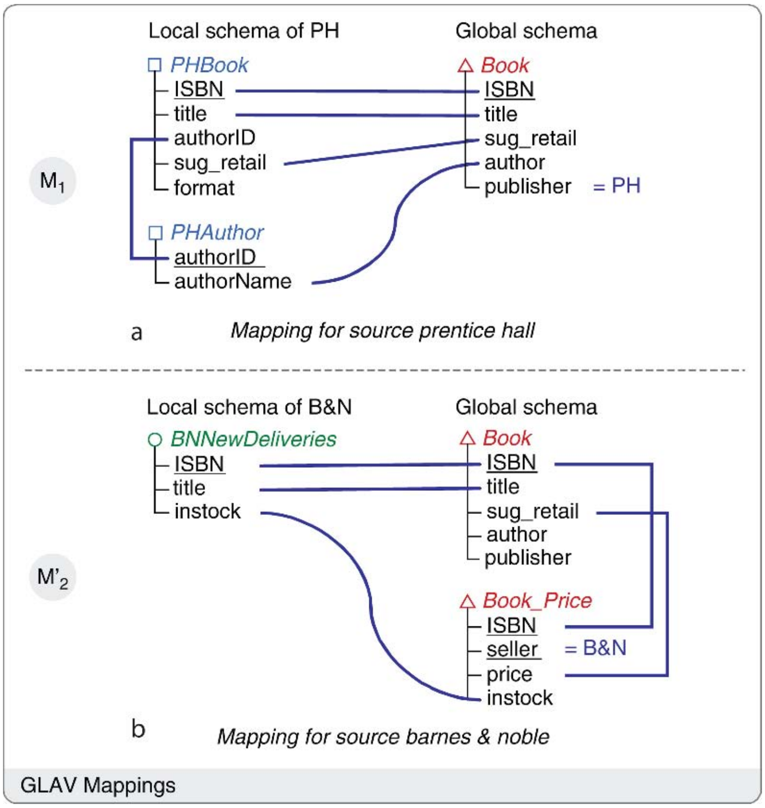
Example: Figure 5 shows two GLAV mappings. The first mapping is the GAV mapping M_1 first presented in Fig. 3a, while the second mapping is the LAV mapping M'_2 used in Fig. 4b.

Since U_i (a.k.a. the conclusion of the mapping) can be an arbitrary query over the global schema, GLAV allows the independent registration of sources in the same way as LAV. However, this also implies that the global database is incomplete. Consequently, query answering in GLAV is usually done under certain answer semantics, by extending query rewriting algorithms for LAV [15].

Alternatives to VDISs

Apart from the VDISs, research and industrial work led to many alternative approaches to data integration of structured data:

1. *Vertical Integration Systems* are specialized applications that solve the problem of data



View-based Data Integration. Figure 5. Example of GLAV mappings.

integration for a specific domain. For example, http://www.mySimon.com or http://www.rottentomatoes.com integrate price and movie information, respectively.

2. *Extract Transform Load (ETL) Tools* generally facilitate the actual migration of data from one system to another. When used for data integration they are closely tied to the problem of materializing the integrated database in a central data warehouse.

Compared to these solutions, VDISs offer a more general approach to data integration with the following advantages: (i) The relationships between the sources and the unified view are explicitly stated and not hidden inside a particular implementation, (ii) a general VDIS implementation can be used in many different domains, and (iii) a VDIS deployment can be easily utilized by many applications, as shown in Fig. 1. In a way VDISs are analogous to Database Management Systems, offering a general way of managing the data (which in VDISs are heterogeneous and distributed), independently of the applications that need those data.

Finally, another alternative to VDISs are Peer-to-Peer (P2P) Integration Systems that drop the requirement for a single unified view, allowing queries to be posed over any source schema. Although it is an active area of research, P2P systems have not yet been widely adopted in industry.

Key Applications

VDISs are used for integration of structured data in many different settings, including among others enterprises, government agencies and scientific communities.

Definition

Views are virtual relations without independent existence in a database. The contents of the instance of a view are determined by the result of a query on a set of database tables or other views in the system.

Key Points

Over the years, there have been several definitions and uses for the term view. From one perspective, a view is a query (or a macro) that generates data every time it is invoked. The term view is also used in association with the derived data that is produced by the execution of the view query. Views have also been used as indexes, summary tables or combinations of both. They provide physical data independence, by decoupling the logical schema from the physical design, which is usually driven by performance reasons. By controlling access to the views, one can control access to different parts of the data and implement different security policies. Views are also used in integration systems in order to provide unified access to physically remote databases.

When the result of the view is stored as an independent table, the view is called materialized. Materialized views can be of two forms. In the first, the materialized table is treated as pure data, detached from the view definition that was used to derive its content. In the second, the view content is treated as derived data that needs to be properly maintained when update statements alter the state of the database, in a way that affects the instance of the view. This is called the view maintenance problem. In a symmetrical way, when a user or a program modifies a view (materialized or not) through an update statement, an implementation is required for translating the view update command into a series of updates on the base relations so that the requested update is observed in the view instance. This process is often termed update through views.

Virtual Partitioning

Marta Mattoso
Federal University of Rio de Janeiro, Rio de Janeiro, Brazil

VP

Definition

Virtual Partitioning (VP) is a distribution database design technique [2] that avoids physical partitioning table design. VP is adopted in Database Clusters to implement intra-query parallelism [3]. VP is based on database replication and aims at designing a table partition dynamically, according to each query specification. The idea is to take advantage of the current configuration of the parallel execution environment, such as the number of nodes available, the tables of the query, the current load, and the available table replicas. Intra-query parallelism can be obtained through VP by rewriting a query into a set of sub-queries to be sent to different virtual partitions. At each node, the local sequential DBMS processes the sub-query on the specified virtual partition of the table. VP requires an extra query processing phase to compose the final result from the partial ones produced by the sub-queries. This way, a database that is not physically partitioned can still be processed transparently through intra-query parallelism.

Key Points

VP is implemented through query rewriting [1]. Basically, a DBC rewrites the original query by adding range predicates to it, which originates as many sub-queries as the number of table replicas and nodes available. Then, each node receives a different sub-query. For example, let **Q** be a query on table `orders`:

```
Q: select sum (price)
   from orders
   where category = 'bolt' ;
```

A generic sub-query on a virtual partition is obtained by adding to Q's `where` clause the predicate "and `order_id` >=v1 and `order_id` < v2." By binding [v1, v2] to n subsequent ranges of `order_id` values, n sub-queries are generated, each for a different node on a different virtual partition of `orders`. These virtual partitions correspond to horizontally partitioned data. After the execution of all sub-queries each partial result would then be inserted into a temporary table, e.g., `tempResult`. Finally, to compose the result, the partitioned results need to be combined by an aggregate query. In this example: `select sum (sprice) from tempResult;`

For VP to be effective, the tuples of the virtual partition must be physically clustered according to the added range predicate. Ideally, there should be a clustered ordered index on table `orders` based on `order_id`, so that the DBMS will not scan tuples outside the VP.

Definition

Visual analytics is the science of analytical reasoning supported by interactive visual interfaces. Over the last decades, data was produced at an incredible rate. However, the ability to collect and store this data is increasing at a faster rate than the ability to analyze it. While purely automatic or purely visual analysis methods were developed in the last decades, the complex nature of many problems makes it indispensable to include humans at an early stage in the data analysis process. Visual analytics methods allow decision makers to combine their flexibility, creativity, and background knowledge with the enormous storage and processing capacities of today's computers to gain insight into complex problems. The goal of visual analytics research is thus to turn the information overload into an opportunity: Decision-makers should be enabled to examine this massive, multi-dimensional, multi-source, time-varying, and often conflicting information stream through interactive visual representations to make effective decisions in critical situations.

Historical Background

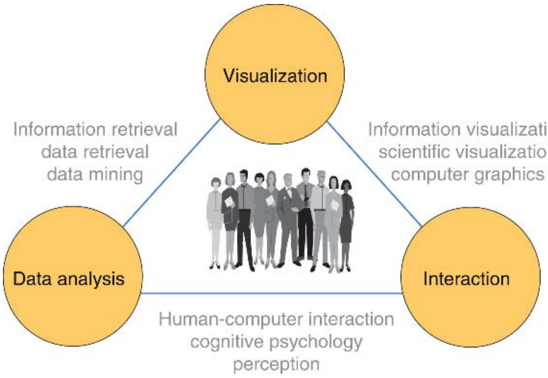
Automatic analysis techniques such as statistics and data mining developed independently from visualization and interaction techniques. However, some key thoughts changed the rather limited scope of the fields into what is today called visual analytics research. One of the most important steps in this direction was the need to move from confirmatory data analysis to exploratory data analysis, which was first stated in the statistics research community by John W. Tukey in his book "Exploratory data analysis" [7].

Later, with the availability of graphical user interfaces with proper interaction devices, a whole research community devoted their efforts to information visualization [1,2,5,8]. At some stage, this community recognized the potential of integrating the user in the KDD process through effective and efficient visualization techniques, interaction capabilities and knowledge transfer leading to *visual data exploration* or *visual data mining* [3]. This integration considerably widened the scope of both the information visualization and the data mining fields, resulting in new techniques and plenty of interesting and important research opportunities.

The term *visual analytics* was coined by Jim Thomas in the research and development agenda "Illuminating the Path" [6], which had a strong focus on Homeland Security in the United States. Meanwhile, the term is used in a wider context, describing a new multidisciplinary field that combines various research areas including visualization, human-computer interaction, data analysis, data management, geo-spatial and temporal data processing, and statistics [4].

Foundations

Visual analytics evolved from information visualization and automatic data analysis. It combines both former independent fields and strongly encourages human interaction in the analysis process as illustrated in Fig. 1. The focus of this section is to differentiate between visualization and visual analytics and thereby motivating its necessity. Thereafter, the visual analytics process is described and technical as well as social challenges of visual analytics are discussed.



Visual Analytics. Figure 1. Visual analytics as the interplay between data analysis, visualization, and interaction methods.

Visualization is the communication of data through the use of interactive interfaces and has three major goals: (i) presentation to efficiently and effectively communicate the results of an analysis, (ii) confirmatory analysis as a goal-oriented examination of hypotheses, and (iii) exploratory data analysis as an interactive and usually undirected search for structures and trends.

Visual analytics is more than only visualization. It can rather be seen as an integral approach combining visualization, human factors, and data analysis. Visualization and visual analytics both integrate methodology from information analytics, geospatial analytics, and scientific analytics. Especially human factors (e.g., interaction, cognition, perception, collaboration, presentation, and dissemination) play a key role in the communication between human and computer, as well as in the decision-making process. In matters of data analysis, visual analytics furthermore profits from methodologies developed in the fields of statistical analytics, data management, knowledge representation, and knowledge discovery. Note that visual analytics is not likely to become a separate field of study, but its influence will spread over the research areas it comprises [9].

Overlooking a large information space is a typical visual analytics problem. In many cases, the information at hand is conflicting and needs to be integrated from heterogeneous data sources. Often the computer system lacks knowledge that is still hidden in the expert's mind. By applying analytical reasoning, hypotheses about the data can be either affirmed or discarded and eventually lead to a better understanding of the data. Visualization is used to explore the information space when automatic methods fail and to efficiently communicate results. Thereby human background knowledge, intuition, and decision-making either cannot be automated or serve as input for the future development of automated processes. In contrast to this, a well-defined problem where the optimum or a good estimation can be calculated by non-interactive analytical means would rather not be described as a visual analytics problem. In such a scenario, the non-interactive analysis should be clearly preferred due to efficiency reasons. Likewise, visualization problems not involving methods for automatic data analysis do not fall into the field of visual analytics.

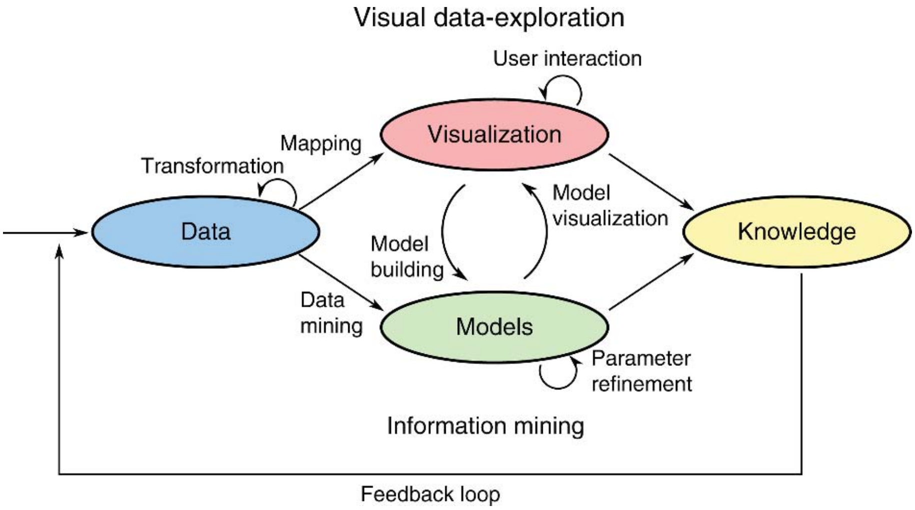
Visual Analytics Process

The visual analytics process is a combination of automatic and visual analysis methods with a tight coupling through human interaction in order to gain knowledge from data. Figure 2 shows an abstract overview of the different stages (represented through ovals) and their transitions (arrows) in the visual analytics process.

In many visual analytics scenarios, heterogeneous data sources need to be integrated before visual or automatic analysis methods can be applied. Therefore, the first step is often to preprocess and transform the data in order to extract meaningful units of data for further processing. Typical preprocessing tasks are data cleaning, normalization, grouping, or integration of heterogeneous data into a common schema.

Continuing with this meaningful data, the analyst can select between visual or automatic analysis methods. After mapping the data the analyst may obtain the desired knowledge directly, but more likely is the case that an initial visualization is not sufficient for the analysis. User interaction with the visualization is needed to reveal insightful information, for instance by zooming in different data areas or by considering different visual views on the data. In contrast to traditional information visualization, findings from the visualization can be reused to build a model for automatic analysis. As a matter of course these models can also be built from the original data using data mining methods. Once a model is created the analyst has the ability to interact with the automatic methods by modifying parameters or selecting other types of analysis algorithms. Model visualization can then be used to verify the findings of these models. Alternating between visual and automatic methods is characteristic for the visual analytics process and leads to a continuous refinement and verification of preliminary results. Misleading results in an intermediate step can thus be discovered at an early stage, which leads to more confidence in the final results.

In the visual analytics process, knowledge can be gained from visualization, automatic analysis, as well as the preceding interactions between visualizations, models, and the human analysts. The feedback loop



Visual Analytics. Figure 2. The *Visual Analytics Process* is characterized through interaction between data, visualizations, models about the data, and the users in order to discover knowledge.

stores this knowledge of insightful analyses in the system, and contributes to enable the analyst to draw faster and better conclusions in the future.

Technical and Social Challenges

While visual analytics profits from the increasing computational power of computer systems, faster networks, high-resolution displays, as well as novel interaction devices, it must be kept in mind that new technologies are always accompanied with a variety of technical challenges that have to be solved.

Dynamic processes in scientific or business applications often generate large streams of real-time data, such as sensor logs, web statistics, network traffic logs, or atmospheric and meteorological data. The analysis of such *large data streams* which can consist of terabytes or petabytes of data is one of the technical challenges since advances in many areas of science and technology are dependent upon the capability to analyze these data streams. As the sheer amount of data does often not allow to store all data at full detail, effective compression and feature extraction methods are needed to manage the data. Visual analytics aims at providing techniques that make humans capable of analyzing real time data streams by presenting results in a meaningful and intuitive way while allowing interaction with the data. These techniques enable quick identification of important information and timely reaction on critical process states or alarming incidents.

Synthesis of heterogeneous data sources is another challenge that is closely related to data streams, because real-world applications often access information from a large number of different information sources including collections of vector data, strings and text documents, graphs or sets of objects. Integrating these data sources includes many fundamental problems in statistics, machine learning, decision theory, and information theory. Therefore, the focus on scalable and robust methods for fusing complex and heterogeneous data sources is key to a more effective analysis process.

One step further in the analysis process, *interpretability and trustworthiness* or the ability to recognize and understand the data can be seen as one of the biggest challenges in visual analytics. Generating a visually correct output from raw data and drawing the right conclusions largely depends upon the quality of the used data and methods. A lot of possible quality problems (e.g., data capture errors, noise, outliers, low precision, missing values, coverage errors, double counts) can already be contained in the raw data. Furthermore, pre-processing of data in order to use it for visual analysis bears many potential quality problems (i.e., data migration and parsing, data cleaning, data reduction, data enrichment, up-/down-sampling, rounding and weighting, aggregation and combination). The concrete challenges are on the one hand to determine and to minimize these errors on the pre-processing side, and a flexible yet stable design of the visual analytics applications to cope with data quality problems on the other hand. From a technical point of view, the design of such applications should either be insensitive to data quality issues through usage of data cleaning methods or explicitly visualize errors and uncertainty to raise awareness for data quality issues.

In many scenarios, interpreting the raw data only makes little or no sense at all if it cannot be embedded in context. Research on *semantics* may derive this context from meta data by capturing associations and complex relationships. Ontology-driven techniques and systems have already started to enable new semantic applications in a wide span of fields such as bioinformatics, web services, financial services, business intelligence, and national security. Research challenges thereby arise from the size of ontologies, content diversity, heterogeneity as well as from computation of complex queries and link analysis over ontology instances and meta data.

Scalability in general is a key challenge of visual analytics, as it determines the ability to process large datasets by means of computational overhead as well as appropriate rendering techniques. Often, the huge amount of data that has to be visualized exceeds the limited amount of pixels of a display by several orders of magnitude. In order to cope with such a problem not only the absolute data growth and hardware performance have to be compared, but also the software and the algorithms to bring this data in an appropriate way onto the screen. As the amount of data is continuously growing and the amount of pixels on the display remains rather constant, the rate of compression on the display is steadily increasing. Therefore, more and more details get lost. It is an essential task of visual analytics to create a higher-level view onto the dataset, while maximizing the amount of details at the same time.

The field of *problem solving, decision science, and human information discourse* constitutes a further visual analytics challenge since it not only requires understanding of technology, but also comprehension of typical human capabilities such as logic, reasoning, and common sense. Many psychological studies about the process of problem solving have been conducted. In a usual test setup the subjects have to solve a well-defined problem where the optimal solution is known to the researchers. However, real-world problems are manifold. In many cases these problems are intransparent, consist of conflicting goals, and are complex in terms of large numbers of items, interrelations, and decisions involved. The dynamics of information that changes over time should not be underestimated since it might have a strong impact on the right decision. Furthermore, social aspects such as decision making in groups make the process even more delicate.

While many novel visualization techniques have been proposed, their wide-spread usage has not taken place primarily due to the users' refusal to change their daily working routines. *User acceptance* is therefore a further visual analytics challenge, since the advantages of developed tools need to be properly communicated to the audience of future users to overcome usage barriers, and to tap the full potential of the visual analytics approach.

Visual analytics tools and techniques should not stand alone, but should *integrate* seamlessly into the applications of diverse domains, and allow interaction with existing systems. Although many visual analytics tools are very specific (i.e., in astronomy or nuclear science) and therefore rather unique, in many domains (e.g., business or network security applications) integration into existing systems would significantly promote their usage by a wider community.

Finally, *evaluation* as a systematic analysis of usability, worth, and significance of a system is crucial to the success of visual analytics science and technology. During the evaluation of a system, different aspects can be considered such as functional testing, performance benchmarks, measurement of the effectiveness of the display in user studies, assessment of its impact on decision-making, or economic success to name just a few. Development of abstract design guidelines for visual analytics applications would constitute a great contribution.

Key Applications

Visual analytics is essential in application areas where large information spaces have to be processed and analyzed. Major application fields are *physics* and *astronomy*. Especially the field of *astrophysics* offers many opportunities for visual analytics techniques: Massive volumes of unstructured data, originating from different directions of space and covering the whole frequency spectrum, form continuous streams of terabytes of data that can be recorded and analyzed. With common data analysis techniques, astronomers can separate relevant data from noise, analyze similarities or complex patterns, and gain useful knowledge about the universe, but the visual analytics approach can significantly support the process of identifying unexpected phenomena inside the massive and dynamic data streams that would otherwise not be found by standard algorithmic means.

Monitoring *climate* and *weather* is also a domain which involves huge amounts of data, collected by sensors throughout the world and from satellites in short time intervals. A visual approach can help to interpret these massive amounts of data and to gain insight into the dependencies of climate factors and climate change scenarios, which would otherwise not be easily identified. Besides weather forecasts, existing applications visualize the global warming, melting of the poles, the stratospheric ozone depletion, as well as hurricane and tsunami warnings.

In the domain of *emergency management*, visual analytics can help determine the on-going progress of an emergency and identify the next countermeasures (e.g., construction of physical countermeasures or evacuation of the population) that must be taken to limit the damage. Such scenarios can include natural or meteorological catastrophes like flood or waves, volcanoes, storm, fire or epidemic growth of diseases (e.g., bird flu), but also human-made technological catastrophes like industrial accidents, transport accidents or pollution.

Visual analytics for *security* and *geographics* is an important research topic. The application field in this sector is wide, ranging from terrorism informatics, border protection, path detection to network security. Visual analytics supports investigation and detection of similarities and anomalies in large data sets, like flight customer data, GPS tracking or IP traffic data.

In *biology* and *medicine*, computer tomography, and ultrasound imaging for three-dimensional digital reconstruction and visualization produce gigabytes of medical data and have been widely used for years. The application area of bio-informatics uses visual analytics techniques to analyze large amounts of biological data.

From the early beginning of sequencing, scientists in these areas face unprecedented volumes of data, like in the Human Genome Project with three billion base pairs per human. Other new areas like Proteomics (studies of the proteins in a cell), Metabolomics (systematic study of unique chemical fingerprints that specific cellular processes leave behind) or combinatorial chemistry with tens of millions of compounds even enlarge the amount of data every day. A brute-force computation of all possible combinations is often not possible, but interactive visual approaches can help to identify the main regions of interest and exclude areas that are not promising.

Another major application domain for visual analytics is *business intelligence*. The financial market, with its hundreds of thousands of assets, generates large amounts of data every day, which accumulate to extremely high data volumes throughout the years. The main challenge in this area is to analyze the data under multiple perspectives and assumptions to understand historical and current situations, and then monitoring the market to forecast trends or to identify recurring situations. Other key applications in this area are fraud detection, detection of money laundering, or the analysis of customer data, insurance data, social data, and health care services.

Visual Association Rules

Li Yang
Western Michigan University, Kalamazoo, MI, USA

Synonyms

Association rule visualization

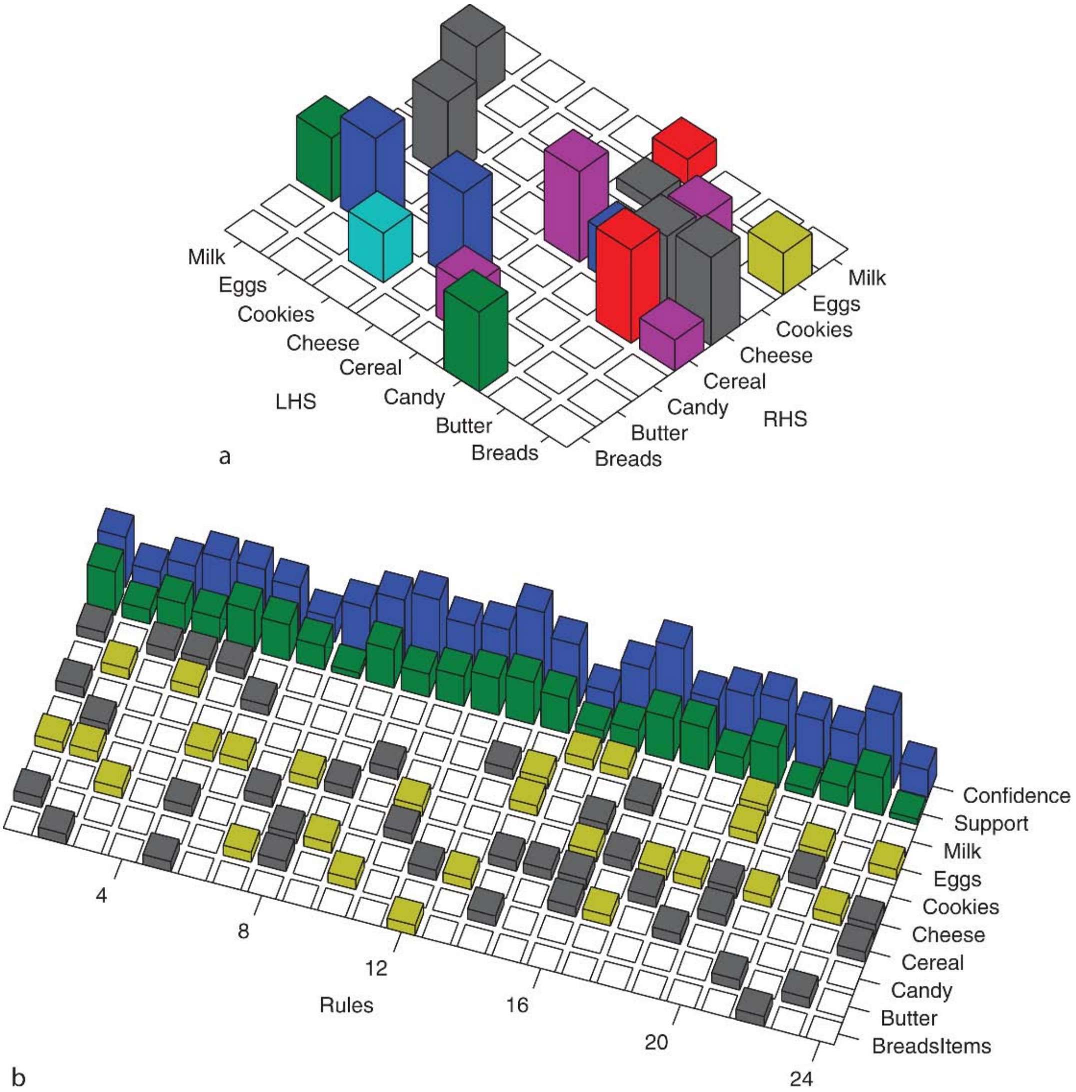
Definition

Association rule mining finds frequent associations between sets of data items from a large number of transactions. In market basket analysis, a typical association rule reads: *80% of transactions that buy diapers and milk also buy beer. The rule is supported by 10% of all transactions*. In this example, the 10% and 80% are called support and confidence, respectively. Depending on the user-specified minimum support and minimum confidence, association rule mining often produces too many rules for humans to read over. The answer to this problem is to select the most interesting rules. As interestingness is a subjective measure, selecting the most interesting rules is inherently human being's work. It is expected that information visualization may play an important role in managing a large number of association rules, and in identifying the most interesting ones.

Historical Background

An association rule reflects a many-to-many relationship. In lacking of an effective visual metaphor to display many-to-many relationships, information visualization has received a technical challenge in order to display and interact with many association rules. Most existing approaches have been designed to visualize association rules in restricted forms. The restriction can be on the number of items on each side of the rule, the type of the rule, the total number of items, or the total number of rules. These existing approaches can be classified into two categories: matrix-based approaches and graph-based approaches.

A rectangular matrix can be used to visualize one-to-one association rules, where the left-hand side (LHS) items of all rules are listed along one axis and the right-hand side (RHS) of all rules are listed along the other axis of the rectangular matrix. A rule could be shown as an icon in the corresponding cell. Figure 1a shows an example 3D visualization, where the height and color of each bar represent support and confidence values of the corresponding rule, respectively. The major restriction of this approach is that it allows only one item on each side of the rule. Wong et al. [9] gave an alternative approach of arranging axes, where one axis is used to list items and the other is used to list rules. A rule is then visualized by a 3D bar chart against all items in the rule. This approach is able to visualize many-to-many rules, as long as the number of rules is kept reasonably small. Figure 1b illustrates the approach where the color of each bar indicates whether the



Visual Association Rules. Figure 1. Two major matrix-based approaches: (a) LHS versus RHS and (b) Rule versus Item.

item is on the LHS or RHS of the rule. Support and confidence values of the rules are visualized alongside the bar charts. Another matrix-based approach is to use mosaic plots and double deck plots [4] to visualize the contingency table of a frequent itemset that gives rise to a many-to-one association rule. However, only many-to-one rules derived from a single frequent itemset can be visualized each time. Fukuda et al. [2] gave a matrix-based approach of visualizing numeric association rules, which contain two numeric attributes on the LHS and a Boolean attribute on the RHS. The approach displays the set of rules as a bitmap image.

Directed graph is another technique to depict associations among items. There are two alternatives to assign graph nodes:

1. Each node represents an itemset. An association rule is visualized as an edge from the node representing its LHS itemset to the node representing its RHS itemset. Such an approach has been used in IBM DB2 Intelligent Miner. A major problem is that there may easily be too many nodes to display.
2. Each node represents an item. An association rule is visualized as a bunch of edges from LHS items to an intermediate node and another bunch of edges from the intermediate node to RHS items. Such an approach may work well only when a few items and rules are involved. The graph can quickly turn into a tangled mess with as few as a dozen rules. Klemettinen et al. [5] introduced a rule visualizer that uses this approach.

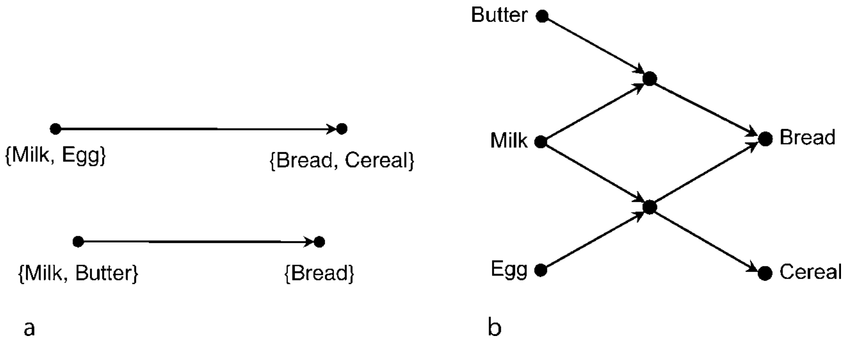
Figure 2 illustrates the two alternatives of visualizing association rules as directed graphs.

Visualization of association rules can be found in commercial data mining packages. SAS Enterprise Miner and SGI MineSet use matrix-based approaches and allow the user to visualize one-to-one association rules. IBM DB2 Intelligent Miner has a Associations Visualizer that uses the directed graph approach where each graph node displays an itemset.

Foundations

Association rule mining [1,3] is one of the mostly researched areas in data mining. Let $I = \{i_1, i_2,...,i_k\}$ be a set of items. A subset $A \subseteq I$ of items is called an itemset. Input data to association rule mining are n subsets $\{T_1, T_2,...,T_n\}$, called transactions, of I. Transaction T_i supports an itemset A if $A \subseteq T_i$. The percentage $P(A)$ of transactions that support A is called the support of A. A *frequent itemset* is an itemset whose support is no less than a minimum value specified by the user. An *association rule* is an expression $A \rightarrow B$ where A and B are itemsets and $A \cap B = \emptyset$. $P(A \cup B)$ is called the *support* of the rule. $P(A \cup B)/P(A)$ is called the *confidence* of the rule. The problem of association rule mining is to find all association rules whose supports are no less than a minimum support value and whose confidences are no less than a minimum confidence value. Frequent itemsets hold a well-known Apriori property: subsets of a frequent itemset are frequent. Efficient association rule mining algorithms [1] have been developed using the Apriori property for early pruning of search space.

The problem of too many discovered rules has also been studied. Klemettinen et al. [5] studied association rules at the border of frequent itemsets and used pattern templates to specify what the user wants to see. Testing criteria such as maximum entropy and



Visual Association Rules. Figure 2. Two major graph-based approaches: (a) Itemset as node and (b) Item as node.

chi-square(χ^2) have been suggested to replace the confidence test for the purpose of finding the most interesting rules. Liu et al. [7] have given a way of pruning and visualizing association rules with the presence of item taxonomy, by allowing a user to specify knowledge in terms of rules. Unexpected rules (that do not conform to the user's knowledge) are selected and visualized in a structured way.

Association rules are difficult to visualize for several reasons. First, an association rule reflects a many-to-many relationship and there is no effective visual metaphor to display many many-to-one, never to say many-to-many, relationships. Second, frequent itemsets and association rules have inherent closure properties. For example, any subset of a frequent itemset is also frequent; if $a \rightarrow bc$ is a valid association rule, then $a \rightarrow b$, $a \rightarrow c$, $ab \rightarrow c$ and $ac \rightarrow b$ are all valid association rules. Third, the challenge is to visualize many such itemsets or rules. With the absence of an effective visual metaphor to present many-to-many relationships and to accommodate the closure properties, frequent itemsets and association rules pose fundamental challenges to information visualization.

Taking a function-theoretic view, the Apriori property basically says that frequent itemsets define an anti-monotone Boolean function $f(i_1,i_2,...,i_k)$ where $i_1,i_2,...,i_k$ are Boolean variables (items). As the function is anti-monotone, there is a border which separates 1's from 0's. Visualization of monotone Boolean functions has been studied by Kovalerchuk and Delizy in [6], although association rules are not their concern. Boolean vectors are displayed in multiple disk form where Boolean vectors of the same norm (equivalently, itemsets with the same number of items) are placed on the same disk. Figure 3 shows visualizations of an anti-monotone Boolean function $f(i_1,i_2,...,i_{10}) = \neg\, i_1$. Such a function is equivalent to frequent itemsets on $\{i_1,i_2,...,i_{10}\}$ where $\{i_2...i_{10}\}$ is a frequent itemset and $\{i_1\}$ is infrequent. In Fig. 3a, Boolean vectors are arranged on each disk in their numeric order. The visualization does not permit any real understanding of the border of frequent itemsets. Fig. 3b rearranges Boolean vectors on each disk so that all vectors on a Hansel chain are aligned vertically. A chain is a sequence of Boolean vectors such that each vector produces the next vector by changing a "0" element to "1," and Hansel chains provide a way to non-repeatedly visit all vectors. As the function is monotone on each chain, Fig. 3b does show a border, although the border is highly zigzagged. Figure 3c rearranges Hansel chains according to the position of the first "1" value within each chain and shows the border in a clearer way.

Frequent itemsets and association rules are often presented in a set-theoretic view. Given a set $I = \{i_1, i_2,...,i_k\}$ of items, its power set $\mathcal{P}(I)$ forms a lattice $<\mathcal{P}(I), \subseteq>$ where the subset relationship $\subseteq$ specifies the partial order. For an example set of items, $I = \{a, b, c, d\}$, this lattice can be illustrated in Fig. 4a. Frequent

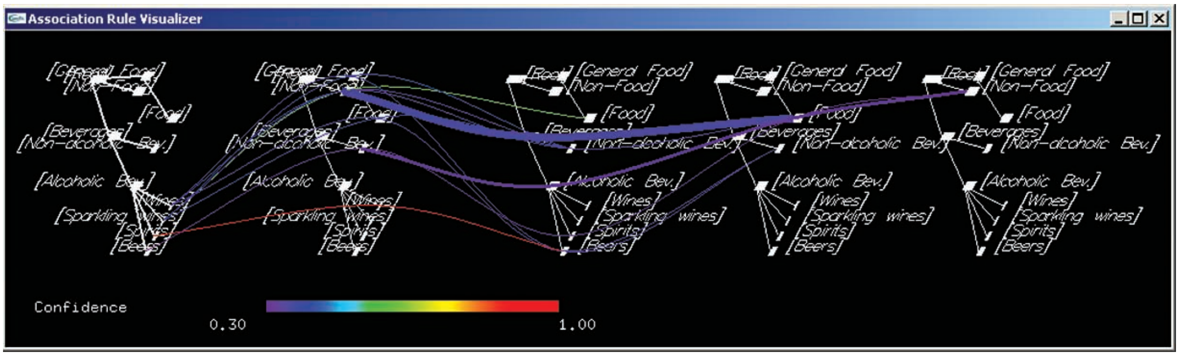
Visual Association Rules. Figure 4. Itemset lattice, item taxonomy tree, and generalized itemset lattice on $I = \{a, b, c, d\}$: (a) Itemset lattice, (b) An item taxonomy tree, and (c) Generalized itemset lattice. (Courtesy of [10].)

itemsets define a border on the lattice: if an itemset is frequent, so is every subset of it; if an itemset is infrequent, so is every superset of it. The objective of frequent itemset visualization is to visualize the border. In fact, this has been tried in the three visualizations in Fig. 3, which have visualized the whole lattice structure. Each disk in Fig. 3 displays $\binom{k}{l}$ itemsets where l is the disk level. Clearly, such an approach would fail when k is large.

In order to deal with the problem of long border of frequent itemsets, Yang has developed an approach [10] for visualizing generalized frequent itemsets and association rules by introducing user interaction with the border. Generalized association rules come from the introduction of item taxonomy. As shown in Fig. 4b, an item taxonomy is a directed tree whose leaf nodes are items and whose non-leaf nodes are item categories. Mining generalized association rules across item taxonomy was studied in [8]. Item taxonomy introduces another dimension of closure property. For example, an ancestor itemset of a frequent itemset is also frequent.

The presence of item taxonomy extends an itemset lattice to a generalized itemset lattice. The user can choose which items or item categories to display in an item taxonomy tree. The partially displayed item taxonomy tree induces a border of displayable itemsets in the generalized itemset lattice. For example, if the



Visual Association Rules. Figure 5. Visualizing association rules with item taxonomy. (Courtesy of [10].)

items *c, d, e, f* in Fig. 4b are displayed, this induces a border of displayable itemsets shown in Fig. 4c. Only non-redundant displayable frequent itemsets, for example, *ec* and *ed* in Fig. 4c, are visualized. In association rule visualization, only non-redundant rules derived from frequent displayable itemsets are visualized.

The non-redundant displayable frequent itemsets and association rules are visualized in 3D through parallel coordinates, where each parallel coordinate is replaced by a standing visualization of item taxonomy tree. An itemset or rule is visualized as a Bézier curve connecting all items in it. Parameters such as support and confidence can be mapped to graphical features such as width or color of the curve. Figure 5 gives a screen snapshot in the interactive visualization of many-to-many association rules, where association rules are aligned according to where the RHSs separate from the LHSs. In Fig. 5, the left two coordinates represent the LHSs of the rules and the right three coordinates represent the RHSs of the rules. The displayed item taxonomy tree can be expanded or shrunk by user interaction, and each change triggers a new set of itemsets or rules to be displayed.

Key Applications

As a standard feature in many data mining software packages, association rule visualization has been used widely in business intelligence and scientific research.

Future Directions

Although approaches have been developed to visualize association rules, none of them has gained predominant acceptance and can simultaneously manage a large number of rules with multiple items on both sides. Visual association rule research has many open problems. An obvious one is how to prune uninteresting itemsets and rules, a topic that has bothered researchers for years. Specific to visualization, open problems include how to visualize a large number of many-to-many rules and how to associate closure properties of itemsets or rules with intuitive visual presentations. Data visualization on the lattice structure has potential applications beyond visual association rules. For example, it can be used in the visualization of iceberg data cubes in data warehousing.

Cooperative classification

Definition

Decision trees have been successfully used for the task of classification. However, state-of the-art algorithms do not incorporate the user in the tree construction process. Through the involvement of the user in the process of classification, he/she can provide domain knowledge to focus the search of the algorithm and gain a deeper understanding of the resulting decision tree. In a cooperative approach, both the user and the computer contribute what they do best: the user specifies the task, focuses the search using his/her domain knowledge and evaluates the (intermediate) results of the algorithm. The computer, on the other hand, automatically creates patterns satisfying the specified user constraints. The cooperative approach is based on a novel visualization technique for multi-dimensional data representing their impurity with respect to their class labels.

Historical Background

The idea of visual classification has been built upon recent progress in the area of information visualization and decision trees.

Many different algorithms for learning decision trees have been developed over the last 20 years. For instance, *CART* [1] was one of the earliest systems which, in particular, incorporates an effective pruning phase. Their so-called minimum cost complexity pruning cuts off branches that have a large number of leaf nodes, yielding just a small reduction of the apparent error. *SLIQ* [2] is a scalable decision tree classifier that can handle both numerical and categorical attributes. In order to make SLIQ scalable for large training sets, special data structures called attribute lists are introduced, which avoid sorting the numerical attributes for each selection of the next split. Furthermore, a greedy algorithm for efficient selection of splits of categorical attributes is presented. An experimental evaluation demonstrates that SLIQ produces decision trees with state-of-the-art accuracy, and tree size with a much better efficiency for large training sets.

Visual representation of data as a basis for the human–computer interface has evolved rapidly in recent years. The increasing amount of available digital information in all kinds of applications has led to the challenge of dealing with both high dimensionality and large amounts of data. [3] gives a comprehensive overview over existing *visualization techniques* for large amounts of multidimensional data, which have no standard mapping into the Cartesian coordinate system.

Foundations

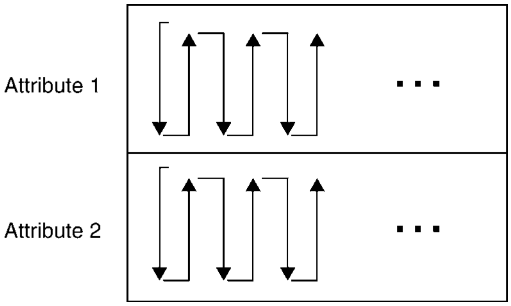
A decision tree classifier constructs a tree in a top-down fashion, performing a greedy search through the very large space of all possible decision trees. At each current node, the attribute that is most useful for the task of classification (with respect to the subset of all training objects having passed all tests on the path to the current node) is selected. Criteria such as the information gain or the gini index have been used to measure the usefulness of an attribute. Domain knowledge about the semantics of the attributes and the attribute values is not considered by the criteria. Note that greedy algorithms for decision tree construction do not allow to backtrack to a previous choice of an attribute when it finally turns out to be suboptimal.

V*isual classification* [4,5] is a user-centered approach to decision tree construction where the user and the computer can both contribute their strengths. The user provides domain knowledge and evaluates intermediate results of the algorithm, the computer automatically creates patterns satisfying user constraints and generates appropriate visualizations of these patterns. In this cooperative approach, domain knowledge of the user can direct the search of the algorithm. Additionally, by providing adequate data and knowledge visualizations, the pattern recognition capabilities of the human can be used to increase the effectivity of decision tree construction. Furthermore, the user gets a deeper understanding of the decision tree than just obtaining it as a result of an algorithm.

The three components of visual classification is visualizing the data, visualizing the decision tree and the integration of algorithms into decision tree construction.

Visualizing the data is done by the pixel-oriented bar technique. The bar visualization technique is performed as follows. Within a bar, the sorted attribute values are mapped to pixels in a line-by-line fashion according to their order. Each attribute is visualized independently from the other attributes in a separate bar. Figure 1 illustrates the method of the bar visualization for the case of two attributes. The amount of training data that can be visualized by the bar technique is determined by the product of the number of data records and the number of attributes.

Visualizing the decision tree is done by a visualization technique, such that each node is represented by the data visualization of the chosen splitting attribute of that node. For each level of the tree a bar is drawn representing all nodes of this level. The top level bar corresponds to the root node of the decision tree. On lower levels of the tree the number of records and thus the number of pixels is reduced if there are leaves in upper levels – leaves are underlined with a black line. Black vertical lines indicate the split points set in the current bar. On lower levels, partitions of the data inherited from upper levels are marked by white vertical lines at the same horizontal position as the original split point. Attribute and node information at the mouse pointer position (attribute name, attribute value, min., max. value and number of records in this node) is displayed on demand. Upon a mouse click the system switches back to the data visualization of the corresponding node.



Visual Classification. Figure 1. Illustration of bar visualization.

Compared to a standard visualization of a decision tree, a lot of additional information is provided which is very helpful in explaining and analyzing the decision tree:

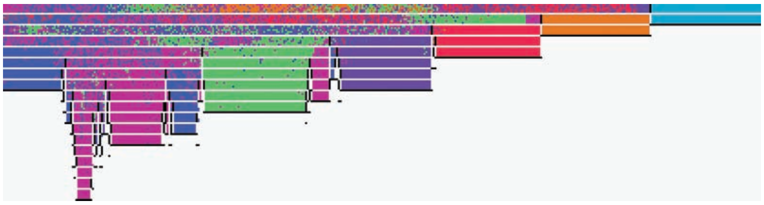
- Size of the node (number of training records corresponding to the node)
- Quality of the split (purity of the resulting partitions)
- Class distribution (frequency and location of the training instances of all classes)

Figure 2 illustrates the visualization of a decision tree for the Segment training data from the Statlog benchmark [6] having 19 numerical attributes.

The integration of algorithms into decision tree construction is solved in the following way.

Propose Split

For a set of attributes selected by the user, the attribute with the best split together with the optimum split point of this attribute is calculated and visualized. If a singleton attribute is specified as input, only the optimum split point for this attribute is determined. The function *propose split* turns out to be useful in two



Visual Classification. Figure 2. Illustration of knowledeg visualization.

cases: first, whenever there are several candidate attributes with very similar class distributions and, second, when none of the attributes yields a good split which can be perceived from the visualization.

Look-Ahead

For some hypothetical split of the active node of the decision tree, the subtree of a given maximum depth is calculated and visualized with the new visualization technique for decision trees. This function offers a view on the hypothetical expansion up to a user specified number of levels, or until a user specified minimum number of records per node. If the lookahead function is invoked for a limited number of levels, it is very fast (some seconds of runtime) because no pruning is performed in this case. The *look-ahead* function may provide valuable insights for selecting the next split attribute. Without the look-ahead function, when there are several candidate attributes the user selects one of them, chooses one or several split points and continues the tree construction. If at a later stage the expanded branch does not yield a satisfying subtree, the user will backtrack to the root node of this branch and will remove the previously expanded subtree. He/she will select another candidate attribute, split it and proceed. Utilizing the new function, however, the user requests a look-ahead for each candidate attribute before actually performing a split. Thus, the necessity of backtracking may be avoided.

Expand Subtree

For the active node of the decision tree, the algorithm automatically expands the tree. Several parameters may be provided to restrict the algorithmic expansion such as the maximum number of levels and the minimum number of data records or the minimum purity per leaf node. The pruning of automatically created subtrees rises some questions. Should one only prune the subtree created automatically or prune the whole tree – including the subtrees created manually? According to the paradigm of the user as a supervisor, pruning is only applied to automatically created trees. It is important to distinguish two different uses of the *expand subtree* function: the maximum number of levels is either specified or it is unspecified. In the first case, the decision tree is usually post-processed by the user. No pruning is performed if a maximum number of levels is specified. Otherwise, if no maximum

Visual Classification. Figure 3. PBC system.

number of levels is specified, the user wants the system to complete this subtree for him and pruning of the automatically created subtree is performed if desired. The function *expand subtree* is useful in particular if the number of records of the active node is relatively small. Furthermore, this function can save a lot of user time because the manual creation of a subtree may take much more time than the automatic creation.

The visual classification approach is implemented in the PBC system, as depicted in Fig. 3.

Key Applications

The visual classification approach can be applied to any domain where decision tree classification is applicable. The value of the approach is the deeper understanding of the data and the decision tree.

Visual Clustering

Mike Sips
Stanford University, Stanford, CA, USA

Synonyms

Visual mining; Visual data mining

Definition

Synthesis of computational methods and interactive visualization techniques that represents a clustering structure, defined in higher dimensions to the human analyst in order to support the human analyst to explore and refine the clustering structure of high dimensional data spaces based on his/her domain knowledge.

Historical Background

The advancements made in computing technology over the last two decades allow both scientific and business applications to produce large data sets with increasing complexity and dimensionality. Automated clustering algorithms are indispensable for analyzing large n-dimensional data sets but often fall short to provide completely satisfactory results in terms of quality, meaningfulness, and relevance of the revealed clusters. With the increasing graphics capabilities of the available computers, researchers realized that an integration of the human into the clustering process based on visual feedbacks helps to improve the effectiveness of automated clustering algorithms. A synthesis of automated clustering algorithm and visualization usually does not only yield better clustering results, but also a higher degree of user satisfaction and confidence in the findings.

Foundations

Clustering is one of the basic data analysis tasks. It is a process of organizing data into similar groups. Unlike classification, clustering is unsupervised learning. In particular, the classes are unknown and no training set with pre-computed class labels is available. A clustering algorithm in general can be seen as an external source that labels the data.

Automated clustering algorithms are indispensable in analyzing large n-dimensional data spaces, but they often fall short in computing completely satisfactory results. In general, two interconnected reasons can be observed. First, many clustering algorithms use assumptions about specific properties of clusters either as built-in defaults or as input parameter settings. Automated clustering algorithms are very sensitive to these input parameters. Analysts often get different clustering results even for slightly different parameter settings. Useful parameter settings are in general hard to determine a priority because humans have huge difficulties in understanding the impact of different parameter settings on the revealed clusters; especially in n-dimensional data spaces. Second, large n-D data spaces often have skewed distributions. The density, distribution and shape of the clusters are quite diverse in different subspaces. Skewed distributions are in general difficult to reveal using just one global parameter setting.

A variety of different visual clustering approaches have been proposed. Visual clustering can be classified into four common approaches, based on their mechanism to incorporate the data analyst into the clustering process. Several exploratory data analysis systems allow an interactive exploration of a given clustering structure based on projections. The aim is to make a given clustering structure in n-D interpretable for the human. A few visual clustering approaches are extensions of an optimized clustering algorithm with advanced visualization techniques. Other approaches extract the clustering structure based on the analyst's feedback. In these scenarios, clusters are characterized based on the analyst's specific domain knowledge. More recently, novel data analysis techniques from related disciplines such as machine learning or statistics supporting visual clustering have been proposed. An interesting approach uses visualization to support the selection of subspaces that contain strong clusters. Another interesting approach is Self-Organizing Maps.

Visual Exploration of a Given Clustering Structure

Many interactive systems use orthogonal standard projections to visualize the given clustering structure of an n-dimensional data space. Orthogonal standard projections are widely used in exploratory data analysis, because they are easy to understand. Unlike in unlabeled data, the data item's class labels are exploited in these approaches to find interesting projections of the clustering structure, i.e., projections that preserve properties of the clusters.

The n23Tool proposed by Yang [15] uses 3–D cluster-guided projections [5]. The idea of cluster-guided projections is to find a 3–D subspace that neatly separates four given clusters. A cluster-guided projection is based on the following observation. Any combination of four distinct and non co-linear cluster centers defines a unique 3-D subspace. Moreover, such a subspace neatly separates the four clusters, and in addition it also preservers the inter-cluster distance between any two of the cluster centers. To support an efficient exploration of clusters in n-dimensional data spaces, the n23 tool combines cluster-guided projections with Grand Tour [3]. A cluster-guided tour allows an analyst to quickly get an impression of all clusters by smoothly moving through the space of cluster-guided projections.

Koren and Carmel [11] propose an alternative measure of goodness to preserve the clustering structure in projections. The basic idea is to weight the distances between points differently depending on whether they have the same class label. Given this objective function, the approach then searches for the best linear transformation of the n-dimensional data. This method has a significant advantage in comparison to traditional PCA or MDS, because it captures the cluster structure of the data, and in addition the intra-cluster shapes. One general problem with general projections and embeddings is that users may have trouble interpreting the display. Another problem is that these approaches work well whether the clusters are neatly separated in n–D or the data contains only small amounts of noise.

The Self-Organizing Map (SOM) is a neural network algorithm based on unsupervised learning (see [10] for further readings). The basic idea is to stretch a 1-D or 2-D neuron grid through the data. The lattice of the grid can be either rectangular or hexagonal. Each neuron is represented by an n-dimensional prototype vector. During the iterative training of a SOM, the neurons become the cluster means, and points closest to the neurons are considered to belong to that cluster. Intuitively, a SOM can be seen as a constraint k-means algorithm (the net of neurons is very flexible and folds onto the data clouds).

SOM's can be used to visualize the clustering structure of an n-dimensional data space. The 1-D or 2-D grids get wrapped into a flat 2-D layout [12]. An alternative visual representation of the clustering structure can be achieved by visualizing either the distances of each grid unit to its neighboring grid units or the similarity of grid units. In most cases, gray shading (U-Matrix) and geometric shapes (Distance-Matrix) are used to represent distances to neighboring grid units, and color to show similarity of grid units (similarity coloring). A detailed discussion of SOM-based data visualization techniques is presented in [14].

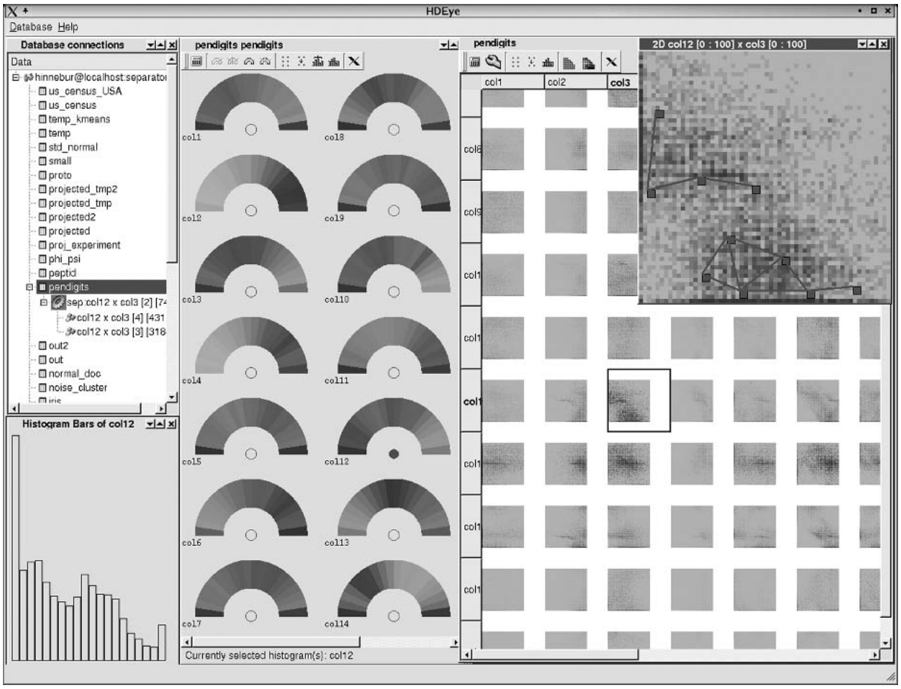
Extension of an Optimized Clustering Algorithm

An interesting extension of OptiGrid [8] with both an iconic visualization technique and kernel- density plots is HD-Eye [9]. OptiGrid is a density-based clustering algorithm that uses contracting projections and separators to build up an n-dimensional grid. Clusters are defined as highly populated grid cells.

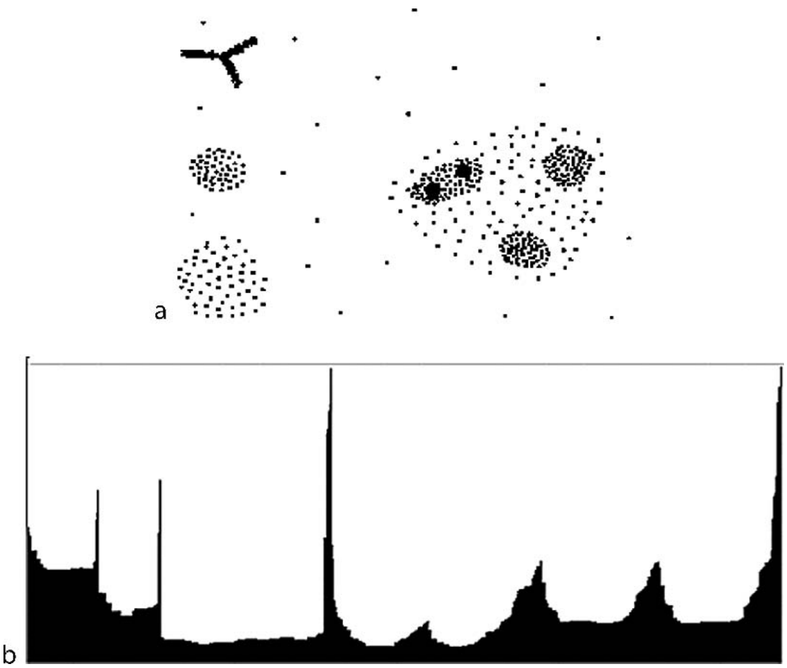
HD-Eye considers clustering as a partitioning problem. A projection is of potential interest in finding cluster separators whether it neatly separates a number of clusters in the projected space. Finding interesting projections and specifying good separators are two difficult problems; both are difficult to compute automatically. The basic idea of HD-Eye is to allow specific user feedbacks in two crucial steps of the partitioning process. To support the user in surveying the vast set of orthogonal projections in order to find potential useful projections, HD-Eye employs an abstract iconic display (Fig. 1). The shapes of the icons are determined based on the number of maxima of the data's density function, and how well the maxima are separated in the projections. The color of the icons represents the number of data items belonging to a maxima. Once a potential interesting projection has been selected, HD-Eye provides 1-D/2-D color-based density plots for a further analysis of the projection. Density plots easily allow the analyst to check whether a projection separates a number of clusters well.

The HD-Eye approach doesn't require that a projection neatly separates all clusters but at least two clusters. HD-Eye follows an iterative partitioning process. Based on his/her domain knowledge and intuition, the analyst interactively selects interesting projections from the iconic display. Then, the analyst defines useful separators within the density plots by drawing either a split line (linear partitions) or a split polygon (non-linear partitions). The analyst can easily follow the interactive partitioning process by inspecting the separator tree. After each interactive partitioning, the clusters get refined, i.e., highly populated regions based on the refined grid, and added into the separator tree.

Another interesting approach is OPTICS [2] (Fig. 2). OPTICS is an extension of the DBSCAN [6] algorithm and creates a one-dimensional ordering of the data items. The ordering of the data items represents its density-based clustering, which can be obtained from a broad range of input parameter



Visual Clustering. Figure 1. The HD-Eye interfaces has three main visual components – the iconic display showing properties of the projections, 1–D and 2–D kernel-density plots for a further analysis of selected projections, and the separator tree. Clockwise starting from the top: separator tree, iconic representation of 1–D projections, 1–D projection histogram, 1–D color-based density plots, iconic representation of multi dimensional projections and color-based 2D density plot. Figure is taken from the exploration of a large molecular biology data set. (used with permission of Alexander Hinneburg).



Visual Clustering. Figure 2. The figure shows an example data (Fig. 2a) and its reachability plot (Fig. 2b) – objects are on the x-axis together with their reachability values on the y-axis. (used with permission of Mihael Ankerst).

settings. Clusters in DBSCAN are determined based on ε and MinPt parameters, when ε is the radius of a local neighborhood around each data item, and MinPt determines the minimal number of data items in the local neighborhood. The basic observation of OPTICS is that given a constant MinPt value, density-based clusters with respect to a higher density (lower ε) are completely contained in density-based clusters with respect to a lower density (greater ε).

The ordering of the data items can be used to visualize how the data items are clustered. These visualizations are called reachability plots. The data items are visualized according to the clustering ordering on x-axis, together with their associated reachability distance on y-axis. Intuitively, data items sharing a common cluster are close to each other in the cluster ordering and have similar reachability distances. The reachability distance jumps whether a different cluster starts in the ordering. In addition, the ordering of the data items can be used to compute a cluster hierarchy (dendrogram).

Clustering Based on Visual User Feedback and Refinement

An interesting approach is presented by Aggarwal [1]. The basic idea is similar to HD-Eye, i.e., the search for projection that neatly separates clusters. In contrast to HD-Eye that uses an iconic display to show properties of the projections and then supports an interactive search for interesting projections, Aggarwal proposed an iterative cluster partitioning based an automated subspace detection algorithm.

The idea of the algorithm is straightforward and follows an iteration process. In each iteration step, a number of data items called polarization points are randomly chosen from the data set. Next, an analytic method is used to find a lower-dimensional subspace that neatly groups the data items around the polarization points. Once an interesting projection has been found, HD-Eye and Aggarwal use kernel-density plots of the projected data in order to discover the clustering structure. In contrast to the HD-Eye approach that allows an interactive separation of clusters in the density plots, Aggarwal's approach separates clusters by choosing noise levels.

The iterative cluster partition process terminates whether all data items belong at least to one cluster. The final clustering structure is extracted in a frequent item analysis based on the recorded user selections in each partitioning step. To control the granularity of the cluster separation in the final clustering structure, the analyst can choose different noise levels for the same projection.

ClusterSculpture [13] is an interesting approach that allows an analyst to interactively refine an initially computed hierarchical clustering structure. The hierarchical clustering structure is described as a dendrogram. The analyst refines that dendrogram by either splitting or merging a number of nodes; if it's necessary the analyst might want to reorganize the whole dendrogram. ClusterSculpture supports the analyst in deciding whether a node should be split or merged by presenting the relationship between the attribute values and the clustering structure, as well as the distances of neighboring data items around a selected cluster.

ClusterSculpture provides three main visualizations. A dendrogram shows the cluster hierarchy, and it allows the analyst to quickly survey the clustering structure. The distribution of the attribute values in each dimension are shown in a point map. Each data item is visualized as a horizontal line with one colored pixel for each dimension. The color of each pixel represents the normalized attribute value in that dimension. Additionally, the data items are sorted along the y-axis to emphasize the clustering structure. The distances of neighboring data points around the leaf cluster closest to a selected data item is presented when the analyst selects a data item in the point map. Three different colors are used to represent the selected data item, and whether or not data items share the same neighbor with the selected data item.

A number of exploratory data analysis systems have interactive visualizations to support the analyst in finding clusters. GGobi [4] supports the analyst by providing a spin-and-brush mechanism. Starting with

an initial projection of the data, the analyst tours through the space of possible projections until an interesting projection is reached. The analyst then paints a cluster in that projection using an easy to distinguish color, and continues touring until no more clusters are revealed.

Visualization Used as Interactive Feature Selection for Clustering

An interesting subspace selection method that effectively identifies subspaces determining strong clusters is proposed by Guo [7]. The method is based on the computation of the pairwise conditional entropy values of 2-D subspaces. The pairwise conditional entropy values are visualized in the so-called entropy matrix, which allows the data analyst to easily understand relationships among dimensions (Fig. 3). Interesting multi-dimensional subspaces can be either automatically extracted or visually identified in the entropy matrix. The selected dimensions can be fed into a clustering algorithm in order to improve the effectiveness of the clustering results. Although designed as a feature selection method, the entropy matrix allows the analyst to get an understanding of the overall clustering structure of an n-dimensional data space.

Key Applications

Effective mining of large traditional relational databases, complex 2-D and 3-D multimedia databases, geo-spatial databases, and bio-databases.

Definition

Visual content analysis is the process of deriving meaningful descriptors for image and video data. These descriptors are the basis for searching large image and video collections. In practice, before the process starts, one applies image processing techniques which take the visual data, apply an operator, and return other visual data with less noise or specific characteristics of the visual data emphasized. The analysis considered in this contribution starts from here, ultimately aiming at semantic descriptors.

Historical Background

Analyzing the content of visual data using computers has a long history, dating back to the 1960s. Some initial successes prompted researchers in the 1970s to predict that the problem of understanding visual material would soon be solved completely. However, the research in the 80s showed that these predictions were far too optimistic. Even now, understanding visual data is still a major challenge.

In the 90s a new field emerged, namely content-based image retrieval (CBIR), where the aim is to develop methods for searching in large image archives. Where the computer vision community was publishing papers on the analysis of 10–50 images, the CBIR researchers started with 1,000 images or more. Nowadays, research papers consider data sets which are orders of magnitudes larger in size. The paper by Smeulders et al. [10] reviewed the state-of-the-art in 2000, almost all of the findings are still very relevant for current research.

The CBIR field has not only developed itself since then, it also had a major impact on the computer vision field. Large visual collections are also becoming the standard in computer vision. It also led to new methods for analyzing visual data. In early methods for understanding the content of the data pre-defined models were used. In current research, models are learned automatically from large sets of annotated examples, based on the appearance of objects in the visual data. This makes the computer vision algorithms more flexible and easier to adapt to new data sets.

Video content analysis started later than image analysis due to the high processing power required. Computer capacity, however, has increased substantially over the last 10 years making it feasible to process also large collections of video. Research in video content analysis started with camera shot segmentation and simple analysis. Soon the research community realized that the result of automatic speech recognition is an important, sometimes decisive, factor in video content analysis. Best results are obtained if the visual and audio modalities are analyzed in conjunction [11]. Relying on speech is fine for video programs with a clear speech signal, nicely separated from environmental sounds and music. More and more, however, people create video data without such clear speech, so the role of visual content has moved to the forefront in video content analysis again.

So, although visual content analysis started around 50 years ago, it is still an active research area with many research challenges ahead.

Foundations

Automatically extracting the semantics of visual data is a notoriously difficult problem which has become known as the semantic gap [10]:

Semantic gap: The semantic gap is the lack of coincidence between the information that one can extract from the sensory data, and the interpretation that the same data has for a user in a given situation.

The existence of the gap has various causes. One reason is that different users interpret the same visual data in a different way. This is especially true when the user is making subjective interpretations of the visual data. In the following part those subjective interpretations are not considered. However, also for objective interpretations like the presence of a car in a picture, developing automatic methods is still difficult. Consequently, their performance is not optimal. The difficulties are due to the large variations in appearance of visual data corresponding to one semantic concept. Cars, for example, come in different models, shapes, and color. The above causes are inherent to the problem. Visual analysis methods should address these fundamental problems.

There are also variations in appearance which are not due to the richness of the semantics. Varying the viewpoint, lighting and other circumstantial conditions in the recording of a scene will deliver different data, whereas the semantics have not changed. These variations induce the so called sensory gap, which is defined as [10]:

Sensory gap: The sensory gap is the gap between the object in the world and the information in an image recording of that scene.

One of the consequences of the semantic and sensory gap is the fact that recordings of semantically different objects might appear more similar than two recordings of the same object in different recording conditions. Methods are needed that are minimally affected by the sensory gap, while still being able to distinguish objects with different semantics. This is the essence of visual content analysis. General methods for doing the analysis are described next.

Methods for deriving the semantics of visual data are mostly based on a supervised learning scheme. In such a scheme, the developer provides the system with a large set of annotated examples. For all of the examples, the system extracts low-level features. The system then uses a machine learner to build a model for each semantic concept. Now, if a new image or video without annotation is given, the system again computes features. It then uses the model to derive a measure of the probability of the concept being present in the visual data. An overview of the general concept based video content analysis scheme is depicted in Fig. 1.

So, the two main things to consider are the features to extract and the machine learning scheme.

Features are many, see [10,11] for an extensive overview. A good starting point for a set of practical visual features is defined in the MPEG-7 standard [8]. There are different categories of features namely color features, texture features, shape features, and motion features, which will now be described.

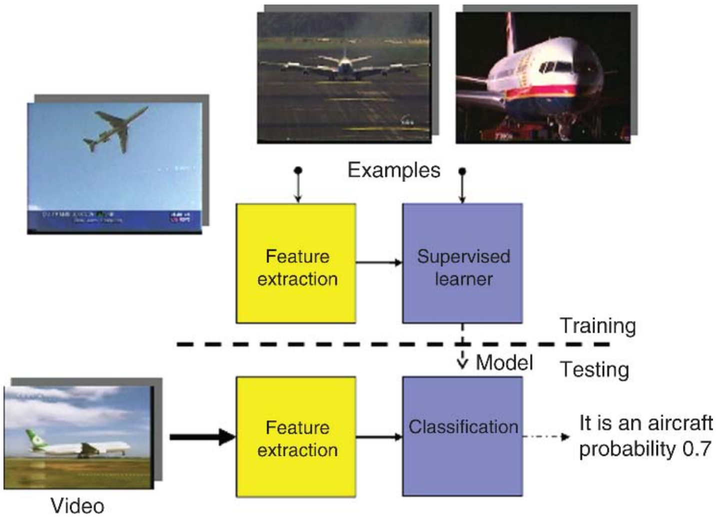
Color features in their simplest form are global descriptions of the visual content based on color histograms. There are numerous color spaces to choose from in which to compute the histogram, including standard *RGB*, the intuitive *HSV* space, the perceptually uniform *Lab* space, or the invariant set of color spaces in [4]. Methods which use more elaborate methods than histograms take the color layout into account, in addition to global characteristics.

Where color is a property which can be measured at every pixel in the visual data, texture is a measure which considers patterns in the image. Again, there is a variety of methods to choose from with varying characteristics in terms of invariance. Many can be traced back to statistics on co-occurrence of grey values in a local neighborhood, or filters emphasizing patterns in certain directions like Gabor filters. In [3], a convenient set of features for texture description has been defined based on natural statistics.

Color and texture often form the basis for segmenting the visual data in homogeneous regions. This process is known as weak segmentation as it is purely based on the visual data itself, not on the interpretation of the data. The latter is known as strong segmentation, which is delineating the contour of a semantic object in the image.

Strong segmentation is required before shape features can be measured. As a consequence, shape features are only applicable for those applications where the background can be controlled easily, like the recognition of logos or a set of objects on a turntable. A distinction is made here between descriptors that describe the object as a region, e.g., based on properties of the medial axis, and measures that take the contour as the basis, like the curvature scale space descriptor.

In most practical cases, strong segmentation is impossible, whereas global descriptors loose too much of



Visual Content Analysis. Figure 1. General scheme for concept-based learning in visual data using annotated examples.

the spatial information. Some methods therefore focus on weak segmentation, describing the resulting regions individually, or move to the detection of key points. These key points are characteristic points on the contours of objects, which in many cases capture the most important information of the object [7].

All of the above features are equally important for video data. However, for video one can also make use of the temporal dimension. One can analyze the motion pattern to find the camera motion, track regions or points of interest through the sequence and describe their tracks, or derive general measures of the activity in the scene. These additional information sources can enhance the interpretation of the data.

Feature extraction yields a feature vector for every image or video segment. As indicated, for interpretation of the data, state-of-the-art systems follow a supervised learning approach.

A good overview of learning methods is presented in [5]. Although there is a large variety of methods, the Support Vector Machine has become the standard choice in most visual indexing schemes [1,14].

The above considers the visual data in isolation, but often the data has associated text data like the automatic speech recognition results for video. This data can be used as an additional source to improve the understanding of the data. In fact, for some concepts the textual data gives almost all the clues to interpret the visual data, others perform best when only the visual data is used. Relations between the concepts detected can also provide essential information for some concepts. Therefore, a method like [13], which learns for a given concept the optimal analysis scheme through appropriate analysis of the data, is the best choice.

Key Applications

Video content analysis plays a role in various application areas, the major ones are considered here.

Broadcasting

The broadcasting field generates enormous amounts of audio-visual data, which should be stored for later reference and re-use. Manual annotation is laborious and expensive. Tools for automatic analysis are of great importance to deal with this flood of videos.

Narrow Casting

Producing video, up to now, has been limited to major film studios or specialized companies. Now, every organization, association or individual can create video and put it on the web. Even more than for broadcasting companies, narrow casters have limited resources to manually analyze the content of their videos.

Law Enforcement

Through the availability of cheap cameras, video content analysis plays a major role in law enforcement. There is a need for content analysis to detect and analyze illicit video material on confiscated hard disks containing hundreds of gigabytes of video data. In video surveillance, a single camera generates 7*24 h of video per week. Any visual content analysis which helps the operator in reducing the load of watching these video streams is of great importance.

Web Search

There is no need to explain that there is a tremendous amount of video available on the Internet. Video search on the web, however, is still mostly limited to keyword-based search for full video clips. Video content analysis is needed to delve into the actual content of all these videos out there.

Future Directions

Obviously the research in video content analysis has not reached its end yet. On the contrary, the community is only beginning to automatically understand the meaning of visual material. To bring the field a step further, researchers should tackle the large number of open questions out there.

Tangential contributions will introduce features with higher discriminatory power, while having better invariant properties, and new machine learning techniques, better suited for the specifics of visual data.

A new direction is tackling the major bottleneck in supervised learning, namely the amount of training examples needed, by employing user tagged visual data like Flickr. The latter annotations are less accurate than the current practice in supervised learning, but the amount of training samples is orders of magnitude larger.

Another promising direction is the use of capture time meta data, contextual information, and social networks to provide additional clues for interpreting the visual data.

Data Sets

The research community in video content analysis is very active. In recent years there was an important role for benchmarks encouraging research in the various subfields. They do so by providing large test collections and uniform evaluation procedures. The benchmarks provide a forum where researchers can compare their results, bringing the research a big step further every year.

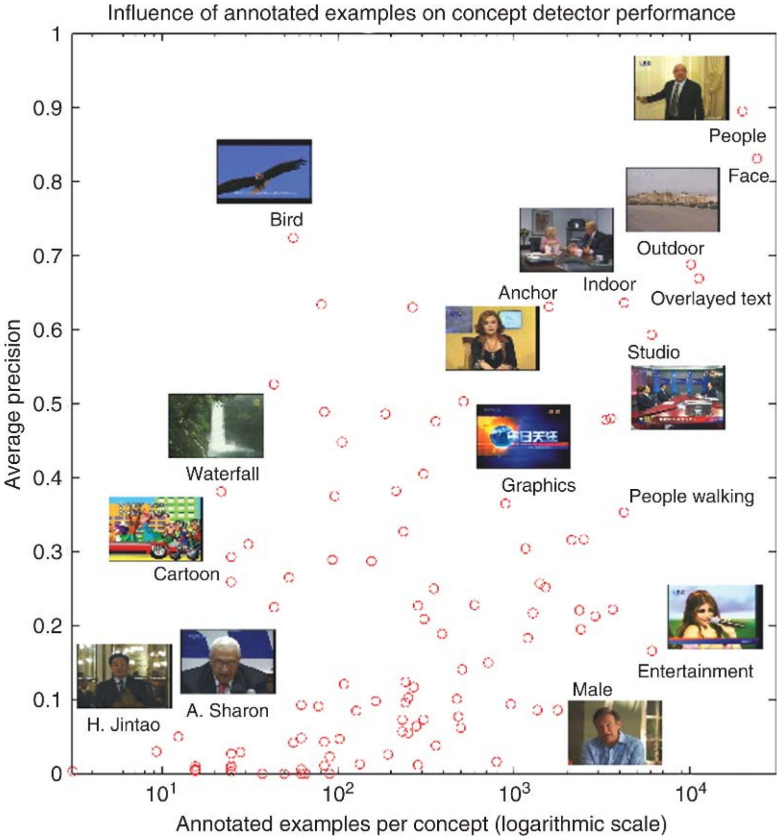
For visual content analysis of images the most elaborate benchmark is the PASCAL VOC challenge [2]. This benchmark contains image sets of several hundreds to thousands of images with a ground truth at the semantic level, a box containing the object, as well as complete outlines of the object in the scene. In this manner, it provides a challenging data set for testing.

Video analysis, especially for the purpose of search, has been studied for several years now in the TRECVID benchmark organized by NIST. In this benchmark, videos from mostly news and other broadcasts have been semantically annotated at the shot level [9].

Collections contain hundreds of hours of video material. Hence they not only pose a challenge at the analysis level, but also at the computer performance level. In addition, one can see that the analysis of such data sets requires expertise from different fields, making the threshold to work on such collections large. Therefore, the MediaMill Challenge [12] has taken the idea of making shared data sets available one step further. This resource not only contains annotations of the TRECVID data, but also a collection of five pre-cooked experiments. To allow an easy start on the topic, the results of each sub-step are provided. Later Columbia and the VIREO group made similar resources available [6,15]. The above efforts allow for visual database research without actually having to perform the visual analysis.

Experimental Results

The performance of video analysis algorithms for information retrieval is typically measured by the average precision. This is a single-valued measure proportional to the area under a recall-precision curve. This value is the average of the precision over all relevant judged



Visual Content Analysis. Figure 2. Indication of the state-of-the-art performance in video content analysis. Note the clear relation between the performance and the amount of annotated examples.

shots. Hence, it combines precision and recall into one performance value. To be precise, let $L^k = \{l_1, l_2, \ldots, l_k\}$ be a ranked version of the answer set A. At any given rank k let $R \cap L^k$ be the number of relevant results in the top k of L, where R is the total number of relevant results. Then average precision is defined by:

$$average\ precision = \frac{1}{R} \sum_{k=1}^{A} \frac{R \cap L^k}{k} \lambda(l_k), \qquad (1)$$

where indicator function $\lambda(l_k) = 1$ if $l_k \in R$ and 0 otherwise. As the denominator k and the value of $\lambda(l_k)$ are dominant in determining average precision, it can be understood that this metric favors highly ranked relevant results. To give an indication of the state-of-the-art, Fig. 2 gives an overview of results for TRECVID data using the features defined for the MediaMill challenge. Performance is shown as function of number of annotated examples as this has proven to be an important indicator for the quality of the result.

One can conclude that performance is not perfect, but a rapid increase in performance over the last years can be observed. Hence, one could expect that more and more reliable concept detectors will become available in the coming years.

Visual Data Mining

SIMEON J. SIMOFF
University of Western Sydney, Sydney, NSW, Australia

Synonyms

Visual data analysis; Visual analysis; Visual discovery; Immersive data mining; VDM

Definition

Visual data mining (VDM) is the process of interaction and analytical reasoning with one or more visual representations of abstract data. The process may lead to the visual discovery of robust patterns in these data or provide some guidance for the application of other data mining and analytics techniques. It facilitates analysts in obtaining deeper understanding of the underlying structures in a data set. The process relies on the tight interconnectedness of tasks, selection of visual representations, the corresponding set of interactive manipulations, and respective analytical techniques. Discovered patterns form the information and knowledge utilized in decision making.

Historical Background

Visual exploration of large data sets had been used as a complementary technique to data mining in order to obtain additional information about the data set. Since the early 1990s there has been recognition of the need for specific visualization techniques for large data sets that enable data mining tasks. The term "visual data mining" emerged in the late 1990s, labeling such techniques combined with interactive functionality and some guidelines for sense making from different visual displays of the data and/or the output of data mining algorithms. Ankerst's and Niggemann's theses around the millennium considered the establishment of more systematic scientific and methodological foundations of the field. The 3D Visual Data Mining (3DVDM) project in Aalborg University added a new twist, placing the analyst literally "within" the visual representation of the data set in various stereoscopic virtual reality systems.

During 2001–2003 a series of workshops on visual data mining, conducted in conjunction with major KDD conferences on both sides of the Atlantic, bridged scholars in the fields of data mining and knowledge discovery in databases, information visualization, human-computer interaction as well as cognitive psychologists related to computing, industry practitioners, and developers of visual data mining tools. They established some common elements that need to be specified when developing methodologies for visual data mining, including: (i) the initial assumptions posed by the respective visual representations; (ii) the set of interactive operations over the respective visual representations and guidelines for their application and interpretation, and; (iii) the range of applicability and limitations of the visual data mining methodology. The majority of the works, published in the proceedings of these workshops after completion, have made their way into the books and special issues, referred in section "Recommended Reading". These and numerous subsequent research and development efforts led to the establishment of visual data mining as an essential component of visual analytics.

Foundations

Visual data mining integrates the abilities of the human perceptual system for pattern recognition and human reasoning from images, with the data processing and display power of computers, aiming at capitalizing on the best of both worlds. From a disciplinary perspective, visual data mining emerged as the confluence of several disciplines, the main of which are grouped into two clusters in Fig. 1. On the right-hand side are those, primarily related to computing, when on the left-hand side are those primarily related to humans. From the perspective of scientific fundamentals, though not exhaustive, this list shows the diversity of sources that contribute to the methods and approaches developed in visual data mining.

The VDM process relies on the interactive visual processing pipeline, shown in Fig. 2. Each step within the pipeline involves interaction with the analyst and all the iterative loops in the process close via the analyst. Data mining algorithms can be used to assist the process before any visualization has been considered, and/or after a visual interaction with the data.

Being the core of this human-centred process, visual processing is constrained by the capacity of the human visual system to somewhat 10^6 to 10^7 observations. Large data sets easily surpass this constraint. Consequently, essential for visual data mining are low-dimensional visual representations of high dimensional data that (i) preserve relations between the data points in the high-dimensional space, and (ii) can make such relations visually detectable. Coupling of visualization algorithms with statistical techniques is one way it generating visual data representations that more accurately present the underlying properties of the data. Such visual representations are expected to fit consistently certain metaphors that are close to human mental models, as humans depict structures in the data by forming a mental model which captures only a gist of the information. These are important design considerations in visual data mining, as visualization

algorithms display data sets that usually lack inherent 2D and 3D semantics.

As manipulation of visual representations of the data set (or subsets of it) is essential in enabling visual pattern detection, the success of the process illustrated in Fig. 2 depends on: (i) the breadth of the collection of visualization techniques, (ii) the consistency of the design of these visual representations, (iii) the ability to remap interactively the data attributes to the parameters of the visual representations, (iv) the set of functions for interacting with the visualization, and (v) the capabilities that these functions offer in support of the sense-making process. From an analyst point of view, the suite of visual representations and interactive techniques is the toolbox for constructing "virtual worlds" from the data. The visual metaphors in such worlds are the vehicles to transfer meaning from the visual structure of the data into the semantics of the underlying problem. The transfer is enabled by the rules of behavior of the visualization elements that constitute a visual language. The consistent design of visual languages and techniques for interaction with different visual representations of a dataset take into account the specifics of human long-term and short-term memory, knowledge of interaction with virtual environments, including frames of reference, orientation, and navigation. These considerations are also central in order to support the sense-making process in Fig. 2 (the process itself has several iterative steps that are not shown in Fig. 2).

Dealing with large volumes of data means *scalability* and interactivity means *real-time response* of the visualization algorithms in the toolbox in Fig. 2, and the overall visual processing pipeline in order to analyze the details available in the large databases. Interactivity also means support of various visual data mining operations, for example, a visual drill down or visual clustering.

The presentation of the extracted information and knowledge during the decision making step in Fig. 2 usually requires a different visualization approach to the visual data mining step. Such separation of visual analysis tasks from the visual presentation of the results is reflected in contemporary visual data mining technology.

Key Applications

Visual data mining is applied in a wide range of areas of human endeavor, which generate large volumes of otherwise incomprehensible data. These include science, business, technology development, medicine, and healthcare. Chemistry and new drug discovery are examples of successful application of VDM methods. The applications in various fields provide feedback to the development of VDM technology, in terms of integration of 1D, 2D, 2.5D, and 3D visual representations, respective sets of interactive operations, and evaluations of the visual data mining capabilities and interfaces by the analysts in respective fields.

Special key application areas of visual data mining are the analysis of geospatial and spatio-temporal data sets, visual link analysis and visual text mining. Spatial data sets include spatially related attributes, which provides guiding information for the choice of visual representations and interaction methods. Visual link analysis is applied in areas where there is a need for identification of hidden links and chain of links between the attributes in a data set, for example, the fraud detection type of problems in different environments – government, corporate, insurance, retailing, and crime. These problems have the same feature: different cases of fraud may differ in terms of the patterns that reflect them in the data, and the nonvisual data mining and analytics methods may not be able to detect them. The advent of social computing has led to embedding visual link analysis technologies in the social computing systems. Visual text mining uses a variety of statistical techniques to relate groups of words with groups of documents, and then generates visual data summarizations using different metaphors.

Future Directions

Visual data mining, as a discovery mode of interaction with databases, plays a central role in visual analytics. Though interaction has been recognized, there is a strong demand on the development of interactive visualizations, which are fundamentally different from the static visualizations. Designed with the foundations of perceptual and cognitive theory in mind, and focused on supporting the processes and methods in visual data mining, these visual data representations are expected to be relevant to specific tasks and effective in terms of achieving the analytics goals. Within this direction essential are methods for: (i) design and evaluation of visualizations for visual data mining, including metrics for the evaluation of the interactivity of visualizations and their ability to facilitate discovery processes; (ii) visualization techniques of projections of high-dimensional data that preserve the statistical properties of the patterns in the original data; (iii) further integration of data visualization and sonification and development of interactive mining methods, including immersive ones, that operate with such data representations; and (iv) enabling VDM systems to support research strategies and inquiry styles of different data analysts.

Experimental Results

As a rule, research papers in visual data mining, reporting on novel visual analysis techniques, present the results from the application of respective techniques to several data sets. Papers, which explore human-computer interaction aspects, report the outcomes of observational case studies and usability experiments.

Data Sets

Data sets are available from the KDNuggets site (http://www.kdnuggets.com/datasets/index.html), government bureaus of statistics, research centers and other sources. For visual link analysis the Enron organizational e-mail data set is available at http://www.cs.cmu.edu/~enron/.

URL to Code

This selective rather than inclusive sample of tools is divided into two categories: (i) visual data exploration and mining tools, and (ii) general visualization platforms that can be used to develop visual data mining tools.

Visual Data Exploration and Mining

Open Source Xmdv Tool: Source: http://davis.wpi.edu/~xmdv/.

Offers five methods for displaying flat form data and hierarchically clustered data and variety of interactive operations.

GGobi: http://www.ggobi.org/

Offers similar variety of visualization and interaction methods.

VizRank: http://www.ailab.si:8088/supp/bi-vizrank

Offers informative scatter-plot projections in high dimensional class-labeled data.

3DVDM: http://www.inf.unibz.it/dis/projects/3dvdm/download.html

Offers tools for exploring data in 3D virtual reality environments.

Commercial Miner3D: http://www.miner3d.com/

Highly flexible visual data mining tool with many display and interaction methods.

NetMap Analytics: http://www.netmap.com.au/

Tool for visual link analysis. Separate visual analysis and visual presentation modes (the presentation mode bears some similarity to VisualLinks (http://www.visualanalytics.com)).

NetMiner: http://www.netminer.com/

A nice collection of visual metaphors for interactive analysis of graph structures in data sets.

IN-SPIRE: http://in-spire.pnl.gov/- visual text miner.

General Visualization Engines and Development Tools

Open Source VTK: http://www.vtk.org/

The Visualization ToolKit (VTK) software system for 3D computer graphics, image processing, and visualization.

Mondrian: http://moose.unibe.ch/tools/mondrian

Information visualization engine that lets the visualization be specified via a script, hence, can be utilized for development of specialized visual data mining tools.

ParaView: http://www.paraview.org/New/index.html

Visualization platform that supports distributed computational models for processing large data sets

Gapminder: http://www.gapminder.org

Based on the original Trendalyzer tool for knowledge extraction from interactive animation of statistical time-series, the development has been overtaken by Google.

Visual Formalisms

David Harel, Shahar Maoz
The Weizmann Institute of Science, Rehovot, Israel

Definition

Visual formalisms are diagrammatic and intuitive, yet mathematically rigorous languages. Thus, despite their clear visual appearance, they come complete with a syntax that determines what is allowed, and semantics that determines what the allowed things mean. The main emphasis in the visuality is typically placed on topological relationships between diagrammatic elements, such as encapsulation, connectedness, and adjacency. Geometric and metric aspects, such as size, shape, line-style, and color, may also be part of the formalism. Icons can be used too. Such languages typically involve boxes and arrows, and are often hierarchical and modular. Visual formalisms are typically used for the design of hardware and software systems. This includes structural as well as more complex behavioral specifications.

Historical Background

Two of the oldest examples of visual formalisms are graphs and Venn diagrams, which are both originally due to Euler [7,8]. A graph, in its most basic form, is simply a set of points, called nodes or vertices, connected by lines, called edges or arcs. Its role is to represent a set of elements S and some binary relation R on them. The precise meaning of the relation R is part of the application and has little to do with the mathematical properties of the graph itself. Certain restrictions on the relation R yield special classes of graphs that are of particular interest, such as ones that are connected, directed, acyclic, planar, or bipartite. Graphs are used intensively in all branches of computer science; the elements represented by the nodes range from the most concrete (e.g., physical gates in a circuit diagram) to the most abstract (e.g., complexity classes in a classification scheme), and the edges have been used to represent many kinds of relations, e.g., logical, temporal, causal, or functional. Many of the fundamental algorithms in computer science are related to graphs. Some open problems are related to graphs too, such as the problem of whether graph isomorphism can be decided in polynomial time.

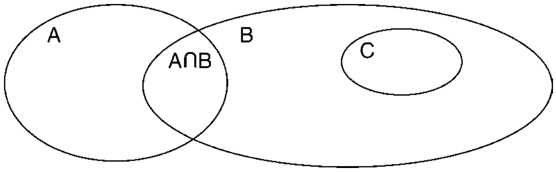
A hypergraph is a generalization of a graph, where the relation R is not necessarily binary (in fact, it need not have a fixed arity). The corresponding edges are called hyperedges. Hypergraphs have applications in database theory (see, e.g., [9]). The information conveyed by a graph (or a hypergraph) is nonmetric, and is captured by the purely topological notion of connectedness; shapes, locations, distances, and sizes, for example, have no significance.

Euler circles, or Venn diagrams (see [8,25] for the original work), represent sets using the fact that simple closed curves partition the plane into disjoint inside and outside regions. They thus give the topological notions of enclosure, exclusion, and intersection the obvious set theoretic meanings of being a subset of, being disjoint from, and having a nonempty intersection with, respectively (see Fig. 1). Typical uses of Venn diagrams include only a small number of circles. However, they can be expanded to *n*-set diagrams (see, e.g., [5]).

A higraph [17] is a formalism that further generalizes graphs, in the spirit of Euler circles. It adds not only hyperedges, but Euler/Venn-like topologically related "blobs" for the nodes, as well as a certain kind of partitioning and adjacency. It thus adds to the relation *R* notions of orthogonality and hierarchy, as well as multilevel and multinode edges (and hyperedges).

The term "visual formalism" appears to be first used in the work on statecharts [16,17], a language for the specification and design of reactive systems. Higraphs [17] are the underlying graphical representation for statecharts.

In general, visual formalisms provide mechanisms for higher levels of abstraction and thus help engineers in coping with the challenges posed by the ever increasing size and complexity of systems. The effectiveness of visual formalisms also relies on the power of human vision and cognitive perception in recognizing and memorizing visual properties, such as topological/spatial relationships between visual entities. They thus provide an appealing representation and communication medium. The advent of modern tools for graphical editing and display has also contributed to the increasing popularity of various visual formalisms among practitioners. Moreover, some tools, indeed go beyond plain editing and syntax correctness checks, and allow their users to take advantage of the rich semantics of some visual formalisms. Thus, some tools have automated procedures for languages that are sufficiently powerful, such as code generation and formal verification. These are directly applied to the visual artifacts and thus indeed exploit their full potential.

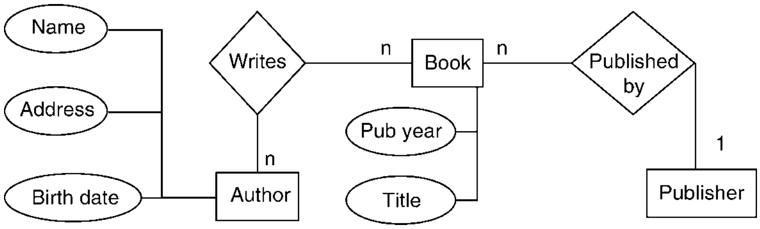


Visual Formalisms. Figure 1. An example of a Venn diagram.

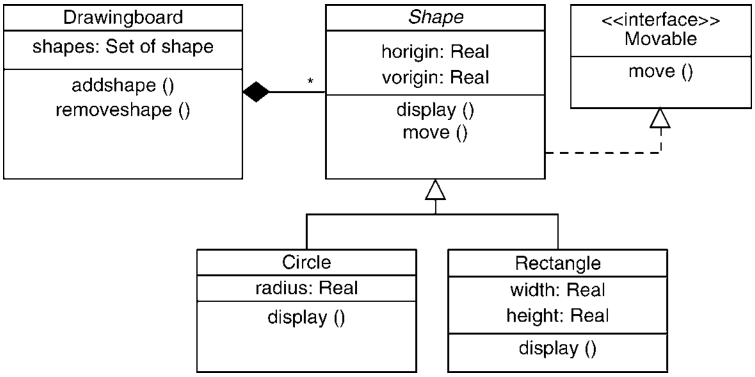
The Unified Modeling Language (UML) [23], an OMG standard formed in the late 1990s, is a collection of visual languages for software and systems specification, defined under a common meta model, and supported by many tools. The standard, however, does not come with satisfactory semantics and hence, by itself, cannot be regarded as a fully fledged visual formalism, though many researchers have provided semantics for many parts thereof.

Foundations

Some widely used visual formalisms include flowcharts, used for the representation of series of actions and decisions, mainly for simple imperative programs (see [14] for what seems to be the original usage thereof, and [12] for a fundamental paper on verification, which was carried out in the framework of flowcharts); data flow diagrams (DFD) (see, e.g., [13]), used to represent the flow of data through a system; entity relationship diagrams (ERD) (Fig. 2, and see [2] for the original work) and their modern application to objects, object model diagrams (OMD) and class diagrams (part of the UML [23], see Fig. 3); message sequence charts (MSC) [21] and their modal extension, live sequence charts [3,19], for inter-object



Visual Formalisms. Figure 2. An example of an entity relationship diagram.



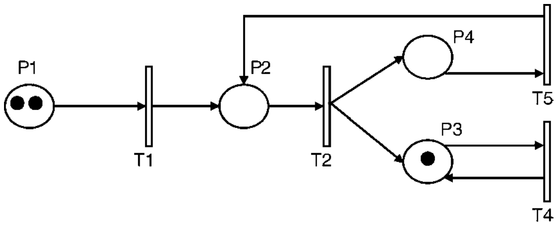
Visual Formalisms. Figure 3. An example of a class diagram.

scenario-based specification; the specification and description language (SDL) [20], for the specification and description of the behavior of reactive and distributed systems; Petri nets (see, e.g., [24], and see Fig. 4); statecharts [16,18] (see Fig. 5); and constraint diagrams [22], used to express logical constraints extended with quantification and navigation of relations.

Statecharts are a prime example of a visual formalism and are therefore shortly discussed below. However, the ideas presented are more general and have indeed been extended to other domains, such as security, databases, and more generally, UML-style behavioral and structural modeling.

In essence, statecharts are finite state machines drawn as state transition diagrams and extended with two key ideas: hierarchy and orthogonality. The hierarchy is introduced using a substating mechanism, and the orthogonality is introduced using a notion of simultaneity. Both are reflected in the graphics themselves, i.e., the hierarchy by encapsulation inspired by Euler/Venn diagrams, and the orthogonality by partitioning blobs into adjacent regions separated by dashed lines.

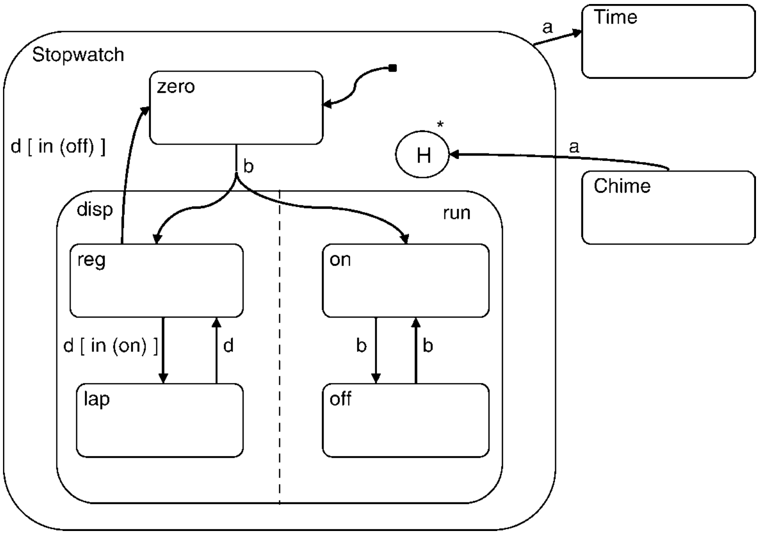
Topological features are a lot more fundamental than geometric ones, in that topology is a more basic branch of mathematics than geometry in terms of symmetries and mappings. One thing being inside another is more basic than it being smaller or larger than the other, or one being a rectangle and the other a circle. Being connected to something is more basic than being green or yellow or being drawn with a thick line or with a thin line. The brain understands topological features given visually much better than it grasps geometrical ones. The mind can see easily and immediately whether things are connected or not, whether one thing encompasses another, or intersects it, etc. (see, e.g., [15], for early work on this).



Visual Formalisms. Figure 4. An example of a Petri net.

Statecharts are not exclusively visual/diagrammatic. Their non-visual parts include, for example, the events that cause transitions, the conditions that guard against taking transitions, and actions that are to be carried out when a transition is taken. For these, statecharts borrow from both the Moore and the Mealy variants of state machines, in allowing actions on transitions between states or on entrances to or exits from states, as well as conditions that are to hold throughout the time the system is in a state.

Unfortunately, some people tend to take diagrams too lightly, finding it difficult to consider a collection of graphics serious or "formal" enough. A common misconception about formality is that textual and symbolic languages are inherently formal, whereas visual and diagrammatic languages are not, as if one could measure formality by how many Greek letters and mathematical symbols the language contains. This myth, together with the deviously deceptive simplicity of graphics, lead to the so called doodling phenomenon – a mindset that says that diagrams are what an engineer scribbles on the back of a napkin but that the real work is done with textual languages.



Visual Formalisms. Figure 5. An example of a statechart.

An interesting topic related to the use of visual formalisms concerns the layout of diagrams, and more generally, their usability and aesthetics. This includes the development of algorithms for the automatic layout of diagrams (see, e.g., [4]), as well as experimental research towards measuring the usability and effectiveness of different visual languages and the development of aesthetic principles.

Another research direction deals with the mechanisms of the language definitions themselves and with the development of new visual languages, for example, domain specific visual formalisms targeted for specific application areas.

Key Applications

Software and Systems Structural Specification

Object model diagrams, and more generally, other structural diagrams, are very popular and are used successfully by software and systems engineers. See the various structural diagrams of the UML [23] and SDL [20].

Reactive Systems Behavioral Specification

Petri nets, statecharts and variants of message sequence charts are successfully used in the design and development of reactive systems. For example, in embedded and real-time safety-critical systems in the automotive, avionics, and telecommunication industries. They are used across the development life cycle of systems, from requirements analysis to specification to simulation to code generation to testing, formal verification, and documentation. In recent years such languages have also been used for the modeling and analysis of biological systems as reactive systems [6,11], which appears to be an application area of great potential.

Data Modeling and Querying

Entity relationship diagrams (ERD) are used for data modeling, or more broadly, for the conceptual specification of databases. Hypergraphs have applications in database theory (see, e.g., [10]). Finally, visual formalisms are also used for the specification of database queries (see [1] for a survey).

Visual interaction design; Graphic design

Definition

In the field of Human-Computer Interaction (HCI), *Visual Interaction* refers to the adoption of user interfaces for interactive systems, which make use of visual elements and visual interaction strategies with the aim of supporting perceptual inferences instead of arduous cognitive comparisons and computations. The design of Visual Interaction focuses on the definition of interaction mechanisms through which (i) the users can perform actions on the interactive system by means of visual elements, and (ii) the system can provide feedback to the user, by visually representing the results of the computations triggered by the user actions. The flow of user actions and system feedback over time then has to be coordinated.

In the field of Databases, Visual Interaction refers to the adoption of visual interfaces that provide access to the collection of data stored in databases, by means of visual formalisms and mechanisms supporting both the presentation and the interaction with data.

Historical Background

The information proliferation that characterized the end of the last century led to an increased use of databases by a continuously growing number of users. As an effect of such a trend, the traditional paradigm to access databases, based on formal, text-based query languages, became inadequate for a large portion of inexperienced users.

In 1977, Moshe Zloof proposed QBE (Query By Example) [14], a pioneer query environment where a skeleton of a database relational schema was presented and, based on it, the users were then able to express queries by entering commands, example elements, and selection conditions in visual tables. QBE was the precursor of a new research line, fully emerged during 1990s on the wave of the consensus gained by interactive systems and visual interfaces. In fact, in that period, several research initiatives, both in the HCI and the database field, focused on enhancing the quality of the interaction with databases, by replacing the traditional, text-based query languages with visual paradigms. A new generation of visual tools, the so called Visual Query Systems (VQSs) (see [4] for a survey), was therefore proposed, which promoted visual formalisms and visual interaction mechanisms at the level of both the presentation of and the interaction with the information contained in databases. The most adopted visual representations were forms, diagrams, and icons, each one being used in accordance with the nature of the information to be represented or queried. Some systems also adopted 3D visualizations [1] or virtual reality techniques [12].

Following the first proposals for VQSs, which especially focused on the interaction with structured, record-based information, some visual query languages for XML were also proposed [2,9]. However, it was the Web that led to the major change in the interaction with databases, proposing a novel, easy-to-use visual paradigm, which suddenly allowed a huge number of users to access huge amounts of data distributed across several data sources.

The Web, today, provides the most widely adopted visual interface for accessing databases.

Foundations

In the interaction with database it is possible to recognize at least two different needs: (i) to let the users *understand* the database content, and (ii) to allow the users to *interact* with the content to extract the information they are interested in. From the visual interaction perspective, the main issue is therefore to find effective mechanisms to transmit to the users the information content of the database and to support users during the interaction with such content. This can result, for instance, in using different *visual metaphors*, defined as a mapping between a data model and a visual model [5], both for the understanding phase and for the interaction phase.

Several works focused on the effectiveness and efficiency of visual metaphors. Some of them (see for example [5,10]) dealt with the effectiveness of schema display, trying to define and formalize the notion of adequate metaphors for representing the database schema, thus supporting the understanding phase. Some other works also covered the effectiveness of the interaction phase. For example, in [3] authors pointed out the need for multi-paradigmatic systems, able to provide querying environments in which *adaptive interfaces* exploit several visual representations and interaction mechanisms depending on the user capabilities and tasks. In [11] the author instead specifically focused on the problem of automatically generating effective presentations of query results, adapting the data representation to the nature of the data themselves, and also to the tasks that such data are meant to support.

The majority of these works were characterized by stratified, multi-component architectures supporting the definition of proper visual formalisms. For example, in [10], authors propose a definition of the visual formalisms adopted for schema display characterized by (i) a *data model* that captures schemas, (ii) a *visual model* that captures visualizations, and (iii) a *visual metaphor* that provides the mapping between data and visual models. Such a stratified definition especially aimed at ensuring flexibility for the selection of the most appropriate metaphor for schema display, and also induced the formalization of many interesting properties. For instance, authors precisely defined the concept of correctness of the visual metaphors (no valid visual schema will map to an invalid data schema and vice versa) through a relationship between the constraints in the data model, and those in the visual model.

While the previous work mainly focused on schema display during the understanding phase, in [3] the authors propose a stratified multi-component structure for the architecture of a multi-paradigmatic VQS, supporting both the understanding and the interaction phase. The most notable features were:

1. The provision of *a formalism for expressing databases*, which is able to represent, in principle, a database expressed in any of the most common data models.
2. The construction and the management of *a user model*, which allows the system to propose to the users the most appropriate visual representation according to their skills and needs.

3. A *transformation layer*, defining the translations among the different available representations, in terms of both database content and visual interaction mechanisms, which allows the users to shift from one representation to another according to their preferences.

Given the always increasing relevance of XML-based data descriptions, in late 1990s some visual query languages for XML also started to be proposed, offering the advantage of letting users manipulate visual objects instead of managing the complexity of the underlying XML-base query languages (e.g., XQuery) [2]. However, even if such languages employed visual primitives, the proposed interaction paradigms still preserved a tight correspondence with the traditional (textual) query formulation. Therefore, their advantages have still to be proved.

An incisive step forward in the visual interaction with databases was, however, determined by the growth of the Internet. The World Wide Web suddenly allowed a huge number of users to easily retrieve and access a large amount of information available in different formats – from unstructured multimedia data to traditional relational data. The Web indeed introduced the *information browsing* paradigm, a very powerful (from the user experience point of view) visual interaction mechanism, based on the "one-click" selection of hyperlinks to explore the information space. This innovation immediately provided an easier alternative to the traditional, text-based way to access and query databases. Especially with the advent of *dynamic Web pages*, relational databases were fully integrated into the Web, and Web pages became a composition of "content units," each one corresponding to an application component in charge of querying at runtime the application data source, and displaying the extracted contents in the page. Additionally, search mechanisms were introduced. Form-based interfaces allowed the users to input (even complex) selection conditions that the Web application was able to transform into suitable SQL queries over the application contents; the query results were then returned into a new Web page, dynamically generated on the fly, typically in the form of an index of linked items.

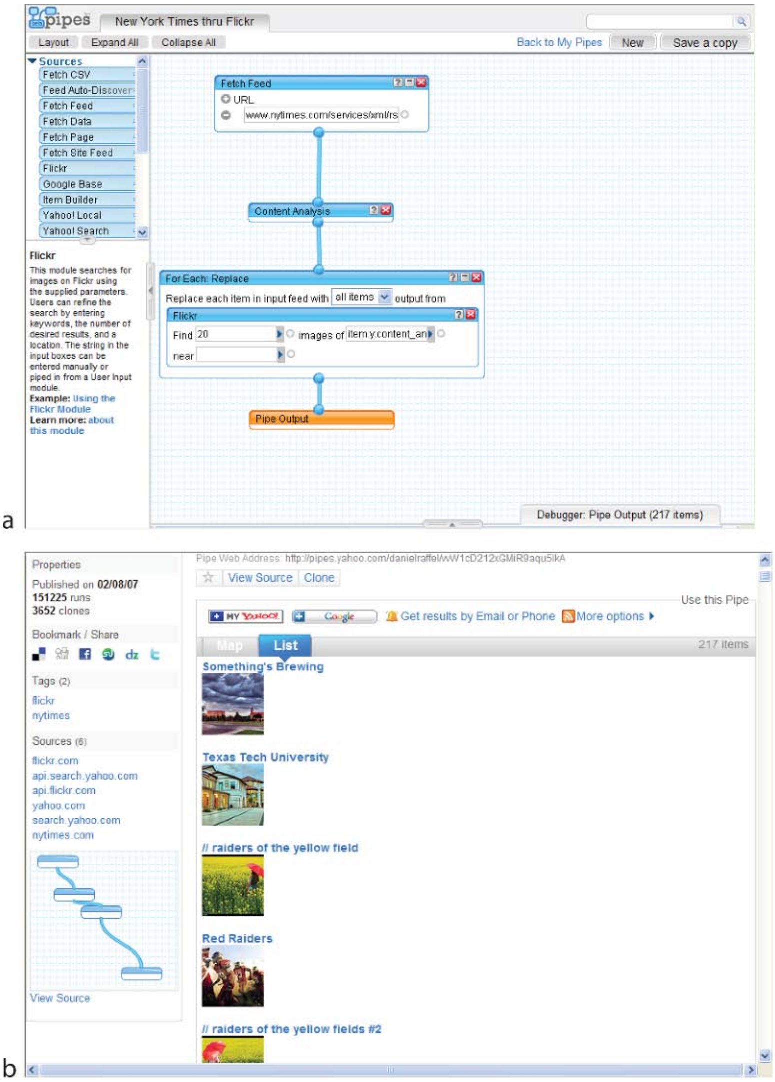
The Web thus definitely became a "de facto" visual interface for databases. The so called "data-intensive" Web applications gained momentum, offering Web interfaces over huge collections of data equipped with both navigation and search mechanisms, as it happened for on-line trading and e-commerce applications, digital libraries, and several other classes of Web applications interfacing large data sources. Such applications share with the initially proposed VQSs a stratified architecture, being characterized by three orthogonal dimensions:

1. The *application data*, collecting the contents to be published by the application.
2. The *hypertext interface*, defining the way in which content units extracted from the application data source are clustered within pages, as well as the navigation mechanisms allowing users to move along the different pages.
3. The *presentation style*, defining layout and graphic properties for the rendering of both contents and navigation mechanisms within pages.

Similarly to VQSs, such a stratified architecture ensures flexibility, by enabling the provision of multiple interfaces over the same content. Hypertext interfaces indeed can be considered *views* over the application data, and therefore several hypertext structures can be constructed over a same database [7] to satisfy the different requirements characterizing different classes of users, different access devices, or even different situations of use. Also, once a hypertext interface is defined, different presentation styles, defining the layout and the graphic properties of the constituent Web pages, can be applied on it. Therefore, especially in the case of adaptive Web applications, several combinations of hypertexts and presentation styles can be adopted to convey contents in the most appropriate modality with respect to the characteristics of the user or of the usage environment, possibly described in a user or a context model [6].

Recently, the so-called *data-driven* methods have been proposed for the design of the hypertext interfaces. They fund their approach on data modeling, and in particular on some properties of the data to be published in the hypertext interface, which can have impact on the effectiveness of the interface itself. In particular, the method proposed in [8] aims to enhance *content accessibility*, which is the ability of a Web application to offer effective and efficient access to its contents, supporting both (i) the identification of the most relevant content entities the application deals with and their mutual relationships (understanding phase), and (ii) the retrieval of the desired content instances (interaction phase). In Latins, "rem tene, verba sequentur" (manage content, words will follow). Rephrasing this motto, the idea behind this method is that if "Rem" is the information globally available to the application, and "Verba" is the hypertext interface enabling information identification and retrieval through navigation and search, one can say that organizing the application content in accordance with some proper modeling abstractions can induce the definition of hypertext interfaces able to effectively support the information access on the Web. Authors therefore propose some data modeling patterns, called *Web Marts*, which suggest a data organization where:

1. Some *core entities* reflect the most important concepts addressed by the application.
2. Some *detail entities* represent additional information that complete the description of the core concepts.
3. Some *access entities* then classify the core contents for facilitating their access.



Flickr

This module searches for images on Flickr using the supplied parameters. Users can refine the search by entering keywords, the number of desired results, and a location. The string in the input boxes can be entered manually or piped in from a User Input module.

Example: Using the Flickr Module

Learn more: about this module

Visual Interaction. Figure 1. An example of visual composition of a Yahoo Pipe (http://pipes.yahoo.com/pipes/) (a) and its corresponding rendering (b). The pipe accesses the New York Times homepage (*Fetch Feed* component), analyzes it (*Content Analysis* component), and uses the extracted keywords to find related pictures at the Flickr Web site (nesting a *For each Replace* component with a *Flickr* component).

By taking into account such data characterization, it is possible to achieve Web interfaces able to highlight the application core concepts, facilitating their retrieval by means of navigation and search mechanism defined on top of access entities, and support the browsing of the core concepts by means of navigation patterns defined on top of detail entities. In other words, the resulting hypertext interfaces are able to effectively support both the understanding of and the interaction with the Web application data.

Key Applications

Nowadays, principles of Visual Interaction design are essential for the construction of any system providing access to databases. Even more, they constitute the basis for the development of modern data-intensive Web applications, especially considering the modern Web 2.0 paradigm that, besides other advantages, also promotes more advanced interaction mechanisms, fully comparable to the mechanisms traditionally adopted for desktop interactive applications.

Future Directions

The current trend in the development of modern Web applications – and in particular of those applications commonly referred to as Web 2.0 applications – clearly points toward a high user involvement in the creation of contents. Users visually interact with Web sites not only as passive actors accessing information, but also as creators of the content instances published by the Web application. The so-called *social applications*, like MySpace, YouTube, or Wikipedia, are indeed living an indisputable success.

However, users are not only more and more being involved in content creation. The phenomenon of *Web mashups* is now emerging to provide Web environments where the users have the opportunity to create online applications starting from contents and functions that are provided by third parties. Typical components that may be mashed up, i.e., composed, are RSS/Atom feeds, Web services, content wrapped from third party Web sites, or programmable APIs (like the one provided by Google Maps). Online mashup tools, like Yahoo Pipes (http://pipes.yahoo.com/pipes/) or the Google Mashup Editor (http://editor.googlemashups.com/), and a number of other academic research efforts (see for example [13]) confirm this trend, which implies the addition of a further level of interaction in the Web: users are not only able to visually access data, but they are also able to visually compose the interfaces providing access to data. Figure 1, for example, shows the Yahoo pipes editor, where a simple application is visually modeled by composing some components that analyze the contents published in the New York Times home page, and then use the retrieved keywords to find related photos at another Web site (www flickr.com).

Since unskilled end users are supposed to “program” the necessary composition logic, special emphasis is therefore currently put on intuitive, visual composition environments, not requiring any programming effort. This seems to be one of the major challenges that will be addressed by future academic and industrial research efforts.

Visual Interfaces

Tiziana Catarci
University of Rome, Rome, Italy

Synonyms

Graphical user interfaces; GUIs; Direct manipulation interfaces

Definition

Visual Interfaces are user interfaces that make extensive use of graphical objects (icons, diagrams, forms, etc.) that the user may directly manipulate on the screen through several kinds of pointing devices (including her/his fingers) and get an almost instantaneous feedback (near real-time interactivity). Information-intensive interfaces typically exploit one or more visual language, i.e., a language that systematically uses visual signs to convey a meaning in a formal way.

Historical Background

The importance of providing the user with an interactive environment where she/he could directly manipulate the computer content, and get an immediately graspable feedback out of her/his actions, was evident since the first demonstration of the Sketchpad system by Ivan Sutherland [7]. This system was the basis of his 1963 MIT Ph.D. thesis. SketchPad supported manipulation of visual objects using a light-pen, including grabbing objects, moving them, changing size, and using constraints. It contained the seeds of hundreds of important interface ideas. Later on, in the 1970s, many of the interaction techniques popular in direct manipulation interfaces, such as how objects and text are selected, opened, and manipulated, resulted from research at Xerox PARC. The concept of direct manipulation interfaces for everyone was envisioned by Alan Kay of Xerox PARC in a 1977 article about the Dynabook [4]. The first commercial systems to make extensive use of direct manipulation were the Xerox Star (1981) [6], the Apple Lisa (1982) [10], and Macintosh (1984) [9]. Ben Shneiderman at the University of Maryland coined the term "direct manipulation" in 1982, identified the components, and gave psychological foundations [5].

As the quantity of information available became larger and larger, as well as the potential user community of databases and other information sources, there was a growing need for user interfaces that require minimal technical sophistication and expertise by the users, and support a wide variety of information intensive tasks. For instance, information-access interfaces must offer great flexibility on how queries are expressed and how data are visualized.

The general idea was to exploit the well-known high bandwidth of the human-vision channel that allows both recognition and understanding of large quantities of information in no more than a few seconds. Thus, for instance, if the result of an information request can be organized as a visual display, or a sequence of visual displays, the information throughput is immensely superior to the one that can be achieved using textual support. User interaction becomes an iterative query-answer game that very rapidly leads to the desired final result. Conversely, the system can provide efficient visual support for easy query formulation. Displaying a visual representation of the information space, for instance, lets users directly point at the information they are looking for, without any need to be trained into the complex syntax of current query languages. Alternatively, users can navigate in the information space, following visible paths that will lead them to the targeted items. Again, thanks to the visual support users are able to easily understand how to formulate queries, and they are likely to achieve the task more rapidly and less prone to errors than with traditional textual interaction modes.

Foundations

One fruitful sign system conceived by humans for the purpose of storing, communicating and perceiving essential information is based on bidimensional visual signs, like those contained in pictures, photographs, geographic maps. Visual signs are characterized by a high number of sensory variables: size, intensity, texture, shape, orientation, and color, which all concur to provide details about the information to be communicated [1]. For instance, Tufte suggests many different purposes for which color may be employed: "...to label (color as noun), to measure (color as quantity), to represent or imitate reality (color as representation), and to enliven or decorate (color as beauty). In a geographical map, color labels by distinguishing water from stone and glacier from field, measures by indicating altitude with contour and rate of change by darkening, imitates reality with river blues and shadows hatchures, and visually enlivens the topography quite behind what can be done in black and white alone" [8]. Exploiting the multidimensionality of the visual representation allows people to perform in a single instant of perception a visual selection, in the sense that all the meaningful correspondences among the visualized elements are captured. Other constructions, for example a linear text, do not permit this immediate grasping, the entire set of correspondences may only be reconstructed in the user memory. This is also due to the fact that visual representations are processed by human beings primarily in parallel, while text is read sequentially.

Visual interfaces capitalize on all the above characteristics of envisioning the information, yet one can say that the basic paradigms adopted for enhancing visual interaction are:

1. The *direct manipulation* interaction
2. The *metaphor*
3. The *visual representation*

These three concepts, although separately investigated in the literature, at the present state are so strictly correlated to deeply influence each other, and constitute the foundations for the development of visual interfaces. All three concepts are covered in specific entries of this Encyclopedia.

A *visual language* may be defined as a language that systematically uses visual representations to convey a meaning in a formal way. Frequently, people have used visual languages, iconic languages and graphical languages as synonyms. If one follows the above definition they are all visual languages, but it may be more precise to call iconic languages only those using icons and pictures extensively, while diagrammatic (or graphical) languages are those primarily using diagrams (such as graphs, flow-charts, block-diagrams, etc). When speaking about visual languages, some people allude to languages handling visual objects that are visually presented, i.e., images or pictorial objects of which a visual representation is given, others intend languages whose constructs are visual [3]. Chang calls the first ones *visual information processing languages* and the others *visual programming languages.* In the first case, one deals with conventional languages enhanced with subroutine libraries to handle visual objects. Image processing, computer vision, robotics, office automation, etc. are the typical application domains for these languages. Visual programming languages handle objects that do not necessarily have a visual representation. Within the class of visual programming languages, a subclass exists which manages a particular kind of non-visual objects, namely data in databases; this subclass of languages is that of *visual query languages (VQLs),* i.e., query languages exploiting the use of visual representations.

While VQLs are usually adopted for query formulation, information visualization mechanisms are used for displaying the results that constitute the answer to a user request. Information visualization, an increasingly important field of Computer Science, focuses on visual mechanisms designed to communicate clearly to the user the structure of information, and allow her/him to make sense out of large quantities of data. Significant opportunities for information visualization may be found today in data mining and data warehousing applications, which typically access large data repositories. Also, the enormous quantity of information sources on the WWW also calls for visualization techniques.

Key Applications

Any kind of traditional database-related activity (e.g., database creation, querying, mining, updating) has been and could be further supported by the usage of suitable visual interfaces, equipped with effective visual representations, easy-to-use interaction mechanisms and data visualizations. For instance, information-discovery interfaces must support a collaboration between humans and computers, for example, for data mining. Due to humans' limited memory and cognitive abilities, the growing volume of available information has increasingly forced the users to delegate the discovery process to computers, greatly underemphasizing the key role played by humans. Discovery should be viewed as an interactive process in which the system gives users the necessary support to analyze terabytes of data, and users give the system the feedback necessary to better focus its search.

Visual interfaces are obviously also extremely important for novel database applications, dealing with non-traditional data, such as multimedia, temporal, geographical, etc.

Moreover, that the user interface has become a crucial component in the success of any modern (information intensive) application is surely witnessed by the extraordinary growth of the Web: a click on the mouse is all users need to traverse links across the world. However, this much easier access to a huge quantity of various information has created new problems to the users, related to information digestion and assimilation that are difficult to achieve if one lets unstructured floods of data collect in perceptually-rich and information-overabundant displays. The information flood can turn out to be useful only if it can be converted in a somehow structured information flow that users can consume. The Information Foraging theory has been indeed developed in order to evaluate the valuable knowledge gainable from a system in relation to the cost of the necessary interaction.

Future Directions

Issues that are being further explored in modern interfaces include how best to array tasks between people and computers, create systems that adapt to different kinds of users, and support the changing context of tasks. Also, the system could suggest appropriate discovery techniques depending on data characteristics as well as data visualizations, and help integrate what are currently different tools into a homogeneous environment. Modern interfaces use (and will further exploit in the near future) multiple modalities for input and output (speech and other sounds, gestures, handwriting, animation, and video) and multiple screen sizes (from tiny to huge), and have an "intelligent" component ("wizards" or "agents" to adapt the interface to the different wishes and needs of the various users).

However, a key challenge in interacting with current information-abundant electronic environments is to shift from data-centric computer systems, which have been characteristic of over 40 years of Computer Science, to task-centric ones. Indeed, current desktop oriented systems propose a mostly disconnected set of generic tools (word processor, e-mail reader, video and image visualizer, etc.). The fact that these tools are running on one system without being connected leads to awkward situations, such as one re-entering or copying the same data among the different applications. Nowdays, users have to cope with an ever-growing amount of information, which they have to manage and use in order to perform their everyday tasks. This trend forces users to focus more on managing their information rather than using it to accomplish their objectives. Managing information basically amounts to saving it, and possibly being able to find (and re-find) it for subsequent reuse. Given the over-abundance of available information, the process of saving, finding, and re-finding itself needs to be supported by algorithms and tools more powerful than standard OS file browsers. During recent years, the creation of such tools has been the ultimate goal of the so-called Personal Information Management (PIM) field [9]. However, not much has been done in order to cope with the original problem, i.e., to support the user in executing her/his tasks so as to achieve her/his goals. Whereas, it would definitely be beneficial for the user to move from a (static and rigid) object-centric world to a (dynamic and adaptive) task-centric one. Tasks are more of an abstract notion than a computer manageable entity. Hence, such a move requires designing a system that is able to interpret the user's aims and to support the execution of the user's tasks. Tasks need to be explicitly represented in the system both in their static aspects, i.e., the kind of information that they manipulate, the kind of programs involved in these manipulations, security and authentication issues that may arise, and in their dynamic ones, i.e., the sequences of actions that they require, the alternative choices that are given to the user, pre-conditions, post-conditions, and invariants for the various activities that are involved in the task. Both static and dynamic aspects are of direct interest to the user, hence, need to be expressed using explicit semantics that the user can share.

Experimental Results

The key point of any interactive system should be to support, at best, people in achieving their goals and performing their tasks. To be more precise, the interaction should favor an increase in efficiency of people performing their duties without this having to cause extra organizational costs, inconveniences, dangers and dissatisfaction for the user, undesirable impacts on the context of use and/or the environment, long periods of learning, assistance and maintenance. In literature, most of the above listed requirements are synthetically associated to the qualitative software characteristic called usability. Precise usability evaluation needs to be conducted at all stages in the system life cycle in order to: (i) provide feedback which can be used to improve design; (ii) assess whether user and organizational objectives have been achieved; and (iii) monitor long term use of the product or system. In the early stage of design, emphasis is placed on obtaining feedback that can be used as a guide in the design process, while later, when a realistic prototype is available, it is possible to assess whether user and organizational objectives have been achieved. Since in the early stages of design and development changes are less expensive than in later stages, evaluation has to be started as soon as the first design proposals are available. Depending on the development stage of the project, evaluation may be used to select and validate the design options that best meet the functional and user-centered requirements, elicit feedback and further requirements from the users or diagnose potential usability problems and identify needs for improvement in the system. Expert evaluation can be fast and economical. It is good for identifying major problems but not sufficient to guarantee a successful interactive system. Controlled experiments with actual users are a key technique to identify usability issues that might have been missed by the expert evaluation, since they are related with the real usage of the system and the knowledge of the application domain. Generally speaking, evaluation techniques vary in their degree of formality, rigor and user involvement depending on the environment in which the evaluation is conducted. The choice is determined by financial and time constraints, the stage of the development lifecycle and the nature of the system being developed.

Visual Interfaces for Geographic Data

Robert Laurini
LIRIS, INSA-Lyon, Lyon, France

Synonyms

Cartography; Visualizing spatial data; Interactive capture; Interactive layout

Definition

Geographic data are in essence visual multimedia data. To enter this data with key-boards and to print them as tables of data are not very practical actions. For entry, special devices exist (theodolites, lasers, aerial photos, satellite images, etc.), whereas visual layout is currently named cartography or mapping. Visual interfaces have two facets, allowing the user to present their output as maps, possibly with very large printers, and to present spatial queries visually.

Historical Background

In the 1970s, the expression used was "computer-aided mapping" to emphasize the idea that printing maps was the sole scope of using computers. Then, in the 1980s, the more important aspect was considered to be structuring of the geographic database, so then the expression "Geographic Information Systems" was coined. From this period, research has been done on presenting maps as well as presenting queries. For centuries cartographers have created a large corpus of rules for manual mapping. Those rules were progressively integrated and enlarged to compose maps. For instance, zone hatching was considered a boring task when manually done, whereas with a computer, this task is straightforward. In contrast, name placement was considered as a relatively easy task, although in computing, this is still a challenge.

Foundations

It is common to say that "approximately 80% of all government data has some geographic component" (Langlois G., "Federal Computer Week," Jan. 08, 2001). This affirmation states the importance of geographic information not only for administration but also for companies, and not only for environmental and urban planning but also for geo-marketing, since all those data are stored in databases, or more specifically, geographic or spatial databases. In addition to non-spatial attributes, geographic objects are characterized by geometric shapes and coordinates, usually in two dimensions, but increasingly with three dimensions and time. Those characteristics imply three consequences:

1. The necessity of special data models for storing.
2. The necessity of distinguishing storage format and layout format.
3. The necessity of specialized interfaces for both querying against databases and presenting the results, essentially by means of cartography.

The scope of this overall presentation is to study those interfaces. But before presenting these interfaces, it is necessary to emphasize that geographic data are not entered via keyboard but are acquired by different devices, such as theodolites, aerial photos, satellite images, and more recently, GPS (Global Positioning System). These devices are essentially characterized by different resolutions and error levels. Just as theodolites can measure objects within accuracy of less than 0.1 mm, some satellite systems or GPS systems have accuracies of 100 m or less.

On the other hand, according to the size of the screens used and the size of the territory to be mapped, different scales must be used. In other words, the resulting map must be simplified or generalized more exactly in order to reach readability and completeness, as it passes from storage format to some other layout format.

This discussion will be organized as follows: after a short introduction, visual interfaces for cartographic output will be examined first, and then interfaces for querying. Then, a small section on new barriers for mobile handheld devices will conclude.

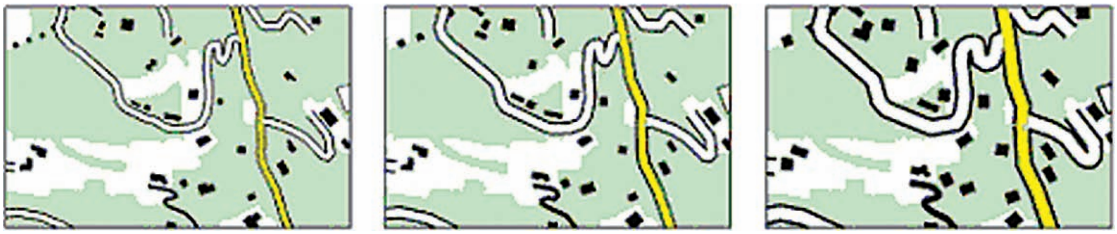
Visual Interfaces for Cartographic Output

A map is the classical way to respond to a spatial query or to layout the results of some spatial analysis. However, over the centuries, cartographers and geographers have elaborated upon sets of knowledge and know-how to make maps. One of the main problems is known as generalization, i.e., the way to simplify a map; for instance, in a geographic database, to have a country that is described with 1 million points/segments, but must be presented in a thumbnail with only 30 points/segments.

Another aspect is called graphic semiology, i.e., the way to select the symbology for mapping.

Generalities A fundamental rule in conventional cartography states that any object, once reduced after scaling to less than 0.1 mm cannot be mapped. For instance, an house or a road that is 10 m wide, at 1:1000 scale will be represented by 1 cm, whereas at 1:100,000 scale they will not be represented at all.

Another rule concerns details to be aggregated. An example would be two houses separated by a road. At some scale they will be represented separately, whereas at other scales they will be aggregated. As a consequence, at some scales a city is seen as a collection of separated houses, then as a set of city-blocks, then as a compact area, and finally as a point.



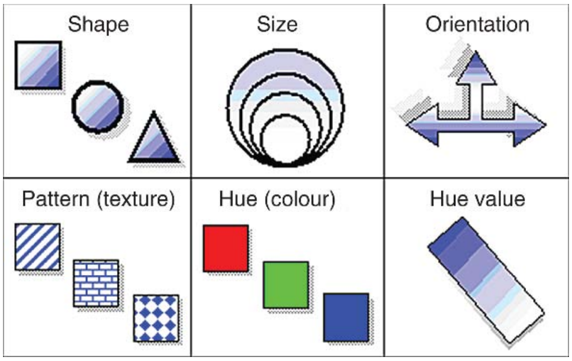
Visual Interfaces for Geographic Data. Figure 1. Example of generalization (1:25000, 1:35000, 1:50000). Source: http://recherche.ign.fr/labos/cogit/arGIGA.php [2].

Generalization By generalization, a piece-wise line can be simplified into a single piece, especially by using the Douglas-Peucker algorithm [3] or variants based on multi-agents systems [5]. Figure 1 gives some examples.

Graphic Semiology Graphic semiology, invented by J. Bertin [1], is the study of the meaning of graphics. In other words, it deals with the signification of drawings, the choice of captions, symbols and icons, together with a methodology to transmit visual messages. Six visual variables have been proposed for representing spatial objects (see Fig. 2) – shape, size, orientation, pattern, hue and value. For instance, to represent a church, a cross symbol (shape) can be used; the symbol's size can be selected according to the initial size of the church, etc.

Animation For some applications, animated cartography can be used, characterized by movement of objects, flickering, mutation, modification of shape or of color, velocity, etc. An excellent example is the animated map for weather forecast, in which some iconized clouds are slowly moving.

Chorems Chorems are a new way of representing schematized territories. Indeed, for several applications, it is not necessary to restitute the complete database contents, but rather to map the more important aspects. Those chorems were usually designed manually, but by means of spatial and spatio-temporal data mining, geographic patterns can be discovered and mapped. In other words, chorems are a new visual representation of geographic database summaries [4] and a way to represent geographic knowledge. The following example (Fig. 3) emphasizes the water problem in Brazil: it is easy to understand that a conventional river map (Fig. 3a) does not show the more crucial aspects as given in Fig. 3b with caption in Fig. 3c.



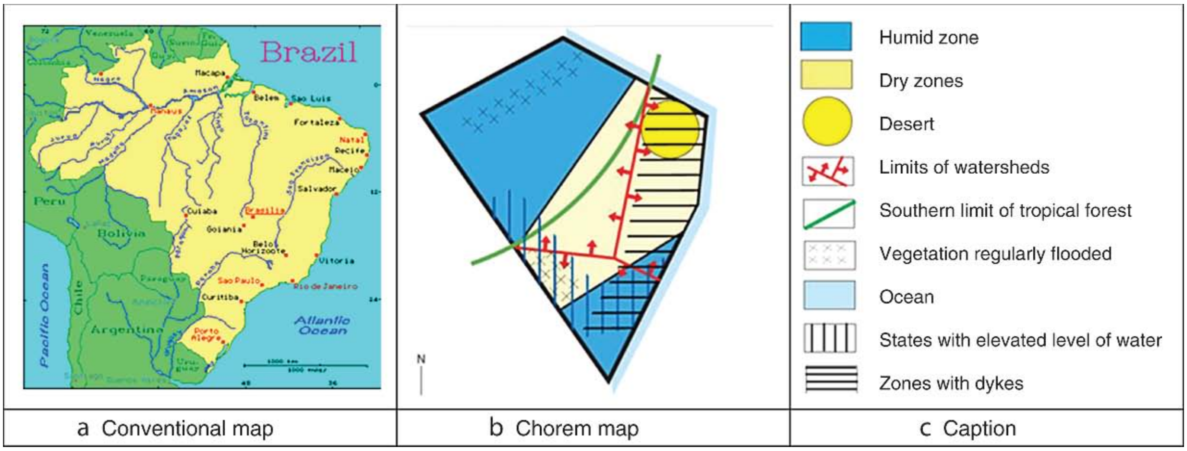
Visual Interfaces for Geographic Data. Figure 2. Bertin's Visual variables. Source: http://atlas.nrcan.gc.ca/site/english/learningresources/carto_corner/vis_var.gif/image_view.

Query Input

Visual interfaces for GIS are not only used for cartography, but also for query input, i.e., by means of interaction. Present systems can be classified into three categories:

1. Textual queries, such as by using spatial extensions of SQL/ORACLE
2. Tabular queries, by means of forms in which some queries are pre-programmed
3. Graphic queries based on widgets such as icons, mice, and clicks

Some basic queries such as point-in-polygon, region or buffer queries are usually given visually and interactively. However, more complex queries are also usually made, such as queries regarding



a Conventional map

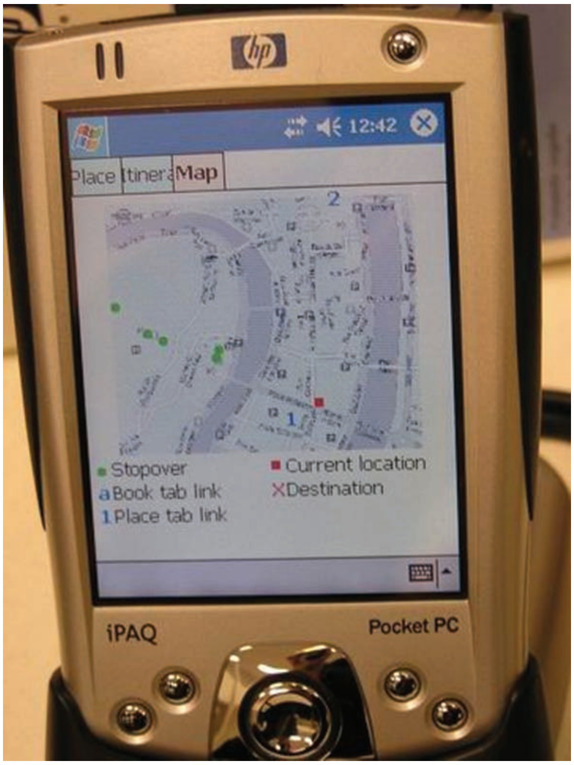
intersection or adjacency by means of Egenhofer's spatial relation. For instance, the LVIS system [2] is a visual system based upon those relations (See Fig. 4).

However, a fourth method seems more interesting, based on a tangible table in which several persons can collaborate. Figure 5 shows such a table (from the Geodan Company); see [11] for details.

Visual Interfaces for Geographic Data. Figure 5. Example of a tangible table from the Geodan Company (http://www.geodan.nl).



Visual Interfaces for Geographic Data. Figure 6. Example of a map presented on a mobile device.

Final Remarks: Challenges for Small Mobile Devices

In the early 1970s, the main problem was producing maps, and then increasingly maps were seen as results of spatial queries or as results of spatial analysis techniques. However, as it is simple to lay out maps in conventional screens or in very big screens, the screen size of the new handheld mobile devices requires discovering new modes of representing maps and interacting with them, essentially for Location-Based Services. A very common example is the need to represent the way to go from one location to another location, as shown in Fig. 6.

These new mobile handheld devices will imply new techniques for visualizing geographic data, essentially due to screen size.

Key Applications

Any domains in cartography, from urban to environmental planning, geology, archaeology, real estate mapping, location-based services, etc.

Visual Metaphor

Maria Francesca Costabile[1], Alan F. Blackwell[2]
[1]University of Bari, Bari, Italy
[2]University of Cambridge, Cambridge, UK

Synonyms

Metaphor; Analogy

Definition

Metaphor is a figure of speech, whose essence is to make a comparison between things that are not literally the same. For example, saying "that man is a lion" asks the reader to imagine how a *topic* (the man) could be reinterpreted in terms of some *vehicle* (a lion).

In Graphical User Interfaces (GUIs), *visual metaphor* refers to a kind of analogy, by which designers present the user with an explanation of system behavior in terms of some image. In the early days of the GUI, attempts were made to present all computer behavior in terms of real world analogies, as in the case of the *desktop metaphor*. However, these large scale metaphors soon broke down, as the challenge of developing and maintaining whole systems of correspondence became apparent. Attempts to replicate the success of the desktop metaphor have failed [1]. In practice, UI designers now use the term to refer to visual conventions and genres that, although familiar, need not resemble any real-world objects (e.g., a dialog box or flowchart). The essential benefits of the original desktop metaphor are those provided by *direct manipulation*. Occasionally, real world analogies are successfully used to introduce real world models for new system behaviors (e.g., the shopping basket metaphor in e-commerce). In all cases, user acceptance is encouraged by the use of familiar visual forms, whether pictorial (an *icon* such as a picture of a shopping basket), or an abstract *visual formalism* (conventional layout of dialog boxes, conventional nodes and links for a flowchart).

Key Points

A common view in cognitive science is that all abstract thought is based on physical metaphors [3] (e.g., adding "up"). Computers also use expressions such as "cut and paste" to convey intended usage by analogy to existing technology. Once such figures of speech become widespread, they are unlikely to change. The best principle for visual metaphor design, therefore, is to present users with concepts and terminology that are familiar, whether from the physical world or from previous experience with computers. In creative product design, metaphor can also help designers to imagine novel forms. This more literary strategy is open to interpretation, and may provide less direct guidance to users of the final product.

In the database area, visual formalisms present abstract database concepts to users. GUIs and the growth of database users in the late 80s pushed towards the development of visual query systems, i.e., "systems for querying databases that use a visual representation to depict the domain of interest and express related queries" [2]. A visual representation combines visual formalisms (diagrams, icons, forms) that can be interpreted from experience of existing representation genres – the more familiar and appropriate, the easier it is for the user to understand the usage intended by the designer.

Visual metaphors create expectations about system functionality that, if not fulfilled, can disorientate users. Poor use of metaphor has caused some significant failures of software products. Since there are several ways of creating and interpreting metaphor, the effectiveness of any interface metaphor must be analyzed and empirically evaluated, firstly to ensure that it is consistent with principles of direct manipulation, and secondly to determine whether users recognize and are familiar with the intended visual formalism.

Visual On-Line Analytical Processing (OLAP)

Marc H. Scholl, Svetlana Mansmann
University of Konstanz, Konstanz, Germany

Synonyms

Visual multidimensional analysis; Interactive visual exploration of multidimensional data

Definition

An umbrella term encompassing a new generation of OLAP (On-Line Analytical Processing) end-user tools for interactive ad-hoc exploration of large multidimensional data volumes. Visual OLAP provides a comprehensive framework of advanced visualization techniques for representing the retrieved data set along with a powerful navigation and interaction scheme for specifying, refining, and manipulating the subset of interest. The concept emerged from the convergence of BI (Business Intelligence) techniques and the achievements in the areas of Information Visualization and Visual Analytics. Traditional OLAP frontends, designed primarily to support routine reporting and analysis, use visualization merely for expressive presentation of the data. In the visual OLAP approach, however, visualization plays the key role as the method of interactive query-driven analysis. Comprehensive analysis includes a variety of tasks such as examining the data from multiple perspectives, extracting useful information, verifying hypotheses, recognizing trends, revealing patterns, gaining insight, and discovering new knowledge from arbitrarily large and/or complex data volumes. In addition to conventional operations of analytical processing, such as drill-down, roll-up, slice-and-dice, pivoting, and ranking, visual OLAP supports further interactive data manipulation techniques, such as zooming and panning, filtering, brushing, collapsing etc.

Historical Background

OLAP emerged in the mid-90s as a technology for interactive analysis of large volumes of accumulated and consolidated business data. The underlying multidimensional data model allows users to view data from different perspectives by shaping it into *multidimensional cubes* of measurable facts, or *measures*, as the cube's cells that are indexed by a set of descriptive categories, called *dimensions*. Member values within a dimension may be further arranged into a *classification hierarchy* (e.g., `city` → `state` → `country`) to enable additional aggregation levels. A data cube in a real-world application may hold millions of fact entries characterized by up to 20 dimensions, each supplied with a single or multiple classification hierarchies of various depth. Obviously, to gain insight into such huge and complex data, analysts need mechanisms for projecting the original set onto a two-dimensional (or at most three-dimensional) space and reducing it to a perceivable number of items.

First proposals on using visualization for exploring large data sets were not tailored towards OLAP applications, but addressed the generic problem of visual querying of large data sets stored in a database. Keim and Kriegel [3] proposed VisDB, a visualization system based on a new query paradigm. In VisDB, users are prompted to specify an initial query. Thereafter, guided by a visual feedback, they dynamically adjust the query, e.g., by using sliders for specifying range predicates on single attributes. Retrieved records are mapped to the pixels of the rectangular display area, colored according to the degree of their conforming to the specified set of selection predicates, and positioned according to a grouping or ordering directive.

A traditional interface for analyzing OLAP data is a pivot table, or cross-tab, which is a multidimensional spreadsheet produced by specifying one or more measures of interest and selecting dimensions to serve as vertical (and, optionally, horizontal) axes for summarizing the measures. The power of this presentation technique comes from its ability to summarize detailed data along various dimensions, and arrange the aggregates computed at different granularity levels into a single view, preserving the "part-of" relationships between the aggregates. Figure 1 exemplifies the idea of "unfolding" a three-dimensional data cube Fig. 1a into a pivot table Fig. 1b, with cells of the same granularity marked with matching background color in both representations. However, pivot tables are inefficient for solving non-trivial analytical tasks, such as recognizing patterns, discovering trends, identifying outliers, etc. [1,4,11]. Visualization has the power to save time and reduce errors in analytical reasoning by utilizing the phenomenal abilities of the human vision system to recognize patterns [2].

Visual On-Line Analytical Processing (OLAP). Figure 1. Projecting a multidimensional data cube onto a pivot table. (a) A sample three-dimensional data cube for storing sales transactions as measures `Quantity` and `Amount` characterized by dimensions `Product`, `Date`, and `Store`. (b) A pivot table view of sales data (measures `Quantity` and `Amount`) broken down vertically by `Product` and `Date` and horizontally by `Store`.

OLAP interfaces of the current state of the art enhance the pivot table view by providing a set of popular business visualization techniques, such as bar-charts, pie-charts, and time series, as well as more sophisticated layouts, such as scatterplots, maps, treemaps, cartograms, matrices, grids, etc. and vendors' proprietary visualizations (e.g., decomposition trees or fractal maps). Some tools go beyond mere visual presentation of data and propose sophisticated approaches inspired by the findings in information visualization research. Prominent examples of advanced visual systems are Advizor by Visual Insights [1] and Tableau by Tableau Software [2].

Advizor implements a technique that organizes the data into three perspectives. A perspective is a set of linked visual components displayed together on the same screen. Each perspective focuses on a particular type of analytical task, such as (i) single measure view using a 3D multiscape layout, (ii) multiple measures arranged into a scatterplot, and (iii) anchored measures presented using techniques from multidimensional visualization (box plots, parallel coordinates, etc.).

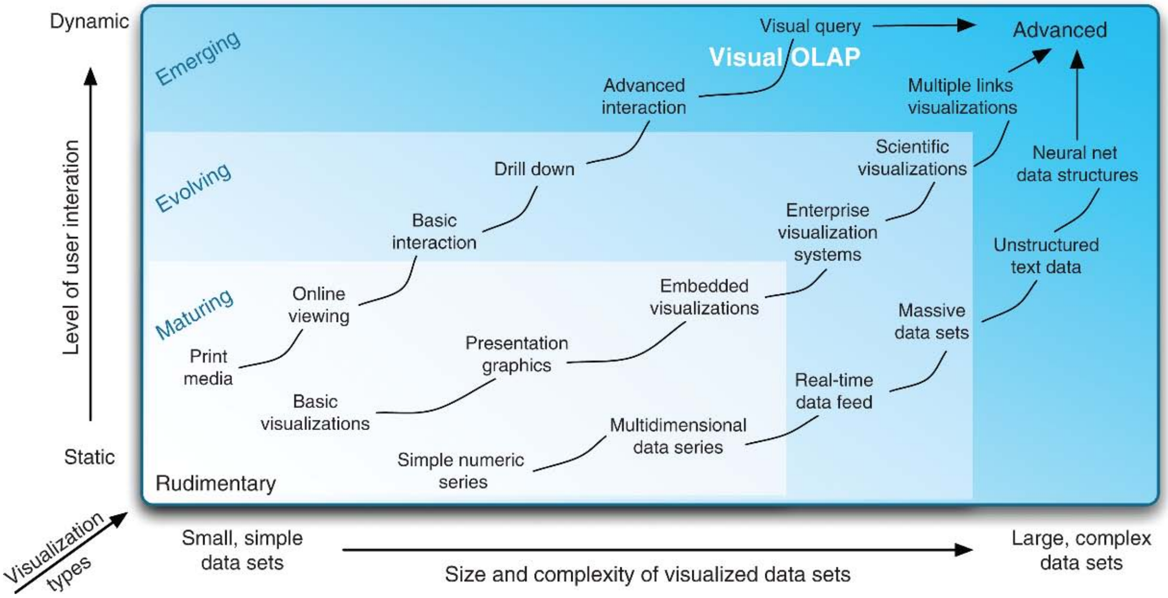
Tableau is a commercialized successor of Polaris, a visual tool for multidimensional analysis developed by a research team of Pat Hanrahan at Stanford University [12]. Polaris inherits the basic idea of the classical pivot table interface that maps aggregates onto a grid defined by dimension categories assigned to the grid's rows and columns. However, Polaris uses embedded graphical marks rather than textual numbers in the table cells. The types of supported graphics are arranged into a taxonomy, comprising rectangle, circle, glyph, text, Gantt bar, line, polygon, and image layouts.

Russom [10] summarizes the trends in business visualization software as a progression from rudimentary data visualization to advanced forms and proposes to distinguish three life-cycle stages of visualization techniques, such as maturing, evolving, and emerging, as depicted in Fig. 2. Within this classification, visual OLAP clearly fits into the emerging techniques for advanced interaction and visual querying.

Ineffective data presentation is not the only deficiency of conventional OLAP tools. Further problems are cumbersome usability and poor exploratory functionality. Visual OLAP addresses those problems by developing fundamentally new ways of interacting with multidimensional aggregates. A new quality of visual analysis is achieved by unlocking the synergy between the OLAP technology, information visualization, and visual analytics.

Foundations

A successful OLAP tool is capable of supporting a wide variety of analytical tasks. As mentioned in the previous



Visual On-Line Analytical Processing (OLAP). Figure 2. Trends in data visualization for business analysis (adopted with modifications from [7]).

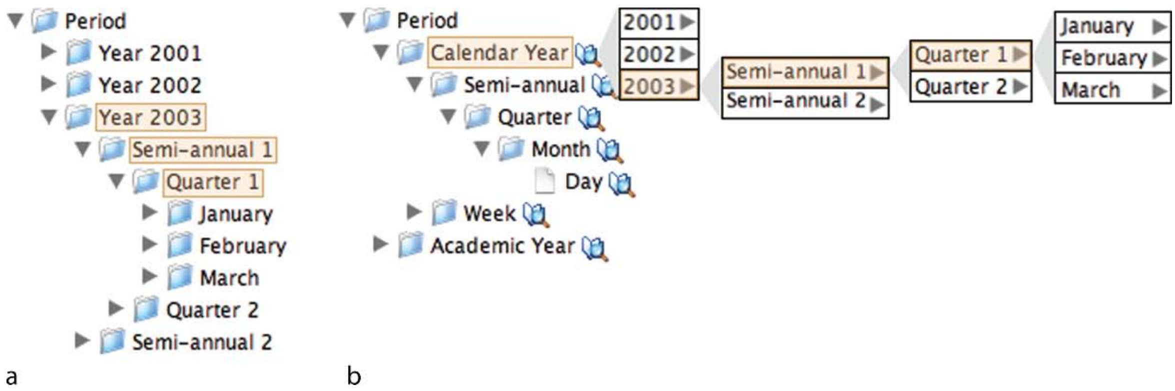
section, different tasks are best solved by applying different visual presentations. OLAP tools account for this diversity by providing a comprehensive framework, which enables users to interactively generate satisfactory visual presentations. The overall query specification cycle evolves by (i) selecting a data source of interest, (ii) choose a visualization technique (e.g., a scatterplot), and then (iii) mapping various data attributes to that technique's structural elements (e.g., horizontal and vertical axes) as well as to other visual attributes, such as color, shape, and size. The main elements of the framework are the navigation structure for visual querying of data sources, a taxonomy of available visual layouts attributes, and a toolkit of interaction techniques for dynamic query refinement and visual representation of the data. A unified framework is obtained by designing an abstraction layer for each element and providing mapping routines (e.g., navigation events to database queries, query results to a visual layout, etc.) implementing the interaction between different layers.

Visual Query Specification

Visual OLAP disburdens the end-user from formulating queries in the "raw" database syntax by allowing purely visual (i.e., by means of using a computer mouse) query specification. Data cubes are represented as a browsable structure whose elements can be queried by "pointing-and-clicking" and "dragging-and-dropping." Visual interface does not trade off advanced functionality for simplicity, it rather facilitates the process of specifying ad hoc queries of arbitrary complexity.

A common navigation paradigm is that of a file browser that represents the contents as a recursive containment of elements. The nodes in the navigation hierarchy may be of types *database*, *schema*, *table* (*cube*), *dimension*, *classification level*, and *measure*. In simplified configurations, the navigation may be limited to a single data cube and, thus, consist solely of dimensions and measures. Dimension hierarchies are presented as recursive nesting of their classification levels, thereby allowing users to browse either directly in the dimension's data or explore its hierarchy schema. In the former approach, denoted *extension-based*, the navigation tree of a dimension is a straightforward mapping of the dimension's data hierarchy: each hierarchical value is a node that can be expanded to access the contained next-level values. Alternatively, the navigation can explicitly display the dimension schema, with each level as a child node of its parent level. This so called *intension-based* approach is especially appreciated for power analysis and employing advanced visualization techniques. The latter navigation strategy becomes the only option when supporting multiple and heterogeneous dimension hierarchies [7] and a multi-cube join or drill-across [6]. Figure 3 shows the difference between instance-based and schema-based browsing for a hierarchical dimension Period.

To navigate in multidimensional aggregates and perform dimensional reduction to extract data for analysis, OLAP defines a number of standard multidimensional analysis operations incorporated into a visual framework in the form of navigation events and interaction options.



Visual On-Line Analytical Processing (OLAP). Figure 3. Browsing options for hierarchical dimensions: extension versus intension navigation. (a) dimension instances arranged in a navigation hierarchy. (b) hierarchy of dimension categories with on-demand data display and an option to switch to extension navigation.

User interactions are translated into valid database queries. From the user's perspective, querying is done implicitly by populating the visualization with data and incrementally refining the view. The output of any OLAP query is a data cube. Visual presentation is generated by assigning the cube's elements – measure values and their dimensional characteristics – to the visual variables of the display. A visualization technique is defined by the visual variables, or attributes, it employs and the way those constructs are combined. Examples of visual attributes are *position*, *shape*, *size*, *color*, and *orientation*. Typically, each of the above visual attributes is used to represent a single data field returned by a query. Various attributes behave differently with respect to the range, data type, and the number of values they can meaningfully represent.

The mapping of the cube's structure to the navigation scheme as well as the translation of navigation events into database queries rely on the metadata of the underlying data warehouse system. Metadata describes the structure of the cubes and their dimensions, measures, and applicable aggregation functions. In an advanced user interface, the analysts are able to define new measures in addition to the pre-configured ones. New measures are obtained by applying a different aggregate function (e.g., average, variance, count) or by specifying a more complex formula over a single or multiple measure attributes (e.g., computing a ratio between two aggregates).

Visualization Techniques

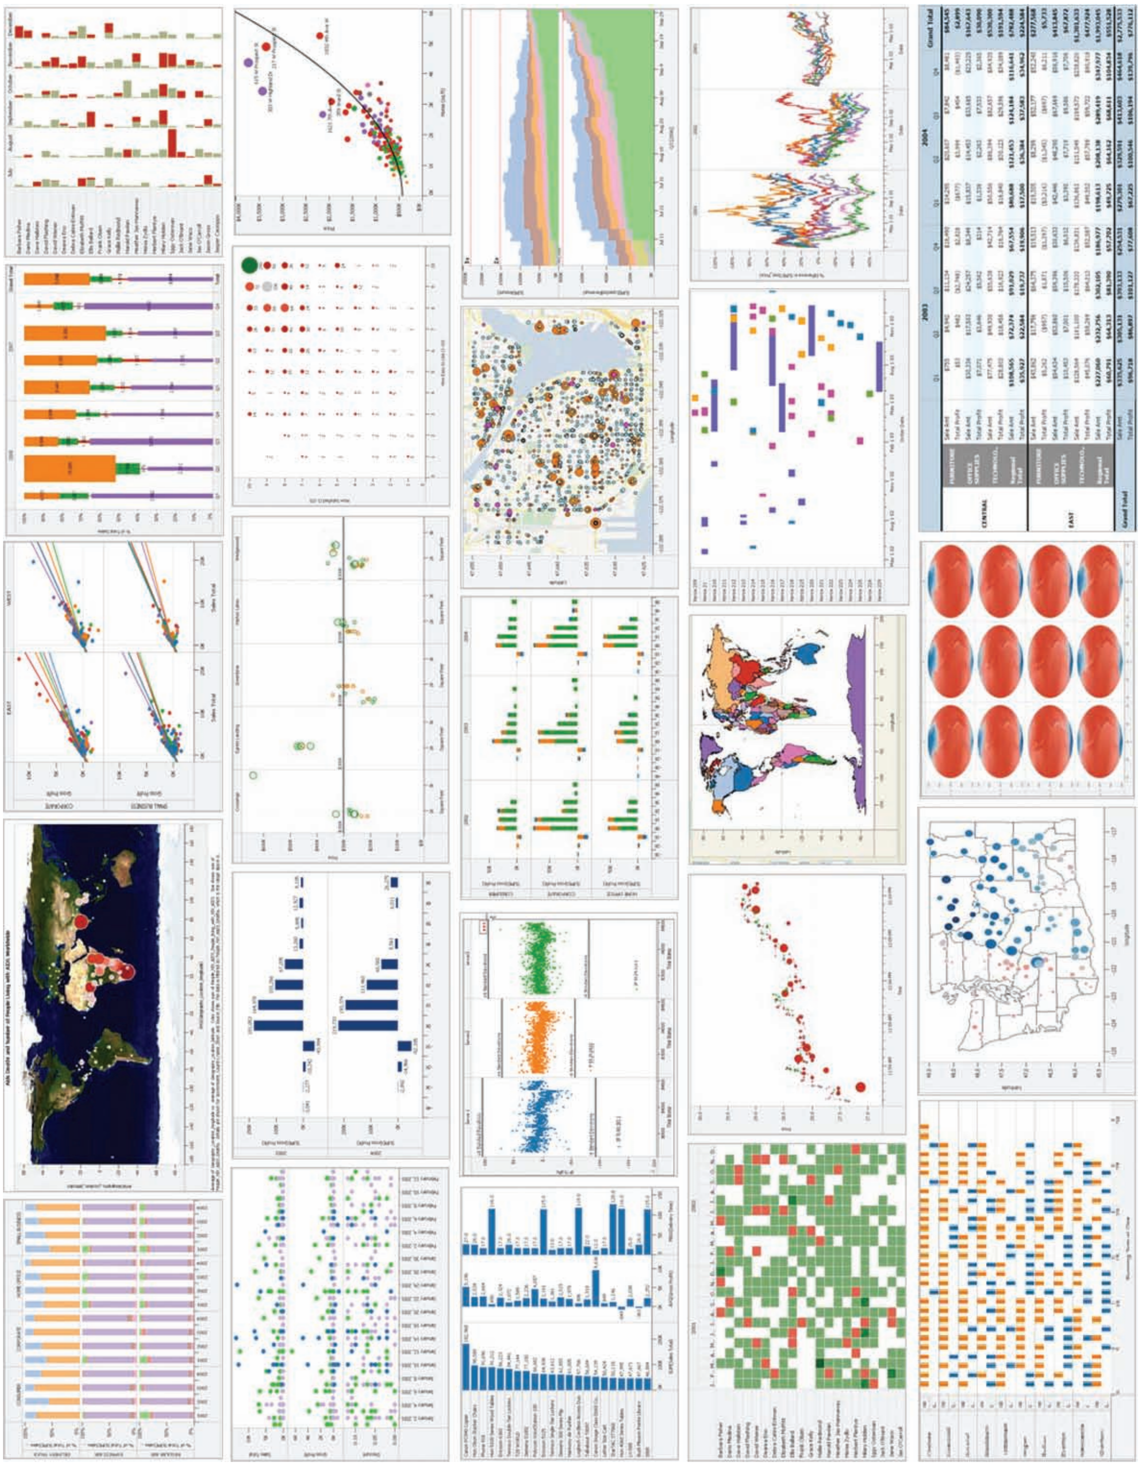
The task of selecting a proper visualization technique for solving a particular problem is by far not trivial as various visual representations (metaphors) may not only be task dependent, but also domain dependent. Successful visual OLAP frameworks need to be based on a comprehensive taxonomy of domains, tasks, and visualizations. The problem of assisting the analyst in identifying an appropriate visualization technique for a specific task is an unsolved issue in state-of-the-art OLAP tools. Typically, a user has to find an appropriate solution manually by experimenting with different layout options.

To support a large set of diverse visualization techniques and to enable dynamic switching from one technique to another, an abstraction layer has to be defined for specifying the relationships between the data and its visual presentation. Maniatis et al. propose an abstraction layer solution, called a *Cube Presentation Model* (CPM) [5], that distinguishes between two layers: a logical layer deals with data modeling and retrieval whereas a presentation layer provides a generic model for representing the data (normally, on a 2D screen). The entities of the presentation layer include points, axes, multicubes, slices, tapes, cross-joins, and content functions. The authors demonstrate how CPM constructs can be mapped to advanced visual layouts at the example of the Table Lens – a technique based on a cross-tabular paradigm with support for multiple zoomable windows of focus.

A common approach to visualization in OLAP application relies on a set of templates, wizards, widgets, and a selection of visual formats. Hanrahan et al. [2] argue, however, that an open set of questions cannot be addressed by a limited set of techniques, and choose a fundamentally different approach for their visual analysis tool Tableau: a declarative visual query language VizQL^{TM} offers high expressiveness and composability by allowing users to create their own visual presentations by means of combining various visual components. Figure 4 illustrates the visualization approach of Tableau by showing just a small subset of sophisticated visual presentations, created using simple VizQL statements, not relying on any pre-defined template layout.

The designers of Tableau deliberately restrict the set of supported visualizations to the popular and proven ones, such as tables, charts, maps, and time series, doubting general utility of exotic visual metaphors [2]. Thereby, Tableau's approach is constrained to generating grids of visual presentations of uniform granularity and limited dimensionality. Other researchers suggest that visual OLAP should be enriched by extending basic charting techniques or by employing novel and less known visualization techniques to take full advantage of multidimensional and hierarchical properties of the data [4,11,14,15]. Tegarden [15] formulates the general requirements of business information visualization and gives an overview of advanced visual metaphors for multivariate data, such as *Kiviat diagrams* and *Parallel Coordinates* for visualizing data sets of high dimensionality, as well as 3D techniques, such as *3D Scattergrams*, *3D line graphs*, *floors and walls*, and *3D map-based bar-charts*.

Another branch of visualization research for OLAP concentrates on developing *multiscale* visualization techniques capable of presenting the data at different levels of aggregation. Stolte et al. describe their



Visual On-Line Analytical Processing (OLAP). Figure 4. Examples of sophisticated multidimensional visualizations generated by simple VizQL statements (used by permission of Tableau Software, Inc.).

implementation of multiscale visualizations within the framework of the Polaris system [13]. The underlying visual abstraction is that of a *zoom graph* that supports multiple zooming paths, where zooming actions may be tied to dimension axes or triggered by a different type of interaction.

Lee and Ong propose a multidimensional visualization technique that adopts and modifies the Parallel Coordinates method for knowledge discovery in OLAP [4]. The main advantage of this technique is its scalability to virtually any number of dimensions. Each dimension is represented by a vertical axis and the aggregates are aligned along each axis in form of a bar-chart. The other side of the axis may be used for generating a bar-chart at a higher level of detail. Polygon lines adopted from the original Parallel Coordinates technique are used for indicating relationships among the aggregates computed along various dimensions (a relationship exists if the underlying sets of fact entries in both aggregates overlap).

Mansmann and Scholl concentrate on the problem of losing the aggregates computed at preceding query steps while changing the level of detail and propose to use hierarchical layouts for capturing the results of multiple decompositions within the same display [9]. The authors introduce a class of multiscale visual metaphors called *Enhanced Decomposition Tree*: the levels of the visual hierarchy are created by decomposing the aggregates along a specified dimension and the nodes contain the resulting sub-aggregates arranged into an embedded visualization (e.g., a bar-chart). Various hierarchical layouts and embedded chart techniques are considered to account for different analysis tasks.

Sifer presents a multiscale visualization technique for OLAP based on *coordinated views of dimension hierarchies* [11]. Each dimension hierarchy with qualifying fact entries attached as the bottom-level nodes is presented using a space-filling nested tree layout. Drilling-down and rolling-up is performed implicitly by zooming within each dimension view. Filtering is realized by (de-)selecting the values of interest at any level of dimension hierarchies, resulting either in highlighting the qualifying fact entries in all dimension views (*global context coordination*) or in eliminating the disqualified entries from the display (*result only coordination*).

A similar interactive visualization technique, called the *Hierarchical Dynamic Dimensional Visualization* (HDDV), is proposed in [14]. Dimension hierarchies are shown as hierarchically aligned barsticks. A barstick is partitioned into rectangles that represent portions of the aggregated measure value associated with the respective member of the dimension. Color intensity is used to mark the density of the number of records satisfying a specified range condition. Unlike in [11], dimension level bars are not explicitly linked to each other, allowing to split the same aggregate along multiple dimensions and, thus, to preserve the execution order of the dis-aggregation steps.

Key Applications

Visual OLAP should be considered an integral part of a BI architecture. The latter appears rather universal with respect to prospective application domains and comprises virtually all business and non-business scenarios that require quantitative analysis. Prominent business application areas are Financial Risk Management, Industrial Process Control, Operations Planning, Capital Markets Management, Network Monitoring, Marketing Analysis, Fraud/Surveillance Analysis, Portfolio Management, Customer/Product Analysis, Budget Planning, Operations Management, and Economic Analysis. Non-business applications are found primarily in government, healthcare, research, and academia.

Future Directions

At present, visual OLAP is lacking a unified formal model and query specification standard. Existing visual analysis frameworks are based on proprietary formalisms and models. Furthermore, advanced OLAP tools claim to turn visualization from the presentation layout into the method of data exploration. This claim implies the need for re-defining visualization as an instrument in terms of its structural components and interaction functions.

A pioneering initiative on addressing the above formalization issues by integrating visualization into a query language is a visual declarative data query language VizQL^{TM} developed at Tableau Software Inc. and released in 2006 [2]. However, VizQL is a proprietary solution and is limited to the visual table paradigm of the Tableau system. To be universally adopted, a new standard for visual exploration of OLAP data has to be open, flexible, and extendible to account for a wide range of visualization approaches.

A promising research direction is to evaluate a wealth of existing visualization techniques with respect to their applicability to multidimensional analysis and to identify classes of techniques efficient for solving particular analysis tasks. One of the major visualization challenges for OLAP is the ability to present a large number of dimensions on a display. An additional visual attribute for mapping a dimension could be *animation*, as found in Gapminder software for interactive data exploration using animated scatterplots where animation is used to show the evolution of values along the timeline [9].

Another emerging research direction is concerned with spatio-temporal analysis that employs specialized techniques for spatial and/or temporal exploration, such as maps, cartograms, times series, and calendar views. These techniques are aware of the rich semantics behind temporal and geographic dimensions of the data. Rivest et al. [8] propose SOLAP (spatial OLAP) as a visual platform for spatio-temporal analysis using cartographic and general displays. The authors define different types of spatial dimensions and measures as well as a set of specialized geometry-aware operators.

Definition

In psychology, visual perception is the ability to transform visible light stimulus reaching the eyes into information supporting recognition processes and action. The various physical and processing components which enable a human to being to assimilate information from the environment are known as the visual system.

The act of seeing starts when the cornea and lens at the front of the eye focus an image of the outside world onto a light-sensitive membrane in the back of the eye, called the retina. The retina is actually the part of the brain which works as a transducer for the conversion of patterns of light into neuronal signals. Precisely, the photoreceptive cells of the retina detect the photons of light and respond by producing neural impulses. These signals are processed in a hierarchical fashion by different parts of the brain, such as the lateral geniculate nucleus, and the primary and secondary visual cortex of the brain.

The major problem in visual perception is that what is seen is not simply and always a translation of retinal stimuli (i.e., the image on the retina). Thus, different theories and experimental studies have been devised to explain what visual processing does to create what is actually perceived. It is worth stressing that visual perception involves the acquisition of knowledge, so it is not merely an optical process but it also entails cognitive activity.

Historical Background

The foundations of modern theories of vision were laid in the seventeenth century, when Descartes and others established the principles of optics, making it possible to distinguish between the physical properties of light, images and the psychological properties of the visual experience. It was proposed that visual perception involves adding information to that present in the retinal image in order to reach properties such as solidity of an object and meaning.

According to the empiricist position, developed primarily by von Helmholtz [8], vision originates from a form of unconscious inference: it is a matter of deriving a probable interpretation from incomplete data (a set of elementary sensations that are integrated and synthesized through a process of learning by association). Inference requires prior assumptions about the world, such as that light comes from above, or that objects are viewed from above and not below. The study of visual illusions (cases when the inference process goes wrong) has yielded a lot of insight into what sort of assumptions the visual system makes.

The unconscious inference hypothesis has recently been investigated in Bayesian studies of visual perception. Proponents of this approach consider that the visual system performs some form of Bayesian inference to derive a perception from sensory data. Models based on this idea have been used to describe various visual subsystems, such as the perception of motion or the perception of depth.

Gestalt psychologists (in the 1930s and 1940s), questioned the assumption that vision is derived from inference mechanisms and previous knowledge [10]. They considered visual perception to be direct and based on the detection of patterns or configurations, as organized wholes available in the perceptual field. According to the Gestalt *Laws of Organization* there are six main factors that determine how things are grouped in visual perception: proximity, similarity, closure, symmetry, common fate and continuity. The major problem with the Gestalt laws and theory is that they are *descriptive* of vision more than *explanatory.*

In Gibson's ecological theory of perception [4], the emphasis is placed on the role played by relations in the visual environment, which are embedded within the spatial and temporal distribution of stimuli an active observer can perceive. According to Gibson, no inference mechanism is needed to detect these *affordances*, that are directly available in the surrounding environment.

Computational approaches to the study of vision, such as Marr's work [5], have provided more detailed explanations of visual phenomena by building artificial intelligence models of the processes involved. Vision is considered as the process of forming a description or representation of what is in the scene from the retinal images. The system at work is modular and serial, consisting of a number of subprocesses, each one taking one representation and transforming it into another. It goes from the creation of the primal sketch (representing changes in light intensity occurring over space in the image and organizing these local descriptions onto a 2D representation of regions and boundaries) to the 2 1/2 D sketch (where the layout of objects surfaces, their distances and orientations relative to the observer are represented) to the creation of 3D model representations (specifying the solid shapes of objects matched against their corresponding representations in memory).

Foundations

According to a multidisciplinary study of visual perception based on perceptual psychology, neuroscience and computational analysis, the purpose of vision is to produce information about objects, locations and events in the world from imaged patterns of light reaching the viewer. Psychology uses the term 'distal stimulus' to refer to the physical world under observation and 'proximal stimulus' to refer to the retinal image. The function of vision is to create a description of aspects of the distal stimulus given the proximal stimulus. Although visual perception is said to be veridical when it produces accurate descriptions of the real world, in practice vision is better understood in the context of the cognitive and motor functions that it serves.

Vision systems create descriptions of the visual environment based on properties of the incident illumination. The human vision system is primarily sensitive to patterns of light rather than to the absolute magnitude of light energy. The eye does not operate as a photometer. Instead, it detects spatial, temporal and spectral patterns in the light imaged on the retina, and information about these patterns of light form the basis of visual perception. A system which measures changes in the light energy rather than the magnitude of energy has an ecological utility, since it makes it easier to detect patterns of light over large ranges in light intensity. This is also an advantage for computer graphics, which can make graphic displays work effectively by only producing similar patterns of spatial and temporal change to the real world.

Depth perception: Human beings can perceive the world as 3D, although images projected onto the retina are 2D (all points placed at different distances in space, but along the same directional axis, project onto a same point of the retina). Depth perception, also called stereopsis, relies mainly on binocular cues (cues that require input from both eyes) and on monocular cues (cues available from the input of just one eye), as well as on the synthetic integration performed by a person's brain based on the full field of view perceived with both the eyes.

Among the most important binocular cues there are: (i) retinal disparity, due to the distance between the two eyes which makes the projection of objects or scenes onto each retina slightly different. By using two images of the same scene obtained from slightly different angles, it is possible to triangulate the distance to an object with a high degree of accuracy. If an object is far away, the disparity of that image falling on both retinas will be small, if it is close the disparity will be large. (ii) accommodation, focusing on far away objects, the ciliary muscles stretch the eye lens, making it thinner. (iii) convergence, to focus on a same object the two eyes need to converge. The angle of convergence is larger when the eye is fixating objects that are far away.

Examples of monocular cues are: (i) focus, the lens of the eye can change its shape to bring objects at different distances into focus. Knowing at what distance the lens is focused when viewing an object means knowing the approximate distance to that object. (ii) perspective, the property of parallel lines converging at infinity allows people to reconstruct the relative distance of two parts of an object, or of landscape features. (iii) occlusion, the blocking of the sight of objects by others is also a clue which provides information about relative distance (the occluded object is perceived as more far away). (iv) peripheral vision, at the outer extremes of the visual field, parallel lines become curved, as in a photo taken through a fish-eye lens. This effect greatly enhances the viewer's sense of being positioned *within* a real, three dimensional space.

Perceptual constancies: To view the world by the exact image projected on the retina would mean to perceive it as very unstable. Objects within a person's field of vision would constantly be changing shape, size, position and color as s/he moved toward and away from them, because the distance and therefore the amount of reflected light detected by the retina would also be changing. Indeed, this is not the case, our surroundings are perceived as solid and stable since the world is not just "seen" but actively constructed from fragmentary perceptual data [4]. It is our brain that by means of perceptual constancies interprets the changing proximal stimulation to reach stability. For instance, in the case of *size* constancy our brain perceives an object in relation not only to its visual angle, but also to the perceived distance. Also, size constancy tells us that objects moving away from us are the same size even though their retinal image is getting smaller and this is because size constancy is a property of the perceptual field (it refers to the relationship between the object and its surrounding context, which remains stable). The same principle works in *form* constancy, where an object is perceives as the same notwithstanding the different shapes that are projected onto the retina as its angle changes. That is to say that perception of the partial view becomes equivalent to perception of the whole object. Also, in the case of *color* and *light* constancies, our retina is able to distinguish the different wavelengths of light entering the eye, however, our perception remains relatively stable since it is affected by our previous experiences or knowledge, as well as by the context one is dealing with (e.g., color and lightness of an object do not depend only on the absolute intensity of light, but also on their relationships with the stimulation arriving from the surrounding areas).

There are primarily two different ways in which visual perception and the perceptual process have been scientifically investigated. Psychophysical analysis has studied how a person's perception is related to the stimulus. As an example, *Stevens' power law* defines the relationship between the magnitude of a physical stimulus and its perceived intensity or strength [7]. The general form of the law is

$$\psi(I) = kI^a,$$

where I is the magnitude of the physical stimulus, ψ is the psychophysical function capturing sensation (the subjective size of the stimulus), a is an exponent that depends on the type of stimulation and k is a proportionality constant that depends on the type of stimulation and the units used.

A second way of studying perception considers its relation to the physiological processes that are occurring within the person's sensors and/or brain. This is called *physiological analysis* of the perceptual process, which measures, for example, some aspects of a person's brain activity when s/he looks at a visual stimulus. Magnetic resonance imaging (MRI) is a typical instrument used for mapping activation patterns in the human brain as a person watches a scene.

Due to the complexity of visual perception, and the intimate relation among its psychophysical, physiological and cognitive aspects, the best way of getting a complete view of this phenomenon is by cross referencing the different disciplines that have addressed its study.

Key Applications

Computer Graphics

Visual perception has become a key component of computer graphics, since it helps to achieve the development of high fidelity virtual environments in reasonable time by exploiting knowledge of how the human visual system works (e.g., rendering time can be saved by avoiding to compute those parts of a scene that the human will fail to notice).

Artificial Intelligence

The results of studies on human visual perception inspire the development of computational models of vision that, in turn, can be used to design and implement visual abilities within artificial intelligence systems (e.g., robots).

Visual Interfaces

Visual perception provides the scientific basis for the design of visual interfaces that can best match the requirements of their users, by enabling an easier and more transparent access and interaction with information.

Information Visualization

In the field of Information visualization, visual perception principles help to produce effective visualizations of non-geometric data retrieved from large document collections (e.g., digital libraries), the World Wide Web, and databases, with the aim of supporting users to make sense of information there contained and of enhancing their creative thinking.

Future Directions

Current theories and methods for the study of visual perception in psychophysics and neuroscience need to be integrated with information processing approaches in the attempt to model vision at a more abstract computational level. An interesting cross-fertilization is expected between neuroscience experimentation and computer vision theories. Particularly, for providing a detailed account of how the brain makes effective use of top-down resources (e.g., knowledge, memories etc.), creates predictions about forthcoming stimuli and constantly matches expectations against signals from the environment [6]. It is likely that as researchers in visual neuroscience and computer vision develop a better understanding of the role played by bottom-up and top-down information processing mechanisms and their interaction, better theories of visual perception can be developed.

Experimental Results

A considerable amount of experimental evidence exists for all the theories and approaches to the study of visual perception cited above. References to results on the physiology, psychology and ecology of vision are provided in [1,3]. Application of visual perception principles to the design of Information visualization and visual interfaces is discussed in [9].

Data Sets

An online laboratory providing a collection of demonstrations and experiments on visual perception can be found at: http://www2.psych.purdue.edu/~coglab/VisLab/welcome.html.

Visual Query Language

Tiziana Catarci
University of Rome, Rome, Italy

Synonyms

Visual query system

Definition

Visual Query Languages (VQLs) are languages for querying databases that use a visual representation to depict the domain of interest and express related requests. VQLs provide a language to express the queries in a visual format, and they are oriented towards a wide spectrum of users, especially novices who have limited computer expertise and generally ignore the inner structure of the accessed database. Systems implementing VQLs are usually called Visual Query Systems (VQSs) [8].

Historical Background

The birth of VQLs was due to several needs, including: providing a friendly human-computer interaction, allowing database search by non-technical users, introducing a mechanism for comfortable navigation even in case of incomplete and ambiguous queries. It is worth noting that the real precursor of VQLs was QBE, already proposed by Moshe Zloof in 1977 [19].

QBE was really ahead of its time. Indeed, the Zloof's paper states: "the formulation of a transaction should capture the user's thought process. . . ." This is a quite common idea today, but at that time (1977) the research on user interfaces and human-computer interaction was still in its infancy. Approximately in the same period, Smith coined the term "icon" in his Ph.D. thesis [16] and Alan Kay introduced the idea of direct manipulation interfaces that are, in principle, usable by everyone [14]. It was necessary to wait until the beginning of 1980s for the first commercial systems making extensive use of direct manipulation, namely Xerox Star, Apple Lisa, and Macintosh.

It is worth noting that QBE is based not only on the usage of examples for expressing queries, but it also relies on the direct manipulation of relational tables inside a basic graphical user interface: an environment and an action modality which were quite unknown at that time, considering the almost simultaneous publication of Alan Kay's paper.

Another anticipatory idea is the incremental query formulation, i.e., ". . .the user can build up a query by augmenting it in a piecemeal fashion." Many papers still recommend to allow the user expressing the query in several steps, by composing and refining the initial formulations [8].

Moreover, QBE was the first proposal of query language in which the attention to the user interface is coupled with a rigorous definition of the language syntax and semantics and a careful study of the language expressive power. Unfortunately, many of the later proposals of visual query languages have emphasized the aspects related to user interaction and ease of learning and of use only, without also focusing on formal aspects, such as syntax, semantics and expressive power [8]. Such query languages are usually presented through examples of query formulation, making both the study of language expressiveness and the comparison with other languages difficult. The opposite is true for QBE, whose usability was also tested comparing it with SQL in several experiments, such as those reported in [15] and [17]. Finally, many of the QBE ideas are still up-to-date and it is amazing to note that QBE-like interfaces are nowadays adopted in commercial database systems, despite the current explosion of sophisticated visualizations and interaction mechanisms.

However, only later on, during the 1980s and early 1990s, VQLs received the greatest attention by the database community with the presentation of several diverse proposals for an effective visual and interactive query language.

Foundations

In [5], VQLs were reviewed and classified based on three criteria, namely:

- *What* can be done using the system, i.e., the *expressive power* of the environment.
- *How* the system may be used in order to build the query, i.e., the concept of *usability* as determined by the available strategies, the interaction and representation models.
- *Whom*, in terms of *classes of users*, the systems are addressed to.

The expressive power of a query system can be defined as the ability of the system to extract meaningful information from the database. More formally, according to [10], the expressive power can be based on the concept of *computable query*. Let U be a fixed countable set, called the universal domain, and let D(B), a subset of U, be a finite set which includes all the elements appearing in the database B. A *query* is a partial function giving an output (if any) which is a relation over D(B). A query Q is said to be *computable* if Q is partial recursive and satisfies a consistency criterion: if two databases are isomorphic, then the corresponding outputs of Q are also isomorphic (under the same isomorphism). In other words, the result of a query should be independent from the organization of the data in a database and should treat the elements of the database as uninterpreted objects. Excluding queries expressing undecidable problems, computable queries can be seen as the more general class of "reasonable" queries. Other meaningful classes of queries have been investigated in [11], giving rise to the so called Chandra's hierarchy. A significant class of queries inside the hierarchy is the one of first order queries, and the term *completeness* was used to indicate that a query language could express all the first order queries. However, it was apparent early that the amount of expressive power provided by such a language is not adequate for expressing useful queries, such as transitive closure and, more generally, fixpoint queries (i.e., queries obtained by augmenting the standard first order operators with the construct of least fixpoint). On the other hand, languages that friendly express queries simpler than first order queries are significant, since average database users make elementary requests.

As a consequence of the above remarks, the expressive power of the majority of visual query languages is lower or equal to the classes of first order or fixpoint queries. More precisely, most of the *iconic* languages fall in lowest level classes, since they are directed to a casual user, who is mainly interested in a friendly expression of simple queries (e.g., select-project queries). On the other hand, most of the *graphical* languages are equally or less expressive than relational algebra and very few are placed in the upper levels of the hierarchy (see [8]).

The notion of usability used in [5] is quite "database-oriented," and different from the ones used in the human-computer interaction (hci) community that is now commonly accepted. Indeed, in [5] usability was specified in terms of the models used in VQLs for denoting both data and queries, their corresponding visual representations and the strategies provided by the system in order to formulate the query. This definition does not reflect the hci view of usability as a software quality related to user perception and fruition of the software system. In particular, the data model has no significant impact on the user perception of the system. Whereas, visual representations and interaction strategies influence the user-system interaction, since they are important parts of the system interface (the only thing the user sees of a system).

As for the visual representation, the query representation is generally dependent on the database representation, since the way in which the query operands (i.e., data in the database) are presented constrains the query representation. For example, given a query on a relational database, the query may be formulated in terms of several representations, e.g., filling some fields in tables visualizing the relations, or following paths in a hypergraph that visualizes the relational schema. In this case the table and the hypergraph are two possible representations associated with the relational database. On the other hand, the visual representation used to display the query result can be different from the database representation. This is mainly due to the fact that what is visualized for the query purpose most often is the schema of the database, while the actual database instances constitute the query result to be displayed to the user.

Visual representations used in VQLs typically use forms, diagrams, icons or a combination of them. *Form*-based representations are the simplest way to provide the users with friendly interfaces for data manipulation. They are very common as application or system interfaces to relational databases, where the forms are actually a visualization of the tables. In query formulation prototypical forms are visualized for users to state the query by filling appropriate fields. In systems such as QBE [19], only the intensional part of relations is shown: the user fills the extensional part to provide an example of the requested result. The system retrieves whatever matches the example. In more recent form-based representations the user can manipulate both the intensional and the extensional part of the database.

Diagrammatic representations are also widely used in existing systems. Typically, diagrams represent data structures displayed using visual elements that correspond to the various types of concepts available in the underlying data model. Diagrammatic representations adopt as typical query operators the selection of elements, the traversal on adjacent elements and the creation of a bridge among disconnected elements.

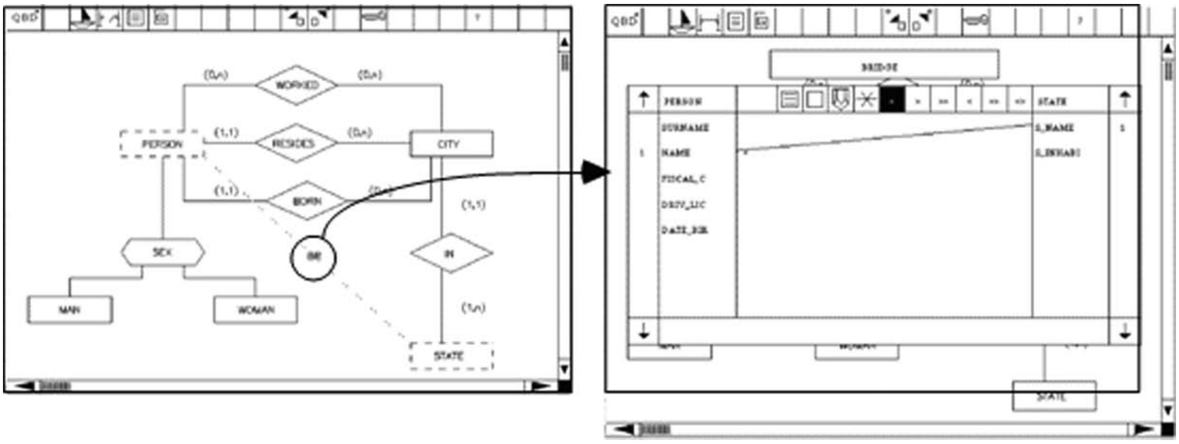
Iconic representations use icons to denote both the objects of the database and the operations to be performed on them. A query is expressed primarily by combining operand and operator icons. For example, icons may be vertically combined to denote conjunction (logical AND) and horizontally combined to denote disjunction (logical OR). In order to be effective, the proposed set of icons should be easily and intuitively understandable by most people. The need for users to memorize the semantics of the icons makes the approach manageable only for somehow limited sets of icons.

The *hybrid* representation is a combination of the above representations. Often, diagrams are used to describe the database schema, while icons are used either to represent specific prototypical objects or to indicate actions to be performed. Forms are mainly used for displaying the query result.

Similarly to most graphical user interfaces, the VQLs that have been developed so far have mainly stressed the user input aspects of the interaction and have given little thought to the visualization of output data. Conversely, an appropriate visualization of the query result allows the user to better capture the relationships amongst the output data, and some systems are progressing in this direction. For instance, AMAZE employs 3D graphs [7]. The data are shown as a 3D snapshot of the n-dimensional results. Different methods of result visualization are also planned to be available to the user. The Film Finder system [1] visualizes information about movies by means of *starfield displays*, which show database objects as small selectable spots (either points or 2D figures). The displayed data can be filtered by changing the range of values on both the Cartesian axes. The query result fits on a single screen and the system quickly, i.e., within a second, computes the new data display in response to the user's requests. This property, called near real-time interactivity, ensures high usability. A different approach is to use virtual reality techniques to present the query result with a simulation of a real environment (i.e., a virtual one) that depicts a situation familiar to the user. VQRH [12] is one of the systems that provide the user with several visual representations for both query formulation and result visualization. One possibility is to use 3D features to present the results in the simulated reality setting. For example, if the database refers to the books in a library, a virtual library can be represented in which the physical locations of the books are indicated by icons in a 3D presentation of the book stacks of the library.

Apart from the visual representation, any VQL is characterized by the way in which it allows the user to express his/her requests. Very often, the actual query specification is the second step of the user interaction, while there is a first step devoted to the understanding of the overall database content. This first phase is in general supported providing the user with browsing and/or filtering and zooming mechanisms.

Query formulation is the fundamental activity in the process of data retrieval. The query strategy *by schema navigation* has the characteristic of concentrating on a concept (or a group of concepts) and moving from it in order to reach other concepts of interest, on



Visual Query Language. Figure 1. Unconnected path in QBD* [19].

which further conditions may be specified. Such a strategy differs according to the type of path followed during the navigation (see Figure 1 for an example of unconnected path).

A second strategy for query formulation is *by subqueries*. In this case the query is formulated by composing partial results. The third strategy for query formulation is *by matching*. It is based on the idea of presenting the structure of a possible answer that is matched against the stored data.

The last strategy for query formulation is *by range selection*, allowing a search conditioned by a given range on multi-key data sets to be performed. The query is formulated through direct manipulation of graphical widgets, such as buttons, sliders, and scrollable lists, with one widget being used for every key. An interesting implementation of such a technique has been proposed in [1], and is called d*ynamic query*. The user can either indicate a range of numerical values (with a range slider), or a sequence of names alphabetically ordered (with an alpha slider). Given a query, a new query is easily formulated by moving the position of a slider with a mouse: this is supposed to give a sense of power but also of fun to the user, who is challenged to try other queries and see how the result is modified. Usually, input and output data are of the same type and may even coincide.

Key Applications

VQLs have been basically proposed to allow non-programmers to express database queries. In [5] it was also conjectured that, depending on the user class and the kind of task (i.e., query), certain VQLs are more appropriate than others. For instance, VQLs based on extensive use of icons and icon composition mechanisms [18], are typically more suited to express simple (select-project-join) queries and be used by naive users. Analysis underlying such statements were usually correct. Nevertheless, they needed to be substantiated by running user trials, and such experiments were (and still are) not so common in the VQL community. However, some of them have been carried on and basically support the hypothesis that different kinds of queries are better supported by different visual representations and interaction mechanisms. Whereas, results on the adequacy of the different visual representations with respect to the various classes of users are not so strong as it was conjectured.

Future Directions

VQLs mainly deal with traditional databases, i.e., databases containing alphanumeric data. However, in recent years the application realms of databases have raised a lot in terms of both number and variety of data types. As a consequence, specialized systems have been proposed for accessing such new kinds of databases, containing non-conventional data, such as images, videos, temporal series, maps, etc. Furthermore, the idea of information repository has been deeply influenced by the beginning of the Web age. Different visual systems have been proposed to cope with the need for extracting information residing on the Web.

Temporal Databases
